Pleurodesis is achieved by administering sclerosing agents that induce pleural inflammation, fibrosis, and, ultimately, a symphysis between parietal and visceral pleural surfaces. This action deters the accumulation of fluid (or air) in the pleural space.<sup>531</sup> Sclerosing agents such as talc (hydrated magnesium silicate) or tetracyclines are commonly used, although talc has been associated with the development of acute respiratory distress and hypoxemia.<sup>532</sup> These complications appear to be related to the talc particle size: Preparations that contain small-diameter particles (11 to 18  $\mu\text{m}$ ) are associated with a greater number of complications than are those preparations with particle diameters of 34  $\mu\text{m}$ .<sup>533</sup> The belief is that the larger talc particles are disseminated through the lymphatic channels to a lesser degree and thus are less likely to induce systemic inflammation.<sup>533</sup>

Adapting protocols from human medicine<sup>534</sup> (given that successful management of malignant effusions in equine medicine has not been described) requires that the horse first be sedated. A chest tube is aseptically placed, and the effusion is drained. Before administering the sclerosing agent, physicians for humans will instill a local anesthetic to reduce patient discomfort. Patients also receive oral antiinflammatory drugs for analgesia. Then, one administers a sclerosing agent (e.g., in human medicine 500 mg doxycycline) in 100 to 500 ml of sterile solution through a chest tube and clamps the tube for 1 hour before reconnecting it to continuous suction.

Poudrage is the most widely used method of instilling talc into the pleural space and is usually performed under thoracoscopic guidance. Before spraying the talc over the visceral pleura, one should remove all pleural fluid; complete collapse aids in distributing the talc. In human medicine, one usually instills 5 g (8 to 12 ml) evenly over the pleural surface, places a chest tube, and applies progressive suction until the amount of fluid aspirated per day is less than 100 ml.<sup>534</sup> A slurry of talc can also be administered through a chest tube to induce pleurodesis if thoracoscopy is not an option.

Another option that is used in human medicine is the placement of a tunneled pleural catheter (TPC, Pleurx, Denver Biomedical, Denver, Colo.) that allows for continuous home drainage of pleural effusions. The catheter, a 15.5-Fr silicone tubing, is 24 inches long and consists of a fenestrated distal end and a valve for draining purposes at the proximal end. The catheter is tunneled under the skin before entering the pleural space.<sup>535</sup> The drainage valve is accessed with a supplied

adapter that can be attached to a plastic disposable vacuum bottle. In a randomized study comparing the efficacy of just TPC to doxycycline pleurodesis in the management of malignant pleural effusions, the degree of symptomatic improvement in dyspneic patients was comparable in both groups, but the late recurrence of pleural effusion was 13% in TPC patients compared with 21% in doxycycline-treated patients. Lastly, 46% of the TPC patients achieved spontaneous pleurodesis at a median of 27 days.<sup>536</sup>

## FUNGAL PNEUMONIA

### CAUSES AND PATHOGENESIS

The typical fungus exists in either a filamentous (mold) or a single-cell (yeast) form, although some fungi may exist in either form (hyphae in nature, yeast in tissue) and are termed *dimorphic*. Based on the mode of spore production and the morphologic characteristics of the colonies and constituent hyphae produced, fungi have been classified into five different phyla. In veterinary medicine, three of the most important phyla are Zygomycota (*Mucor*, *Absidia*, *Rhizopus*), Ascomycota (*Aspergillus*, *Acremonium*, *Blastomyces*, *Coccidioides*, *Emmonsia*, *Histoplasma*, *Pneumocystis*), and Basidiomycota (*Cryptococcus*). Primary fungal pathogens causing respiratory disease in the horse include *Blastomyces dermatitidis*, *C. immitis*, *C. neoformans*, and *Histoplasma capsulatum*. Opportunistic fungi that cause respiratory disease include *Aspergillus* spp., *Pneumocystis carinii*, *Emmonsia crescens*, and *Acremonium strictum*.

*Blastomyces dermatitidis* is a thermally dimorphic fungus; it exists as a mold at room temperature and as a budding, round yeastlike cell when cultured at 37° C or when replicating in the host. As a soil saprophyte, *B. dermatitidis* can be found near decomposed vegetation or rotting wood.<sup>537</sup> In humans, inhalation of the fungi produces pulmonary infection that can disseminate to other organs and systems, including the central nervous system (CNS) and the reproductive and gastrointestinal tracts. Disease develops in both immunocompromised and immunocompetent individuals.<sup>538</sup> Although respiratory tract disease caused by this organism is rare in the horse, inhalation of the spores can cause a pyogranulomatous pneumonia.<sup>539</sup> No cases of animal (canine)-to-human transmission have been reported.

*Coccidioides immitis*, a soil saprophyte, is also dimorphic, existing as a mold on most culture media and as a nonbudding spherical form in the host tissue. Two variants, a California and non-California variant, exist, which are now classified as *C. immitis* and *C. posadasii*.<sup>540</sup> In humans, pulmonary infections ensue after inhalation of wind- or dust-borne arthroconidia. The infection is usually an acute and self-limiting respiratory disease in most hosts but can progress to chronic and sometimes fatal disseminated disease. Spontaneous healing can occur in 95% of healthy humans. Disease may also develop in immunocompromised individuals.<sup>540</sup> In horses, fungal pneumonia and pleuritis may occur after inhalation of arthrospores. Lymphohematogenous dissemination of the organisms may lead to the development of lesions in the bones, skin, and meninges, as well as cause abortion or mastitis.<sup>541-543</sup>

*Cryptococcus neoformans* is a yeastlike fungus that reproduces by budding, forming cells 4 to 7  $\mu\text{m}$  in diameter. The organism has a predilection for the respiratory tract and for the CNS. The proposed route of infection is via inhalation with secondary hematogenous spread to the CNS. The virulence

factors of the organism include an enzyme (phenol oxidase), a polysaccharide capsule, and the ability to grow at 37° C. The phenol oxidase enzyme aids in the production of melanin, which is thought to prevent formation of toxic hydroxyl radicals and to protect the fungal cell from oxidant stress and immune defenses.<sup>544</sup> The large polysaccharide capsule, which appears as a clear halo around the cell when organisms are stained with India ink, is antiphagocytic and immunosuppressive. Secreted capsular antigens bind opsonizing antibody before it reaches the organism.<sup>545</sup> Based on the capsular antigens, three variants of *C. neoformans* exist: *C. neoformans* var. *grubii* (serotype A), *C. neoformans* var. *gatti* (serotypes B and C), and *C. neoformans* var. *neoformans* (serotype D).<sup>546</sup>

*Histoplasma capsulatum* is a dimorphic fungus found in the soil and on decaying vegetation. Heavy concentrations of the organism accumulate in soils containing bat or bird feces. The organism is highly infectious as an airborne spore (microconidia) but is of low virulence when it converts to the yeast phase (2 to 4 µm) in the host.<sup>546</sup> In humans, acute benign pulmonary infection may become chronic pulmonary disease or progress to disseminated fatal systemic disease.<sup>547</sup> Systemic histoplasmosis is uncommon in proportion to the equine population exposed; the horse seems particularly resistant to infection.<sup>548</sup> The proposed route of infection is via inhalation or ingestion of the microconidia. Because the organism parasitizes mononuclear phagocytes and has an affinity for the reticuloendothelial system, it may disseminate to the liver, spleen, lymph nodes, and bone marrow.<sup>549</sup>

Opportunists such as *Aspergillus* spp., *P. carinii*, *E. crescens*, and *A. strictum* also cause pneumonia in horses that are immunosuppressed or have concurrent illnesses.<sup>550-557</sup> *Aspergillus* is a mold with septate hyphae 2 to 4 µm in diameter. The most prevalent pathogenic species is *A. fumigatus*, but *A. flavus*, *A. nidulans*, and *A. niger* also may cause disease.<sup>558</sup> These fungi are ubiquitous in the environment, growing on dead leaves, stored grain, compost piles, hay, and decaying vegetation.<sup>545</sup> In humans, *Aspergillus* spp. play a role in three clinical settings: (1) opportunistic infections; (2) allergic states; and (3) toxicoses (mycotoxins). Immunosuppression is the major factor leading to the development of opportunistic infections in humans.<sup>559</sup> In horses, aspergillosis has involved the guttural pouches, lungs, and mediastinum.<sup>560,561</sup> Inhalation of *Aspergillus* spores is suspected to be common, but disease is rare unless the horse is immunocompromised (neoplasia, steroid therapy), has been treated extensively with broad-spectrum antimicrobials, has a concurrent colitis (disruption of the mucosal barrier, allowing hematogenous spread), or has been stabled in an environment that contains high numbers of fungal organisms.<sup>562</sup> Infection is characterized by hyphal invasion of blood vessels, thrombosis, necrosis, and hemorrhagic infarction in pulmonary tissues. Because *Aspergillus* spp. occurs widely as an environmental contaminant, diagnosis may require repeated isolation or histologic demonstration. Dual mycotic pulmonary infections, although rare, have also been reported in horses involving *Aspergillus* spp. and fungal organisms in the order Mucorales (*Absidia corymbifera*, *Rhizopus stolonifer*).<sup>560,562</sup>

*Pneumocystis carinii* had been formerly considered a protozoan organism because of its morphologic features and its susceptibility to antiprotozoal agents.<sup>563</sup> However, the genes encoding the small subunit ribosomal RNA (16s) and the large subunit of mitochondrial rRNA demonstrate similarities to the genes encoding for the rRNA of several different fungal species.<sup>564</sup> As a result, *P. carinii* was reclassified as a fungus in

1988. Electron microscopy has revealed two parasite forms: trophozoite and cystic. The trophozoite is an ameboid form 2 to 5 µm in diameter with filopodia that attach to the surface of the type I epithelial cells. The trophozoite is visible with hematoxylin and eosin stains. The mature cyst is 4 to 6 µm in diameter and contains eight uninucleate intracystic bodies. The cyst stains with Gomori's or Grocott's methenamine silver stain and periodic acid-Schiff (PAS) stain. In keeping with the new taxonomic classification, some authors recommend replacing the terminology of the different parasite forms by the terms yeast cell (trophozoite), sporangia (cyst), and spores (intracystic bodies).<sup>564</sup> The infective stage or source of *P. carinii* is unknown, although several studies have reported discovery of *P. carinii* DNA in water and air samples, suggesting that these are environmental reservoirs.<sup>565</sup> It was long believed that *Pneumocystis* occurred only after reactivation of quiescent organisms (lung saprophytes) that had previously entered the lower respiratory tract of an immunocompetent host.<sup>563</sup> In rodent models, *P. carinii* can be transmitted from one animal to another via the airborne route, and evidence now exists that person-to-person transmission is the most likely mode of acquiring new pneumocystis infections.<sup>566</sup> *Pneumocystis* organisms have been identified in nearly every mammalian species, but the organisms have genetic characteristics that determine host specificity. For example, the *Pneumocystis* organism that infects humans (renamed as *P. jirovecii*) is unable to infect rodents.<sup>567</sup> In humans, pneumocystis pneumonia remains the most prevalent opportunistic infection in patients infected with human immunodeficiency virus (HIV) or in individuals receiving immunosuppressant medications.<sup>568</sup> In horses, it is a rare cause of pneumonia, affecting the younger foal as compared with the adult horse.

Other soil saprophytes that have been reported as rare causes of fungal pneumonia in the horse include *A. strictum* (a plant and insect pathogen)<sup>569</sup> and *E. crescens* (an opportunist pathogen of carnivores, insectivores, marsupials, lagomorphs, and rodents).<sup>557</sup> Both of these fungi are *cosmopolitan*, commonly isolated from soil and debris. In immunocompromised humans, *Acremonium* causes keratitis, endophthalmitis, endocarditis, meningitis, peritonitis, and osteomyelitis. Because *Acremonium* spp. can be an environmental contaminant, its isolation from respiratory tract secretions requires careful evaluation.<sup>570</sup> *Emmonsia* spp. are an occasional cause of animal and human infections, being endemic in the southwestern United States, Australia, and Eastern Europe. In rodents, an asymptomatic pulmonary infection develops after inhalation of the conidia. Rarely, in immunocompromised humans, disseminated infection may occur.<sup>571</sup>

## EPIDEMIOLOGY

Fungal pneumonia in the horse as a primary entity is uncommon. Disease usually results when debilitating conditions that favor the penetration or growth of fungi exist. Contributory factors include (1) exposure to large numbers of mycotic organisms in the environment,<sup>572</sup> (2) stabling of horses within a moist or unhygienic environment,<sup>573</sup> (3) prolonged administration of antibiotics that upset the microfloral balance or interfere with vitamin synthesis, (4) existence of an immunosuppressive state primarily (combined immunodeficiency disorder) or secondarily because of the administration of drugs, development of an endocrinopathy, or neoplasia.<sup>556,558</sup>

For the pathogenic fungi, prevalence of the disease may be determined geographically. For example, *B. dermatitidis* is

endemic to the Mississippi, Missouri, and Ohio River basins; the Canadian provinces of Quebec, Ontario, and Manitoba; the Great Lakes region; and the Eastern seaboard of the United States.<sup>539</sup> Although *H. capsulatum* is endemic to the Mississippi, Ohio, and St. Lawrence River valleys, it also is found in the southern United States.<sup>549,574</sup> *Coccidioides immitis* is endemic to the arid and semiarid regions of North America, including the states of California, Texas, Arizona, New Mexico, Nevada, and Utah.<sup>541,575</sup> In contrast, *Cryptococcus neoformans* is widespread, being found in high concentrations in the soil and in avian manure (*C. neoformans* var. *neoformans*). In Australia, an epizootiologic relationship of *C. neoformans* var. *gatti* exists with the eucalyptus tree (*Eucalyptus camaldulensis*). Environmental dispersal of the fungus coincides with flowering of the eucalyptus tree in the spring, resulting in greater exposure and more cases of disease during that time.<sup>576</sup> A disproportionately large number of published equine cases have been recorded by Australian investigators, supporting the impression that this disease is more common in Australia than in North America or Europe.<sup>577</sup>

For the opportunistic fungus *P. carinii*, human clinical infections develop only in immunodepressed subjects, those individuals with low CD4<sup>+</sup> counts and with certain viral infections (cytomegalovirus, HIV), those in weakened nutritional states, or those receiving immunosuppressive therapy.<sup>563,564</sup> To date, most of the reported cases of equine pneumocystosis have occurred in foals 1.5 to 4 months of age. Predisposing factors include the existence of a combined immunodeficiency disorder,<sup>554</sup> *R. equi* or chronic bacterial pneumonia,<sup>555,578</sup> low CD4<sup>+</sup> counts,<sup>579</sup> and chronic debilitation or weight loss.<sup>580,581</sup> In two reports of equine pneumocystosis in foals, predisposing factors could not be identified.<sup>582,583</sup> The occurrence of pneumocystosis in young foals may reflect an age-dependent maturation of the immune system. Cell-mediated immune responses (in vitro) of foals younger than 2 months are reduced relative to those of adult horses, perhaps increasing the susceptibility of the foal to pneumocystosis.<sup>584</sup> If an adult horse becomes immunodeficient, it may be at risk for developing pneumocystis pneumonia as described in a 5-year-old Paso Fino mare.<sup>163,585</sup> This debilitated mare with respiratory distress had foaled 2 months previously. Immunologic testing of the mare at a tertiary referral center demonstrated an absence of serum IgM, low concentrations of serum IgG (800 mg/dl), and a low percentage of peripheral blood mononuclear cells expressing MHC class II molecules (28% compared with a normal range of 54% to 81%), suggesting immunocompromise.

### CLINICAL SIGNS

Horses with primary fungal pneumonia (blastomycosis, histoplasmosis, cryptococcosis, and coccidioidomycosis) may have a chronic cough, anorexia, weight loss, exercise intolerance, and nasal discharge.<sup>586-588</sup> Tachypnea or respiratory distress may or may not be a clinical feature of the fungal pneumonia. Pleural effusion is found more commonly with coccidioidomycosis but has also been reported in cases of cryptococcosis and blastomycosis.<sup>539,541,588</sup>

In addition to causing pneumonia, these fungal organisms may cause disease in other body systems. *B. dermatitidis* causes weight loss, intraabdominal abscesses<sup>539</sup>; superficial abscesses around the anus, vulva, and udder.<sup>589,590</sup>; and generalized cutaneous ulcerative skin lesions.<sup>590</sup> In a review of 15 cases of equine coccidioidomycosis, 43% of the cases had hepatic lesions, 29% had bone or periosteal involvement,

22% had lesions in the peritoneum, and 64% had pulmonary parenchymal disorders.<sup>541</sup> Other reports describe *Coccidioides immitis* lesions in the mammary gland,<sup>543</sup> the placenta and fetus,<sup>542,591</sup> and the skin.<sup>592</sup> *Cryptococcus neoformans* has been reported to cause granulomata in the skin, nasal cavity, paranasal sinuses, orbits, intestines, bones, meninges, placenta, and fetus.<sup>576,593-597</sup> In addition to pulmonary lesions (including abscessation),<sup>598</sup> *H. capsulatum* infections have been associated with abortions, disseminated histoplasmosis of foals, granulomatous colitis of adult horses, intraabdominal abscessation, and keratitis.<sup>548,574,599-601</sup>

A horse developing pneumonia caused by opportunistic fungi (aspergillosis, pneumocystosis) may have evidence of a debilitating or immunosuppressive problem such as colitis, peritonitis, septicemia, endotoxemia, an endocrinopathy, or chronic bacterial pneumonia. Young horses (foals) may be at an increased risk for developing opportunistic infections (*P. carinii*).

In the majority of cases of pulmonary aspergillosis, pneumonia appears to be a sequela to mycotic invasion of the intestinal tract, the integrity of which has been compromised by severe acute enterocolitis.<sup>550,551,553,572</sup> Such horses also have typically received broad-spectrum antimicrobials and nonsteroidal anti-inflammatory drugs and are neutropenic—factors that may also predispose them to the development of systemic aspergillosis. Nevertheless, pulmonary aspergillosis also has been reported in horses with pleuropneumonia, myositis, renal failure, pituitary adenoma, and myelomonocytic leukemia.<sup>553,556,558</sup>

Horses with pulmonary aspergillosis may suddenly become febrile and tachypneic and may exhibit adventitious lung or pleural sounds and have a nasal discharge. Other horses with pulmonary aspergillosis may show only mild respiratory signs or fail to demonstrate any abnormalities of the respiratory tract.<sup>553,599,602</sup>

Pneumocystosis is a rare clinical entity. In the majority of cases, foals have evidence of chronic respiratory disease that has progressed to respiratory distress. Weight loss, dehydration, and inappetence also may be evident.<sup>555,579-581,583</sup> Similar signs were reported in a 5-year-old Paso Fino mare that developed pneumocystosis.<sup>585,603</sup>

### DIAGNOSIS

Tracheobronchial aspirates may reveal degenerated neutrophils, yeast cells, and bacteria. In the case of aspergillosis, the diagnosis may be difficult because one may recover fungal elements (*Aspergillus* spp., *Penicillium* spp., and *Mucor* spp.) from the tracheal washings of normal horses.<sup>38</sup> Definitive diagnosis may require repeated isolation of the *Aspergillus* organisms or histologic demonstration of hyphal elements in the pulmonary parenchyma. Transtracheal aspirates may be of limited usefulness in diagnosing pneumocystosis because the organism is rarely isolated by this method. For horses not in respiratory distress, isolation of the organism may be possible by bronchoalveolar lavage (BAL) or endobronchial brushings.<sup>555,579-581</sup> Cyto centrifugation of BAL samples followed by silver-staining of slides facilitates identification of *P. carinii*. Indeed, in human medicine, diagnostic sensitivity of cytology is considered to be 89% to 94% compared with sensitivity of histopathologic examination of lung biopsies of 73%.<sup>585</sup> A culture system has not been developed for diagnosis of *P. carinii*.

In horses with fungal pneumonia, radiographs may reveal circular masses with or without fluid lines and an accentuated interstitial pattern. In horses with cryptococcal pneumonia,

the most common presentation is large cavitating granulomas (cryptococcomas) that tend to be located in the dorsocaudal lung lobes. Less commonly, miliary interstitial granulomas evenly distributed throughout the lung fields are evident.<sup>577</sup> Radiography or ultrasonography may detect pleural effusion. Ultrasonographic examination may reveal comet-tail signs, indicative of pleural roughening or inflammation, small areas of pulmonary consolidation, or masses of variable echogenicity delineated by hyperechoic capsules.<sup>577,604</sup> Ultrasound-guided aspirates of the masses may provide samples for culture and cytologic evaluation.

Serologic detection of an antibody response to *Coccidioides immitis*, *Cryptococcus neoformans*, and *H. capsulatum* has been useful in diagnosing fungal pneumonia because the organisms can be difficult to culture and tissue biopsies may lack evidence of the organisms. Repeated measurement of titers may be necessary. In a survey of immunoglobulin responses in healthy asymptomatic horses stabled in a *C. immitis* endemic area, only 4% of the horses developed an IgG titer (all of which were  $\leq 8$ ). On resampling, the titer decreased or became negative within 2 to 6 months while horses remained disease free.<sup>605</sup> These data suggest that an elevated titer in a clinically ill animal strongly supports the diagnosis of *C. immitis* infection.<sup>606</sup> Interestingly, for *C. immitis* infections, the magnitude of the antibody response is associated with the clinical form. In comparing horses with miliary or interstitial pneumonia (sans thoracic effusion), with pneumonia and thoracic effusion (pleural or pericardial), and with pneumonia and disseminated disease, the geometric mean titers were 51, 225, and 104, respectively. Horses that had *C. immitis* abortions had titers less than 8. Similarly, in horses with cryptococcosis, serologic detection of capsular antigens (serum latex agglutination test) also has proved effective in the diagnosis.<sup>588,593</sup> In horses with histoplasmosis, an agar gel immunodiffusion (AGID) test has been used. There are two possible bands of precipitation in the test: an M-band that may indicate recent past infection (within 12 months) or active infection and an H-band. The simultaneous precipitation of both bands indicates current active infection.<sup>548</sup> The histoplasmin skin test is of little diagnostic value; in one endemic area, 73% of horses had a positive skin test.<sup>607</sup> Serologic diagnosis of pulmonary aspergillosis can be difficult because titers are detectable in healthy and diseased horses.<sup>553</sup> Nevertheless, Moore et al.<sup>561</sup> reported the existence of two precipitin bands against *Aspergillus* antigens in a horse confirmed to have an *Aspergillus* mediastinal granuloma. Precipitin bands were not evident in the eight control horses sampled. In a description of a horse with bronchial lymphadenitis caused by *Aspergillus*, precipitin bands against the fungus (titer of 1:8) were measured.<sup>608</sup> Recently, Guillot, Sarfati, DeBarros, et al.<sup>609</sup> reported the usefulness of an immunoblot analysis for the diagnosis of aspergillosis, detecting reactivity to low-molecular-mass antigens (22–26 kDa) in the sera of diseased horses that were not evident in clinically healthy horses. The investigators suggested that these antigens were released during mycelial growth in the tissues, a phase that would not develop in clinically healthy horses. However, until this experimental assay is commercially available, one should use the serologic diagnosis cautiously in suspected cases of pulmonary aspergillosis. One may confirm the diagnosis with lung biopsy and by the presence of other systemic alterations.

The immunocompetence status of the horse can be superficially evaluated by quantitation of immunoglobulin levels, by performing mitogen stimulation tests, and by

immunophenotyping of peripheral blood leukocytes (granulocytes, monocytes, CD5<sup>+</sup>, CD4<sup>+</sup>, and CD8<sup>+</sup> T cells, B cells, and MHC I and II expression). Diagnostic investigations should rule out the existence of endocrinopathies and neoplasia.

## TREATMENT

Treatment against the primary fungal pathogens requires long-term administration (weeks) of antifungal drugs and correction or elimination of the inciting cause of the fungal pneumonia. Many of the newer antifungal drugs have been designed to target differences in the cellular and biochemical properties of fungi compared with mammalian cells. Recall that fungi are eukaryotes that have DNA organized into chromosomes within the cell nucleus and endoplasmic reticulum, Golgi, mitochondria, and storage vacuoles within the cytoplasm. The fungal cell walls are rigid and consist of mannoproteins,  $\beta$ -glucans, and chitin. The fungal cell membrane is a lipid bilayer that contains ergosterol instead of cholesterol as the predominant sterol.

Four basic classes of antifungal drugs are commonly used in veterinary medicine. The polyenes are *cidal* compounds that are derived from *Streptomyces* species. Representatives of this class of drugs include amphotericin B, nystatin, and natamycin. The drugs work by combining irreversibly to the ergosterol in the fungal cytoplasmic membrane, causing depolarization, pore formation, and increased cell membrane permeability. Most bacteria are resistant to polyenes because they lack the necessary cell membrane binding sites. At high enough doses, the polyenes will bind with cholesterol and cause organ toxicity, most notably renal disease in mammals.

A second class of drugs includes the azoles—miconazole, ketoconazole, itraconazole, fluconazole, and enilconazole (topical). These synthetic compounds reduce ergosterol production by inhibiting the P450 3A-dependent enzyme 14 $\alpha$ -demethylase. As a result, aberrant sterols accumulate in the fungal cell membrane. This inhibition affects nutrient utilization and causes leaky cell membranes.<sup>545</sup> These compounds are considered to be either fungistatic or fungicidal. However, unlike the polyenes, some of these compounds have activity against gram-positive bacteria and protozoa. Because these drugs can inhibit the P450-dependent enzymes involved in cholesterol synthesis, hormone (cortisol, androgen, and testosterone) concentrations may be decreased.<sup>610</sup> Hepatotoxicities are also a potential side effect.

The allylamines are a third class of antifungals and include terbinafine and naftidine. These compounds also inhibit ergosterol synthesis in a site earlier than that of the azoles, specifically targeting the enzyme squalene epoxidase. Hepatotoxicities can also ensue.

A fourth class of antifungals includes the antimetabolites or substituted pyrimidines that inhibit DNA and protein synthesis. An example is flucytosine, which is converted to 5-fluorouracil. Resistance develops when the active transport mechanism for flucytosine uptake is reduced.

Newer antifungal drugs are being marketed that target the synthesis of cell wall constituents by inhibiting the production of  $\beta$ -1,3 glucan (caspofungin, micafungin, and anidulafungin) or chitin (nikkomycin Z). However, because fungal pneumonia is relatively uncommon, the efficacy of various protocols has not been stringently assessed. Selection of the antifungal drug to use should also be guided by sensitivity patterns of the fungal isolates but more importantly on clinical response.

Amphotericin B has been used successfully to treat histoplasmosis,<sup>549</sup> pulmonary aspergillosis,<sup>609</sup> and pulmonary

cryptococcosis.<sup>577</sup> The recommended dose is 0.1 to 0.6 mg/kg administered in a 5%-dextrose solution intravenously over 60 minutes, one to three times per week, although more frequent administration has been described.<sup>577</sup> Some clinicians have recommended starting at 0.35 mg/kg intravenously once daily for 3 days, then 0.4 mg/kg intravenously once daily for 3 days, and 0.5 mg/kg intravenously once daily for the remainder of the treatment course.<sup>577</sup> Possible adverse effects include anorexia, anemia, arrhythmias, hepatic and renal dysfunction, hypersensitivity reactions, tremors, and fever.<sup>595</sup> Pretreatment with flunixin meglumine has been suggested to ameliorate the adverse effects, although the risk of nephrotoxicity should be considered. Studies conducted in France have suggested that preheating amphotericin B to 60° to 70° C for 10 minutes before the administration increases the clinical efficacy and decreases nephrotoxicity by changing the physicochemical properties of the constituent colloidal dispersion.<sup>577,611</sup> Neither amphotericin B nor ketoconazole were found to be curative in a series of cases of coccidioidomycosis.<sup>541</sup> However, long-term administration of itraconazole (2.6 mg/kg orally twice daily) was effective in treating coccidioidomycosis vertebral osteomyelitis in a foal,<sup>575</sup> and long-term fluconazole (5 mg/kg orally once daily) proved efficacious for two horses with *C. immitis* interstitial pneumonia.<sup>604</sup> Higgins has found in horses with *C. immitis* pneumonia that the magnitude of the titer is associated with the severity of the infection and hence with prognosis.<sup>606</sup> Thus, when identified early in the course of their disease, horses with only miliary (interstitial) pneumonia have a better prognosis than horses with concurrent pleural effusion or disseminated disease. In the two horses with *C. immitis* interstitial pneumonia, clinical cure was achieved after a 4- to 6-month course of fluconazole (administered at a loading dose of 14 mg/kg orally followed by 5 mg/kg orally once daily).<sup>604</sup> Based on human medicine, clinicians should attempt to achieve peak plasma concentrations in the range of 4 to 8 µg/ml. Fluconazole therapy is terminated when clinical signs dissipate (weight gain is noted) and serum IgG titers decrease.

Too few cases of blastomycosis have, as yet, been described in the literature to recommend treatment protocols for this disorder. In the single case report of pneumonia caused by *Acremonia crescens*, fluconazole (loading dose of 14 mg/kg orally followed by 5 mg/kg orally once daily) for 30 days was efficacious. *P. carinii* infections require treatment with antiprotozoal drugs; Ewing et al.<sup>581</sup> has reported success using trimethoprim sulfamethoxazole (25 mg/kg orally twice daily) in combination with procaine penicillin G in foals with pneumocystosis. Furthermore, Flaminio et al.<sup>579</sup> supplemented trimethoprim sulfamethoxazole (30 mg/kg orally twice daily) with interferon- $\alpha$  (100 U orally once daily) and *Propionibacterium acnes* (EqStim) in an effort to increase CD4<sup>+</sup> and CD8<sup>+</sup> counts in a foal with pneumocystosis. The pneumonia eventually resolved and lymphocyte counts returned to normal. In another foal with pneumocystosis, dapsone, a dihydropterate synthase inhibitor, was administered at 3 mg/kg orally with a successful outcome.<sup>612</sup> In humans with acute respiratory distress caused by pneumocystosis and secondary hypoxemia, concurrent administration of glucocorticoids is recommended.<sup>568</sup>

### MYCOPLASMAL PNEUMONIA

Several species of *Mycoplasma* may be isolated from the upper and lower respiratory tracts of healthy horses and from the nasal cavities of healthy foals soon after birth.<sup>613</sup> *M. felis* has

been isolated from clinical and experimental cases of parapneumonic effusions<sup>525,614,615</sup> and from foals with pneumonia.<sup>616</sup> *M. felis*, *M. equirhinis*, and a non-*M. felis* glucose-fermenting mycoplasma (NFGM) species have been isolated, along with bacterial organisms, from the tracheobronchial aspirates of young athletic horses with inflammatory airway disease (IAD).<sup>617,618</sup> In a recent epidemiology survey of 800 young racehorses consisting of 632 controls and 170 with signs of IAD (cough at rest or exercise, mild pyrexia, abnormal mucous or serous nasal discharge), the isolation of *M. felis* but not *M. equirhinis* or NFGM mycoplasma was associated with an increased risk of IAD.<sup>618</sup> Furthermore, a recent Canadian survey documented serologic evidence of *M. felis* or *M. equirhinis* infection in 9% and 10%, respectively, of horses showing clinical signs of acute respiratory disease.<sup>418</sup>

The pathogenesis of the inflammatory or infectious airway disease (pneumonia) is generally believed to involve adherence of the organism to ciliated epithelium, causing loss of the cilia and subsequent death of the cell. This belief is supported by the finding of degenerative epithelial cells in the tracheobronchial aspirates of horses with mycoplasma infections.<sup>617</sup> Diagnosis of mycoplasmosis depends on isolation of the organism from tracheobronchial aspirates or from pleural fluid and on demonstration of seroconversion. The clinician should initiate treatment with broad-spectrum antibacterials (oxytetracycline) until antimicrobial culture and sensitivity reports are available given that bacterial coinfections are likely.

## INTERSTITIAL LUNG DISEASE

### DEFINITION

Interstitial pneumonia describes an acute or chronic inflammatory process that involves primarily the alveolar walls (endothelium, basement membrane, and alveolar epithelium) and contiguous bronchiolar interstitium.<sup>619,620</sup> Horses that develop acute respiratory distress syndrome (discussed elsewhere in this chapter) may do so because of interstitial lung disease.

### EPIDEMIOLOGY

Buergelt<sup>621</sup> has suggested that two types of equine interstitial disorders exist: one occurring in foals 6 days to 6 months of age<sup>622,623</sup> and one developing in adult horses older than 2 years. This discussion focuses on interstitial lung disorders in the adult horse.

### CAUSES

Interestingly, in humans, interstitial lung disease is attributed to more than 200 different etiologic factors, including bacterial, fungal, viral, protozoal, and parasitic agents; collagen vascular disorders (systemic lupus erythematosus, rheumatoid arthritis, progressive systemic sclerosis, Sjögren syndrome); vasculitides; hypersensitivities; silica; asbestos; beryllium; and drugs.<sup>624</sup>

Most of the spontaneously occurring interstitial lung disorders in horses have been attributed to toxic or infectious (bacterial, viral, or parasitic agents) agents.<sup>619</sup> Toxic lung injury occurs after ingestion of Crofton weed (*Eupatorium adenophorum*, toxic agent unknown),<sup>625,626</sup> mist flower (*Eupatorium riparium*, toxic agent unidentified),<sup>627</sup> *Crotalaria* seeds (*Crotalaria juncea*, toxic agent is a pyrrolizidine alkaloid),<sup>628</sup> or exposure to Perilla mint (*Perilla frutescens*, toxic agent is a ketone).<sup>629-631</sup> Exogenous deposition of lipid (mineral oil) causes an interstitial pneumonia, often known as a lipid

pneumonia or lipid pneumonitis.<sup>632-635</sup> (Aspiration of mineral oil can occur after esophageal intubation if the oil is administered under pressure, in an incompletely emptied stomach, or after removal of the tube that still contains oil.<sup>633</sup>)

Viral infections, particularly in foals or young horses,<sup>304,308</sup> also cause interstitial lung disease. Specific etiologic agents include equine influenza A2; EHV1 and 4; AHV4, 5, and 6; EVA; Hendra virus; and AHS virus.<sup>327,636</sup> In a recent retrospective study of 24 horses with clinical signs and radiographic evidence of interstitial lung disease, EHV5 was detected by PCR in 79% of the paraffin-fixed lung samples from these horses.<sup>392</sup> However, causality between EHV5 and this multinodular interstitial lung disease remains to be established as EHV5 can be isolated from PBMC or nasal swabs of 24% to 33% of healthy horses.<sup>381,389</sup>

Mycobacterial infections<sup>637-639</sup> are a rare cause of interstitial pneumonia in the horse. Etiologic agents include members of the *Mycobacterium tuberculosis* complex (*M. bovis*, *M. tuberculosis*) and of the *M. avium* complex (*M. avium* subsp. *avium*, *M. avium* subsp. *hominissuis*, *M. avium* subsp. *paratuberculosis*). In surveys of European abattoirs conducted in the mid-1950s, prevalence of mycobacterial infections was 0.3%, suggesting that horses were relatively resistant to infection.<sup>640</sup> Of the mycobacterial infections reported in that study, *M. avium* spp. *avium* was considered to be the most common cause of tuberculosis in the horse having been isolated from 91% of the affected horses. *M. bovis* was identified in 3% of the isolates.<sup>641</sup> Although airborne infections cannot be dismissed, the most common route of infection for equine tuberculosis is alimentary, with hematogenous dissemination to the liver, spleen, lung, lymph nodes, and bones.<sup>638,640</sup> Thus the clinical signs of tuberculosis will depend on which organ systems are affected. Fungal agents<sup>569,603</sup> also cause interstitial pneumonia. (See previous discussion on fungal pneumonia.)

Unfortunately, for many cases of interstitial pneumonia, a well-defined cause is lacking, and thus are known as *idiopathic interstitial* or *granulomatous disease*.<sup>642-648</sup> Idiopathic eosinophilic granulomatous pneumonia may occur as part of the syndrome of equine multisystemic eosinophilic epitheliotropic disease, or it may affect only the lungs, causing disseminated eosinophilic granulomas.<sup>649</sup>

## PATHOPHYSIOLOGY

The inciting agent damages pulmonary epithelial or endothelial cells, causing coagulative necrosis of the alveoli. Pulmonary congestion, interstitial edema, erythrocyte extravasation, and alveolar flooding characterize the acute (exudative) phase of the disease. Fibrin, protein-rich fluid, cellular debris, and inflammatory cells (neutrophils and macrophages) form hyaline membranes. During the acute phase (1 to 5 days after the initial insult), the horse may exhibit respiratory distress. The exudative phase is followed by a proliferative stage in which the type II pneumocytes—the pulmonary stem cells—replace damaged type I pneumocytes. Interlobar septae widen because of the proliferation of fibroblasts and inflammatory cell infiltration by neutrophils and macrophages.<sup>619</sup> Chronic interstitial lung disease is characterized by fibrosis of the alveolar walls and accumulation of mononuclear cells in the interstitium. Granulomas and smooth muscle hyperplasia may form during the chronic phase, although this finding is not unequivocal in all cases of interstitial pneumonia.<sup>620</sup> For example, in an experimental model of interstitial lung disease (induced by intravenous administration of Perilla mint ketone), acute

alveolar damage did not progress to interstitial fibrosis despite the enhanced collagen gene expression (COL1A1 and COL3A1).<sup>631</sup> It is possible that the changes of chronic interstitial lung disease require persistence of or repeated exposure to the causative agents—dusts, drugs, or infectious agents.<sup>619</sup>

The pathophysiologic stages of lipid pneumonia have been described in humans. The first stage consists of hemorrhage and bronchopneumonia, which is followed by a severe macrophagic infiltrate that engulfs the oil droplets. The third and fourth stages entail fibroblastic proliferation and paraffinoma (fibrosis). Depending on the quantity of oil aspirated, the human patient can progress to stage 4 in a little as 3 to 4 weeks.<sup>650</sup>

## CLINICAL SIGNS

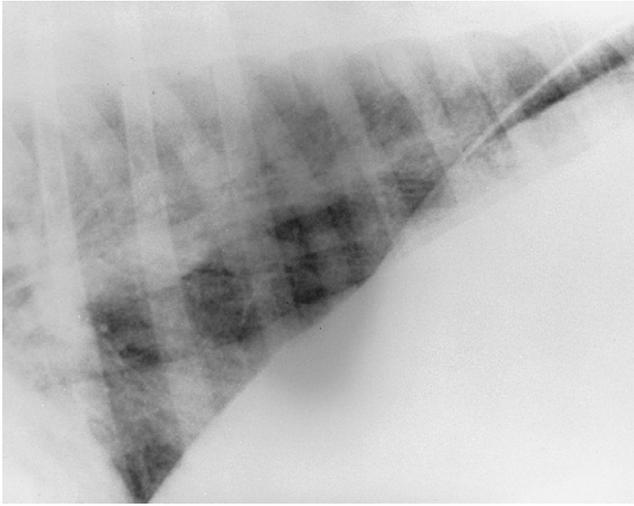

Clinical signs of interstitial lung disease vary, depending on the stage of the disease and the causative agent involved. In the acute phase, horses may exhibit acute respiratory distress (tachypnea), adventitious lung sounds, and signs of hypoxemia caused by poor gas exchange (ataxia, altered mucous membrane color) with or without a fever.<sup>630,651</sup> In the later stages of the disease, horses also have clinical signs resembling those of heaves-affected horses—tachypnea, an accentuated expiratory effort, cough, and nasal discharge.<sup>642-644</sup> In chronic stages, horses may exhibit exercise intolerance,<sup>643</sup> weight loss, anorexia, and fever. Horses terminally affected by the pulmonary form of tuberculosis are febrile, exhibit respiratory distress, and have a cough. Occasionally, interstitial lung disease may produce pulmonary hypertension and cor pulmonale.<sup>652</sup> Interstitial lung disease also may be present in the absence of clinical signs.<sup>643</sup>

## DIAGNOSIS

The diagnosis is based on the cumulative results of clinical examination, history, radiographic or ultrasonographic examination (or both), or isolation of a causative agent from respiratory secretions or tissue samples obtained from biopsy or postmortem examination. Clinical pathologic data are often nonspecific. Arterial hypoxemia may be evident on blood gas analysis. The CBC and serum chemistry panels may be normal or may demonstrate leukocytosis and hyperfibrinogenemia.<sup>646,653</sup> Confirmation of the horse's prior travel and area of residence may aid in the diagnosis. Silicosis develops in horses that have lived in arid or desert areas where soils are rich in silicates, as occurs, for example, in selected regions of California.<sup>654</sup> Other relevant historical information includes vaccination history (viral) and prior medications (e.g., lipid pneumonitis secondary to mineral oil administration).

Evaluation of tracheobronchial secretions or BALs may reveal the presence of a nonseptic inflammation characterized by neutrophilia with or without Curschmann's spirals.<sup>646,648</sup> Depending on the causative agent, analysis of respiratory secretions may also demonstrate pulmonary macrophages with (1) intracytoplasmic eosinophilic crystalline inclusions (silicosis),<sup>655</sup> (2) intracytoplasmic fungal organisms (fungal pneumonia),<sup>569</sup> or (3) acid fast-stained intracellular bacilli (tuberculosis).<sup>639</sup> In horses with lipid pneumonitis, the tracheal aspirates may be red to orange in color as a result of the presence of erythrocytes and contain a predominance of neutrophils. Sudan and Oil-Red-O stains of the aspirates confirm the presence of free lipid droplets, as well as lipid-laden macrophages.<sup>633-635</sup>

Radiographs demonstrate (1) an increase in the interstitial pattern of the lung (Figure 9-19) or (2) the presence of pulmonary infiltrates that form discrete and diffuse nodules. A reticulonodular radiographic pattern has been observed in horses

**FIGURE 9-19** Overall increase in interstitial pulmonary opacity represents interstitial lung disease. (Courtesy D. S. Biller, Manhattan, Kan., 1991.)

with silicosis,<sup>655</sup> mycobacterial or fungal pneumonia, and EHV5 infections, as well as in idiopathic cases of interstitial lung disease. Radiographic changes do not allow one to distinguish these cases from those with neoplasia. Few descriptive studies of the ultrasonographic changes in interstitial lung disease exist. In general, the predominant changes in influenza consist of diffuse comet-tail signs with or without parenchymal defects consisting of consolidation,<sup>304</sup> or hypoechoic lesions in the caudal dorsal lung fields.<sup>569,646</sup>

Serology may be helpful in the diagnosis of viral infections<sup>651</sup> especially if acute and convalescent titers can be obtained for comparison. More rapid diagnostic approaches entail molecular techniques such as PCR (AHV4, AHV5, EHV5, EHV1, EIV, EHV).

Skin testing to diagnose mycobacterial infections are of low specificity and sensitivity,<sup>641</sup> given that up to 70% of clinically normal horses have a positive skin test.<sup>656</sup>

### **PATHOLOGIC SIGNS**

The lung changes are a function of the stage and the causative agent. Histologic evaluation of lung biopsies confirms the diagnosis of interstitial pneumonia in the acute (exudative, proliferative) or chronic (fibrotic) stages. Postmortem examination may reveal diffuse pulmonary fibrosis, hypercellularity of the alveolar septa, and scarring of the interlobular septa and parts of the pleura. Severe chronic bronchitis and bronchiolitis also may be evident if concurrent airway disease exists, but this feature is atypical of interstitial pneumonia.<sup>482</sup> Multifocal granulomata may be detectable.<sup>644,654</sup> Microscopically, granulomas consist of epithelioid cells, giant cells, and lymphocytes. In horses with eosinophilic granulomatous pneumonia, the granulomas consist of central degenerated eosinophils surrounded by epithelioid macrophages, multinucleated giant cells, and collagenous fibrotic tissue.<sup>649</sup>

### **TREATMENT**

Horses with acute interstitial pneumonia should receive supportive care, as outlined in the section Acute Respiratory Distress Syndrome. The following treatment recommendations

pertain to horses with chronic interstitial lung disease. In human medicine, patients with chronic interstitial lung disease characterized by fibrosis (especially idiopathic pulmonary fibrosis) have received a variety of treatments, including corticosteroids, immunosuppressive or cytotoxic agents (azathioprine, cyclophosphamide), and antifibrotic agents (colchicine, D-penicillamine, *N*-acetylcysteine) alone or in combination.<sup>657</sup> Newer therapeutic approaches entail the administration of interferon-gamma, endothelin-1 receptor antagonists, and tyrosine kinase inhibitors,<sup>658</sup> although well-designed clinical trials for many of the drug treatments are lacking.

In equine medicine, the standard approach to the treatment of chronic interstitial lung disease, which lacks evidence of an active infection, has been corticosteroid administration singly or in combination with bronchodilators and broad-spectrum antimicrobials. Doxycycline, because of its anti-inflammatory effects, may also be indicated in the treatment of interstitial pneumonia. Well-controlled prospective studies are lacking, but the horse occasionally responds to treatment and is able to resume athletic ability.<sup>646</sup> For example, in one study of seven horses with idiopathic granulomatous interstitial pneumonia, only one of three horses that received a course of corticosteroid improved, although tachypnea remained.<sup>648</sup> Similarly, in a report of equine silicosis, of the eight horses that were treated with corticosteroids, 50% responded. Four of the eight had progressive radiographic pulmonary consolidation necessitating euthanasia within 12 months of initial diagnosis, whereas the remaining four showed no improvement in radiographic signs despite weight gains.<sup>655</sup> The prognosis for horses with lipid pneumonia is poor, although Henninger, Hass, and Freshwater (2006) described the successful treatment of a 10-year-old Clydesdale stallion that had aspirated mineral oil administered by its owner for treatment of colic.<sup>635</sup> The treatment regimen consisted of antimicrobials (initially trimethoprim-sulfadiazine, later procaine penicillin, metronidazole and gentamicin before referral for 10 days) followed by a protracted course (weeks) of dexamethasone.

## **LUNGWORMS**

### **CAUSES**

Lungworm infections in the equine species are caused by *Dictyocaulus arnfieldi*. Infections in the donkey and mule are asymptomatic but provide a source of viable eggs for clinically apparent infections in the horse and pony.

### **EPIDEMIOLOGY**

Lungworm infections have been diagnosed by recovery of larvae in live animals by bronchoscopic examination or at postmortem evaluation. Using this approach, the prevalence of lungworm infection is approximately 68% to 80% in donkeys, 29% in mules, and 2% to 11% in horses.<sup>659,660</sup>

### **PATHOGENESIS**

Donkeys, mules, and asses are asymptomatic reservoirs of the parasite, but instances of lungworm infections have occurred in horses in which no contact with donkeys could be established, suggesting horse-to-horse transmission may be possible.<sup>660</sup> Experimental studies provide evidence that under field conditions, *Pilobolus* spp. fungi may facilitate the spread of lungworm infections in a manner similar to that which occurs in cattle lungworm infections.<sup>661</sup> The infective larvae ascend the coprophilous fungus as it grows on the manure and invade

the sporangia. When the sporangia rupture, the infective larvae disperse with the fungal spores. After the infective larvae (0.4 mm) are ingested, they migrate through the gut wall and are carried to the lungs via the lymphatics. In hosts in which infections are patent, the larvae mature to egg-laying adults in the peripheral bronchioles. The prepatent period is approximately 2 to 3 months. Eggs are transported out of the lungs by the mucociliary apparatus, swallowed, and excreted in the feces where they become infective by 4 days.<sup>662</sup> First-stage larvae have survived for at least 49 days but do not survive over the winter.<sup>663</sup> In horses and ponies, larval development in the lungs is arrested (fifth stage), but airway inflammation still occurs.

### CLINICAL SIGNS

Clinical signs can develop as early as 12 days after infection with a large number of larvae but are often delayed for several weeks in milder cases. Horses exhibit chronic coughing and an increased expiratory effort. Auscultation reveals crackles and wheezes, especially over the dorsal and caudal parts of the lung fields.<sup>664</sup> Signs are often indistinguishable from those associated with recurrent airway obstruction. Donkeys do not typically exhibit clinical signs of infection even when heavily parasitized.

### DIAGNOSIS

Endoscopic examination may reveal a mild lymphoid follicular hyperplasia and copious amounts of exudate in the trachea and bronchioles. Tracheobronchial aspirates or BAL may contain a predominance of eosinophils, although isolated cases of probable lungworm infection have been reported in which eosinophils were absent in the lavage fluid. A peripheral eosinophilia is a variable finding in these horses. Definitive diagnosis is made by identification of *D. arnfieldi* larvae in the sediment of centrifuged mucus, although this process may be difficult.<sup>663</sup> One should examine stained and unstained cytologic preparations. In donkeys and in horses with patent infections, bronchoscopic identification of the lungworm, 16 cm in length, confirms the diagnosis. The Baermann technique is useful for diagnosing lungworms when the infections are patent. It is useful in testing the feces of potential in-contact reservoir hosts to help establish a diagnosis.

### TREATMENT

Ivermectin (0.2 mg/kg) is effective against *D. arnfieldi* in controlled studies and field evaluations and did not cause any detrimental side effects.<sup>665</sup> Moxidectin (0.4 mg/kg) was found to be 99.9% effective in treating lungworm infections in donkeys.<sup>666</sup>

### PREVENTION

Horses should not be pastured with donkeys or mules unless they are confirmed to be free of lungworms.

## ACUTE RESPIRATORY DISTRESS SYNDROME

### CAUSES

Acute respiratory distress syndrome (ARDS) is a syndrome of lung injury characterized by alveolar damage, high-permeability pulmonary edema, and respiratory failure. Primary lung injury may result from aspiration (near drowning), improper administration of medications via nasogastric tubes, inhalation of smoke or noxious gases, oxygen toxicity, or pulmonary infection by viral, bacterial, mycoplasmal, or fungal agents. (See interstitial

pneumonia.) Secondary lung injury may be a sequela of anaphylaxis, gram-negative sepsis or endotoxemia, trauma, embolism, and hypertransfusion.<sup>510,632,667-670</sup> Acute heart failure caused by rupture of the chordae tendinae, severe mitral valve regurgitation, or atrial fibrillation may increase left atrial and pulmonary capillary pressures, causing pulmonary edema.<sup>671</sup>

In human medicine, strict criteria have been established to define ARDS: impaired oxygenation (ratio of  $P_{aO_2}/F_{iO_2} \leq 200$  mm Hg, where  $F_{iO_2}$  is fractional inspired oxygen), detection of bilateral pulmonary infiltrates in chest radiographs, and a pulmonary artery wedge pressure less than 18 mm Hg or no clinical evidence of elevated left atrial pressures.<sup>672,673</sup> The milder form of ARDS is acute lung injury characterized by a  $P_{aO_2}/F_{iO_2}$  ratio at or below 300 mm Hg. Similar criteria have been recommended for use in equine neonatal medicine. For example, in a retrospective study, Dunkel, Dolente, and Boston (2005) described acute lung injury or ARDS in 15 foals using radiographic, microbiologic, and gas exchange criteria. Unfortunately, unless the animal is mechanically ventilated, determining the fractional inspired oxygen level is difficult because it depends on the oxygen flow rate and the animal's ventilation.

### PATHOGENESIS

Many different insults cause capillary permeability and alveolar damage leading to ARDS. This pathway may include complement and leukocyte activation with release of oxygen-free radicals and inflammatory mediators (IL-1, TNF) and secondary destruction of surfactant.<sup>674</sup> The net result is a deterioration of gas exchange and pulmonary mechanics. Whether horses that survive are more predisposed to the development of chronic interstitial lung disease with fibrosis has not been established (see the previous discussion of interstitial lung disease).

### CLINICAL SIGNS

Horses with ARDS are tachypneic or in respiratory distress or both. A red-tinged or yellow frothy material, indicative of pulmonary edema, may be evident at the nares. Fever may be a component of the syndrome, depending on the primary cause. In cases of smoke inhalation, clinical signs may not become evident for several days after exposure to noxious gases.

### DIAGNOSIS

Diagnosis depends on the physical findings and history. One may detect crackles on auscultation and may auscultate fluid within the trachea. Endoscopic examination, if performed without stressing the horse, may reveal the extent of airway edema, inflammation, mucosal necrosis, or sloughing and the presence of soot (smoke inhalation). Radiographs reveal an interstitial pattern, although an alveolar pattern caused by ventral consolidation of the lung fields may follow aspiration pneumonia. Arterial blood gases reveal hypoxemia and hypocapnia. In smoke inhalation, carboxyhemoglobin concentrations exceed 10%, indicating carbon monoxide toxicity.<sup>670</sup>

Echocardiographic evaluation of the heart should be performed to assess left ventricular function, chamber size, and valve patency. Serum troponin levels should be measured to ascertain cardiac injury.

### TREATMENT

The clinician should direct treatment at the primary cause with the understanding that the prognosis is guarded. Lipid pneumonia resulting from aspiration of mineral oil is nearly always

fatal.<sup>632</sup> (See interstitial pneumonia.) Cases of near drowning and smoke inhalation have been treated successfully, with return to athletic function in some cases.<sup>667,668,675</sup> Although in the latter, extensive lung injury and secondary necrosis of airways may eventually cause a fatal obstructive disease.

In horses with ARDS, one should administer intravenous fluid cautiously. Plasma may be needed if hypoproteinemia develops. Furosemide (1 mg/kg intravenously) helps mobilize lung extravascular water, and repetitive dosing at 2- to 4-hour intervals may be required. A continuous-rate infusion of furosemide may also be administered (0.12 mg/kg intravenous loading dose followed by 0.12 mg/kg/hr) in these cases.<sup>676</sup> Because of the reduced bioavailability, oral furosemide administration should be avoided.<sup>677</sup>

Humidified intranasal oxygen (10 to 15 L/min) or mechanical ventilation through a tracheotomy may be necessary. Although technically difficult to perform, adult horses in respiratory failure have been ventilated mechanically.<sup>678</sup> The clinician may perform tracheal suction to remove cell debris and other materials through the endoscope or through a tracheotomy. Surfactant, although expensive, may improve oxygenation and pulmonary mechanics when administered by intratracheal instillation. One may use bronchodilators to treat bronchospasm.  $\beta$ -Adrenergic agonists may be administered through an inhaler (see Table 9-5) or via nebulization. For example, one might nebulize a solution containing 0.9% saline (20 ml), 20% acetylcysteine (10 ml), and albuterol (5 mg). Antimicrobials can be added to the nebulizate. (See previous discussion on pneumonia.) Nonsteroidal antiinflammatory drugs and corticosteroids are also indicated for treating severe permeability edema. One should administer broad-spectrum antimicrobials, including metronidazole, in many of these cases but especially those involving aspiration pneumonia, bacterial and viral pneumonia, and smoke or noxious gas inhalation lung injury.

## RECURRENT AIRWAY OBSTRUCTION

### DEFINITION

Recurrent airway obstruction (RAO) is a naturally occurring respiratory disease characterized by periods of reversible airway obstruction caused by neutrophil accumulation, mucus production, and bronchospasm. The condition has been termed chronic obstructive pulmonary disease, chronic pulmonary disease, chronic airway reactivity, hyperactive airway disease, heaves, broken wind, and hay sickness. The consensus at the International Workshop of Equine Chronic Airway Disease was that the term chronic obstructive pulmonary disease not be used to describe this condition in horses because the pathophysiologic and morphologic aspects of the equine disease are quite different from those of human chronic obstructive pulmonary disease.<sup>679</sup>

Pulmonary function testing demonstrates a decrease in lung compliance, an increase in lung resistance, an increase in the work of breathing, and the development of arterial hypoxemia, usually in the absence of hypercapnia.<sup>680,681</sup> During airway obstruction, affected horses are hyperresponsive to nonspecific stimuli such as histamine, methacholine, and water.<sup>682</sup>

### EPIDEMIOLOGY

The condition occurs worldwide, but the highest prevalence in the United States is in northeastern and midwestern horses that are fed hay and stabled. The condition is also found in

horses stabled in the United Kingdom and in Europe. A similar condition, described in horses maintained on pasture in the southeastern United States, is termed summer pasture-associated obstructive disease (see later discussion). These horses improve when stabled.<sup>683</sup>

Recurrent airway obstruction affects middle-age or older horses, the median age of which is 12 years.<sup>684</sup> No breed predilection occurs, but a familial tendency has been found; a horse born to a dam and sire with RAO is at an increased risk for developing RAO.<sup>685</sup> Jost and colleagues investigated the genetics of RAO by focusing on the linkage association of the IL-4 receptor alpha chain gene (IL4RA), located on equine chromosome 13, to the severity of clinical signs of chronic airway disease.<sup>686</sup> They rationalized this approach because the IL-4 receptor is an integral component of a T helper cell type 2 (Th<sub>2</sub>) (IL-4, IL-13)-mediated immune disorder (see the later discussion on etiopathogenesis) and because, in human asthmatics, linkages between the IL4RA gene (on human chromosome 16) and several distinct populations of asthmatics have been found.<sup>687</sup> Interestingly, Jost and colleagues found a significant haplotype association with clinical signs of airway disease (as assessed by surveys completed by owners) in the offspring of one sire but not that of another sire. This finding suggested the possible existence multiple genetic linkages to the severe chronic airway disease of the phenotype.

### CAUSES

Much debate still occurs concerning the cause of RAO. Many investigators consider RAO to be a hypersensitivity reaction to organic dusts or molds commonly found in poorly cured hay or straw. Dust in horse stables contains more than 50 species of molds, large numbers of forage mites, endotoxins, and inorganic components—a variable mixture of agents, any one of which might induce pulmonary inflammation in a susceptible horse. The two most frequently implicated molds are *Aspergillus fumigatus* and *Faenia rectivirgula* (formerly *Micropolyspora faeni*, a thermophilic actinomycete).<sup>688</sup> Inhalation of aqueous extracts of *A. fumigatus*, *F. rectivirgula*, or *Thermoactinomyces vulgaris* partially but not fully induces RAO in susceptible horses.<sup>682,689,690</sup> Inhalation of endotoxin, a component of hay dust, induces airway neutrophilia but not all of the changes in pulmonary function that characterized RAO.<sup>691,692</sup> Full disease manifestation requires inhalation of hay dust either by natural challenge or by nebulization.

### PATHOGENESIS

Recurrent airway obstruction is characterized by periods of reversible small airway obstruction caused by smooth-muscle contraction and accumulations of mucus and neutrophils. One hypothesis is that inhalation of the organic molds, dusts, and endotoxin induces a Th<sub>2</sub> response involving IgE-mediated degranulation of mast cells. This hypothesis is based on the following findings: (1) increased anti-*Micropolyspora faeni* and anti-*A. fumigatus* IgA and IgE concentrations in the BALF of asymptomatic and symptomatic RAO-affected horses,<sup>693</sup> (2) increased histamine levels in the BALF of RAO-affected horses 5 hours after natural challenge,<sup>690</sup> (3) increased serum IgE levels against recombinant *Aspergillus* antigens in RAO-affected horses,<sup>694</sup> and (4) increased numbers of BAL cells that are positive for IL-4 and IL-5 messenger RNA in RAO-affected horses.<sup>695,696</sup>

Data suggesting that RAO is not a Th<sub>2</sub> immune disorder include the following observations: (1) a poor correlation

between antigen-specific IgE levels and expression of disease<sup>694,697</sup>; (2) the lack of a pulmonary eosinophilic response, as occurs in the Th<sub>2</sub> disorder of human asthma<sup>698</sup>; (3) the finding that the increased allergen-specific isotypes in the BALF of diseased horses are IgGa and IgGb (isotypes not compatible with a Th<sub>2</sub> response)<sup>693</sup>; (4) the lack of increase in IL-4 and IL-5 mRNA concentrations, as detected by quantitative PCR analysis of BAL lymphocytes<sup>699-701</sup>; (5) the lack of increase in IgE protein-positive cells in the lung tissue of RAO-affected horses as compared with controls<sup>702</sup>; and (6) the lack of up-regulation of GATA-3, a transcription factor required for IL-4 gene expression, in the bronchial epithelium of RAO-affected horses.<sup>703</sup>

In horses with RAO, IL-8 concentrations in the BALF are increased relative to levels found in healthy horses.<sup>700,704</sup> This cytokine may be derived from macrophages, neutrophils, or airway epithelial cells and is one of the primary chemoattractants for neutrophil migration into the airways. The gene expression of another neutrophil chemoattractant, IL-17, has also been found to be increased in the BALF cells of RAO-affected horses during the chronic but not acute stages of the disease and is thought to contribute to the persistent influx of neutrophils into the airways.<sup>705,706</sup> Furthermore, in horses chronically affected with RAO, pulmonary macrophages are not more hyperresponsive (*ex vivo*) to hay dust solutions than are cells isolated from controls.<sup>707</sup> This finding suggests again that the continued neutrophil influx in the chronic stages or RAO may be more dependent on the presence of neutrophil and bronchial-epithelial-derived chemokines than on macrophage activation.<sup>706,707</sup>

Other neutrophil- and macrophage-derived products such as reactive oxygen species and proteases also may contribute to the inflammatory process of RAO. Art, Kirschvink, Smith, et al.<sup>708</sup> suggested that an oxidative stress caused by the release of reactive oxygen species from granulocytes and macrophages develops in the airways of RAO-affected horses. Their conclusion is based on the finding that oxidized glutathione levels and glutathione redox ratios (the ratios of oxidized glutathione to total glutathione levels) are elevated in the pulmonary epithelial lining fluid of RAO-affected horses relative to controls. They further suggested that the oxidant stress does not incite but rather exacerbates the existing inflammation.

Interestingly, oxidative stress<sup>709</sup> has been found to activate NFκB, a transcription factor that regulates the expression of many proinflammatory cytokines and adhesion molecules, including tumor necrosis factor, IL-1β, IL-8, and intercellular adhesion molecule 1.<sup>710</sup> Recently, Bureau, Bonizzi, Kirschvink, et al.<sup>711</sup> demonstrated that levels of NFκB in the bronchial brushing cells of RAO-affected horses were increased many fold, the magnitude of which correlated with the severity of the clinical disease. Furthermore, the airway epithelial cell expression of intercellular adhesion molecule 1, a protein required for migration of neutrophils from the pulmonary vasculature into the lung parenchyma, paralleled the expression of NFκB, suggesting that this protein, along with IL-8, enhances the airway neutrophilia. Up-regulation of IL-8 in RAO-affected horses occurs at least 24 hours after hay dust exposure, suggesting that this epithelial chemokine is not responsible for early neutrophil influx into the airways.<sup>706</sup>

Proteases released from neutrophils and macrophages in the airways of RAO-affected horses may contribute further to inflammatory cell influx and possible tissue damage. The tracheal epithelial lining fluid of horses with RAO has increased concentrations of matrix metalloproteinases that exhibit

collagenolytic, gelatinolytic, and elastinolytic activities.<sup>712-714</sup> The importance of these proteases, as well as other inflammatory mediators and arachidonic acid metabolites, to the initiation and development of bronchospasm, mucus secretion, and neutrophil influx remains to be determined.

## CLINICAL SIGNS

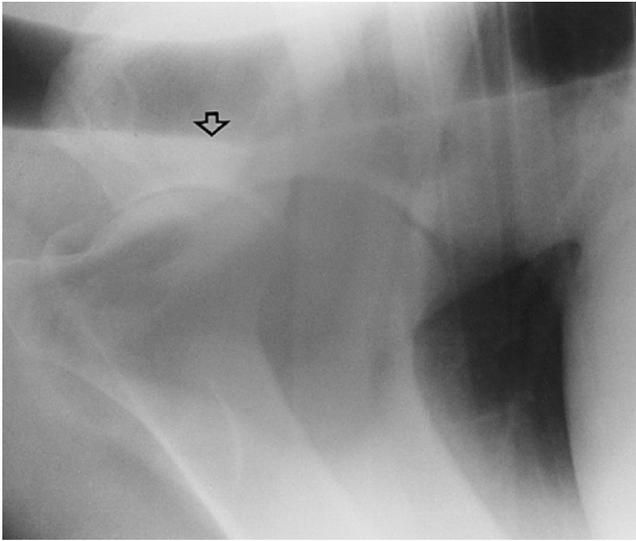

Horses with RAO are usually afebrile and exhibit a chronic spontaneous cough, mucopurulent nasal discharge, and accentuated expiratory effort. Hypertrophy of the external oblique and rectus abdominis muscles caused by continued muscle recruitment is evident (heave line). Associated abdominal pressure changes may be large enough to cause the anus to protrude during expiration. The respiratory rate may be normal or increased. Exercise intolerance, weight loss, nostril flaring, reluctance to move, and cachexia may be evident in severe cases. Despite the development of pulmonary hypertension when horses are symptomatic,<sup>715,716</sup> RAO-affected horses rarely develop cor pulmonale—tachycardia, jugular distention, jugular pulsation, and ventral edema. Between episodes of severe RAO, cardiovascular alterations return to normal.<sup>717</sup> Nevertheless, a small percentage of horses do develop right ventricular hypertrophy and signs of right heart failure.<sup>716</sup>

## DIAGNOSIS

The diagnosis is based on clinical signs, history of a seasonal disorder associated with husbandry alterations (e.g., being fed hay or being maintained in a dusty lot), and cytologic evidence of tracheobronchial aspirates supporting a nonseptic inflammation. Auscultation may reveal inspiratory or expiratory wheezes, crackles, or tracheal rattles, although it may require examination after a rebreathing bag to detect abnormal lung sounds in mildly affected horses. Percussion may be normal, or an expanded lung field may be detectable. A clinical scoring system has been developed to categorize the severity of RAO. Total clinical score is calculated as the sum of the score for nostril flaring (ranging between 1 to 4) and abdominal breathing effort (ranging between 1 to 4). Horses with a clinical score of 3 to 4, 5 to 6, or 7 to 8 are diagnosed as mild, moderate, or severe, respectively. However, for mildly affected horses, the physical examination findings underestimate the severity of changes in pulmonary function tests.<sup>718</sup>

Endoscopic examination reveals excessive mucopurulent exudate within the trachea. A bronchoalveolar lavage supports a nonseptic inflammatory reaction with increases in mucus and the percentage of intact neutrophils (>25% of the total nucleated cell count). In the BALF, the percentage of neutrophils may be as great as 90%, far exceeding the normal 5% to 15% found in healthy horses that are stabled and fed hay. In most affected horses, the percentages of eosinophils or mast cells are not increased. Albumin and immunoglobulin levels within the BAL may not increase.<sup>719</sup> Gram positive organisms may be retrieved by tracheobronchial aspirates if a concurrent septic inflammation exists, but this is rare. Pollen, fungal hyphae, and Curschmann's spirals (inspissated mucus plugs) also may be visible.

Thoracic radiography may demonstrate an increase in the interstitial and bronchial pattern throughout the lung fields. However, these changes may be difficult to interpret relative to the normal aging changes that occur. One may also detect exudate within the trachea by thoracic radiography (Figure 9-20). Radiographs are useful in ruling out thoracic neoplastic or infectious disorders in horses that have clinical signs

**FIGURE 9-20** Tracheal fluid or exudate (arrow) is visible ventrally in the trachea at the level of the thoracic inlet. (Courtesy D. S. Biller, Manhattan, Kan., 1991.)

resembling RAO. In severely affected horses with RAO that repeatedly fail to respond to bronchodilators and glucocorticoids, radiographs should be obtained to rule out the existence of bronchiectasis (dilation or deformation of the bronchi or bronchioles).<sup>720</sup> This relatively uncommon complication of RAO causes irreversible airway obstruction as a result of collapse of the affected airways during expiration.

Ultrasound evaluation of RAO-affected horses confirms a shift of the caudal lung border caused by alveolar hyperinflation. However, gas in the large colon (left side) or in the cecum (right side) may preclude complete imaging of the most caudal extent of the lung fields at the sixteenth intercostal space. On ultrasound examination, small hypochoic areas of irregularity on the lung surface may be detected, but, in general, this imaging modality does not detect airway inflammation.<sup>721</sup>

Echocardiographic findings of RAO-affected horses demonstrate an increase in the pulmonary artery diameter, an increase in the ratio of the diameters of the pulmonary artery to the aorta, and abnormalities in ventricular septal motion.<sup>717</sup> However, no changes in serum troponin I concentrations occur during experimentally induced RAO.<sup>717</sup>

Intradermal skin testing has been occasionally advocated for diagnosing RAO and for detecting sensitizing allergens. Theoretically, RAO-affected horses should react if sensitized to a given allergen, but the results supporting this theory have been inconclusive. For example, in some studies, clinically normal horses have positive skin test reactions to the allergens, whereas RAO-affected horses lack positive reactions.<sup>722-724</sup> In other studies, the percentage of RAO-affected horses exhibiting positive skin reactions (to any antigen) exceeds that of controls<sup>725</sup> or the response of RAO-prone horses to histamine challenge (measured at 0.5 hours after injection) or to *Aspergillus* spp. antigens (measured at 24 hours after injection) is enhanced.<sup>726</sup> Apparently, positive skin tests and serum precipitins to fungal and thermophilic actinomycete antigens are found in many normal and in RAO-affected horses and probably reflect a level of exposure of the horse rather than a susceptibility to RAO. In general, intradermal skin testing does

not allow one to identify RAO-affected horses or the specific inhaled particulate that is inciting the inflammation.

A CBC and serum chemistry panel are of limited usefulness in diagnosing RAO because no abnormalities are detectable in the leukogram or in serum biochemistries.<sup>684</sup> These tests may be used to rule out the existence of a pneumonia or a neoplastic process. Arterial blood gas analyses are normal in approximately 25% of the horses with RAO, but in others, the development of arterial hypoxemia ( $\text{PaO}_2 < 85$  mm Hg) in the absence of arterial hypercapnia is noted.<sup>727</sup>

### **PATHOLOGIC SIGNS**

Postmortem examination reveals a diffuse bronchiolitis with goblet cell metaplasia, airway smooth-muscle hypertrophy and hyperplasia, excess mucus, and inflammatory cells in the small airways.<sup>728,729</sup> Eosinophilic infiltration around the bronchioles is a variable finding present in approximately one third of affected horses. Varying degrees of alveolar overinflation and atelectases also are found, as well as evidence of fibrosis of the alveolar septa.<sup>730</sup> The larger airways—the bronchi and trachea—may show variable changes, including epithelial hyperplasia with loss of ciliated cells, goblet cell hyperplasia, and inflammatory cell infiltration.<sup>731</sup>

### **TREATMENT**

Elimination of the source of mold or dust is not only the most beneficial step in the treatment regimen but also the most difficult management change to implement and achieve long term.<sup>684</sup> Horses should be switched to a diet consisting of pelleted feeds or hay cubes, making the dietary transition over 3 to 5 days. Some horses will tolerate hay that has been soaked in water, but this practice reduces the nutrient value of the hay and is often forsaken when the weather becomes cold. Unless pasture exacerbates the condition, the owner should keep horses outside, blanket them in the winter, and allow access to a three-walled shelter affording protection from the wind and rain. For chronically affected horses that have been turned out to pasture, clinical remission and normalization of conventional pulmonary function tests takes 4 to 8 weeks, depending on weather conditions. Recent data suggest that when RAO-susceptible horses are maintained in a low-dust environment (outside, no hay) for a prolonged period (years), they still exhibit a reduction in forced expiratory flow despite the absence of clinical signs. This finding suggests the existence of irreversible airway remodeling in affected animals.<sup>732</sup>

If the horse must be stabled, tall bedding should be shredded paper or shavings to reduce inhaled dusts and molds. Surrounding stalls should be bedded similarly. Although such stabling changes improve lung function somewhat, airway hyperreactivity still remains.<sup>733,734</sup> In a recent study of 12 RAO-affected horses that were stabled and fed a pelleted ration, pulmonary function tests and BALF neutrophil percentages improved within 4 weeks of implementing environmental changes. However, in four horses, pulmonary health (as assessed by BALF neutrophil percentages, maximal pleural pressure changes, and inflammatory cytokine profiles of the BALF cells) had not returned to normal by the conclusion of the study.<sup>735</sup>

Medical management is recommended in horses with clinical signs of RAO because environmental change alone takes several weeks to quiet the pulmonary inflammation. Corticosteroids are efficacious in reducing the inflammatory reaction in the lungs, whereas nonsteroidal antiinflammatory drugs provide no benefit. One potential regimen is to give oral prednisolone at

2.2 mg/kg once daily in the morning for 7 to 10 days, 1.1 mg/kg once daily for 7 to 10 days, 0.50 mg/kg once daily for 7 to 10 days, and 0.50 mg/lb every other day for 7 to 10 days. Alternatively, one may institute a course of parenteral or oral dexamethasone. For the 500-kg horse, the course is 40 to 50 mg intramuscularly once daily every other day for three treatments followed by 35 to 45 mg intramuscularly once daily every other day for three treatments, 30 to 40 mg intramuscularly once daily every other day for three treatments, and so forth until the horse is weaned off of the dexamethasone. A similar dosing schedule may be used when the parenteral dexamethasone formulation is given orally except that the initial dosage is 0.165 mg/kg for three treatments, followed by 0.084 mg/kg for three to four treatments, and 0.042 mg/kg for three to four treatments. In horses that remain stabled, are fed a pelleted feed, and receive oral dexamethasone protocol, a normalization of pulmonary function and a significant reduction in airway epithelial and luminal cell inflammatory gene expression (IL-8, IL-1 $\beta$ ) is seen by 4 weeks after implementing the regimen.<sup>735</sup>

Other parenteral glucocorticoids that have been evaluated in RAO-affected horses maintained in dusty environments and fed hay include triamcinolone acetonide (0.09 mg/kg intramuscularly once) and isoflupredone (0.03 mg/kg intramuscularly once daily for several days).<sup>736,737</sup> The latter, because of its mineralocorticoid effects, can cause hypokalemia; therefore serum electrolytes should be supplemented and monitored. Corticosteroid use may be contraindicated in horses predisposed to laminitis or exhibiting endocrinopathies or those that have gastritis or gastric ulceration.

Inhaled steroids have been recommended to treat the pulmonary inflammation of RAO but may not provide a therapeutic benefit for 24 to 72 hours. For horses in respiratory distress, intravenous dexamethasone can provide an improvement within 4 to 6 hours. This application may be followed by treatment with inhaled steroids. A metered-dose inhaler containing fluticasone can be attached to a spacer on the Aeromask (Trudell Medical, London, Ontario, Canada) or to another drug delivery system (Equinehaler, Equine Health Care, Inc.) and administered to the horse during inspiration. The recommended dose is 2 mg twice daily. In RAO-affected horses that were still fed hay, fluticasone administration was associated with a marked improvement in pulmonary function, a normalization of BALF neutrophil counts, and a reduction in IL-8 copy numbers in BALF cells.<sup>700</sup>

Bronchodilators also are recommended for treating RAO. Three types of compounds are used to relax airway smooth muscle:  $\beta$ -adrenergics, methylxanthines, and anticholinergics.  $\beta_2$ -Adrenergic compounds include clenbuterol, albuterol, salmeterol, fenoterol, and trimetoquinol. Experimental investigations with clenbuterol suggest that when given at a dosage of 0.8  $\mu$ g/kg once daily by mouth, the drug may be efficacious in alleviating some of the signs of RAO. In addition to a direct smooth-muscle effect, clenbuterol may stabilize mast cells, increase mucociliary clearance, improve airway secretions, and decrease inflammatory cytokine production.<sup>738,739</sup> If effects are not obtained at 0.8  $\mu$ g/kg orally, then the dose may be increased step-wise by 25% increments. Adverse effects (tachycardia, tachypnea, sweating) are signs of toxicity. Albuterol is absorbed poorly from the gastrointestinal tract; thus inhalation is the recommended method of administration. Salmeterol is purported to be a long-acting  $\beta_2$ -agonist. However, in one study in RAO-affected horses, the investigators found that significant improvements in pulmonary function lasted

for only 6 hours after its administration.<sup>740</sup> Aerosolized trimetoquinol (1000  $\mu$ g administered via an ultrasonic nebulizer) significantly improved pulmonary function tests that lasted for 4 hours.<sup>741</sup> Some suggested doses of  $\beta_2$ -agonists that can be administered by metered-dose inhalers through the Aeromask are these: albuterol, 720  $\mu$ g three to four times daily; fenoterol, 1 to 2  $\mu$ g three to four times daily; and salmeterol, 210  $\mu$ g three to four times daily. Administration of the  $\beta_2$ -agonist before corticosteroid dosing enhances the deposition of the latter in the smaller airways.<sup>742</sup> Long-term use of  $\beta_2$ -agonists has been associated with a down-regulation of  $\beta$ -receptors in humans, but whether this occurs in horses is unknown.

The methylxanthines include aminophylline (theophylline) and pentoxifylline, which dilate smooth muscle by increasing cyclic adenosine monophosphate levels intracellularly. Cyclic adenosine monophosphate also inhibits degranulation of mast cells and subsequent mediator release. One may give aminophylline at 4 to 6 mg/kg orally three times daily. However, in a recent study, aminophylline at 18 mg/kg intravenously provided clinical improvement in only 50% of horses.<sup>743</sup> Pentoxifylline, another methylxanthine derivative and phosphodiesterase inhibitor, is well absorbed orally and improves pulmonary function tests in RAO-affected horses when administered at 16 g twice daily by mouth.<sup>744</sup> It does not reduce BALF neutrophilia.

The third class of compounds used to affect smooth-muscle dilation is the anticholinergics, of which atropine, glycopyrrolate, and ipratropium are representatives. Atropine provides clinical improvement when administered intravenously at 0.02 mg/kg, but the duration of the effect is short lived (2 hours), and atropine may be associated with the development of ileus, abdominal pain, tachycardia, mydriasis, and thickening of airway secretions.<sup>743</sup> Atropine is generally used for emergency relief of airway obstruction. Glycopyrrolate is efficacious at a dose of 0.007 mg/kg, but it may also cause colic. One can also administer ipratropium bromide by inhalation at a dose of 180 to 360 mg three times daily with a low risk of inducing systemic side effects.<sup>679</sup> The powder form may be nebulized (dose of 2 to 3  $\mu$ g/kg).

Disodium cromoglycate acts to stabilize mast cell degranulation and inhibit the vagal efferent component of histamine response. A suggested dose<sup>688</sup> is 80 mg once daily for 4 days administered by nebulization. Mucolytics (acetylcysteine, dembrexine) and mucokinetics (iodides, bromhexine) may provide some relief.<sup>745</sup> Antimicrobials are indicated if microorganisms are isolated on the tracheobronchial aspirate.

## OTHER THERAPIES

In horses that develop respiratory distress caused by bronchospasm and airway inflammation, additional therapies are required. Administering nasal oxygen at flow rates as low as 5 L/min improves arterial oxygen tensions by as much as 30 mm Hg in some severely affected horses.<sup>746</sup> As the total nasal oxygen flow increases, so too will the mean arterial oxygen tension, although not to the same degree that occurs in healthy horses. Flow rates of 30 L/min (delivered by two nasal cannulae at 15 L/min) are associated with coughing and gagging in the horse. Nasal oxygen supplementation does not reduce breathing frequency, suggesting that stimulation of vagally mediated afferents—perhaps responding to inflammatory mediators—is responsible for the tachypnea.

Furosemide (1.0 mg/kg intravenously or nebulized) provides beneficial effects to RAO-affected horses within 20 minutes of its administration, decreasing total lung resistance

( $R_L$ ) and increasing  $C_{dyn}$  without affecting  $P_{aO_2}$ .<sup>747</sup> Beneficial effects appear to be mediated by prostaglandin  $E_2$ , derived from either the renal or airway epithelium, that promotes smooth muscle relaxation. Prior treatment with the cyclooxygenase inhibitor flunixin meglumine prevents furosemide-induced bronchoconstriction.<sup>748</sup>

Therapies that are not efficacious in the treatment of RAO-affected horses include a single acupuncture treatment,<sup>749</sup> the oral administration of an herbal preparation containing thyme and *Primula*,<sup>750</sup> or the rapid intravenous administration of 30 L of isotonic saline.<sup>751</sup>

## PROGNOSIS

RAO-prone horses are likely to develop acute exacerbations of the disease when husbandry practices lapse or when weather conditions become adverse. Horses do not *outgrow* the disorder, and, in fact, some clinicians believe that the inflammation becomes more difficult to manage as the horse ages. The basis for the lack of clinical response is unknown but might be the result of lung remodeling—development of fibromuscular hyperplasia in the alveolar septae,<sup>716</sup> excessive smooth-muscle hyperplasia,<sup>729</sup> bronchiectasis,<sup>720</sup> or potential down-regulation of the glucocorticoid receptor.

If proper environmental management changes are implemented, and if the appropriate therapy is initiated, clinical remission occurs in most cases. In a survey of RAO-affected horses that had been examined and treated at a referral center 2 to 4 years previously, 20% of the original cases (3 of 15) had been euthanized, 33% were still receiving bronchodilators on an as-needed basis, and athleticism had not decreased in 92% of the horses.<sup>752</sup> In a similar survey,<sup>684</sup> 13% of horses diagnosed with RAO 3 to 4 years earlier had been euthanized. However, more than 50% of the respondents in that survey stated that the athletic performance of the horse had been compromised by the disease. Perhaps this difference between the two surveys simply reflects a failure of the owners to comply with environmental management recommendations. When queried about the husbandry practices, 77% of the respondents still stabled the horse for part of the day, and 84% still fed dry hay. Because the effects of repetitive episodes on the development of irreversible changes in lung structure have yet to be determined, clients should be encouraged to implement effective husbandry changes that minimize the recurrences of RAO.

## PREVENTION

Once the clinician has diagnosed RAO, the horse will always be susceptible to recurrences of disease. Husbandry changes should be implemented to decrease environmental dust and organic mold exposure. During periods of hot, humid, or dusty conditions, prophylactic administration of a steroid and bronchodilator via the metered-dose inhaler may be indicated. Routine immunizations against the viral respiratory pathogens and good management practices are logical suggestions.

## SUMMER PASTURE-ASSOCIATED OBSTRUCTIVE PULMONARY DISEASE

### DEFINITION

In the southeastern United States, a condition clinically similar to RAO, called summer pasture-associated obstructive pulmonary disease (SPAOPD), develops in mature horses that are maintained at pasture. Clinical signs typically show during

late spring, summer, and early autumn.<sup>683</sup> This disorder has also been reported to occur in horses in the United Kingdom that are out on pasture.<sup>753,754</sup>

Horses with SPAOPD exhibit airway neutrophilia, excessive mucus production, and accentuated breathing efforts,<sup>755</sup> although the inciting environmental factors and the immunopathogenesis of this disorder have yet to be determined.

Because of its similarity to RAO, investigators have sought to determine if SPAOD reflects a TH<sub>2</sub> immune response to inhaled molds or antigens by examining BALF antibody isotypes and BAL cell cytokine profiles. Neither the total nor the antigen-specific IgE and IgG titers to *Aspergillus* spp., *Cladosporium herbarum*, *Penicillium* spp., *F. rectivirgula*, *Saccharomonospora viridis*, *Thermoactinomyces thalophilus*, and the forage mite *Lepidoglyphus destructor* in tracheal lavage fluid are increased in SPAOD-affected horses relative to controls.<sup>756</sup> During the winter months, when horses are free of clinical signs, *A. fumigatus*-specific IgG titers in SPAOPD-affected horses exceed those of controls, but whether this increase reflects ongoing production or decreased consumption cannot be determined. Cytokine profiles of BALF cells isolated from SPAOPD-susceptible and -affected horses have also been examined. When horses are symptomatic, the mRNA copy numbers of both IL-4 and interferon-gamma in BALF cells are increased relative to controls.<sup>757</sup> This difference is not apparent when horses are asymptomatic, although the copy number of IL-4 in the SPAOPD-prone horses does not decrease during the asymptomatic periods either.

### TREATMENT

Recommendations for treatment of RAO-affected horses include environmental management changes such as moving the horse from the pasture to a clean stable with wood shavings for bedding. Dusty and hot environments should be avoided because these conditions exacerbate SPAOD, although this task may be difficult to achieve in the southeastern United States.<sup>758</sup> As with RAO, corticosteroids and bronchodilators may be administered to reduce inflammation, airway hyperreactivity, and bronchoconstriction.

## INFLAMMATORY AIRWAY DISEASE

### DEFINITION

In a recent ACVIM Consensus Statement, the following criteria were listed to define the IAD phenotype: (1) poor performance, exercise intolerance or coughing, with or without excess tracheal mucus; (2) nonseptic inflammation detected by cytologic examination of BALF; and (3) pulmonary dysfunction based on evidence of lower airway obstruction, airway hyperresponsiveness, or impaired blood gas exchange at rest or during exercise.<sup>759</sup> Excluded from this group are horses with evidence of systemic infection (fever, depression, inappetence) and those with increased respiratory efforts at rest (RAO, SPAOPD). In defining the syndrome, the panel stated that airway inflammation should be determined by assessing inflammatory cell percentages in the BALF as opposed to tracheal washes.

### EPIDEMIOLOGY

Although IAD is encountered predominantly in young performance horses,<sup>65,144</sup> those of any age may be affected.<sup>760</sup> A prevalence of 20% to 80% among racehorses in training has been reported.<sup>144,761</sup> The variation in prevalence may reflect

differences in methods used. The amount of tracheal exudates detected endoscopically increases as a function of exercise intensity,<sup>144</sup> thus one may miss the diagnosis of IAD if one performs endoscopic examination in the resting horse.<sup>762</sup> A second factor contributing to the range in prevalence rates may be the age of the horse evaluated. In an epidemiologic survey of young racehorses in Britain, the prevalence rate of IAD decreased with age: In 4-year-old horses, it was 2% compared with 9% in the 2-year-old horses.<sup>763</sup> The relationship between IAD in young horses and RAO in mature horses is unknown. Current thinking holds that IAD progresses to RAO.<sup>679</sup> In non-racehorses or in sport horses, IAD is usually diagnosed at an older age than in racehorses.<sup>764</sup>

## ETIOPATHOGENESIS

The definitive cause of lower airway inflammation observed in horses with IAD is currently unknown. It may be multifactorial, with the relative importance of a causative agent dependent on the age of the horse, its environment, and its athletic use. IAD may reflect the response of the lung to the presence of one or all of the following factors: (1) low-grade persistent bacterial or viral infections; (2) autologous blood from exercise-induced pulmonary hemorrhage; and (3) inhaled stable dusts, molds, endotoxin, particulate matter, or environmental pollutants such as hydrogen sulfide, ammonia, ozone, sulfur dioxide, nitrogen oxide, and carbon monoxide.

Studies in the United Kingdom and Australia suggest that bacterial agents may be involved in the pathogenesis of IAD.<sup>144,765-770</sup> Using an inflammatory score based on the amount of mucus, total nucleated cell count, and neutrophil percentages in endoscopically obtained tracheobronchial aspirates, investigators found that as the inflammatory score increased, the percentage of positive bacterial cultures also increased.<sup>768</sup> The most commonly isolated organisms were *S. equi* subsp. *zooepidemicus*, *S. pneumoniae*, *A. equuli*, and *Pasteurella* spp. *Mycoplasma* spp. were also isolated from some horses with IAD.<sup>617,763</sup> That the prevalence of IAD decreased with increasing age of the horse was attributed to the development of an effective immune response.

In studies in the United Kingdom and in Australia, no association between the onset of IAD and seroconversion to EHV1, ERAV, ERBV1, or equine influenza existed,<sup>765,767,769</sup> suggesting that IAD is not associated with viral infection. Nevertheless, a viral cause had been proposed for IAD based on the cytologic improvements in BALF constituents in horses treated with oral interferon- $\alpha$ . In a study of 32 Standardbred horses with a history of poor performance referable to the respiratory tract, the BALF total nucleated cell count and the percentages of BALF neutrophils, lymphocytes, and monocytes in horses with IAD were significantly increased as compared with control horses.<sup>771-773</sup> Lymphocytosis and monocytosis were consistent with a low-grade viral infection. A 5-day course of oral interferon- $\alpha$  (50 U/day) lowered total nucleated cell counts and converted the cell distribution to a noninflammatory profile for at least 15 days. The investigators did not describe whether the amelioration of pulmonary inflammation was associated with an improvement in athletic performance. They also did not evaluate horses endoscopically beyond 2 weeks to determine if cessation of interferon- $\alpha$  therapy was associated with a return of IAD.

Autologous blood, derived from rupture of pulmonary capillaries during intense exercise, has also been suggested as a cause of IAD. Instillation of blood causes a neutrophilic

pulmonary inflammatory reaction in the lungs, suggesting that pulmonary hemorrhage may contribute to IAD.<sup>774</sup> Inoculation of blood into the bronchial tree of retired racehorses induced an inflammatory response 8 and 14 days later characterized by increased macrophage activity, alveolar septal thickness, and collagen content.<sup>775</sup> Similarly, in horses (2 to 4 years of age), a single intrabronchial instillate of autologous blood was associated with increased numbers of alveolar macrophages by 24 hours, 48 hours, and 7 days after blood inoculation. In contrast, by day 14, no evidence of alveolar fibrosis was found in lung tissues.<sup>776</sup>

Inhalation of stable dusts, environmental particulates, mites, endotoxin, and fungal wall components may also cause or contribute to IAD. The risk of IAD increases in horses that are stabled.<sup>777,778</sup> Episodes of IAD are shorter in horses bedded on shredded paper.<sup>765</sup> Environmental pollutants also have been suggested as a cause of IAD. Many racetracks and training facilities are located in metropolitan areas with significant accumulations of smog. No data exist verifying this agent as a cause of IAD, although Mills et al. (1996) found that when healthy horses were exposed to ozone, indices of oxidant stress in the pulmonary epithelial lining fluid increased (e.g., the amounts of reduced glutathione or glutathione disulfide, the glutathione redox ratio, the total iron concentrations), which were similar to those found in horses with poor performance. However, these changes can also occur in pulmonary disease not induced by ozone.

Another environmental factor that may contribute to development of IAD is the temperature of inspired air. In experimental studies of horses performing submaximal exercise, chilling of the inspired air to  $-5^{\circ}\text{C}$  was associated with a modest increase in BALF neutrophil percentages (16% versus 11% in controls) measured 24 hours after the exercise cessation. Significant increases were found in the expression of IL-1, IL-5, IL-6, IL-8, and IL-10 in BALF relative to the control horses.<sup>779</sup>

Finally, Hare and Viel<sup>63</sup> have also suggested that a type I (IgE-mediated) hypersensitivity reaction to inhaled environmental allergens could be the cause of IAD. They studied young Standardbred racehorses with a history of poor performance and found evidence of peripheral blood and BALF eosinophilia (12% eosinophils). Normally, the percentage of eosinophils in BALF is less than 2%. Because they found no evidence of pulmonary or intestinal parasitism in this group of affected horses, the investigators attributed the eosinophilic IAD to an allergic reaction.

## CLINICAL SIGNS

Inflammatory airway disease is frequently subclinical but in some cases may be associated with poor athletic performance, a chronic intermittent cough, and increased mucoid airway secretions. Serous to mucopurulent nasal discharge is commonly observed in young horses.<sup>765</sup> Thoracic auscultation is usually unremarkable. Affected horses may occasionally have increased respiratory rates and enhanced abdominal breathing. However, if maximal pleural pressure changes are measured, they are within the normal reference range ( $<10\text{ cm H}_2\text{O}$ ).<sup>65</sup> Pyrexia is generally not a feature of the disorder. Horses may have evidence of concurrent EIPH.

## DIAGNOSIS

With the exception of cases of IAD associated with pulmonary eosinophilia, CBC and chemistry profiles are usually within normal limits but are helpful in ruling out bacterial

or viral pneumonia. The diagnosis of IAD is aided by endoscopic examination of the respiratory tract and the finding of exudate in the nasopharynx and in the trachea. Anecdotal reports that pulmonary inflammation is associated with thickening and blunting of the tracheal septum have recently been challenged.<sup>780</sup> Endoscopy permits one to obtain a sample of tracheobronchial aspirates for culture if so desired (using a guarded swab) and to perform a BAL. Cytologic analysis of the BALF demonstrates an increased total nucleated cell count, a mild neutrophilia, lymphocytosis, and monocytosis. In some young racehorses with IAD, the percentage of mast cells (>2%) and eosinophils (>1%) in the BALF are increased. Although it has been recommended that the diagnosis of IAD be based on BALF cytologic findings, a recent study demonstrated that this approach alone would miss the diagnosis of IAD in approximately one third of the affected horses.<sup>781</sup> These investigators suggested that the diagnosis of airway inflammation should be based on tracheal (>20% neutrophils) or BALF (>5% neutrophils) cytologic evaluations obtained 1 to 2 hours after the horse has performed a standardized treadmill exercise test. The exercise test is performed for two reasons: (1) the exercise hyperpnea enhances endoscopic and cytological evidence of IAD,<sup>762,782</sup> and (2) the exercise test eliminates (or identifies) other causes (musculoskeletal, cardiovascular) of poor performance. During the standardized treadmill exercise test, one should assess the upper respiratory tract with videoendoscopy; the cardiovascular system with electrocardiogram, post-exercise echocardiogram, and pre- and postexercise serum troponin concentrations; and the musculoskeletal system with lameness examination and pre- and postexercise serum creatine kinase and aspartate transaminase concentrations. During the treadmill exercise testing, arterial blood gases should also be obtained for analysis. In exercising horses, the PaO<sub>2</sub> of select horses with IAD alone or in combination with EIPH was significantly less than in healthy control horses.<sup>783</sup>

Thoracic radiographs are a low-yield diagnostic modality in IAD cases because no correlation exists among radiographic score, BALF cytologic findings, lung function, and measures of airway hyperreactivity.<sup>784</sup> Thoracic radiographs can be used to exclude alternative diagnoses but not to confirm the diagnosis of IAD.

Specialized pulmonary function tests such as forced expiration and forced oscillation mechanics have been used to identify horses with IAD.<sup>65,785,786</sup> Measures of airway hyperreactivity, performed by determining dose-dependent alterations in respiratory mechanics after nebulization of methacholine or histamine, have demonstrated that some horses with IAD have hyperresponsive airways or airway narrowing or both.<sup>63-65</sup>

## TREATMENT

Because the cause of IAD remains uncertain, most treatment recommendations aim at environmental alterations to decrease exposure to dust, molds, and allergens. Horses should have pasture turnout whenever possible. When stabled, horses should be maintained in a well-ventilated barn free of noxious gases. Horses with bacterial infections should receive a 7- to 10-day course of an antibiotic, the selection of which is based on culture and sensitivity results from the tracheobronchial aspirate. Horses may benefit from a 1-week period of rest coupled with a 5-day course of orally administered interferon- $\alpha$  (natural human interferon- $\alpha$  50 U or recombinant human interferon- $\alpha$  90 U). In a clinical trial of 34 young Standardbreds diagnosed with IAD, treatment with interferon- $\alpha$  was

associated with recurrence of cough 4 weeks later in only 23% of the horses as compared with relapse in 75% of controls.<sup>787</sup> Interferon- $\alpha$  could reduce inflammation via elimination of persistent viral infections, modulation of an allergic response, or attenuation of proximal mediators of inflammation.<sup>787</sup>

One should also implement efforts to decrease the severity or frequency of EIPH by having horses train and race with furosemide. In the absence of an infectious cause, horses may also benefit from a 2- to 4-week course of corticosteroids: prednisolone at 2.2 mg/kg orally once daily for 7 to 10 days, followed by 1.0 mg/kg orally once daily for 7 to 10 days, and then 1.0 mg/kg orally once every other day for 7 to 10 days. As is the case with glucocorticoids, controlled studies examining the efficacy of bronchodilators in horses with IAD are lacking. Aerosolized albuterol (900  $\mu$ g) administered to eight Standardbred horses (four of which exhibited airway hyperreactivity without clinical evidence of IAD) did not alter maximal oxygen consumption, maximal carbon dioxide production, or treadmill speed at which horses exhibited a heart rate of 200 beat/min.<sup>788</sup> Whether horses with overt signs of IAD benefit from treatment with bronchodilators remains to be determined.

## EXERCISE-INDUCED PULMONARY HEMORRHAGE

### CAUSES

Strenuous exercise is associated with hemorrhage from the pulmonary vasculature into the alveoli and airways, primarily in the caudal dorsal lung segments. Histologically, EIPH is characterized by the presence of edema, rupture of the pulmonary capillaries, and intraalveolar hemorrhage.

### EPIDEMIOLOGY

Exercise-induced pulmonary hemorrhage has been detected in most breeds of horses undergoing strenuous exercise. The prevalence of EIPH is estimated to be between 44% and 75% in Thoroughbreds, 26% and 77% in Standardbreds, 62% in racing Quarter Horses, 50% in racing Appaloosas, 68% in steeplechasers, 67% in timber racing horses, 40% in 3-day event horses, 10% in pony club event horses, and 11% in polo ponies.<sup>789-796</sup> Indeed, EIPH probably occurs in any breed of horse that is strenuously exercised, but, apparently, the intensity of exercise rather than the duration of exercise is more important in its development. No clear correlation exists between EIPH and the location of stables, the condition of the track, or the track type.<sup>797</sup> In a recent study of Australian racing Thoroughbreds (ages 1 to 10 years) that were not permitted to receive furosemide prerace or to wear nasal dilator strips during the race,<sup>798</sup> EIPH was associated with the presence of excess tracheal mucus or tracheal dirt and with concentration of airborne particulates. EIPH was not associated with the age of the horse, gender, weight carried, and race distance, although previous studies have indicated a greater prevalence of EIPH in older horses.

### PATHOGENESIS

Numerous mechanisms have been suggested to cause EIPH including ventilation inhomogeneities caused by inflammatory airway disease (IAD),<sup>799,800</sup> upper airway obstruction,<sup>801,802</sup> mechanical concussive forces associated with locomotion,<sup>803,804</sup> redistribution of blood flow in the lung,<sup>805</sup> and stress failure of the pulmonary capillaries.<sup>806</sup>

Robinson and Derksen<sup>799</sup> proposed that poor collateral ventilation in the horse coupled with small airway disease, and thus altered time constants for alveolar filling, caused underventilation of certain lung units. Extreme fluctuations in the alveolar pressure of these underventilated regions during exercise produced parenchymal tearing or alveolar capillary rupture. Small airway disease (IAD) has been detected in a large percentage of horses with EIPH.<sup>800</sup> However, its absence in the lungs of young racehorses that exhibit evidence of EIPH suggests that small airway disease, at least, is not an inciting cause of EIPH.<sup>807</sup> The role of small airway disease in propagating the cycle of EIPH cannot be dismissed.

Clarke<sup>803</sup> speculated that visceral constraint of the diaphragm caused greater mechanical forces or stresses to develop in the dorsal thorax. Thus, in the caudodorsal lung, these mechanical forces would be borne over a narrow area, leading to parenchymal tearing or rupture of capillaries during inspiration. However, evidence of widespread hemorrhage in the dorsal portions of the lung suggests that the distribution of extremely negative intrapleural pressures is more complex and not simply restricted to the region in close proximity to the caudal dorsal lung. An alternative mechanical theory has proposed that forelimb locomotory impact forces are transmitted through the chest wall, setting up waves converging caudodorsally in the lung parenchyma.<sup>804</sup> Although support for locomotory-impact forces as a cause of EIPH comes from the higher percentage of steeplechasers that bleed as compared with flatracers, the difference could simply reflect a greater exercise intensity and hence cardiac output and pulmonary artery pressures generated in the jumpers.<sup>808</sup> Furthermore, because horses still develop EIPH during swimming when concussive forces would be minimal, it seems less likely that mechanical forces alone cause EIPH.<sup>809</sup>

Currently, the most widely accepted hypothesis for the development of EIPH is stress failure of pulmonary capillaries.<sup>806,810</sup> Stress failure is thought to occur after development of high transmural pressures (the pressure difference between the pulmonary capillary bed and the adjacent alveoli) that disrupt capillary endothelial and alveolar epithelial tight junctions, leading to hemorrhage within the interstitium and alveoli. Elevated pulmonary capillary pressures, which may exceed 70 mm Hg in strenuously exercised horses, are a consequence of the high cardiac output, lack of sufficient pulmonary vascular vasodilation, and increased blood viscosity that occurs during exercise. The second component of transmural pressures is very negative intrapleural and alveolar pressures that are required to generate airflows exceeding 120 L/s through high resistance passages (nasal cavity, larynx).<sup>811</sup> More negative pressures would be generated when nasal, laryngeal, or pulmonary passages are narrowed from disease or if larger tidal volumes are generated, for example during exercise on an incline.<sup>802,812</sup> Evidence supportive of the stress failure theory is provided by electron micrographs prepared from lung segments taken from strenuously exercised horses. These micrographs demonstrate a breakdown of the endothelial and epithelial tight junctions and exudation of red blood cells into alveoli.<sup>806</sup> Although some investigators have found no correlation between pulmonary capillary pressures in exercising horses and the development of EIPH ascertained endoscopically,<sup>813</sup> others have found a correlation between mean pulmonary artery pressures in exercising horses and the number of erythrocytes in postexercise BALF samples.<sup>814</sup>

Thus the etiopathogenesis of EIPH may represent a complex interplay of many factors relating to the physiologic and pathologic features of pulmonary function and exercise.<sup>815</sup>

## CLINICAL SIGNS

Physical examination of the resting horse that develops EIPH is unremarkable. In one study of 20 Standardbred racehorses, thoracic percussion, but not thoracic auscultation, identified abnormalities in the caudodorsal region of 50% ( $n = 5$ ) of horses with EIPH.<sup>816</sup>

Epistaxis is an infrequent finding, occurring in less than 7% of Standardbreds, Thoroughbreds, or Quarter Horses after racing.<sup>789-791,794,795</sup> In one retrospective study of Japanese racehorses examined 30 minutes after racing either on the flat track or over hurdles, epistaxis was detected in 0.13% of the Thoroughbreds (>246,000 starts) and in 0.10% of the Anglo-Arabs (>4000 starts).<sup>817</sup> Similar prevalence rates were reported by Weideman et al. (2003) who found epistaxis in 0.17% of South African Thoroughbred racehorses (51,465 horses in 778,532 races). In the study by Takahashi et al.,<sup>817</sup> epistaxis occurred more frequently in horses that were older (0.04% in 2-year-olds versus 0.27% in horses > 5 years), raced over hurdles (0.11% flatracers versus 0.76% steeplechasers), and sprinted (0.13% in races < 1600 m long versus 0.11% in races 1601-2000 m long). They also found that the rate of recurrence of epistaxis was 13%. The lower frequency of epistaxis reported in this study by Takahashi et al.<sup>817</sup> may be because horses were examined 30 minutes after racing, and the horses were young (64% of horses were < 3 years of age). Sudden death attributed to EIPH is reported to occur in 82% to 87% of racehorses that die suddenly.<sup>818,819</sup>

Additional clinical signs that may be exhibited by some horses with EIPH after competition include difficult or labored breathing, coughing, or excessive swallowing.

Although long suspected to cause decreased athletic performance, it had been difficult to objectively ascertain because investigations had been confounded by any or all of the following: concurrent use of medications in horses (furosemide), statistical methods, and the numbers of horses evaluated. Nevertheless, owners or trainers often report that an affected horse does not perform up to expectations or that it exhibits a sudden loss of speed during competition.<sup>809</sup> In a prospective study of 744 Australian Thoroughbred racehorses (2396 starts) that competed without the benefit of furosemide or nasal dilator strips, an association between the presence and severity of tracheal blood and race performance was found.<sup>798</sup> Horses with a tracheal score at or above 2 (based on a scale of 0-4; see later discussion) had lower odds of winning or finishing in the first three positions and a lower likelihood of being in the 90th percentile or higher for race earnings. Although the exact pathophysiologic effect of EIPH on performance was not known, the investigators suggested that it may have reflected a deleterious effect of the bleeding on arterial oxygenation or on maximal oxygen consumption or both.<sup>783,820</sup>

## DIAGNOSIS

Endoscopic detection of frank blood within the trachea is the usual method of diagnosis of EIPH. Optimal time for endoscopic examination is within 90 minutes of a race or a strenuous workout. An endoscopic scoring system for tracheal blood accumulation has been developed and achieves a high degree of concordance among evaluators.<sup>798</sup> The numeric scores

range from 0 to 4, with a 0 assigned to cases for which no blood is detected in the pharynx, larynx, trachea, or mainstem bronchi and a 4 assigned to cases with multiple coalescing streams of blood covering more than 90% of the tracheal surface with blood pooling at the thoracic inlet. One limitation of the scoring system is that it does not provide a quantitative measure of the amount of hemorrhage.<sup>798</sup> Furthermore, confirmation of EIPH may require multiple endoscopic examinations of the same horse after exercise bouts of the same intensity. Whether, in a given horse, the tracheal blood score increases in severity over time is currently unknown.

Cytologic analysis of tracheobronchial or BAL constituents can aid one in the diagnosis of EIPH. Although total nucleated cell counts in BALF do not differ between racehorses and yearlings, the number of free erythrocytes and hemosiderophages in the BALF is greater in horses in training compared with horses not being trained.<sup>821</sup> Concern has surfaced that simple enumeration of erythrocytes recovered in the BALF to semiquantify the severity of EIPH may not be accurate and reproducible.<sup>822</sup> When EIPH positive and negative racehorses are compared, the total hemosiderin score (a reflection of cytoplasmic iron in alveolar macrophages) agrees well with EIPH status. Specifically, a total hemosiderin score above 75 has a sensitivity and specificity of 94% and 88%, respectively, in identifying EIPH-positive horses.<sup>823</sup> Hemosiderin scores should be interpreted cautiously because hemorrhage from prior episodes of pneumonia, pleuropneumonia, or abscessation will increase hemosiderin scores.

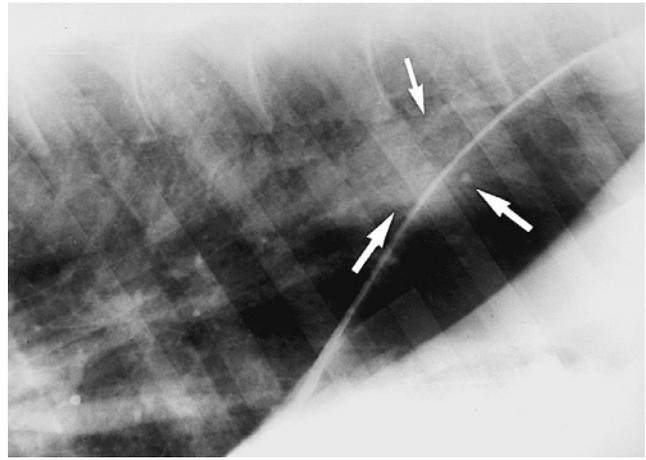

Pulmonary biopsy specimens obtained from the seventh or eighth intercostal space (10 cm above the level of the point of the elbow) from the lungs of EIPH-positive horses do not demonstrate histologic abnormalities that would distinguish affected horses from EIPH negative horse.<sup>816</sup> In contrast, histologic evaluation of lung samples obtained from the caudal dorsal lung regions (postmortem) of horses with EIPH reveals bronchiolitis, hemosiderophages, focal eosinophilic infiltration, and increased connective tissue.<sup>800</sup>

Radiographs are of limited usefulness in diagnosing horses with EIPH, given that the signs found in affected horses—an accentuated bronchial, bronchointerstitial, or interstitial pattern<sup>824</sup>—can also be observed in racehorses that do not exhibit evidence of pulmonary bleeding.<sup>823</sup> In severe cases of hemorrhage, a radiopaque region in the caudal dorsal lung lobe that obscures the pulmonary vasculature is detected<sup>825,826</sup> (Figure 9-21). Nuclear scintigraphy has not been useful in detecting areas of pulmonary hemorrhage after exercise.

Hemogram, serum biochemistry, and arterial blood gas values obtained from resting horses with EIPH are within normal limits. The mean platelet counts of EIPH-positive horses ( $128 \times 10^9$  cells/L) are significantly lower than those of EIPH negative horses ( $159 \times 10^9$  cells/L), although the total counts are within the normal range.<sup>816</sup>

## TREATMENT

Drugs that reduce pulmonary capillary pressure during exercise have gained the most widespread use in the treatment and prevention of EIPH. Furosemide, 250 to 300 mg, is given intravenously 4 hours before the horse is strenuously worked or raced. Furosemide decreases plasma volume and decreases exercise-associated pulmonary artery and pulmonary capillary pressures.<sup>827-829</sup> Although furosemide administration has failed to prevent the development of EIPH in horses that were previously EIPH negative,<sup>830,831</sup> some evidence indicates

**FIGURE 9-21** Focal area of increased interstitial pulmonary opacity (arrows) in the dorsal caudal lung field represents exercise-induced pulmonary hemorrhage. (Courtesy D. S. Biller, Manhattan, Kan., 1991.)

that it reduces the red blood cell counts in BALF or the EIPH endoscopic score.<sup>832</sup> Furosemide administration is also associated with improved performance in Thoroughbred racehorses.<sup>833</sup>

Nitric oxide, a potent vasodilator, has been administered to horses with EIPH. In one laboratory investigation of strenuously exercised horses, intravenous nitric oxide failed to reduce pulmonary artery or pulmonary capillary pressures and failed to prevent EIPH.<sup>834</sup> In another study, inhaled nitric oxide administered to horses maximally exercised on the treadmill reduced pulmonary arterial pressures but worsened erythrocyte counts in the BALF.<sup>835</sup>

Nasal dilators (Flair nasal strips) have been advocated as a treatment for horses with EIPH. These nasal dilators are adhesive strips containing springs that are applied externally 3 cm above the nostrils with the purpose of maintaining upper airway patency and reducing airway resistance during inspiration. In laboratory studies of exercising horses, the application of nasal strips failed to change arterial blood gases, pulmonary artery pressures, peak esophageal pressures, or tracheal blood accumulation compared with controls.<sup>836,837</sup> In one study, the nasal strips reduced erythrocyte counts in the BALF.<sup>837</sup>

The finding of concomitant small airway disease (IAD) in some horses suggests that one should attempt to minimize environmental dusts and molds. Corticosteroids and bronchodilators, inhaled or administered parenterally, have not been shown to reduce EIPH but may lessen the severity of small airway disease. In a laboratory study simulating airway responses in horses with EIPH (produced by intrapulmonary inoculation of 50 ml of autologous blood), each of three treatments consisting of oral prednisolone (1 mg/kg once daily), inhaled beclomethasone dipropionate (3.75 mg twice daily), or oral clenbuterol hydrochloride (0.8 µg/kg) decreased total erythrocyte count in BALF compared to nontreated controls. This study suggested that the treatments suppressed numbers and possibly phagocytic function of macrophages.<sup>838</sup> In contrast, the antiinflammatory cromoglycate, which is believed to stabilize mast cell membranes, has not been efficacious in the treatment of EIPH.<sup>839</sup>

Other formulations that have been advocated for the treatment of EIPH include intratracheal immunoglobulin, oral herbal remedies (e.g., Yunnan paiyao, Single Immortal, Red Lung, and Red Lung Plus), intravenous aminocaproic acid, bioflavonoids, aspirin, and estrogens, but no scientific data exist that demonstrates their efficacy.<sup>840</sup>

Rest has been recommended, but pulmonary hemorrhage will likely recur once the horse resumes training. In severe cases of EIPH, a short course of broad-spectrum antimicrobials may be indicated to lessen the chance of secondary pneumonia or abscess formation.

## PREVENTION

World wide, EIPH is of concern because of financial losses resulting from decreased performance, suspension of horses from racing, lost training days, and the cost of prerace medication.<sup>841</sup> The efficacy of treatment regimens in the prevention of EIPH under race conditions has been difficult to determine even when speed handicapping methods are used. Variables such as the administration of drugs unknown to the investigators or the inability to diagnose or reproduce EIPH within a given horse on consecutive days make interpretation of these studies difficult.

## TUMORS OF THE RESPIRATORY SYSTEM

### CAUSES

Based on postmortem surveys, the most frequently encountered tumors in the horse, regardless of the body system, are sarcoids, squamous cell carcinomas, fibromas, melanomas, papillomas, fibrosarcomas, and lymphomas.<sup>653,842,843</sup> Neoplastic involvement of the thoracic structures or pulmonary parenchyma *per se* is rare in horses and occurs at a prevalence rate of 0.15 to 0.62.<sup>524,843</sup> Tumors in the thoracic cavity arise as either primary neoplasms or from metastases and may involve extrapulmonary structures or the lung parenchyma. Examples of primary thoracic tumors are lymphomas and mesotheliomas.<sup>524,761,844-847</sup>

In addition to being the most common thoracic neoplasm, lymphoma is also the most common tumor of the equine hematopoietic system (see the discussion in the hematopoietic Chapter 14).<sup>845,847</sup> Lymphoma is classified according to its anatomic distribution as mediastinal, alimentary, cutaneous, multicentric, and generalized, although several forms may exist in the same horse. Horses affected with mediastinal lymphoma are young to middle-aged (mean age of 10 years) and exhibit weight loss, ventral edema, jugular distention caused by the presence of a mediastinal mass, tachypnea, or respiratory distress caused by pleural effusion secondary to compression of vessels.<sup>845,848</sup> Ultrasonography allows one to define the size and extent of the tumor, as well as to assess potential responses to treatment. Most mediastinal lymphomas are homogeneous hypoechoic masses greater than 4 × 4 cm in size, but some tumors exhibit focal hyperechoic areas.<sup>849</sup> As the size of the mass increases, the heart is displaced caudally causing it to be imaged in the sixth through the eighth intercostal spaces. Anechoic fluid surrounding the mass—indicative of pleural effusion—enhances the ultrasonographic image but may contribute to lung compression and breathing difficulties. Differential diagnoses for a cranial mediastinal mass include abscess, inflamed mediastinal lymph node, fatty tissue, and the thymus, which may be present in horses up to 4 years of age.<sup>850</sup> With the horse well sedated and its forelimb extended

cranially, an ultrasound-guided biopsy specimen of the mass may be obtained aseptically through the third intercostal space.<sup>850</sup> Short-term intravenous anesthesia provides an alternative method of obtaining the ultrasound-guided biopsy if the horse will not remain stationary with sedation. In horses with concurrent pleural effusion, thoracocentesis may yield a modified transudate or nonseptic exudate, but neoplastic cells—lymphoblasts with mitotic figures—are not consistently found. After drainage of the pleural effusion, thoracic radiographs should be obtained to determine if the lung parenchyma is involved. Thoracoscopy may be another option to determine the extent of involvement of intrathoracic structures and possibly to obtain a biopsy, although the cranial and ventral position of the mass may preclude its clear visualization.<sup>75,77,850,851</sup> In affected horses, rectal examination and ultrasonographic evaluation of the abdomen should always be performed to detect involvement of abdominal organs or structures. The clinical course of the disease, from onset of signs until euthanasia, is often rapid and may be less than 8 weeks for most cases.<sup>845</sup> A recent report describes the successful treatment of a mixed-cell mediastinal lymphoma using cytarabine (170 mg/m<sup>2</sup> intramuscularly), cyclophosphamide (142 mg/m<sup>2</sup> intravenously), and prednisolone (86 mg/m<sup>2</sup> orally).<sup>852</sup>

Mesothelioma is the second most common primary thoracic tumor in the horse. This tumor arises from the serosal lining cells of the pleura and pericardium. In contrast to human disease, its development in horses has not been linked to asbestos exposure. Affected horses are often young to middle aged (2 to 13 years) and may exhibit respiratory distress caused by pleural effusion.<sup>844,846,853-855</sup> Thoracocentesis usually yields a dark to blood-tinged fluid of normal cellularity but with an increased total protein concentration. Cytologic examination of pleural fluid may reveal pleomorphic mesothelial cells with mitotic figures.<sup>846</sup> However, in other cases, distinguishing mesothelioma from other neoplasms or from reactive mesothelial cells may be impossible. Thoracoscopy may be used to confirm the presence of neoplastic nodules on the pleura, which should be biopsied for histologic examination and classification.<sup>856</sup> Malignant mesothelioma can be classified into three main histologic types: epithelioid, biphasic, and sarcomatoid. An immunohistochemical marker for epithelioid-type mesotheliomas that differentiates them from metastatic adenocarcinomas is calretinin, a protein that is related to the calcium-binding proteins and may be helpful in the diagnosis.<sup>857</sup> Treatment is not usually attempted in horses with mesothelioma. Whether pleurodesis would reduce the effusion and prolong the horse's life is unknown.

Primary equine lung tumors include granular cell tumors,<sup>858-868</sup> bronchial myxomas,<sup>869</sup> bronchial and pulmonary carcinomas,<sup>653,870,871</sup> bronchial and pulmonary adenocarcinomas,<sup>872,873</sup> bronchogenic squamous cell carcinomas,<sup>871</sup> bronchioalveolar carcinoma,<sup>872</sup> pulmonary chondrosarcomas,<sup>874,875</sup> and pulmonary leiomyosarcoma.<sup>876</sup> The prevalence rate of primary lung tumors (0.15%) is much less than that of metastatic pulmonary tumors. Of the primary lung tumors, the most common one is granular cell tumor (myoblastoma or Schwann cell tumor), and it is the only primary lung tumor that is mesenchymal rather than epithelial in origin. Based on a review of 26 reported cases,<sup>651,858,860-866,868,877-880</sup> the mean age of affected horses is 13 years; the majority of cases occur in mares (22 of 26 horses), and the tumor is often located in the

right lung (16 of 26 horses). In a small number of horses, the tumor occurred in both lung lobes. In some horses, the tumor may be an incidental finding detected at necropsy; however, in most cases, clinical signs of chronic respiratory disease—coughing, increased respiratory rate or effort, and weight loss—develop. In the absence of an extensive workup, these signs may lead to a misdiagnosis of RAO. However, because the tumor or tumors protrude into the bronchus, airflow into that lung lobe may be reduced or completely lacking, making lung sounds difficult or impossible to detect. (This finding is in contrast to RAO in which adventitious lung sounds may be heard over an expanded lung field.) Secondary bacterial infections may develop in the affected lung presumably because of impaired clearance of secretions caused by the tumor. In a few cases, hypertrophic osteopathy (Marie's disease) develops concurrently.<sup>858,866,877,879</sup> This condition is characterized by enlargement of the joints and the presence of bony swellings in the distal limbs caused by subperiosteal bony proliferation. As a result, affected horses exhibit generalized stiffness and shifting limb lameness. The diagnosis of granular cell tumor is based on imaging and endoscopic findings. On thoracic radiographs, single or multiple radioopaque nodules are evident. Endoscopic examination reveals mucosal-covered nodules protruding into the bronchi. A definitive diagnosis is obtained after histologic evaluation of endoscopically obtained biopsies. The cells are globoid or stellate and contain eosinophilic, PAS-positive cytoplasmic granules.<sup>651,862</sup> Immunohistochemical staining of the cells is positive for vimentin, an intermediate filament most commonly associated with cells of mesenchymal origin, and for S-100, a calcium-binding protein most commonly found in cells of neural crest origin.<sup>865</sup> Currently, no medical treatment has been developed for pulmonary granular cell tumors. In two cases, the tumor was resected successfully by transendoscopic electrocautery<sup>881</sup> or via lung resection.<sup>880</sup> In general, the tumor does not usually metastasize to other sites, but bilateral lung involvement is a possibility.

The limited number of case reports in the literature describing clinical features of other primary lung tumors<sup>653,869-876</sup> precludes a detailed description of these tumors. In general, middle-aged to older horses are affected and exhibit weight loss, chronic cough, and tachypnea. In the absence of a thorough evaluation, the chronicity of the clinical signs may lead to a misdiagnosis of RAO, pneumonia, or even EIPH (epistaxis). Thoracic radiographs demonstrate the presence of pulmonary nodules that are confirmed to be neoplastic in lung biopsy obtained by ultrasound guidance. Cytologic examination of tracheal aspirates is not usually diagnostic. Treatment has not been attempted.

Thoracic tumors involving the pleural surfaces, lymph nodes, mediastinum, esophagus, diaphragm, or lungs may also arise from metastases from other neoplastic sites. Examples of metastatic tumors that affect the thoracic cavity include adenocarcinoma (primary sites of origin are in the kidney, uterus, ovary, mammary gland, and pancreas),<sup>521,522,882-884</sup> squamous cell carcinoma,<sup>516,885-888</sup> hepatoblastoma,<sup>517</sup> hymoma,<sup>889</sup> fibrosarcoma,<sup>515</sup> melanoma,<sup>890</sup> hemangiosarcoma,<sup>518,524,891-903</sup> and lymphoma.<sup>524,845,904,905</sup>

Hemangiosarcoma remains a rare tumor, occurring in 2 of 1322 horses in a study by Sundbery, Burnstein, Page, et al.<sup>842</sup> and in 1 of 4739 cases in a survey reported by Hargis and McElwain.<sup>892</sup> It is a malignant tumor of endothelial cells but does not appear to develop from a preexisting hemangioma.<sup>895</sup>

A comprehensive review<sup>896</sup> provides a description of the clinical aspects of 35 cases of disseminated hemangiosarcoma, 21 of which were diagnosed at a participating veterinary hospital and 14 of which were previously reported in the literature.\* The median age of horses was 12 years, and most clinical signs were referable to the respiratory or to the musculoskeletal systems. For example, respiratory distress and epistaxis were noted in 26% of cases, and muscular or subcutaneous swellings were noted in 24%. The majority of horses exhibited mucous membrane pallor either alone or in combination with icterus, reflecting prior hemorrhage. Ultrasonographic evaluation detected pleural effusion or hemothorax in four cases. Cytologic analysis of either the pleural or tracheobronchial aspirates (in horses that developed epistaxis) failed to demonstrate neoplastic cells. Antemortem diagnosis is difficult and may require thoracoscopy or pleuroscopy to visualize neoplasms and to obtain samples for histopathologic examination.<sup>74,894</sup> Microscopically, one may see vascular channels lined with plump, spindle-shaped cells. In some cases, well-differentiated channels are less conspicuous or are lacking, and cells have epithelioid morphologic appearance. When present, the tumor is classified as epithelioid (histiocytoid) hemangiosarcoma.<sup>902</sup> Immunohistochemical staining of tumor samples demonstrates cells that can be poorly reactive against factor VIII reactive antigen, positive for UEA-agglutinin I (a receptor of *Ulex europaeus* I) and negative for cytokeratin.<sup>901,902</sup> In affected horses, supportive care, including thoracocentesis, blood transfusions, and intravenous fluids, is generally unrewarding. Clinical deterioration is rapid, with death occurring, on average, 17 days from the onset of clinical signs. In a study of 11 young horses (younger than 4 years) with hemangiosarcoma, the investigators reported that the majority of cases had cutaneous masses or diffuse limb and joint swellings.<sup>903</sup> Although only one horse in this study developed disseminated hemangiosarcoma, the exact percentage of horses with cutaneous neoplasms that develop disseminated disease and over what time period is unknown.

In general, horses with metastatic thoracic neoplasia exhibit nonspecific clinical signs of depression, inappetence and weight loss, or clinical signs referable to the site of the primary neoplasm. In some cases, respiratory distress may occur if pleural effusion develops, or coughing may occur if the tumor compresses an airway.<sup>847</sup> Diagnostic examination, which requires a combination of imaging techniques including endoscopy, thoracic radiography, ultrasonography (and possibly thoracoscopy), and cytologic evaluation of respiratory secretions along with evaluation of the abdominal cavity and other body systems should be undertaken. Usually, hematologic and serum biochemical abnormalities are nonspecific and include anemia, leukocytosis, neutrophilia, and hyperfibrinogenemia.<sup>846</sup> The prognosis is poor for horses with neoplasms, and most patients are euthanized. In horses in which the tumor is localized and has a low metastatic potential, as exists with granular cell tumors, lung resection may be an option.<sup>880</sup> In cases with pleural effusion, the clinician may achieve temporary stabilization by thoracocentesis, but the therapeutic benefits of pleurodesis have not been established for equine patients (see the section on pleural effusion).

# CARDIOVASCULAR DISEASES

## CHAPTER 10

*John D. Bonagura, Virginia B. Reef, Colin C. Schwarzwald\**

Cardiovascular (CV) system function is critical to exercise, thermoregulation, and the blood flow-dependent functions of the lungs, kidneys, gut, and reproductive system. Heart and vascular diseases are common in horses, but fortunately the underlying lesion is often minor and well tolerated. However, clinically significant CV disease can develop in horses with clinical signs that can include arrhythmia, exercise intolerance, congestive heart failure (CHF), weakness or collapse, systemic infection, or sudden death.

The clinical evaluation of the equine CV system is often perplexing. Horses are renowned for a variety of physiologic murmurs and arrhythmias. Furthermore, only when horses are undergoing exercise at the highest levels do they reach the limits of normal CV function. Clinical assessment is best served by an awareness of normal variation, the appreciation of relevant diseases, diagnostic studies and prognostic indicators, and an understanding of available management options. Communication of these issues constitutes the focus of this chapter.

Equine cardiology has advanced from a study of physiologic variation and speculation to one of accurate diagnosis and focused therapy, although many clinical issues remain unresolved. Much of the important groundwork in clinical equine cardiology was established by studies of normal CV physiology, cardiac catheterization, pathology, cardiac auscultation, electrocardiography, and echocardiography. These data, defining the normal anatomic and physiologic features of the equine CV system, constitute the backdrop of the clinical examination. Other examinations of importance to CV assessment include ambulatory electrocardiography, functional exercise testing, and biochemical tests of cardiac injury. Appropriate selection and interpretation of these tests allows the clinician to identify and quantify most diseases of the heart and circulation.

No recent comprehensive studies of CV *disease prevalence* are available. Holmes, Darke, and Else<sup>33</sup> observed that 2.5% of hospitalized horses were in atrial fibrillation (AF).<sup>33</sup> Else and Holmes<sup>27-29</sup> noted myocardial fibrosis in 14.3% of horses examined at necropsy and evidence of chronic valvular disease in approximately 25% of the hearts examined. Various CV lesions were considered important in 8.5% of 480 consecutive

losses in a necropsy study conducted by Baker and Ellis.<sup>52</sup> CV diseases are probably the third most common cause of poor performance after musculoskeletal and respiratory diseases.<sup>53-56</sup> Occult heart disease, cardiac arrhythmias, and vascular lesions are considered important reasons for unexplained sudden death.<sup>52,57-69</sup> Certainly, most clinicians encounter manifestations of CV disease or dysfunction on a regular basis.

The assessment of CV disease in a horse is predicated on a competent clinical examination, the clinician's knowledge, and the ability to order and evaluate diagnostic studies. Incomplete information may impede an accurate diagnosis, foster miscommunication of risks to the client, or delay the proper course of management. Fundamentals of CV anatomy, physiology, and electrophysiology are reviewed elsewhere.<sup>9,20,70-77</sup> This chapter offers a framework for understanding the lesions, pathophysiology, diagnosis, and management of important congenital and acquired conditions of the heart and major vessels. Clinical aspects of circulatory shock are described in this volume, and the reader is referred elsewhere for the management of cardiopulmonary arrest.<sup>78,79</sup>

## ANATOMIC CORRELATES OF CARDIOVASCULAR DISEASES

Most diagnostic techniques, including cardiac auscultation, electrocardiography, cardiac catheterization, and echocardiography, are predicated on an understanding of cardiac anatomy and physiology. The CV system is divided into two separate circulations: (1) systemic and (2) pulmonary. The systemic circulation has a greater venous capacitance, ventricular pumping pressure, arterial pressure, and vascular resistance.<sup>73,75-77</sup> Despite these differences, the functions of these two circulations are interdependent, as the following examples illustrate. Systemic and pulmonary circulations are arranged in series, therefore cardiac output (CO) from the left ventricle (LV) and the right ventricle (RV) must be equivalent. Accordingly, failure of either ventricle limits CO. Isolated LV failure, as with severe mitral regurgitation (MR), can cause right-sided failure; this is explained by the increased pulmonary venous pressure causing pulmonary hypertension and imparting a pressure load on the RV. A third example is the case of isolated RV failure with marked RV dilatation. Here the leftward bulging of the ventricular septum impairs filling of the LV. This last situation also can develop in chronic pericarditis. Arrhythmias also affect both sides of the

\*When  appears, a corresponding video can be found on the DVD inside this book.

## BOX 10-1

## CARDIAC DIAGNOSES

**Anatomic Diagnosis**

Cardiac malformation  
 Valvular (endocardial) disease  
 Myocardial disease  
 Pericardial disease  
 Cor pulmonale (pulmonary disease leading to secondary heart disease)  
 Disorder of the impulse-forming or conduction system  
 Vascular disease

**Physiologic Diagnosis**

Systemic: pulmonary shunting  
 Left to right  
 Right to left  
 Valvular insufficiency  
 Valvular stenosis  
 Myocardial (systolic) dysfunction  
 Diastolic dysfunction  
 Cardiac rhythm disturbance  
 Cardiac-related syncope  
 Heart insufficiency or failure (limited cardiac output)

Congestive heart failure  
 Shock  
 Sudden cardiac death  
 Cardiopulmonary arrest

**Etiologic Diagnosis**

Malformation (genetic)  
 Degenerative disease  
 Metabolic or endocrine disease  
 Neoplasia  
 Nutritional disorder  
 Inflammatory disease  
 Infective or parasitic  
 Noninfective  
 Immune-mediated  
 Idiopathic  
 Ischemic injury  
 Idiopathic disorder  
 Iatrogenic disease  
 Toxic injury  
 Traumatic injury

heart so that the development of AF in the setting of structural heart disease can promote biventricular heart failure.

The heart consists of unique active and passive components,<sup>75</sup> and different diagnostic methods are needed to evaluate these structures and associated functions. Normal heart action requires coordination of electrical activity, muscular contraction and relaxation, and valve motion. When reviewing heart anatomy, and subsequently cardiac pathology, it is useful to consider the anatomic integrity of the pericardium, myocardium, endocardium, and valves, specialized impulse-forming and conduction systems, and blood vessels.<sup>70</sup> Using this approach, the causes of CV disease can be conveniently subdivided into anatomic, physiologic (functional), and causative diagnoses (Boxes 10-1 and 10-2).

**PERICARDIAL DISEASE**

The pericardium limits cardiac dilatation, acts as a barrier against contiguous infection, and contributes to the diastolic properties of the heart. The pericardial space is formed by the reflection of the two major pericardial membranes—(1) the parietal pericardium and (2) the visceral pericardium (the epicardium)—and normally contains such a small amount of serous fluid that it cannot be seen by echocardiography. Pericardial effusion leading to cardiac compression (tamponade) impairs ventricular filling and diastolic function, typically causing right-sided CHF. Some cases of pericarditis progress to constrictive pericardial disease, which severely limits ventricular filling.

Pericardial effusion can develop as a primary disorder or secondary to pleuropneumonia. Infective pericarditis can produce an effusion sufficient to cause cardiac tamponade or eventual constriction of the heart.<sup>55,80-97</sup> Sterile, idiopathic pericardial effusion also has been reported in horses. The

volume of effusion can be substantial and can lead to cardiac decompensation.<sup>87</sup> Cardiac mass lesions and intrapericardial tumors have been reported sporadically.<sup>89,92,98,99</sup> Cranial mediastinal tumors (lymphosarcoma) or abscesses secondary to pleuropneumonia also can compress the heart and mimic pericardial disease.<sup>100</sup> Clinical aspects of pericardial disease are discussed later in this chapter.

**MYOCARDIAL DISEASE**

The myocardium forms the bulk of the atrial and ventricular muscular walls. The right atrium (RA) communicates with the RV inlet through the right atrioventricular (AV) or tricuspid valve. The RV appears crescent shaped on cross-sectional echocardiographic examination and is functionally *U* shaped. The RV inlet is located in the right hemithorax and the outlet, pulmonary valve, and main pulmonary artery (PA) on the left side of the chest. The left atrium (LA) is caudal to the RA and separated by the atrial septum. The LA is dorsal to the LV through which it communicates across the left atrioventricular (mitral) valve. The LV is circular in cross-section when viewed by echocardiography and separated from the RV by the ventricular septum. The septum and free walls are thicker than the RV free wall (by approximately 2.5 to 3 times). Persistent embryologic openings in the cardiac septa are known as *septal defects*, with the ventricular septal defect (VSD) representing the most common cardiac anomaly in most equine practices (see Box 10-2). The LV is functionally *V* shaped with an inlet and outlet separated by the cranioventral (septal or “anterior”) leaflet of the mitral valve (Figure 10-1). The aorta originates in the LV outlet, continuous with the ventricular septum cranially and in fibrous continuity with the septal mitral leaflet caudally. This great vessel exits from near the center of the heart and to the right of the main PA.

## BOX 10-2

## CAUSES OF CARDIOVASCULAR DISEASE

**Congenital Cardiac Malformation**

Simple systemic-to-pulmonary shunts (left to right)  
 Atrial septal defect  
 Ventricular septal defect  
   Paramembranous defect  
   Ventricular inlet defect  
   Subarterial (subpulmonic) defect  
   Muscular defect  
 Patent ductus arteriosus  
 Patent foramen ovale (permitting right-to-left shunting)  
 Valvular dysplasia  
   Mitral stenosis/atresia  
   Pulmonic stenosis (bicuspid pulmonary valve)  
   Pulmonary atresia (leading to a right-to-left shunt)  
   Tricuspid stenosis/atresia (leading to a right-to-left shunt)  
   Aortic stenosis/insufficiency (bicuspid or quadricuspid valve)  
 Subaortic rings with stenosis  
 Tetralogy of Fallot  
 Pulmonary atresia with ventricular septal defect (pseudotruncus arteriosus)  
 Double-outlet right ventricle  
 Subaortic stenosis  
 Hypoplastic left-side of the heart  
 Other complex malformations

**Valvular Heart Disease Causing Valve Insufficiency or Stenosis**

Congenital valve malformation  
 Semilunar valve fenestrations causing valve insufficiency  
 Degenerative (fibrosis) or myxomatous disease causing valve insufficiency  
 Valvular prolapse  
 Bacterial endocarditis causing valve insufficiency with or without stenosis  
 Rupture of a chorda tendinea causing mitral or tricuspid valve insufficiency  
 Rupture of a valve leaflet causing flail leaflet and valve insufficiency  
 Noninfective valvulitis  
 Valvular regurgitation following dilation of the heart or a great vessel  
 Papillary muscle dysfunction causing valvular insufficiency

**Myocardial Disease**

Idiopathic dilated cardiomyopathy: ventricular dilation and myocardial contractility failure  
 Myocarditis  
 Myocardial fibrosis  
   Ischemic (embolic?) myocardial fibrosis  
   Parasitic (*Strongylus*) embolization  
 Myocardial degeneration/necrosis  
   Myocardial ischemia  
   Myocardial infarction  
   Toxic injury (e.g., monensin)  
   Nutritional deficiencies (e.g., selenium deficiency)  
 Myocardial neoplasia  
   Lymphosarcoma  
   Melanoma  
   Hemangioma/hemangiosarcoma  
   Pulmonary carcinoma  
 Infiltrative myocardial disease (e.g., amyloidosis)

**Pericardial Disease**

Pericardial effusion with or without cardiac tamponade  
   Infective: bacterial or viral  
   Idiopathic pericardial effusion  
   Constrictive pericardial disease  
   Mass lesion (intrapericardial or extrapericardial) compressing the heart

**Pulmonary Hypertension and Cor Pulmonale**

Pulmonary hypertension following left-sided heart disease  
 Pulmonary vascular disease following left-to-right shunt  
 Immature pulmonary circulation  
 Primary bronchopulmonary or pulmonary vascular disease  
 Alveolar hypoxia with reactive pulmonary arterial vasoconstriction  
 Severe acidosis  
 Pulmonary thromboembolism

**Cardiac Arrhythmias** (see Box 10-9)

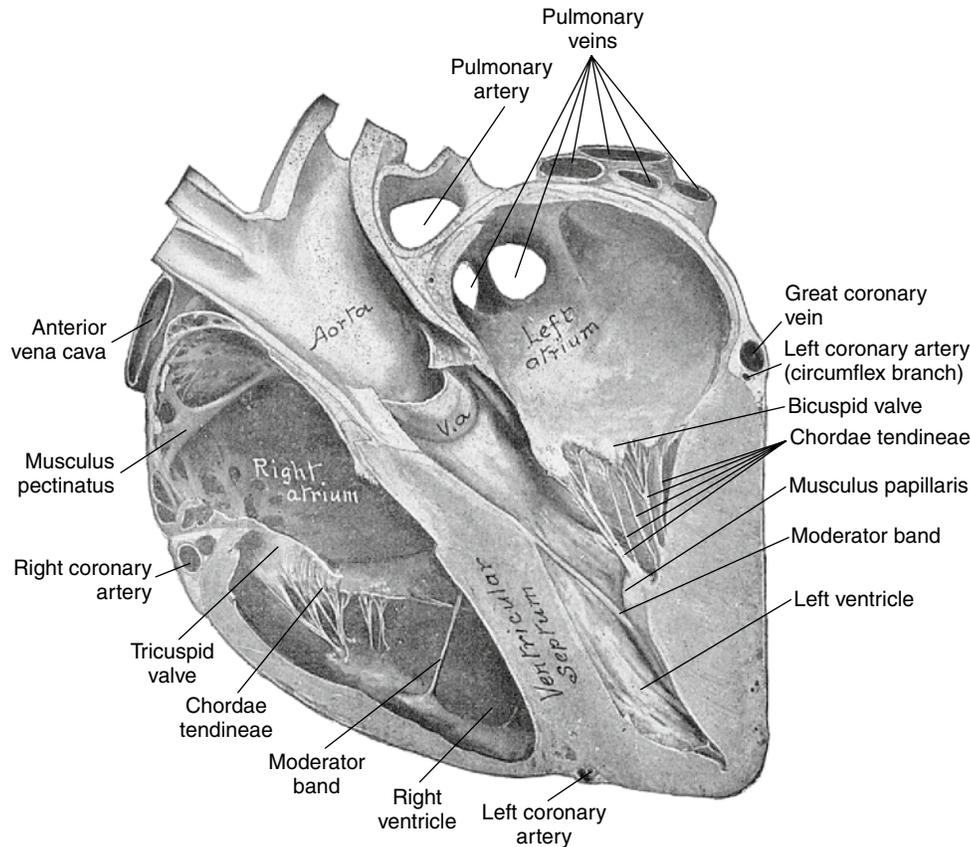

Atrial arrhythmias  
 Junctional (nodal) arrhythmias  
 Ventricular arrhythmias  
 Conduction disturbances

**Vascular Diseases**

Congenital vascular lesions  
 Rupture of the aorta, pulmonary artery, or systemic artery  
 Aneurysm of the aortic sinus of Valsalva  
 Aortic or aortoiliac degenerative disease  
 Arteritis  
   Infective  
   Immune-mediated  
 (Jugular) Venous thrombosis/thrombophlebitis  
 Pulmonary embolism  
 Mass lesion or tumor obstructing blood flow  
 Aorto-iliac thrombosis

The myocardium may dilate or hypertrophy in response to exercise,<sup>101,102</sup> increased work caused by structural cardiac disease, or as a consequence of a noncardiac disorder. Ventricular or atrial dilatation is recognized echocardiographically

or at necropsy by distention and rounding of the affected chambers, including a "double-apex" sign when marked RV enlargement occurs. Lesions causing systolic pressure overload lead to concentric hypertrophy.<sup>103</sup> More common in horses

**FIGURE 10-1** Sagittal view of the equine heart. The thicknesses of the ventricles, the position of the atria relative to the ventricles, and the relationship of the left ventricular (LV) inlet and outlet are evident. The bicuspid valve referred to in this figure is the mitral valve. The circular appearance of the left atrium (LA) and the relationship of the septal cusp of the mitral valve to the LV inlets and outlets are notable. These aspects are important when examining the heart by echocardiography. *v.a.*, Segment of aortic valve. (From Sisson S, Grossman JD: *Anatomy of the domestic animals*, ed 4, Philadelphia, 1953, WB Saunders.)

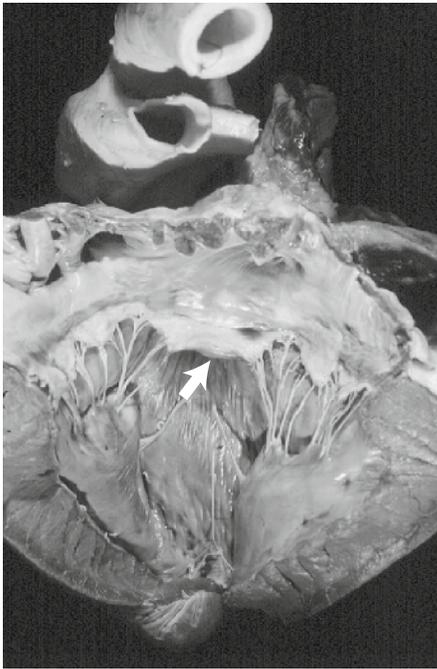

are lesions such as incompetent valves or shunts that cause ventricular volume overload with dilatation and eccentric ventricular hypertrophy. Increased cardiac work also occurs in response to exercise, severe anemia, and infections. In these situations, compensatory increases in CO, sympathetic activation, and peripheral vasodilation occur to maintain oxygen delivery to the tissues.<sup>104,105</sup>

The overall prevalence of myocardial disease is unknown; however, multifocal areas of fibrosis are commonly found at necropsy.<sup>28,29,106-110</sup> Whether these areas indicate prior inflammation, toxic injury, or ischemic necrosis caused by intramural coronary disease is uncertain. Cases of multifocal or diffuse myocarditis have been observed. Myocardial inflammation and myocardial failure can lead to cardiac arrhythmias and heart failure.<sup>4,111,112</sup> Idiopathic dilated cardiomyopathy develops sporadically and is recognized echocardiographically or by nuclear studies as a dilated, hypokinetic LV or RV.<sup>90,113</sup> Ingestion of monensin or other ionophores can cause mild to severe myocardial injury.<sup>114-120</sup> Neoplastic infiltration is considered rare.<sup>59,98,99,121</sup> Impaired myocardial function as a consequence of regional ischemia has been sought using stress echocardiography immediately after treadmill exercise or pharmacologic stress, but this diagnosis requires further definition.<sup>122</sup> Myocardial contraction is dictated by electrical activity of the myocardium; accordingly, cardiac arrhythmias—especially AF or ventricular

tachycardia (VT)—can limit CO and cause exercise intolerance in performance animals (see later discussion). Clinical aspects of myocardial disease are discussed later in this chapter.

## VALVULAR AND ENDOCARDIAL DISEASES

The cardiac chambers are lined by the endocardium, which also covers the four cardiac valves and is continuous with the endothelium of the great vessels. Normal valves govern the one-way flow of blood through the heart by preventing significant regurgitation of blood from higher to lower pressure zones. The AV inlet valves—the tricuspid and the mitral—are anchored by the collagenous chordae tendineae and papillary muscles and are supported by a valve “annulus” and the caudal atrial walls (see [Figures 10-1 and 10-2](#)).<sup>70</sup> The mitral valve consists of two major cusps and several accessory cusps.<sup>45</sup> The tricuspid valve is the largest valve and consists of three well-defined leaflets. Lesions of any portion of the AV valve apparatus or dilatation of the ventricle can lead to valvular insufficiency (see [Box 10-2](#)). The aortic and pulmonary valves each consist of three semilunar leaflets that close during diastole to protect the ventricles from the higher arterial blood pressure (ABP). Aortic valvular tissue in horses is not simply passive and will contract in response to a number of adrenergic and vascular agonists, such as angiotensin II and

**FIGURE 10-2** Anatomy of the left atrioventricular (mitral) valve. Opened left atrium (LA) and LV viewed from the caudal perspective. The large anterior (cranioventral or septal) leaflet in the center of the figure is notable. Chordae tendineae attach the valve to the papillary muscles. The ventricle has been cut so that the multiple cusps of the posterior (caudodorsal or mural) leaflet are visible to the left and the right of the anterior leaflet.

endothelin.<sup>123</sup> The left and right main coronary arteries originate within the aortic valve sinuses (of Valsalva).

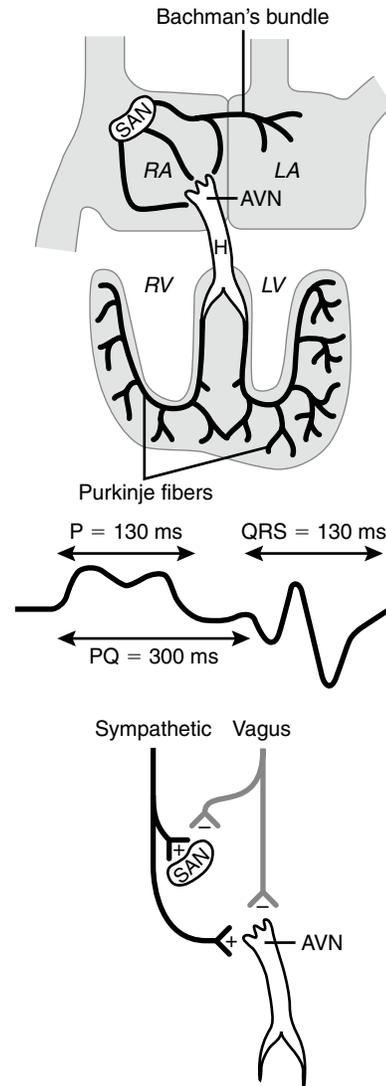

Valvular disorders in horses are common.\* Congenital valve stenosis, dysplasia, or atresia are recognized sporadically in foals.<sup>4,111,127,155-168</sup> Degenerative diseases of the aortic, mitral, and tricuspid valves are very common in mature horses,<sup>4,127,155-168</sup> and endocarditis can develop on any cardiac valve† (see Box 10-2). Valvular lesions of obscure cause, including nonseptic valvulitis, have been recognized sporadically. Tricuspid and MR, of unspecified cause, is often detected in high performance animals, including Standardbred and National Hunt horses.<sup>182-185</sup> MR caused by rupture of a chorda tendineae is recognized in both foals and mature animals.<sup>38,132,147,186</sup> Clinical aspects of valvular heart disease are discussed later in this chapter.

## DISEASE OF THE IMPULSE-FORMING AND CONDUCTION SYSTEMS

The specialized cardiac tissues consist of the sinoatrial (SA) node, internodal pathways, AV node, bundle of His, bundle branches, fascicles, and Purkinje system (Figure 10-3). The SA node, a relatively large, crescent-shaped structure, is located subepicardially at the junction of the right auricle and cranial vena cava. Well-documented sinus node disease, although suggested,<sup>187</sup> is

\* References 5, 27, 28, 38, 45, 48, 56, 91, 109, 124-154.

†References 4, 31, 83, 84, 90, 91, 109, 111, 125, 139, 135, 144, 148, 169-181.

**FIGURE 10-3** Impulse-forming and conduction systems of the heart. The impulse originates in the sinoatrial node (SAN) and is propagated across the right atrium (RA) and left atrium (LA), generating the P wave. Specialized internodal and interatrial (Bachmann's bundle) pathways facilitate impulse conduction. The impulse is delayed in the atrioventricular node (AVN) and rapidly conducted through the bundle of His (H), bundle branches, and Purkinje network (top). Electrical activation of ventricular myocytes generates the QRS complex. The automaticity of the SA node and conduction across the AV node are modulated by the autonomic nervous system (bottom). (Courtesy Dr. Robert L. Hamlin. From Schwarzwald CC, Bonagura JD, Muir WW: The cardiovascular system. In Muir WW, Hubbell JA, editors: Equine anesthesia: monitoring and emergency therapy, ed 2, St Louis, 2009, WB Saunders.)

rare; in contrast, vagally induced sinus arrhythmias are common.<sup>9,187-189</sup> The equine atrial muscle mass is large and predisposes the horse to development of re-entrant rhythms and fibrillatory conduction.<sup>190</sup> The AV node, situated in the ventral atrial septum, and the bundle of His, which continues into the bundle branches, are sites for AV block, both physiologic (vagal), and infrequently, pathologic in nature. Conduction is slow across the normal AV node.<sup>191-193</sup> The His-Purkinje system in the ventricular septum and ventricular myocardium can act as substrates for junctional and ventricular ectopic

impulses and tachycardias. Because the horse has relatively complete penetration of Purkinje fibers in the ventricles—except for a small portion of the LV free wall—the substantial equine ventricles are electrically activated in a relatively short time ( $\approx 110$  msec).<sup>7</sup>

The autonomic nervous system extensively innervates the heart and influences cardiac rhythms.<sup>4,111,134,194-199</sup> Interplay between the sympathetic and parasympathetic branches normally controls heart rate and rhythm in response to changes in ABP.<sup>9,200</sup> The vagus nerve innervates supraventricular tissues extensively and probably affects proximal ventricular tissues to a minor extent. Vagal influence generally depresses heart rate, AV conduction, excitability, and myocardial inotropic (contractile) state. However, because vagotonia also shortens the action potential and refractory period of atrial myocytes, high vagal activity is a predisposing factor in the development of AF.<sup>201</sup> Innervation of the stimulatory sympathetic nervous system is extensive throughout the heart and has effects generally opposite to those of the parasympathetic system.  $\beta_1$ -Adrenergic receptors dominate in the equine heart,<sup>202</sup> but presumably, other autonomic subtype receptors exist, including  $\alpha$ -adrenergic receptors and small numbers of  $\beta_2$ -adrenoceptors.<sup>76,203</sup> The notable increase in heart rate that attends exercise is related to increased sympathetic efferent activity and withdrawal of parasympathetic tone.<sup>9</sup> Increases in heart rate to 220 to 240 beats/min are not uncommon with maximal exercise.<sup>204-208</sup> The exact role of dysautonomia in the genesis of cardiac arrhythmias has not been determined; however, infusion of autonomic receptor agonists and antagonists can be associated with direct or baroreceptor-induced changes in heart rate and rhythm.<sup>209-212</sup> Cardiac arrhythmias are discussed later in this chapter.

## VASCULAR DISEASES

There are three major subdivisions of the circulation: (1) systemic, (2) coronary, and (3) pulmonary. The arteries and veins consist of three layers: (1) adventitia, (2) media, and (3) intima. The overall structure and function of each layer varies with the vessel and location. Vascular receptors<sup>20,73,75,76</sup> and anatomic lesions influence vascular resistance and blood flow.  $\alpha$ -Adrenoceptors dominate in the systemic vasculature, and blood pressure (BP) is generally raised by vasoconstriction after stimulation of postsynaptic  $\alpha$ -adrenergic receptors by norepinephrine, epinephrine, or infused  $\alpha$ -adrenergic receptor agonists like phenylephrine.<sup>213,214</sup> The presence of vasodilator  $\beta_2$ -adrenergic receptors is clinically relevant, insofar as infused  $\beta_2$ -agonists cause vasodilation in circulatory beds that contain high  $\beta$ -agonist adrenergic receptor density. Many vascular beds also dilate after the production of local vasodilator substances, such as nitric oxide, released during exercise, stress, or metabolic activity.<sup>73,75</sup> Dopaminergic receptors, when present in vascular walls, may be stimulated, causing vasodilation, provided vasoconstricting  $\alpha$ -adrenergic activity does not dominate. Stimulation of histamine ( $H_1$ ) receptors or serotonin (5-HT) receptors causes arteriolar dilatation, venular constriction, and increased capillary permeability.<sup>75</sup> Infusion of endothelin<sup>215</sup> or of calcium salts causes arterial vasoconstriction,<sup>216</sup> whereas administration of calcium channel antagonists (e.g., verapamil, diltiazem) causes vasodilation of vascular smooth muscle.<sup>217</sup>

Various vascular lesions have been reported in horses (see Box 10-2). Rupture of the aorta, PA, or middle uterine artery is

devastating and often lethal.\* The aorta may also rupture into the heart, creating an aortic to cardiac fistula.<sup>220,221</sup> Although parasitic arteritis may predispose to vascular injury, the cause of most vascular lesions, including aortic-iliac thrombosis, is unknown.<sup>222-227</sup> Causes of vasculitis include *Strongylus vulgaris* infestation of the cranial mesenteric artery, infective thrombophlebitis of the jugular veins, equine viral arteritis, and suspected immune-mediated disease.<sup>106,108,228</sup> Neoplasms can obstruct blood flow by external compression or through invasion, more often affecting the right side of the circulation. Examples include obstruction of the PA by a lung tumor and obstruction of venous return by neoplastic compression or invasion of the vena cava. Clinical features of vascular disease are discussed later in this chapter.

## CLINICAL CARDIOVASCULAR PHYSIOLOGY

The clinician must appreciate elementary aspects of normal heart function to perform a clinical CV examination and understand the abnormalities associated with heart disease and CHF.<sup>229</sup> Central to this are the electrical-mechanical correlates of Wiggers cardiac cycle.

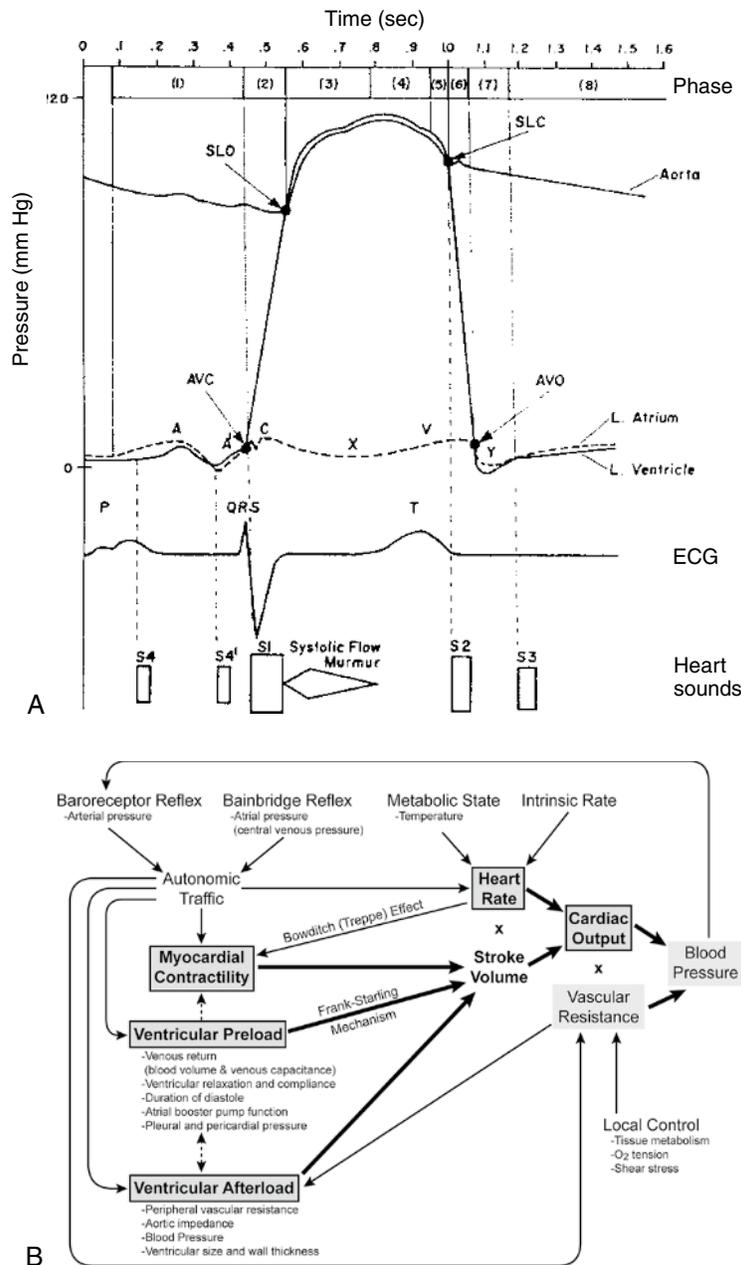

### CARDIAC CYCLE

The association between electrical and mechanical events of the heart first described by Wiggers has been reviewed in standard physiology textbooks (Figure 10-4).<sup>73,75-77</sup> From a study of this cycle, it is evident that cardiac electrical activity precedes pressure and volume changes; therefore arrhythmias can exert deleterious hemodynamic effects, especially during exercise, illness, or anesthesia. Relevant aspects of this cycle are now considered.

The P wave of the electrocardiogram (ECG) stems from electrical activation of the atria, late in ventricular diastole and after the ventricles have been largely filled. During the ensuing atrial contraction, the *atrial sound* (fourth heart sound or  $S_4$ ) is generated and the ventricle is filled to its end diastolic volume. The increase in atrial pressure, the atrial *a* wave, is reflected as a normal *jugular pulse* in the ventral cervical region. The magnitude of the atrial contribution to ventricular filling generally placed at 15% to 20% at rest, but increases dramatically during high heart rates. Therefore atrial tachyarrhythmias such as AF have the greatest effect on CO during exercise or tachycardia.

The QRS complex heralds ventricular systole. After depolarization of the ventricular myocytes, calcium enters the cell to trigger release of calcium stores in the sarcoplasmic reticulum. Increased cytosolic calcium interacts with the cardiac troponin complex on actin and myosin filaments to shorten the myofilaments and develop tension. These events are enhanced by sympathetic activity or drugs such as digoxin or dobutamine and depressed by anesthetics and drugs that impair calcium entry into cells. The abrupt increase in ventricular wall tension and chamber pressure closes the AV valves (coinciding with the vibrations of the *first heart sound*,  $S_1$ ) and increases intraventricular pressure (*isovolumetric period*) until the semilunar valves open.<sup>23,25</sup> At this instant the ventricular walls move inward (Figure 10-5, B and C) and blood is ejected

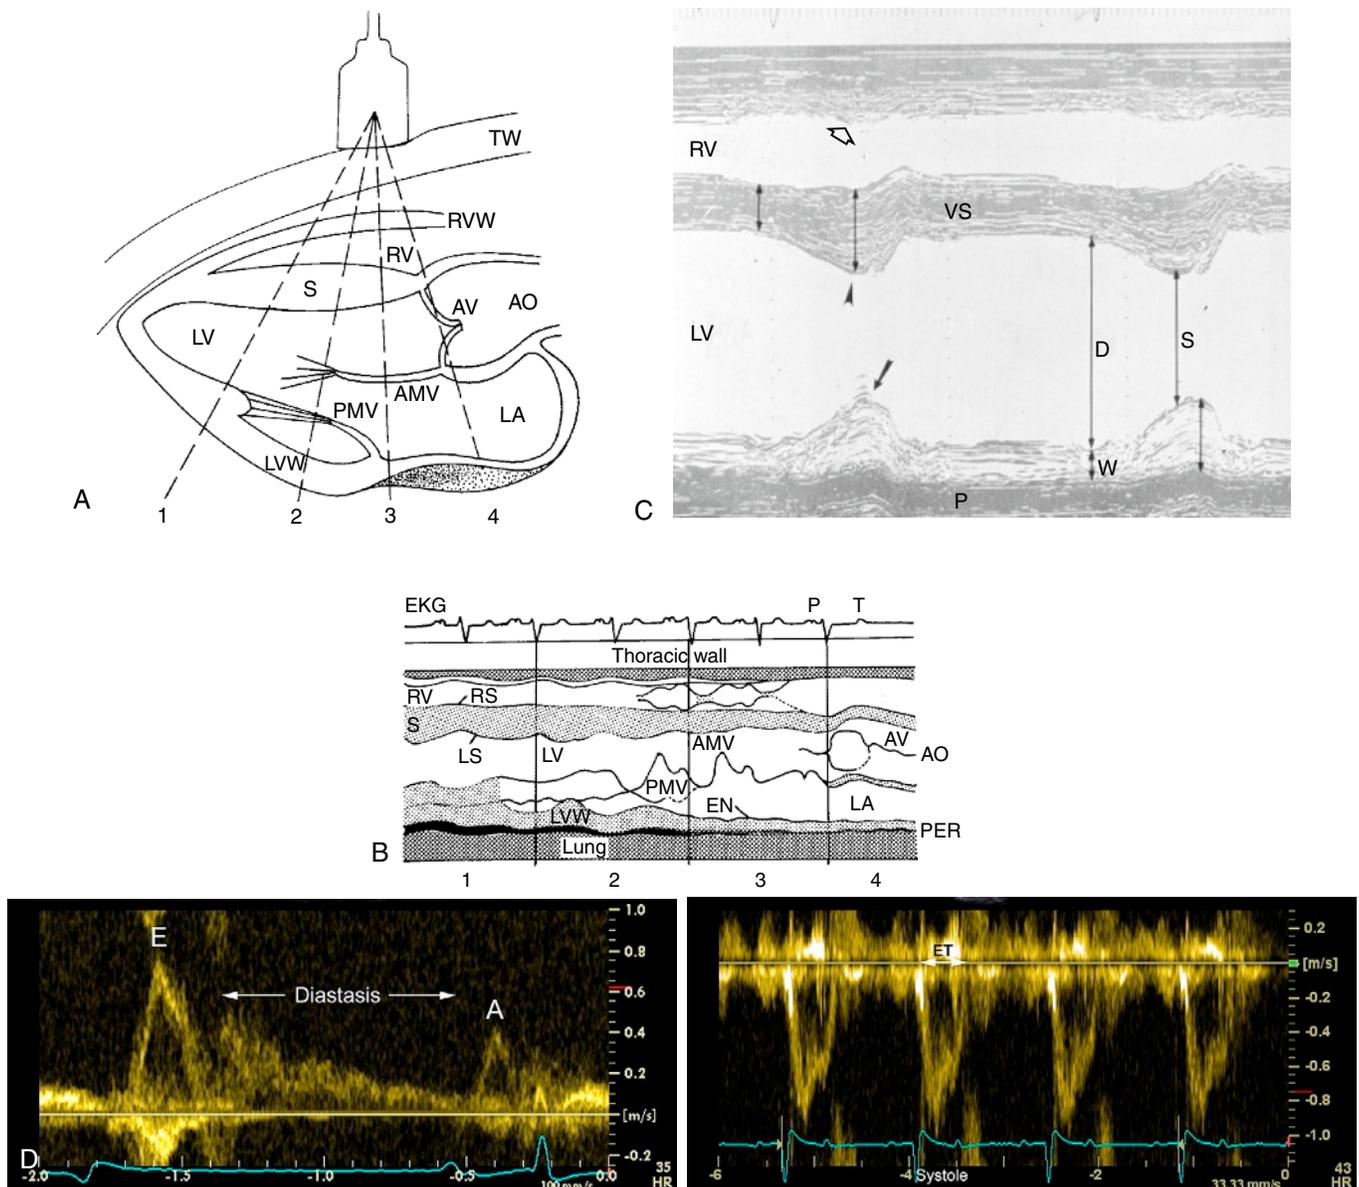

\*References 4, 34, 58, 111, 152, 218, 219.

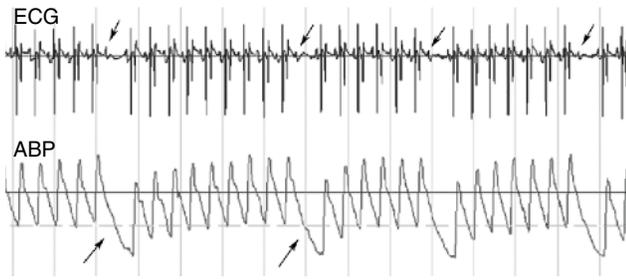

**FIGURE 10-4** A, The cardiac (Wiggers) cycle of the horse. This drawing integrates the electric, pressure, mechanical, and flow events of diastole and systole and demonstrates the origins of the heart sounds. Electric activity precedes mechanical events. See the text for a full description. AVC, Closure of the mitral (atrioventricular) valve; AVO, opening of the mitral (atrioventricular) valve; SLO, opening of the aortic (semilunar) valve; SLC, closure of the aortic (semilunar) valve. B, Determinants of cardiac output (CO) and blood pressure (BP). (A, Modified from Detweiler DK, Patterson DF: The cardiovascular system. In Cattcott EJ, Smithcors JF, editors: Equine medicine and surgery, ed 2, Santa Barbara, CA, 1972, American Veterinary Publications. B, From Muir WW, Hubbell JA: Equine anesthesia, ed 2, St Louis, 2009, Saunders.)

into the great vessel as the ventricular pressure increases to peak value and creates a similar peak ABP (see Figures 10-5, D, and 10-6). The contracting heart twists during systole, and the LV strikes the chest wall caudal to the left olecranon causing the *cardiac impulse* or “apex beat.” This early systolic movement, coincident with opening of the aortic valve, is a useful timing clue for cardiac auscultation and for identifying the mitral valve area for auscultation. The delay between the onset of the QRS and the opening of the semilunar valves, termed the

*pre-ejection period*, can be measured by Doppler echocardiography and is an index of ventricular myocardial contractility such that positive inotropic drugs shorten the pre-ejection period.<sup>46,230-237</sup> Blood is ejected into the aorta and PA with an initial velocity that generally peaks near 1 ms/sec and can be measured by Doppler echocardiography.<sup>149,230</sup> The aortic ejection time usually exceeds 400 ms in a horse at rest, and reductions of either ejection velocity or ejection time are suggestive of reduced LV function. A *functional systolic ejection*

**FIGURE 10-5** Ventricular function and echocardiography. **A**, Derivation of the M-mode echocardiogram. The lines demonstrate typical paths of M-mode recording planes (1, ventricular/papillary muscle; 2, chordae tendineae; 3, anterior mitral valve [AMV]; 4, aortic root and left atrium [LA]/auricle; TW, thoracic wall; RVW, right ventricular wall; RV, right ventricle; S, septum; LV, left ventricle; AV, aortic valve; AO, aortic outflow tract; LVW, left ventricular wall; PMV, posterior mitral valve; LA, left atrium). **B**, The drawing demonstrates the appearance of the M-mode echocardiogram at each level (PER, pericardium; RS, LS, right and left sides of the ventricular septum; EN, endocardium). **C**, M-mode echocardiogram demonstrating the method of measuring left ventricular shortening fraction (LVSF), in which  $D$  is diastolic dimension and  $S$  is systolic dimension ( $\text{LVSF} = D - S/D$ ). The prominent thickening of the walls during systole is notable. The end systolic excursion of the LV wall is visible (arrow). In practice, the systolic dimensions of the ventricular septum and the LV wall generally are measured along the same line as demonstrated for the LV lumen in systole ( $S$ ) ( $W$ , LV wall;  $VS$ , ventricular septum). **D**, *Left*: Doppler echocardiographic recordings of LV filling (*left*) and ejection (*right*). Transmitral inflow is characterized by an early diastolic rapid-filling wave ( $E$ ), low-velocity mid-diastolic filling (diastasis), and a presystolic atrial filling wave ( $A$ ). *Right*: The velocity profile of aortic ejection is characterized by a roughly triangular appearance with rapid acceleration of blood flow into the ascending aorta in early to midsystole and termination of flow at the time of aortic valve closure. The area under the velocity spectrum curve (velocity-time-integral) correlates directly with ventricular stroke volume. The pre-ejection period (the time between the start of the QRS and beginning of ejection) and the ejection times ( $ET$ , arrows) are load-dependent indices of LV function.

**FIGURE 10-6** Compressed electrocardiogram (ECG) with simultaneous arterial blood pressure (ABP) recording in a horse with second-degree atrioventricular block. The progressive increase in ABP triggers a baroreceptor reflex leading to atrioventricular conduction block (upper arrows) and a corresponding fall in the ABP (lower arrows). Presumably this mechanism, along with sinus arrhythmia and sinus arrest, represents vagally induced mechanisms for controlling ABP in the standing horse.

*murmur* is often heard during ejection (see Figure 10-4, A). Such murmurs, by definition, must begin after the first sound and end before the second sound. The difference between the diastolic and systolic pressure (pulse pressure) and rate of rise of pressure contribute to a palpable *arterial pulse* during mid-systole (see Figures 10-4, A, and 10-6). The precise timing of the pulse depends on the proximity of the palpation site relative to the heart. At the end of the *ejection period*, as ventricular pressures fall below those of the corresponding arteries, the semilunar valves close coincident with the high-frequency *second heart sound* (S<sub>2</sub>) or sounds and the incisura of the arterial pressure curves.<sup>19,23,25</sup> The pulmonary valve may close either after or before the aortic valve.<sup>3,4,238</sup> Asynchronous valve closure may lead to audible splitting of S<sub>2</sub>, which is normal but can be extreme in some horses with lung disease. During the ejection period the ventricular volume curve graphs a marked reduction from the end diastolic volume: this volume ejected is defined as the *stroke volume*. The ratio of the stroke volume to the end diastolic volume is the *ejection fraction*, a commonly used index of systolic heart function and correlated to the often-used shortening fraction of the M (motion)-mode echocardiogram (see Figure 10-5). Contraction of the ventricles causes the atrial pressures to decline leading to the *x* descent of the atrial pressure curve and a brief systolic collapse of the jugular vein. Subsequent to atrial filling during ventricular systole, a positive pressure wave, the *v* wave, occurs in the atrial and venous pressure curves. Severe TR accentuates this wave and may lead to pathologic systolic pulsations extending up the jugular furrow. Finally, a decline in ventricular pressure (*isovolumetric relaxation*) occurs, related to off-loading of calcium from the troponin apparatus and resequestration into the sarcoplasmic reticulum. This active ventricular relaxation is associated initially with closure of the semilunar valves and eventually by opening of the AV valves. Relaxation in healthy hearts is enhanced by sympathetic activity. Conversely, myocardial ischemia can impair active relaxation, and it is likely that subendocardial ischemia combined with reduced diastolic filling time contribute to the marked elevations in LA pressures observed during galloping or other high-intensity exercise.<sup>239,240</sup>

Ventricular filling commences just as the AV valves open. As shown in Figure 10-5, D, ventricular diastole can be subdivided into three general phases: (1) rapid ventricular filling,

(2) diastasis, and (3) atrial contraction.<sup>73,75,76</sup> These phases are readily observed using pulsed-wave Doppler echocardiography or Doppler tissue imaging.<sup>241</sup> Once the ventricles have relaxed and the atrial pressure exceeds the corresponding ventricular pressure, the AV valves open. At that instant, rapid filling ensues with a peak velocity of about 0.5 to 1 m/sec, but varying directly with the heart rate.<sup>149</sup> The ventricular pressures increase only slightly during this phase, whereas the ventricular volume curves change dramatically from the venous return. Rapid filling may be associated with a *functional protodiastolic murmur*, which is concluded by the *third heart sound* (S<sub>3</sub>), the low-frequency vibrations occurring near the termination of rapid ventricular filling. The loss of atrial volume and corresponding decline in the atrial pressure (the *y* descent) is reflected in the jugular furrow as the vein collapses. After rapid filling, a period of greatly reduced low-velocity-filling diastasis ensues. This period may last for seconds during vagal arrhythmias such as sinus bradycardia, pronounced sinus arrhythmia, or second-degree AV block. With markedly exaggerated pauses, the jugular vein may begin to fill prominently. The last phase of diastole is the contribution to ventricular filling caused by the atrial contraction. A functional *presystolic murmur* has been associated with this period between the fourth and first heart sounds.

During the cardiac cycle the atrium functions as a reservoir for blood (ventricular systole), a conduit for venous return (early to mid-diastole), and as a pressure pump (atrial systole). Mechanical atrial function of the LA can be studied using two-dimensional (2D) echocardiography and advanced Doppler echocardiographic methods. Impaired electrical and mechanical function of the atria may predispose to recurrent atrial arrhythmias such as AF.<sup>190,242-245</sup>

## ASSESSMENT OF VENTRICULAR FUNCTION

The ability of the ventricles to eject blood depends on both systolic and diastolic ventricular function, as well as heart rate and rhythm (Box 10-3). The most commonly used measurements of overall ventricular performance and circulatory function are invasively or noninvasively determined ABP, rate of ventricular pressure change (dp/dt), CO, stroke volume, ejection fraction, LV shortening fraction, systolic time intervals, central venous pressure, PA or wedge pressures, and arteriovenous oxygen difference (A-V DO<sub>2</sub>). \*CO, the amount of blood pumped by the left (or right) ventricle in 1 minute (L/min), is the product of ventricular stroke volume (ml/beat) multiplied by the heart rate (beats/min; see Figure 10-4, B). *Cardiac index* refers to the CO divided by (indexed to) the body surface area (or body mass). CO coupled to systemic vascular resistance determines the mean ABP: an increase in either variable raises mean arterial pressure. Values for CO vary widely with the size and activity of the horse and are often influenced by drug therapy or anesthesia.<sup>210,260-275</sup> A noninvasive estimate of CO can also be obtained using Doppler techniques.<sup>233,234,257,276-285</sup>

Ventricular stroke volume depends on myocardial contractility and loading conditions (preload and afterload; see Figure 10-4, D).<sup>24,26</sup> Although traditionally considered independent determinants of myocardial function, these variables are all interconnected and influence force, velocity, and duration of ventricular contraction.<sup>76</sup> Ultimately, the availability

## BOX 10-3

## DETERMINANTS OF CARDIAC FUNCTION

**Systolic Function: Determinants of Ventricular Stroke Volume**

Preload [+]  
—ventricular end-diastolic volume  
Determinants of diastolic function (see below)  
Plasma volume  
Venous pressure/venous return  
Myocardial inotropism [+]  
—contractility of the myocardium  
Sympathetic activity  
Myocardial disease  
Drugs (positive or negative inotropic agents)  
Myocardial perfusion  
Ventricular afterload [–]  
—wall tension required to eject blood  
Aortic impedance  
Vascular resistance  
Ventricular volume (tension increases with dilation)  
Ventricular wall thickness (thin walls have higher tension)  
Cardiac lesions increasing workload [–]  
Valvular regurgitation (common)  
Valvular stenosis (rare)  
Septal defects and shunts

**Diastolic Function: Determinants of Ventricular Filling**

Pleural/mediastinal factors (pressure, mass lesions)  
Pericardial function (intrapericardial pressure, constriction)  
Myocardial relaxation  
Myocyte stiffness  
Ventricular wall distensibility (chamber and myocyte compliance)  
Venous pressure and venous return (must be matched with compliance)  
Heart rate and ventricular filling time (shortened by tachycardia)  
Myocardial perfusion (ischemia impairs relaxation)  
Atrial contribution to filling (lost in atrial fibrillation)  
Cardiac rhythm (arrhythmias can alter atrioventricular contraction sequencing)  
Atrioventricular valve function

**Cardiac Output**

Cardiac output = Stroke volume [+]  
× heart rate [+]

**Arterial Blood Pressure**

Arterial blood pressure = Cardiac output [+]  
× vascular resistance [+]

of calcium to the sarcomere is modulated by the inotropic state, the initial myocardial stretch (preload), and the tension that must be generated to eject blood into the vascular system (afterload).

Myocardial *contractility* is increased by catecholamines, calcium, digitalis glycosides, and phosphodiesterase inhibitors.\* Contractility is difficult to measure in the clinical setting but can be estimated noninvasively by observing directional changes in load-dependent pre-ejection or ejection phase indices of ventricular function. These include shortening and ejection fractions by M-mode and 2D echocardiography; pre-ejection period, ejection time, flow acceleration, velocity time integral of aortic or pulmonic ejection, and peak myocardial velocity by Doppler echocardiography; and myocardial deformation or strain by computerized analysis of 2D echocardiograms or tissue Doppler studies (see Figure 10-5).<sup>49,50,51,237,303-306</sup> Measured variables will be influenced by physiologic state, altered mildly by day-to-day variation<sup>307,308</sup> or sedatives,<sup>231</sup> and affected markedly by general anesthesia.

Ventricular fiber length or preload is a positive determinant of ventricular systolic function that depends on venous return and ventricular size and distensibility. The normal ventricle is highly preload dependent, such that increases in preload increase stroke volume. Dehydration, venous pooling, loss of atrial contribution to filling (AF), and recumbency all

reduce ventricular filling and decrease stroke volume. When hypotension develops consequent to decreased ventricular filling, intravenous (IV) crystalloid or colloid is often administered initially to increase venous pressure and ventricular preload. Increased preload also can be observed in horses with heart disease as a consequence of impaired pump function, cardiac lesions, or fluid retention. Moderate to severe valvular insufficiency increases ventricular filling pressures and preload.<sup>38,105,309-311</sup> The increased ventricular diastolic dimension serves as a compensatory mechanism that maintains forward stroke volume in the setting of a failing ventricle or regurgitant heart valve.

Ventricular preload can be estimated by determining ventricular end diastolic volume or size, as measured by echocardiography, or by measuring venous filling pressures.<sup>310</sup> The measurement of venous filling pressures (central venous pressure, pulmonary diastolic or pulmonary capillary wedge pressure)<sup>310-314</sup> provides an accurate gauge of preload provided that heart rate and ventricular compliance (distensibility) are normal and ventilation is relatively stable. Myocardial ischemia, which impairs myocardial relaxation, and pericardial diseases, which constrict the ventricles, both reduce ventricular compliance; in such cases, the venous filling pressures may not accurately reflect chronic changes in ventricular preload.

Ventricular *afterload* is represented by the ventricular wall tension that must be developed to eject blood and relates to forces impeding this ejection. Peak wall tension occurs immediately before aortic valve opening. Vascular impedance

\*References 209, 210, 213, 216, 234, 259, 264, 286-302.

during ejection also relates to the elastic, resistive, and dynamic properties of the connected great vessel and vascular tree. Increases in ventricular chamber size, arterial stiffness, or resistance, as well as marked increases in hematocrit, increase the impedance to ventricular ejection and reduce stroke volume. Afterload is difficult to measure clinically, and although BP is not identical to afterload, it may be used to estimate directional changes in afterload. LV failure, alveolar hypoxia-induced pulmonary vasoconstriction, atelectasis, and PA or venoocclusive diseases are important causes of increased RV afterload. Arterial vasodilators such as hydralazine and angiotensin converting enzyme (ACE) inhibitors decrease afterload.<sup>268,315</sup>

*Ventricular synergy* refers to the normal method of ventricular activation and contraction. Normal electrical activation causes a burst of activation of great mechanical advantage.<sup>20</sup> Cardiac arrhythmias, especially ventricular rhythm disturbances, can cause dyssynergy (dyssynchrony), with a resultant decrease in stroke volume. Coronary occlusions leading to ischemic myocardial necrosis also cause dyssynergy but are considered relatively rare.<sup>57,108,316</sup>

Structural and functional competency of the cardiac valves and the ventricular septa influence ventricular systolic function. Valvular insufficiency (or the rare stenosis) reduces ventricular stroke volume unless adequate compensation develops from ventricular dilatation and hypertrophy. Ventricular remodeling, combined with heart rate reserve, often allows small septal defects or mild to moderate valvular lesions to be well tolerated even during exercise. However, large defects or severe valvular lesions can create significant volume overload of the left heart, progressive myocardial dysfunction, and heart failure. Development of CHF is particularly likely when an arrhythmia such as AF is superimposed on a serious structural lesion.

Ventricular *diastolic function* determines ventricular filling and preload.<sup>73,75,76,259</sup> Factors that affect diastolic function are indicated in **Box 10-3**. When diastolic function is abnormal, often greater heart rate and higher venous pressure dependencies occur for maintenance of CO. A well-recognized cause of diastolic dysfunction is constriction or compression of the heart caused by pericardial disease. Marked ventricular chamber dilatation or hypertrophy also decreases ventricular compliance and requires higher ventricular distending pressures for filling. LV diastolic dysfunction as a consequence of severe RV dilatation or hypertrophy can be explained by bulging of the ventricular septum into the LV, which impedes left-sided filling. This influence of ventricular interdependence is observed clinically with chronic pericardial disease and severe pulmonary hypertension. Ventricular diastolic function also is affected by arrhythmias. Persistent tachycardia shortens diastole, cardiac filling time, and coronary perfusion. With AF, the atrial contribution to filling is lost. Junctional and ventricular arrhythmias lead to AV dissociation preventing normal AV sequencing and can also create marked dyssynchrony of ventricular contraction.

Objective measures of diastolic function are complicated, and no good clinical indicator of diastolic function is currently available for horses. However, diastolic dysfunction may be assumed when one of the aforementioned conditions is recognized. It is possible to measure transmitral and tricuspid inflow using Doppler techniques, but these methods are crude and depend on atrial pressure. Tissue Doppler imaging and rate of myocardial deformation also may provide insight into

diastolic cardiac function but currently represent investigational techniques in horses.

Imbalance between *myocardial oxygen demand* and delivery can reduce both ventricular systolic and diastolic function and may affect cardiac rhythm as well. This relationship is also relevant when there is airway obstruction or bronchopulmonary disease, which can reduce arterial oxygenation.<sup>317</sup> Myocardial oxygen demand is augmented by increasing myocardial inotropic state, heart rate, and ventricular wall tension (related to preload and afterload).<sup>76</sup> Oxygen delivery depends on coronary anatomy and vasomotion (degree of vessel constriction), diastolic ABP, diastolic (coronary perfusion) time, and metabolic activity of the myocardium.<sup>10,75,318-325</sup> Normal coronary flow is highest to the LV myocardium in the ventricular septum and LV wall.<sup>325</sup> The immediate subendocardial layer of myocardium is probably most vulnerable to ischemic injury,<sup>9,318</sup> and altered ventricular depolarization may develop secondary to an imbalance in oxygen delivery. This probably accounts in part for the ST-T depression and changes in the T waves observed in hypotensive animals and in normal horses during sinus tachycardia. Coronary vasomotion is effective in augmenting coronary perfusion even at high heart rates (up to 200/min in ponies); however, coronary autoregulation is not as effective if diastolic perfusing pressure decreases in the aorta.<sup>319,320,322</sup>

The clinician may use the “double product” of ABP × heart rate as a general estimate of myocardial oxygen demand.<sup>76</sup> Persistent ST segment depression or elevation, especially at rest and normal heart rates, suggests deficient myocardial perfusion. However, ST segment and T wave changes are normal in horses examined during treadmill exercise and are therefore difficult to interpret.

## ☞ CARDIOVASCULAR EXAMINATION OF THE HORSE

### GENERAL APPROACH

A general approach to the recognition and diagnosis of heart disease and an assessment of its severity is summarized in **Box 10-4**. Undoubtedly, history and auscultation are the most important initial evaluation procedures in the CV examination of the horse. With the exception of abnormalities in ventricular function, normal cardiac auscultation in a horse with good exercise tolerance practically precludes significant heart disease. The initial CV physical examination should include a thorough auscultation of the heart at all valve areas, auscultation of both lung fields, palpation of the precordium, evaluation of the arterial pulses (head and limbs), inspection of the veins, and evaluation of the mucous membranes for pallor, refill time, and cyanosis, which may develop secondary to a right-to-left cardiac shunt or severe respiratory disease (see **Box 10-4**). An accurate resting heart rate and respiratory rate also should be recorded.

It is worth emphasizing that physical examination and a stethoscope can detect most serious cardiac disorders initially. Sustained or recurrent cardiac arrhythmias are easily discovered through cardiac auscultation and palpation of the arterial pulse, and diagnosis of the rhythm can be verified through electrocardiography. Pericarditis and cardiac tamponade are characterized by muffled heart sounds or pericardial friction rubs, jugular distension, and often RV failure.

## BOX 10-4

## CLINICAL EXAMINATION OF THE EQUINE CARDIOVASCULAR SYSTEM

**History and Physical Examination**

Work history and identification of possible hemodynamic dysfunction  
 Heart rate and rhythm  
 Examination of the arterial and venous pulses, refill, and pressure  
 Inspection of the mucous membranes  
 Evaluation for abnormal fluid accumulation: pulmonary, pleural, peritoneal, and subcutaneous  
 Auscultation of the heart and lungs  
 Measurement of arterial blood pressure (indirect method)

**Electrocardiography**

Heart rate, rhythm, and conduction sequence  
 P-QRS-T complexes: configuration, amplitude, duration, and axis (axis has limited value in horses)  
 Postexercise and exercise electrocardiography<sup>†‡</sup>  
 Holter (digitally recorded) electrocardiogram<sup>†‡</sup>

**Echocardiography**

M-mode echocardiography: cardiac dimensions and systolic ventricular function, cardiac anatomy and valve motion, and estimation of cardiac output  
 Two-dimensional echocardiography: cardiac anatomy and size, systolic ventricular function, identification of lesions, and estimation of cardiac output  
 Doppler echocardiography<sup>‡</sup>: identification of normal and abnormal flow, estimation of intracardiac pressures, estimation of cardiac output, and ventricular function  
 Postexercise echocardiography<sup>‡</sup>: identification of regional or global wall dysfunction or valve dysfunction exacerbated by exercise

**Thoracic Radiography<sup>‡</sup>**

Evaluation of pleural space, pulmonary parenchyma, and lung vascularity  
 Estimation of heart size (more beneficial in foals)

**Clinical Laboratory Tests**

Complete blood count and fibrinogen to identify anemia or inflammation  
 Serum biochemical tests, including electrolytes, renal function tests, and muscle enzymes: These studies may be useful for assessing arrhythmias, identifying low cardiac output (azotemia), and recognizing myocardial cell injury (cardiac isoenzymes of creatine kinase or lactic dehydrogenase)  
 Cardiac troponin-I concentration (cTnI): can be measured at rest and after exercise testing to identify myocardial damage  
 Serum protein to identify hypoalbuminemia and hyperglobulinemia  
 Arterial pH and blood gas analysis to evaluate pulmonary and renal function and to assess acid-base status  
 Urinalysis to identify renal injury from heart failure or endocarditis  
 Blood cultures for bacteremia and diagnosis of endocarditis  
 Serum/plasma assays for digoxin, quinidine, and other drugs

**Radionuclide Studies<sup>§</sup>**

Detection of abnormal blood flow or lung perfusion and assessment of ventricular function

**Cardiac Catheterization and Angiocardiography<sup>§</sup>**

Diagnosis of abnormal blood flow and identification of abnormal intracardiac and intravascular pressures

Modified from Bonagura JD: Clinical evaluation and management of heart disease, *Equine Vet Educ* 2:31–37, 1990.

\*Most important part of the cardiac evaluation.

<sup>†</sup>May be needed to identify paroxysmal atrial fibrillation.

<sup>‡</sup>Generally done after referral.

<sup>§</sup>Not commonly performed.

Significant myocardial disease is usually associated with heart failure, arrhythmias, or a cardiac murmur, especially when ventricular dilatation or dysfunction causes insufficiency of the mitral or tricuspid valves. The presence of a cardiac murmur is the essential finding that leads one to consider degenerative or infective valvular disease or a congenital heart malformation.<sup>111,156</sup>

Laboratory studies, electrocardiography, and echocardiography are additional tests that are particularly useful in recognizing the underlying basis and severity of CV disease. Mild or subtle CV disease may require a detailed examination, including exercise testing before abnormalities can be objectively detected.<sup>326-332</sup>

**HISTORY**

Cardiovascular disease may be suspected from the history or a serendipitous finding during the course of a routine examination.\* The horse with CHF may be presented for generalized venous distention, jugular pulsations, or edema. Conversely, other cardiac problems such as arrhythmia or murmur can be incidental findings, detected during a routine physical, prepurchase, or insurance examination. Once an abnormality has been found, a complete CV examination is aimed at

\*References 32, 111, 112, 196, 256, 333-335.

## BOX 10-5

**CARDIOVASCULAR ASSOCIATION OF POOR PERFORMANCE****Arrhythmias**

Atrial premature complexes  
 Ventricular premature complexes  
 Atrial fibrillation  
 Supraventricular tachycardia  
 Ventricular tachycardia  
 Advanced second-degree atrioventricular block  
 Complete third-degree atrioventricular block

**Congenital, Valvular, or Myocardial Heart Diseases Associated with Murmurs**

Ventricular septal defect  
 Mitral regurgitation  
 Tricuspid regurgitation  
 Aortic regurgitation  
 Cardiomyopathy with secondary atrioventricular valvular regurgitation

**Occult Heart Disease**

Pericardial disease  
 Cardiomyopathy or myocarditis  
 Ischemic myocardial disease (?)

Aortic-iliac thrombosis  
 Jugular vein thrombosis/thrombophlebitis (bilateral)  
 Aortic root rupture (aorto-cardiac fistula)  
 Peripheral vein thrombosis/thrombophlebitis

determining the lesion and the significance of disease in terms of safety, performance capabilities, and expected longevity.

The horse with clinically apparent CV disease may have subtle performance problems that are only apparent at peak performance levels. For example, slowing in the last quarter to three eighths of a race is a common historical complaint. In many cases, performance may deteriorate by only 2 to 3 seconds. In other horses, particularly in cases of AF, racing performance may decline greatly by 20 to 30 seconds or more. Horses with malignant VT may stop abruptly or even collapse. Horses with CV disease also may demonstrate excessively high heart and respiratory rates during and after exercise or may take a longer than normal time to return to a resting rate (or “cool out”). Coughing, either at rest or during exercise, tachypnea, and exercise-induced pulmonary hemorrhage are respiratory signs reported in some horses with heart disease. CV disease must always be considered along with musculoskeletal, respiratory, metabolic, and neurologic problems in the differential diagnosis of poor performance (Box 10-5).<sup>54-56,122,317,336,337</sup> Other performance-related problems with CV disease can include weakness, ataxia, collapse, and sudden death (Box 10-6).<sup>52,57-68,219</sup>

**AUSCULTATION****CLINICAL METHOD**

Cardiac auscultation is the systemic examination of the heart using a stethoscope. Auscultation is expedient and relatively sensitive for detection of serious heart disease when performed

## BOX 10-6

**CAUSES OF SUDDEN CARDIOVASCULAR DEATH****Electric Disorders of the Heart (Arrhythmias)**

Ventricular tachycardia, flutter, or fibrillation  
 Complete atrioventricular block  
 Asystole

**Toxic Injury to the Heart**

Acute myocardial failure  
 Anesthetics  
 Drug- or toxin-induced arrhythmia  
 Toxic plants  
 Myocardial toxins  
 Systemic toxin secondarily affecting the heart

**Cardiac Tamponade**

Bacterial pericarditis  
 Idiopathic pericarditis  
 Viral pericarditis

Carotid air embolism  
 Coronary embolism or thrombosis

**Electrocution**

Lightning  
 Alternating current electrocution

**Cardiac Trauma**

Cardiac catheterization or needle puncture of a ventricle leading to ventricular fibrillation  
 Penetrating thoracic wound

by a knowledgeable and experienced examiner. It provides information about heart rate, persistent arrhythmias, and presence or absence of congenital and acquired heart diseases. Pericardial diseases also may be recognized by auscultation. Auscultation should be conducted within the context of a medical history and general physical examination, which includes assessment of the precordium and pulses, auscultation of the thorax, and inspection for edema and abnormal ventilatory patterns.

Effective auscultation requires an understanding of anatomy, physiology, pathophysiology, and sound. Extensive clinical data regarding cardiac auscultation in the horse have

been published\* and experience with Doppler echocardiography has refined the clinician's understanding of heart sounds and murmurs.<sup>130,145,354</sup> Experience and training are also significant factors in effective cardiac auscultation,<sup>355,356</sup> and this examination method should be considered an acquired skill that can be constantly honed. The overall sensitivity of auscultation is high for identification of congenital heart diseases, *significant* valvular disease, and *persistent* cardiac arrhythmias. Sensitivity is lower for primary myocardial or pericardial diseases, unless obvious associated abnormalities exist (e.g., murmur, arrhythmia, prominent friction rub). The specificity of auscultation in the horse (e.g., the ability to distinguish a functional from a pathologic murmur or identify a specific flow disturbance) has not been sufficiently studied but most certainly depends on the clinician's knowledge and experience,<sup>355</sup> as well as one's opinion related to the physiologic versus pathologic nature of valvular regurgitation in some high-performance horses.

A prerequisite for auscultation is an appreciation of the normal heart sounds, the genesis of which has already been described (see Clinical Cardiovascular Physiology). The examiner must be familiar with the causes and clinical features of arrhythmias and murmurs (Tables 10-1, 10-2, and 10-3) and the areas for auscultation (Figure 10-8).<sup>†</sup> Auscultation is best carried out in a very quiet area because extraneous noise makes detection of soft to moderate murmurs quite difficult. The horse or foal should be sufficiently restrained so that the examiner can concentrate on listening. The venous pulse should be inspected and then the arterial pulse and the precordium palpated before commencing auscultation. Although uncommonly used today, practiced examiners can use percussion of the precordial area effectively to identify the region of cardiac dullness to identify heart size.<sup>357</sup>

The stethoscope examination generally commences on the left side. Both stethoscope chest pieces—the diaphragm (applied tightly) and the bell (applied lightly)—should be used. When using a single-piece tunable diaphragm, the pressure on the chest piece should be gradually increased to optimize the sounds of interest. All auscultatory areas should be examined. The locations of the cardiac valve areas can be identified using the following method:

- The left apical impulse located at the left thoracic wall is adjacent to or under the olecranon near the fifth intercostal space; this location identifies the ventral region of the LV inlet. The mitral valve is dorsal to the cardiac impulse, but mitral sounds and murmurs often project well to the apex while also radiating dorsally into the LA. The first heart sound ( $S_1$ ) is best heard at this location, and the ventricular filling or third heart sound ( $S_3$ ) is also heard well over this point.
- The aortic valve area is located one (or two) intercostal spaces cranially and is dorsal to the left apical impulse. The second sound ( $S_2$ ) is loudest at this point, and aortic valve murmurs are heard best over this valve. The murmur of MR may also radiate dorsally and cranially to this area. Because of the central location of the aortic valve and the orientation of the ascending aorta to the right, aortic flow murmurs and the murmur of aortic regurgitation (AR)

generally can be heard bilaterally, just medial to the triceps muscles.

- The pulmonic valve is located slightly cranioventral (generally one intercostal space) to the aortic valve, and the pulmonary component of  $S_2$  is loudest at this point. This is also the location where splitting of the second sound is most obvious. The main PA extends dorsally from the pulmonic valve, high on the left cranial base. Murmurs that radiate into the PA are heard best at this location, including some functional murmurs and the murmur of patent ductus arteriosus (PDA). The murmur associated with an atrial septal defect (ASD) or a subarterial VSD, as well as the rare murmur of pulmonic stenosis, are typically loudest over the pulmonary valve and PA.
- The tricuspid valve area is located over a wide area on the right hemithorax, dorsal to the sternum and just cranial to the mitral valve; sounds and murmurs associated with tricuspid valve disease are usually heard best over the right hemithorax. Murmurs of paramembranous VSD are often detected ventral and slightly cranial to the tricuspid valve area, dorsal to the sternum.

It is worthwhile to concentrate first on the individual heart sounds when assessing the heart rhythm, because the generation of cardiac sounds depends on the underlying electrical rhythm and heart murmurs are timed relative to the heart sounds (Figure 10-9). The atrial sound ( $S_4$ ) is heard after the P wave. The first and second heart sounds ( $S_1$  and  $S_2$ ) encompass systole, indicating the presence of a QRS complex. A murmur detected between the first and second sounds is termed *systolic*. In contrast, a murmur heard after  $S_2$  is designated as *diastolic*. The distinctive atrial sound ( $S_4$ ) is absent in AF. Normal variation in the P-R interval causes gradual changes in the  $S_4$  to  $S_1$  interval. Absence of a QRS complex, which occurs with second-degree AV block and with nonconducted atrial premature complexes (APCs), causes a pause in which the first and second heart sounds are absent. The heart sounds and precordial movements often can be palpated, especially over the left thoracic wall. Frequently the cardiac movements and low-frequency vibrations corresponding to the atrial contraction ( $S_4$ ), onset of ventricular contraction ( $S_1$ ), and closure of the semilunar valves ( $S_2$ ) can be detected. With ventricular volume overloading or vigorous normal filling, an accentuated apex beat and third sound ( $S_3$ ) will be palpable. Cardiac enlargement or displacement of the heart by an intrathoracic mass may lead to an abnormal location of the cardiac impulse. A loud cardiac murmur is often associated with a palpable vibration or *precordial thrill*.

## HEART SOUNDS

Heart sounds should be readily heard on each side of the thorax, although some variability is found based on body type, and sounds are louder over the left thoracic wall. All four heart sounds can be detected in healthy horses, but all may not be present or evident at the same location (see Figures 10-9 and 10-10).<sup>3,23,25</sup> The ventricular filling sound ( $S_3$ ) is most localized and variable, and may be difficult to detect unless the bell is placed lightly over the left apex. The intensity of the heart sounds should be consistent when the rhythm is regular, but variation of heart sound intensity occurs with arrhythmias (irregular cardiac filling). Muffled heart sounds are heard with pericardial effusions or pericardial abscesses (the muffling may only be on one side of the thorax) but also occur in some horses with large pleural

TABLE 10-1

<b>Auscultation of Cardiac Arrhythmias</b>			
<b>Rhythm</b>	<b>Heart Rate per Minute</b>	<b>Heart Sounds</b>	<b>Auscultation</b>
<b>SINUS MECHANISMS</b>			
Sinus rhythm	Variable	S4-1-2 (3)*	Rate and rhythm dependent on autonomic tone
Sinus arrest/block	<26	S4-1-2 (3)	Irregular, long pauses
Sinus bradycardia	<26	S4-1-2 (3)	Generally regular unless escape rhythm develops
Sinus arrhythmia	25-50	S4-1-2 (3)	Irregular, cyclic change in heart rate; often interval varying between S4 and S1; often associated with second-degree atrioventricular block or sinus bradycardia
Sinus tachycardia	>50	S4-1-2-3	Typically regular, but second-degree atrioventricular block may develop if sympathetic tone decreases
<b>SUSTAINED ATRIAL TACHYARRHYTHMIAS</b>			
Atrial tachycardia and atrial flutter	>30	S1-2 (3)	Ventricular regularity and rate dependent on atrioventricular conduction sequence, sympathetic tone; consistent S <sub>4</sub> absent; variable-intensity S <sub>1</sub> ; may detect independent atrial sounds
Atrial fibrillation	>30	S1-2 (3)	Ventricular response irregular; rate related to sympathetic tone; heart rates consistently above 60 beats/min suggestive of significant underlying heart disease or heart failure; absence of consistent S <sub>4</sub>
<b>ECTOPIC RHYTHMS</b>			
Junctional rhythm	26-200	S1-2 (3)	Heart rate usually regular idionodal rhythms or junctional tachycardia; heart rate dependent on the mechanism and sympathetic tone; inconsistent S <sub>4</sub> ; variable intensity sounds
Ventricular rhythm	26-200	S1-2 (3)	Heart rate possibly regular during monomorphic, unifocal ectopic rhythm or irregular during polymorphic or multifocal ectopic activity; heart rate dependent on the mechanism (e.g., escape rhythm versus ventricular tachycardia); variable intensity and split heart sounds possibly audible
Premature atrial and junctional beats	Varies	Early S1-S2	Intensity of S <sub>1</sub> may be louder or softer than normal; the sounds are not usually split; less than compensatory pause often follows premature beat; nonconducted atrial premature complexes result in pauses but not premature first heart sounds.
Premature ventricular beats	Varies	Early S1-S2	Intensity of S <sub>1</sub> often variable and ventricular beats possibly softer than normal; heart sounds possibly split from asynchronous ventricular activation heart sounds; compensatory pause typically following a premature beat
<b>ATRIOVENTRICULAR BLOCKS</b>			
Incomplete (first- and second-degree)	<50	S4-1-2 (3)	Heart rate variable; cyclic arrhythmia, variable S <sub>4</sub> -S <sub>1</sub> interval; some variation in heart sounds
Complete (third-degree)	<26	S4-S1-2 (3)	Ventricular escape rhythm, usually regular; independent atrial (S <sub>4</sub> ) sounds; variable-intensity heart sounds

\*Heart sounds in parentheses may be audible.

effusions and cranial mediastinal masses. Accentuation of all heart sounds, especially the third sound, may be detected with volume-loaded ventricles or with marked sympathetic activity. Projection of heart sounds over a wider area is sometimes evident in cases of pleuropneumonia with pulmonary consolidation.

The first heart sound varies with arrhythmias and often becomes louder (or sometimes softer) after prolonged diastolic periods. This in itself is not diagnostic of an abnormality. Splitting of the first heart sound, if pronounced, may indicate

abnormal ventricular electrical activation or ventricular premature complexes.<sup>238</sup> Close splitting of the first sound may be more obvious when AF is present, and in the absence of an atrial sound, the split S<sub>1</sub> may be misinterpreted as a closely timed S<sub>4</sub> to S<sub>1</sub> complex.

The second sound is loudest normally over the aortic valve area and may be audibly split over the pulmonic valve area.<sup>3,4,238</sup> This sound can be very soft or absent after a premature beat, and it may be obscured by a holosystolic murmur. Audible splitting of S<sub>2</sub> occurs commonly in normal horses,

varies with heart rate or respiration, and only infrequently is associated with pulmonary hypertension. The relative closure of the semilunar valves probably varies with the heart rate and PA pressure,<sup>3,238</sup> although the pulmonic component is most often detected after the aortic component in the healthy, resting horse. If the pulmonary component of the second sound develops a tympanic quality, becoming equal to or louder than the aortic component of  $S_2$ , then the clinician should consider pulmonary hypertension. Identification of a loud pulmonic  $S_2$  is a useful clinical finding in cases of right-sided heart failure because it often indicates that a lesion on the *left* side of the heart has led to pulmonary hypertension and right-sided CHF.

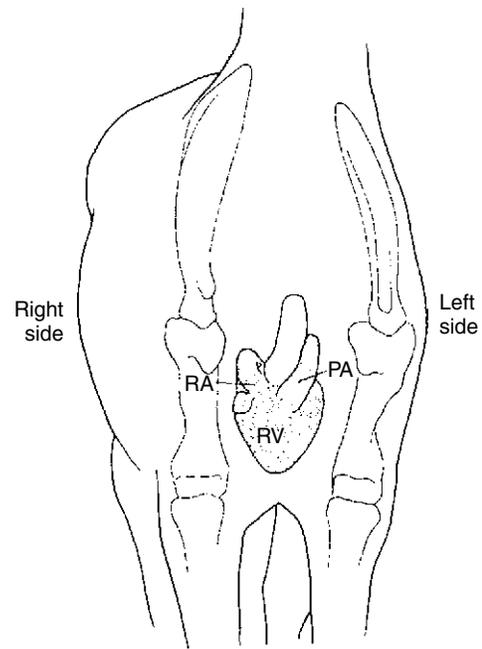

Diastolic transient sounds are normal.<sup>16,17,19,350</sup> The atrial sound ( $S_4$ ) should be detected in virtually all horses, and this sound may be quite loud in some cases. Isolated atrial sounds are commonly auscultated at slow resting heart rates caused by second-degree AV block; however, multiple isolated  $S_4$  sounds indicate high-grade AV block. The ventricular sound ( $S_3$ ) is normal and as a low-pitched sound may be difficult to hear. The sound often increases transiently in the setting of sinus tachycardia and enhanced rapid filling. This sound also achieves greater intensity when ventricular dilatation and elevated filling pressures develop, as with heart failure.

Other sounds may be detected with heart disease. Systolic clicks are uncommonly heard over the great vessels where they are thought to be benign. A systolic click loudest over the mitral area may be a marker for mitral valve disease or prolapse of the valve into the LA. Constrictive pericardial disease can create a loud early diastolic ventricular filling sound, a ventricular “knock,” indicating abrupt termination of rapid filling under high venous pressures. In addition to muffling of sounds, pericarditis is often associated with a pericardial friction rub. These rubs are classically detected during three portions of the cardiac cycle (systole, early diastole, late diastole). These sounds must be distinguished from pleural friction rubs or respiratory mediated sounds, which are occasionally associated with the cardiac cycle. Pleural and pulmonary rubs tend to be heard only during one or two phases of the cardiac cycle and may not correlate closely.

## HEART RATE AND RHYTHM

Heart rate can change rapidly and dramatically, varying with autonomic efferent traffic and level of physical activity. Changes in the rate and rhythm are reflected in cardiac auscultation and palpation of the pulse (see [Table 10-1](#)).<sup>344</sup> The normal arterial pulse and cardiac rhythm is regular or cyclically irregular. Heart rate in mature horses varies between 28 and 44 beats/min, although slightly slower heart rates can be detected in some very fit racehorses and higher heart rates are often present in foals,<sup>348</sup> yearlings, draft horses,<sup>358</sup> and healthy but nervous horses. An elevated resting heart rate is commonly detected with late pregnancy, fever, pain, hypovolemia, severe anemia, infection, or shock. Persistent, otherwise unexplained tachycardia is also typical of heart failure wherein the standing heart rate usually exceeds 60 beats/min.

Physiologic arrhythmias associated with high resting vagal tone must be differentiated from pathologic arrhythmias. Vagal-induced arrhythmias are most often observed in healthy relaxed horses. The most common of these are sinus arrhythmia and second-degree AV block (see [Figure 10-6](#)), which is reported in 15% to 18% of normal horses at rest and has been detected in up to 44% of normal horses with 24-hour continuous electrocardiographic monitoring.<sup>194,197,199,359,360</sup> This

**FIGURE 10-7** Cranial view of the heart demonstrating the U shape of the right ventricle (RV). The tricuspid valve and the right ventricular inlet are located on the right side, whereas the outlet and pulmonary artery (PA) are on the left side. Murmurs of tricuspid regurgitation and perimembranous ventricular septal defects are typically loudest over the right hemithorax, whereas flow murmurs, and those caused by subaortic or subpulmonic septal defects are loudest over the left cardiac base. RA, Right atrium. (From Bonagura JD, Muir WW: The cardiovascular system. In Muir WW, Hubbell JAE, editors: *Equine anesthesia*, St. Louis, 1991, Mosby-Year Book.)

arrhythmia is most common in fit racehorses or in other high-performance animals and disappears with stimulation of sympathetic nervous system activity. Sinus arrhythmia also occurs regularly in horses and is often associated with sinus bradycardia and resting heart rates between 24 to 28 beats/min. Sinus arrhythmia may wax and wane with respiration; however, synchronization with ventilation is not a consistent finding in the horse, and it is more likely related to changes in baroreceptor activity. SA block and SA arrest occur sporadically in fit horses. Because these physiologic arrhythmias are associated with high vagal tone, it is typical for the heart rate to range from a low-normal value to overt bradycardia. Maneuvers that reduce vagal activity and increase sympathetic tone can be undertaken to ensure that the rhythm becomes normal. Successful methods include leading the horse through three or four tight circles, jogging, or lunging. It should be recognized, however, that some horses redevelop physiologic AV block within 10 to 60 seconds after such maneuvers. If the arrhythmia persists after exercise, or if the auscultatory findings suggest another arrhythmia (see [Table 10-1](#)), then an ECG should be obtained.

The arrhythmias associated with heart disease occur most often with normal to increased heart rates, with the exception of advanced second-degree and complete (third-degree) AV block.\* Atrial premature beats are characterized by a regular cardiac

TABLE 10-2

<b>Causes of Cardiac Murmurs</b>	
<b>Cardiac Murmur</b>	<b>Lesion Identified by Echocardiography, Catheterization, or Necropsy</b>
Functional murmurs*	No identifiable lesions
Congenital heart disease murmurs	Defect(s) in the atrial or ventricular septa; patent ductus arteriosus; atresia/stenosis of the tricuspid or pulmonic valve; valve stenosis; other malformations of the heart
Mitral regurgitation	High-level training; degenerative thickening of the valve; bacterial endocarditis; mitral valve prolapse into left atrium; rupture of a chorda tendinea; dilated-hypokinetic ventricle (dilated cardiomyopathy); papillary muscle lesion or dysfunction; valvulitis; malformation
Tricuspid regurgitation	High-level training <sup>†</sup> ; same causes as for as mitral regurgitation; also pulmonary hypertension from severe left-sided heart failure or chronic respiratory disease
Aortic regurgitation	Degeneration of the aortic valve; congenital fenestration of the valve; bacterial endocarditis <sup>‡</sup> ; aortic prolapse into a ventricular septal defect or the left ventricle; flail aortic valve leaflet; valvulitis; malformation; ruptured aorta or aortic sinus of Valsalva
Pulmonary insufficiency	Bacterial endocarditis <sup>‡</sup> ; pulmonary hypertension; flail pulmonic valve leaflet; valvulitis; malformation; rupture of the pulmonary artery
Murmur associated with vegetative endocarditis	Insufficiency of the affected valve <sup>‡</sup>

Modified from Bonagura JD: Clinical evaluation and management of heart disease, *Equine Vet Educ* 2:31–37, 1990.

\*Functional murmur may be innocent (unknown cause) or physiologic (suspected physiologic cause). Functional murmurs are common in foals and trained athletes (athletic murmur), associated with fever and high sympathetic nervous system activity (pain, stress, sepsis), and often are heard in anemic horses. Functional murmurs depend on the physiologic state and can be altered by changing the heart rate. Such dynamic auscultation is useful in detecting functional murmurs.

<sup>†</sup>Doppler echocardiography can identify “silent” regurgitation across a right-sided cardiac valve in some horses; this is probably a normal finding of no clinical significance.

<sup>‡</sup>Anatomic stenosis generally is caused by a large vegetation and also should be associated with a diastolic murmur of valvular insufficiency; increased flow across the valve, even in the absence of a true stenosis, may generate a murmur of “relative” valvular stenosis (e.g., with aortic regurgitation a systolic ejection murmur may occur because of an increased stroke volume).

rhythm, which is suddenly interrupted by earlier than normal beats. Because the sinus node is reset during an atrial premature beat, the following pause is usually incomplete or less than compensatory (provided the underlying sinus rhythm is regular). Premature atrial beats can also be blocked in the AV node, leading to a sudden pause in the rhythm without a premature first heart sound. A ventricular premature beat is often followed by a fully compensatory pause unless the extrasystole is interpolated between two normal sinus beats. Pulse deficits (more first sounds than arterial pulses) are common with premature beats.

Atrial fibrillation is characterized by an irregularly irregular pulse and ventricular rhythm, with some beats occurring sooner than expected, and with pauses in the rhythm demonstrating no consistent diastolic interval. The atrial contraction and hence the fourth sound are absent in AF. Infrequently, AF develops with recurring periodicity of cycle lengths that can cause difficulty in distinguishing this from second-degree AV block.<sup>191,193,201</sup> Another diagnostic pitfall can be the presence of a split first sound, because the clinician may mistake this for a closely timed S<sub>4</sub> to S<sub>1</sub> complex.

Conversely, atrial tachycardia can be conducted with patterns leading to a rapid but regular heart rhythm. However, most horses with atrial tachycardia develop irregular rhythms owing to frequent block of atrial impulses in the AV node, especially at rest. Heart rates are usually higher than normal at rest. Auscultation of the horse in a quiet area may reveal isolated audible fourth heart sounds associated with the second-degree AV block.

Junctional or nodal tachycardia and VT are usually manifested by a rapid regular rhythm, although some VTs cause

an irregular rhythm. Owing to associated AV dissociation or abnormal ventricular activation, the heart sounds may sound split or variable in intensity.

## CARDIAC MURMURS

Cardiac murmurs are prolonged audible vibrations developing in a usually quiet portion of the cardiac cycle. In general, murmurs are manifestations of either normal (functional) or abnormal (pathologic) blood flow in the heart and blood vessels. Although many heart murmurs are functional (physiologic, athletic, innocent), other murmurs provide evidence of heart disease and may require further investigation. Most *functional* cardiac murmurs are caused by vibrations that attend the *ejection* of blood from the heart during systole or the *rapid filling* of the ventricles during early diastole.\* Causes of abnormal murmurs include incompetent cardiac valves, septal defects, vascular lesions, and (very rarely) valvular stenosis (see Tables 10-2 and 10-3). The continuous murmur of PDA is a normal finding in full-term foals for up to 3 days after parturition, but it occasionally persists for almost 1 week after foaling.<sup>265,343,348,367</sup>

One of the challenges of physical diagnosis is determination of the cause and clinical significance of a cardiac murmur. With knowledge and experience, the clinician can accurately determine the *likelihood* that a murmur is physiologic or pathologic in origin and efficiently select animals requiring additional

Auscultation	Considerations	Further Observations	Probable Assessment	Other Tests
Continuous murmur PMI: Left or right thorax	→ Organic murmur	⇒ PMI: Pulmonary artery Foal or other signs of CHD	→ Patent ductus arteriosus (PDA) or a systemic to pulmonary shunt	→ Echo
		Mature horse	→ Aortic to cardiac fistula or Aortic to pulmonary artery fistula	→ Echo
Pericardial Friction Rub**	→ Organic murmur	⇒ Systolic or multi-phasic Distant (muffled) heart sounds Jugular venous distension	→ Pericarditis	→ Echo

**Footnotes**

<sup>†</sup>Endogenous sympathetic activity can be transiently increased by suddenly leading the horse in four or five tight circles or through trotting or lunging; the horse should be examined *immediately* after the activity has stopped.

<sup>‡</sup>Vagally induced rhythms include sinus bradycardia, pause or arrest, sinoatrial block, sinus arrhythmia, and second-degree atrioventricular block.

<sup>†</sup>Resting tachycardia exceeding 90/minute should be evaluated with an ECG to qualify the rhythm; the cut-off rate is arbitrary but clinically useful.

<sup>§</sup>Ectopic rhythms include ectopic atrial tachycardia, junctional (nodal) tachycardia, and ventricular tachycardia.

<sup>%</sup>Functional murmurs due to ejection of blood into the great vessels often become transiently louder following an increase in sympathetic activity.

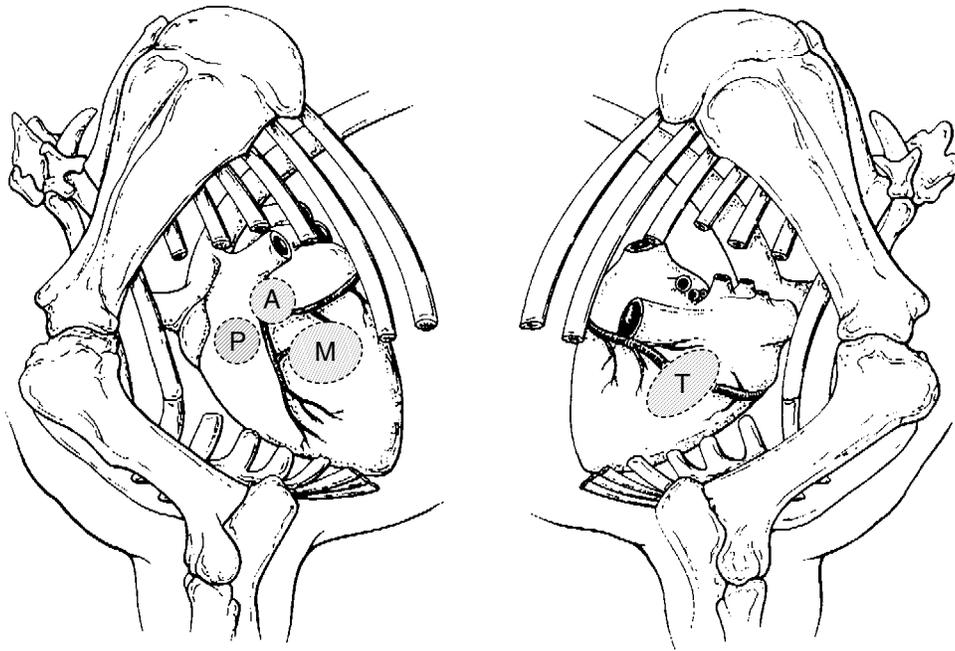

<sup>§</sup>Loud ejection murmurs over the semilunar valves and great vessels may indicate pulmonic stenosis or complex defects such as tetralogy of Fallot.

<sup>#</sup>Judgment should be exercised regarding the need for echocardiography. An echocardiogram might be indicated in the pre-purchase examination of any valuable foal or horse with a cardiac murmur; whereas, echocardiography may not be indicated in an older horse with a soft murmur of aortic regurgitation with normal arterial pulses or in a fit racehorse with a typical murmur of tricuspid regurgitation.

\*\*Classic pericardial friction rubs are heard during systole, early diastole, and late diastole. Occasionally a functional pre-systolic murmur exhibits a frequency quality similar to a brief friction rub.

**Abbreviations & Terminology:**

- *Configuration* = the phonocardiographic 'shape' of a murmur, for example a plateau-shaped murmur that extends from the first sound through the second sound is termed holosystolic or pansystolic (e.g. MR or VSD); a 'diamond-shaped' murmur is crescendo-decrescendo in configuration (e.g., functional ejection); a "blowing" murmur that starts suddenly but dissipates gradually is decrescendo (e.g., aortic regurgitation), while a murmur that becomes progressively louder and then stops is crescendo in configuration (e.g., MR from mitral valve prolapse)
- *ECG* = perform an electrocardiogram to determine heart rhythm
- *Echo* = perform an echocardiogram to identify abnormal structure, cardiac size, or function; Doppler studies are added to assess normal and abnormal blood flow patterns and are optimal for evaluating horses with cardiac murmurs; Doppler studies must be interpreted relative to auscultatory findings.
- *Grade* = intensity of the murmur on a 1 through 6 scale; in most systems a grade 5 or 6 murmur is accompanied by a precordial thrill
- *HR* = heart rate
- *Organic* = related to a structural lesion in the heart or great vessels
- *PMI* = point of maximal murmur intensity
- *Precordial thrill* = the palpable thoracic vibration associated with a loud cardiac murmur
- *Troponin-I* = serum level of inhibitory cardiac troponin or cTn<sub>i</sub>, a biomarker used to detect cardiomyocyte injury or necrosis
- *Valve* = refers to the general valve area of auscultation (see text for details)

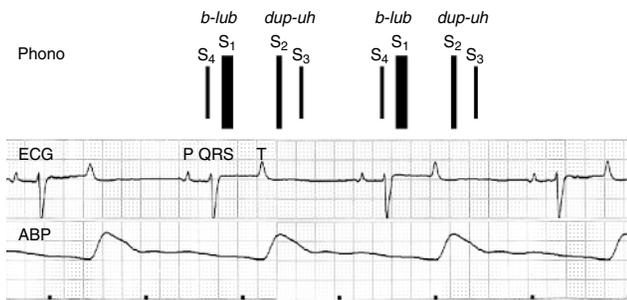

**FIGURE 10-8** Cardiac auscultation areas in the horse from the left (A) and the right (B) side of the thorax. Note the size and anatomic position of the heart within the thorax. The cardiac apex (apical area) is usually located slightly above the level of the olecranon and can be identified by palpation of the apical beat. The cardiac base (basilar area) is located more cranially and at the level of the scapulohumeral joint. The shaded areas represent the respective valve areas (P, pulmonic; A, aortic; M, mitral; T, tricuspid). The right atrium (RA) (*above T*), tricuspid valve, and right ventricular (RV) inlet (inflow region, *below T*) are located on the right side of the thorax. Paramembranous ventricular septal defects (VSDs) that communicate with the RV inlet (*below the tricuspid valve*) are usually heard best along the lower right hemithorax (*below T*) and typically radiate from the right ventricle (RV) into the pulmonary artery (left hemithorax). Most (but not all) murmurs of tricuspid valve disease are heard best over the right chest wall, usually heard best more dorsally as they radiate into the RA (*above T*). The RV outlet projects to the left side of the thorax and continues into the pulmonary artery, which is located at the left dorsal cardiac base (*above P*). Thus murmurs originating in the RV outlet (e.g., murmurs from subpulmonic VSDs) systolic murmurs of relative pulmonic stenosis (from cardiac shunting), murmurs of pulmonic insufficiency (rare), and functional pulmonary arterial murmurs are heard best over the left chest wall (*P*). The aortic valve is located centrally, and diastolic murmurs of aortic insufficiency may be heard at either hemithorax, although they are usually loudest on the left (*A*). Functional murmurs generated in the ascending aorta are heard over the cranial basilar region of the heart. The systolic murmur of mitral regurgitation (MR) radiates to the left apex and is usually heard across the left ventricular (LV) inlet (area caudoventral of *M*). The regurgitant mitral jet can be directed craniodorsal or caudodorsal into the left atrium (LA) and can account for variability in murmur radiation. The functional protodiastolic murmurs associated with ventricular filling are usually evident over the ventricular inlets and may be heard on either side of the thorax. (From Reef VB: Cardiovascular system. In Orsini JA, Divers TJ, editors: Manual of equine emergencies: treatment and procedures, ed 2, Philadelphia, 2003, WB Saunders.)

studies. The clinician should describe the *timing, duration, quality or pitch, grade, point of maximal murmur intensity, and radiation* of a murmur, as well as the effect of changing heart rate on the sounds. Determination of timing is made relative to the heart sounds so that murmurs are designated as *systolic, diastolic, or continuous*. When the overall timing is not obvious, the clinician can either palpate the apical impulse, which occurs in early systole, or the systolic pulse in the brachial or median artery to identify the timing of the murmur. Skilled auscultators subdivide the timing of murmurs into proto-(early), meso-(middle), or tele-(late) systole or diastole, because the timing and duration of the murmur often correlate with specific flow disturbances. Shorter murmurs, especially those occurring in early systole or protodiastole, are more likely to be functional, although this is not always the case. Experience also teaches that relatively loud or long murmurs are more likely to be associated with cardiac

pathology (see [Figure 10-10](#) and [Table 10-3](#)), but again exceptions occur. The pitch or quality of the murmur provides additional insight. For example, mixed frequency (harsh or blowing) murmurs are typical of cardiac disease. A brief vibratory or musical murmur is typically functional; however, a prolonged musical murmur is suggestive of a valvular lesion. Applying the characteristics of murmurs to the clinical setting requires study, an organized scheme (see [Table 10-3](#)), and practice.

Functional, innocent, or physiologic heart murmurs are very common and are not attributed to cardiac pathology. Such murmurs may be related to the large size and tremendous inflow and outflow volumes of the equine heart.<sup>364</sup> Physiologic causes of functional murmurs include fever, high sympathetic activity (e.g., colic, exercise, pain), moderate to severe anemia, and peripheral vasodilation. These murmurs are typically soft (grades 1 to 3/6, of a possible 6), localized, relatively short,

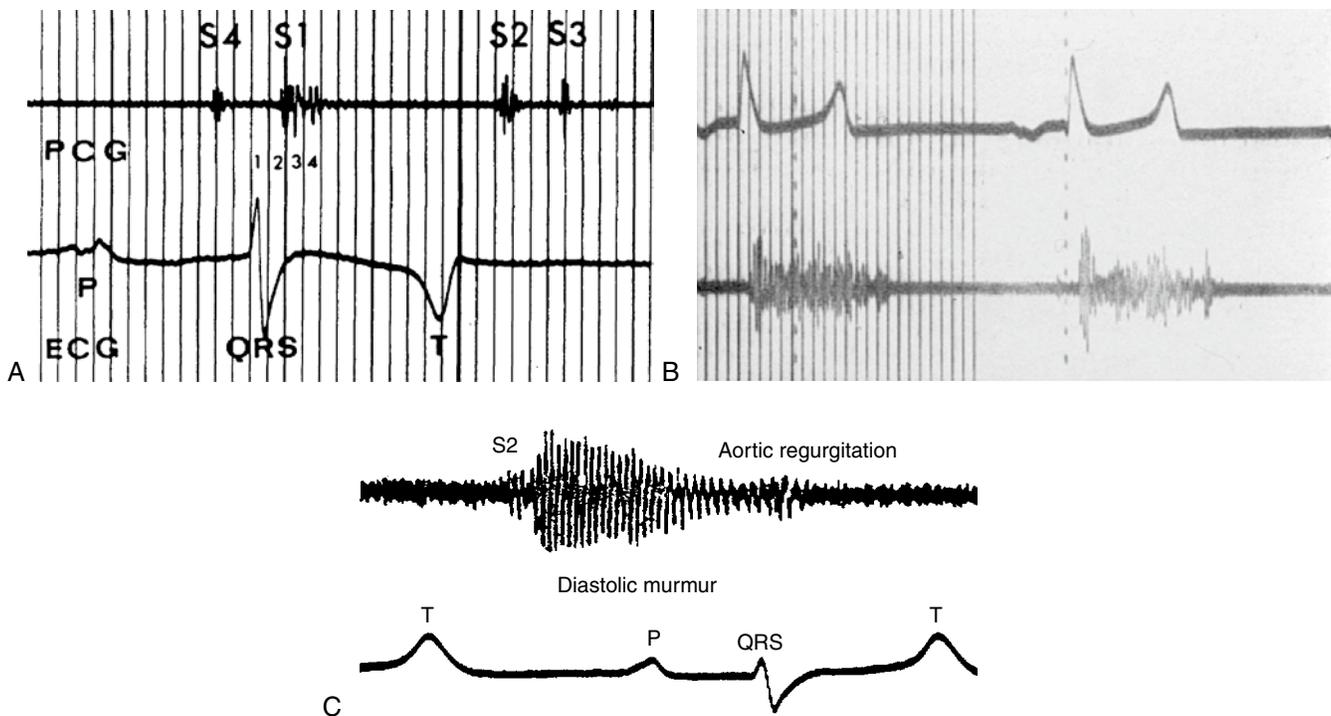

crescendo-decrescendo in timing, and labile. Increasing heart rate usually increases the intensity and duration of a functional murmur, although in some horses the murmur becomes less intense. Functional murmurs are neither holosystolic nor holodiastolic; therefore the heart sounds should still be evident.

**FIGURE 10-9** Schematic diagram of the normal heart sounds (Phono) in relation to a surface electrocardiogram (ECG) and an arterial blood pressure tracing (ABP) recorded from the transverse facial artery. *S1*, First (systolic) heart sound; *S2*, second (diastolic) heart sound; *S3*, third heart sound; *S4*, fourth (atrial) heart sound. *B-lub dup-uh* describes the sounds heard on auscultation. Note the timing of the heart sounds and the (peripheral) pulse pressure wave relative to the ECG. (From Schwarzwald CC, Bonagura JD, Muir WW: *The cardiovascular system*. In Muir WW, Hubbell JAE, editors: *Equine anesthesia: monitoring and emergency therapy*, ed 2, St Louis, 2009, WB Saunders.)

The most common functional murmur is the systolic ejection murmur heard over the aortic and pulmonic valves and projecting into their respective arteries at the left cardiac base (see Figure 10-8).<sup>3</sup> The functional ejection murmur is generated by flow into the great vessels, and by definition it must start after *S1* and end before *S2*. Nonetheless, in some horses, the functional ejection murmur can achieve substantial intensity (rarely, a grade 4 or 5) and may seem holosystolic at higher heart rates. At times a remarkable change in functional murmur intensity is seen from day to day. An example of this is the varying murmurs identified in some horses with emergent colic. Because a loud functional murmur can radiate caudally, it may be confused with MR. In terms of diagnostic considerations, the clinician should not mistake a functional ejection murmur for that of aortic or pulmonic stenosis. Pulmonic stenosis is rare in the horse, and aortic stenosis even less common. Accordingly, these valvular malformations are rarely entertained in the differential diagnosis. The murmurs resulting from subpulmonic (subarterial) VSDs or the stenosis associated with tetralogy of Fallot may be loudest over the great vessels, but such murmurs are usually loud and prompt echocardiographic investigation.

Functional diastolic murmurs are also common, especially in young horses and in the Thoroughbred breed. These murmurs are generally soft and are detected over the LV or RV inlets—from the dorsal atrium to the ventricular apex. The functional protodiastolic murmur is an early diastolic murmur detected between *S2* and *S3*. The murmur may be musical, vibratory, or “squeaky” and typically accentuates

**FIGURE 10-10** Phonocardiograms (PCG). **A**, The four normal heart sounds (*S1* through *S4*) are evident in this recording. (The numbers 1 through 4 indicate the various components of the first heart sound; ECG, electrocardiogram.) **B**, Systolic murmur recorded from a yearling with a ventricular septal defect (VSD) (P waves on the ECG are negative in this tracing). **C**, Decrescendo, musical, holodiastolic murmur recorded from a horse with aortic regurgitation (AR). The murmur begins in early diastole (after the T wave) and ends at the QRS complex. (A recording courtesy of D. Smetzer, R.L. Hamlin, and C.R. Smith.)

with increased heart rate.<sup>3</sup> It most reasonably represents the rapid early filling of the ventricles. The presystolic functional murmur is heard between  $S_4$  and  $S_1$ , and the vibrations may sound like a *rub* or long heart sound after the atrial contraction. It can be confused with an early systolic murmur or a friction rub.

The most commonly detected murmurs associated with structural or *organic heart disease* are those generated by tricuspid regurgitation (TR), MR, AR, and VSD. Typical causes and auscultatory features of these murmurs are indicated in [Tables 10-2 and 10-3](#)) and described in detail later in this chapter.

When a murmur is believed to represent underlying cardiac pathology, further investigation is required. The overall significance of the hemodynamic abnormality should include consideration of the work history, general physical examination, presence or absence of heart enlargement or cardiac failure, and results of ancillary tests such as echocardiography, electrocardiography, and exercise performance (or testing). Certainly, the history should be considered, because the horse with excellent performance and good exercise tolerance is less likely to have serious heart disease. Auscultation, however, is insufficient to distinguish trivial from significant heart disease in the poorly performing horse or in a horse with a cardiac arrhythmia. Echocardiography is helpful in these cases to quantify heart size and objectively assess ventricular function. Underlying lesions such as a valve vegetation, ruptured valve chorda tendineae, or dilated cardiomyopathy can be identified or discounted. Although there are no well-defined echocardiographic or Doppler correlates to functional heart murmurs, these studies can document abnormal blood flow and can pinpoint the cause of a pathologic murmur.

### PULMONARY AUSCULTATION

Auscultation of the lungs should reveal normal breath sounds with the horse at rest, while ventilating into a rebreathing bag, and after exercise. Decreased or absent airway sounds or large airway sounds in the ventral portions of the thorax indicate a pleural effusion, a common finding in biventricular or right-sided heart failure. Moist or bubbling (fluid) sounds or crackles (i.e., rales) are uncommonly auscultated in the lungs of horses with pulmonary edema and left-sided heart failure. Instead, tachypnea associated with harsh bronchovesicular breath sounds is usually heard, because horses with chronic left-sided CHF seem to develop more interstitial than alveolar pulmonary edema. When alveolar edema does develop, respiratory distress may be severe, crackles may become evident, and free fluid may be auscultated in the trachea. On rare occasion, primarily with peracute left-sided heart failure, froth will be visible at the nares and the horse will cough and expel large quantities of pulmonary edema ([Figure 10-11](#)). Such horses demonstrate severe respiratory distress (marked tachypnea and dyspnea), anxiety, and agitation.

### EXAMINATION OF THE PERIPHERAL VASCULATURE

An evaluation of the peripheral vasculature is part of a CV workup and should include examination of the arteries and veins in the head, forelimbs, and hindlimbs. When important, ABP also should be measured. The genesis of the arterial and venous pulses has been described previously. The heart sounds

should be correlated with both the jugular and the arterial pulses.

Normal-quality *arterial pulses* should be palpable in the facial, median, carotid, great metatarsal, coccygeal, and digital arteries. The arterial pulse represents the pulse pressure (i.e., the difference between peak systolic and diastolic pressures), the rate of rise of arterial pressure, and the physical characteristics of the artery and surrounding tissues. Palpating the facial artery pulse may identify heart rate and rhythm, as well as altered hemodynamic states. The arterial pulse can be described as *normal*, *hypokinetic (weak)*, *hyperkinetic*, or *variable*. Irregularity often indicates a cardiac arrhythmia.

Thready or hypokinetic arterial pulses are associated with reduced stroke volume and peripheral vasoconstriction and therefore may be detected in CHF and in diseases associated with volume depletion or profuse hemorrhage. Thready arterial pulses may also be detected only in the hindlimbs with aortoiliac thrombosis. Bounding, hyperkinetic arterial pulses are palpable with clinically significant AR, PDA, and aortic to pulmonary or aortic to right-sided heart fistulas. The pulse in septic animals may be weak, owing to reduced pulse pressure, or normal to rapidly declining if peripheral vasodilation occurs. Marked variation in the intensity of the pulse usually occurs with arrhythmias, particularly AF and rapid or multi-form VT. A pulse deficit (first heart sound without palpable pulse) occurs when developed LV pressure does not exceed aortic pressure. Deficits are likely to be palpated in association with pathologic arrhythmias, particularly premature beats, or after very short diastolic periods of tachyarrhythmias.

Palpation of the arterial pulse cannot quantify the actual ABP, which must be measured directly by arterial puncture or cannulation or indirectly using various auscultatory, Doppler, or oscillometric techniques.<sup>71,253,269,368-393</sup> Percutaneous placement of an arterial catheter in the facial or transverse tibial artery is frequently used to monitor pressure invasively in critically ill or anesthetized horses. Indirect methods have been used successfully to monitor pressure in the coccygeal artery; however, these methods are less sensitive in hypotensive animals and may lag in response during rapid changes in BP.<sup>371,373,375</sup> Attention must be directed to placement and

**FIGURE 10-11** Peracute pulmonary edema in a horse with a ruptured chorda tendinea. The photo was taken immediately after euthanasia. An important note is that tracheal froth is often a post-mortem artifact, particularly when observed hours after death.

diameter of the occluding cuff when indirect methods are used,<sup>385</sup> and the optimal width of the cuff (bladder) is between approximately one quarter to one fifth of the circumference of the tail when measuring pressure in the middle coccygeal artery.<sup>379,384</sup> The arterial pulse wave itself varies, depending on the site of measurement, and the distal arterial systolic pressure may be higher, and the diastolic pressure lower, than the corresponding central aortic pressures.

ABP monitoring includes determination of systolic, diastolic, and mean pressures. Arterial pressure is determined by the interplay between stroke volume, heart rate, and vascular resistance (see Box 10-3 and Figure 10-4, B). Marked increases in CO can lead to significant increases in ABP with systolic pressures exceeding 200 mm Hg.<sup>246,390,394</sup>

Normal reported values for indirect arterial pressure are 111.8 mm Hg systolic (ranging between 79 to 145 mm Hg) and 67.7 diastolic (ranging between 49 to 106 mm Hg).<sup>\*</sup> BP is lowest in neonates and rises during the first month of life to the normal adult range.<sup>253,373</sup> Some variation is found among breeds. Draft breeds tend to have lower pressures than racehorses, and Standardbreds have lower pressures than Thoroughbreds.<sup>389</sup> Arterial pressures fluctuate slightly with ventilation and significantly under positive pressure ventilation or during cyclic changes in heart rate (see Figure 10-6). Posture imposes a significant influence on arterial pressure, because raising the head from the feeding position necessitates a higher aortic pressure to maintain cerebral perfusion. Obviously, when the head is lowered, the hydrostatic pressure imposed by an elevated head position is minimized. Mean arterial pressure measured in the middle coccygeal artery can vary approximately 20 mm Hg with the changing head position.<sup>386</sup> Abnormalities of arterial pressure and perfusion can result in changes in mucous membrane color and capillary refill time. Refill time is prolonged during hypotension or peripheral vasoconstriction; conversely, it may be shortened with vasodilation.

The systolic arterial pressure is generated by the LV and is consequently affected by the interplay between the stroke volume, heart rate, aortic compliance, and previous diastolic BP.<sup>46</sup> Arterial *pulse pressure* is highly dependent on stroke volume and the peripheral arteriolar resistance that determines the run off of diastolic pressure. Ventricular failure or reduced venous return reduces pulse pressure, creating a hypokinetic pulse; whereas abnormal diastolic run off (AR, generalized vasodilation) widens the pulse pressure, producing a stronger peripheral pulse. Diastolic and mean pressures are better estimates of perfusion pressure in anesthetized or critical equine patients; these variables are increased by arteriolar vasoconstriction or by higher CO. Mild variation in pulse pressure is normal across the respiratory cycle related to variation in ventricular filling. However, marked differences can be associated with cardiac tamponade, and the dramatic fall in pressure during inspiration is termed *pulsus paradoxus*.

The cutaneous veins should be examined for distensibility, refill, thrombosis, and estimated venous pressure. The jugular veins in normal horses are collapsed, but the veins of the limbs and torso are visible and somewhat filled. Venous pressure in the jugular vein is normally less than 10 cm of water above the phlebostatic point, and *jugular pulsations* are normally confined to the thoracic inlet and the ventral one third (10 cm) of the neck. These pulsations are reflections of the RA

pressure changes that range from positive to subatmospheric over the cardiac cycle (discussed previously). Pulsations are normally visible along the entire length of the jugular vein when the head is lowered below the level of the heart and should not be misinterpreted. A pathologic jugular pulse also can be misdiagnosed if transmission of carotid arterial pressure into the jugular furrow occurs. Occluding the jugular vein ventrally can demonstrate if the pulses are actually originating within the RA or not, because venous pulse transmission, or prominent collapse, will be prevented by light digital pressure over the vein. Pronounced jugular pulsations are observed occasionally in excited but otherwise normal horses with high sympathetic tone. This might be caused by either vigorous RA contraction. Alternatively, an exaggerated venous collapse can create a "jugular pulse" that is simply a reflection of normal venous refilling during periods of positive RA pressure. When doubt persists, this finding can be verified by simple ultrasound imaging of the ventral portion of the vein.

Jugular abnormalities include abnormal pulses or elevated venous pressure. An abnormal jugular pulse is one that extends proximally up the jugular vein for more than 10 cm in systole (with the horse's head held in a normal position) or that demonstrates retrograde filling from the heart when the vein is occluded dorsally. Duplex Doppler studies of the jugular vein can distinguish a prominent pulse caused by retrograde flow from an apparent pulse caused by prominent collapse and normal filling. Abnormal jugular pulses are observed with arrhythmias causing AV dissociation (nonconducted atrial premature beats, junctional tachycardia, VT); with diseases of the tricuspid valve (moderate to severe TR or the rare case of tricuspid stenosis); and with RV failure from any cause including cardiac tamponade or constrictive pericardial disease. Elevated jugular venous pressure generally indicates right-sided CHF, pericardial disease, or hypervolemia. Generalized venous distention, particularly when accompanied by subcutaneous edema, is characteristic of CHF (Figures 10-12 and 10-13). Isolated distention of the veins cranial to the thoracic inlet is suggestive of a cranial mediastinal or pulmonary mass (or abscess) with obstruction of the cranial vena cava.<sup>100</sup> Prolonged refill of the saphenous vein indicates the possibility of aortoiliac thrombosis and decreased arterial supply to the affected limb.<sup>222-227,396,397</sup> A distended vein that is firm to palpation, and associated with marked distention of associated veins, indicates probable venous thrombus.<sup>398</sup> Pain or heat associated with venous swelling is suggestive of thrombophlebitis.

## CONGESTIVE HEART FAILURE

Congestive heart failure in horses is relatively uncommon; however, the diagnosis often can be made from a thorough physical examination.<sup>399</sup> Clinical findings include persistent tachycardia (generally at 60/min or greater), jugular venous distention and pulsations, abnormal arterial pulses, fluid retention (ventral subcutaneous edema, pleural effusion, or pulmonary edema), and loss of body condition (see Figure 10-13). LV failure secondary to valvular or myocardial heart disease causes pulmonary venous congestion with pulmonary interstitial or, uncommonly, alveolar edema. Tachypnea or coughing associated with left-sided CHF can be misdiagnosed as pneumonia or chronic obstructive pulmonary disease. Exercise intolerance, lethargy, collapse (or syncope), anorexia, depression, and weight loss are other potential signs of heart

\*References 371, 374, 375, 379, 380, 382-386, 389, 391, 395.

failure. This subject and management are discussed more fully later in this chapter.

## DIAGNOSTIC AND LABORATORY STUDIES

### EXERCISE TESTING

Because most horses function as athletes, exercise testing represents an important method for identifying CV and other disorders in the underperforming horse. Additionally, some form of exercise testing should be included in the prepurchase CV examination, unless the animal is too young to perform or is to be used solely for breeding. Even in these situations, evaluation of a foal, weanling, or yearling after a period of free exercise is optimal. Furthermore, it should be determined that a stallion has sufficient stamina to perform in the breeding shed. For these reasons, it is recommended that CV system be evaluated at rest, immediately after exercise, and under the anticipated form of work required by the prospective owner. Having advanced this recommendation, it is also acknowledged that more data and information are needed to establish the reliability and predictive values of such studies relative to CV disease.

High-speed treadmill and other forms of exercise testing are increasingly used to detect subtle clinical abnormalities that limit peak performance.\* The exercise examination provides valuable information about musculoskeletal diseases, airway diseases, and CV disorders. Treadmill exercise is also useful when evaluating the horse with a history of collapse or syncope, because the cardiac response to exercise can be evaluated without risk to a rider. A number of components to a standardized treadmill examination are available. Gait and lameness are evaluated and pre- and postexercise serum creatine kinase (CK) measured to identify subclinical myopathy. Videoendoscopy is used to identify laryngeal and other dynamic airway disorders. Arterial blood gases are often analyzed to assess pulmonary function. An exercise and

**FIGURE 10-13** Ascites, ventral edema, and weight loss are evident in this mare with right-sided congestive heart failure (CHF). The distended lateral thoracic vein (*arrow*) is evident caudal to the triceps.

postexercise ECG is recorded to identify heart rhythm disturbances. Pre- and postexercise echocardiography may be used to identify regional or global LV dysfunction. Doppler studies can be added to evaluate valvular insufficiency.<sup>184</sup>

Changes in heart rate with exercise have been well studied.<sup>205,326-330,403,426</sup> The normal horse develops sinus tachycardia, shortening of conduction intervals, and marked ST-T alterations associated with exercise. The maximal heart rate achieved depends on the level of exercise performed. At heart rates of less than 100 to 120 beats/min, SA node discharge is very labile and subject to psychologic influences. Once exercise has commenced, the heart rate should accelerate and then stabilize at a level appropriate for the work being performed. As a general guideline, heart rates of 70 to 120 beats/min are normal at the trot, 120 to 150 beats/min are normal at the canter, 150 to 180 beats/min are normal at the gallop, and more than 180 beats/min are normal when galloping at maximal exertion. The maximal heart rate for most horses is between 210 and 240 beats/min, although some develop higher rates. A linear relationship relates the heart rate and the velocity or work effort of exercise when the heart rate is between 120 and 210 beats/min. Heart rate usually recovers rapidly and falls to less than 100 beats/min within 2 to 5 minutes of cessation of exercise. The recovery of heart rate to the resting level is influenced by many factors, including the humidity, ambient temperature, training fitness, work performed, psychologic factors, and state of CV health. After maximal work, such as a race, 1 hour may pass before the heart rate completely recovers to the resting rate. An inappropriately high heart rate for a given level of exercise may simply denote a healthy, but unfit, horse; however, this finding can also indicate the presence of CV, pulmonary, or musculoskeletal disease. Information about the heart rate is particularly useful when a horse has the heart rate monitored routinely during exercise.

Exercise-induced arrhythmias may be observed during or after exercise. An exercising ECG obtained by radiotelemetry is necessary to determine if an arrhythmia is present during exercise. A heart rate monitor may provide some indication regarding arrhythmias during exercise; however, the detection

\*References 122, 204, 273, 311, 313, 317, 327-330, 332, 337, 394, 400-425.

of erratic heart “blips” or “beeps” does not adequately characterize the rhythm disturbance. Exercise may induce supraventricular premature complexes, AF, ventricular extrasystoles, or VT. Exercise-induced (paroxysmal) AF should be included in the differential diagnosis of horses with poor performance during high-intensity exercise.<sup>39,427,428</sup> Exercise-induced ventricular arrhythmias are a particular concern because ventricular rhythm disturbances can lead to poor performance, sudden stopping, or even falling, and they have been suspected as one cause of sudden death.<sup>60,62-65</sup> Repetitive ventricular activity (paroxysmal VT) is particularly worrisome and may indicate preexisting myocardial disease or myocardial ischemia with altered cardiac electrical activity. In some horses, a maximal work effort is required to elicit heart rhythm disturbances. Thus when the history indicates performance problems only at the peak of exercise, or if other indicators of heart disease are present, a treadmill exercise test to exhaustion may be needed to reveal cardiac arrhythmias.

Horses demonstrate marked fluctuations in sympathetic and parasympathetic tone during the recovery period after exercise.<sup>420,429,430</sup> Arrhythmias are especially common during this time,<sup>317,337</sup> even if the resting and peak exercise heart rhythms were normal. Marked sinus arrhythmia, second-degree AV block, supraventricular ectopia, and ventricular premature complexes can be evident in the immediate postexercise period. With the exception of vagally mediated arrhythmias, postexercise arrhythmias should be considered suspicious. AF, ectopic supraventricular tachycardias, and VTs are considered abnormal at any point in the exercise test. However, the importance of single (isolated) ectopic complexes identified only in the immediate postexercise phase is less certain,<sup>337</sup> which is not surprising considering similar issues persist in assessing human athletes. In assessing these horses, attention also should be directed to the presence of coexisting respiratory disease, baseline auscultation and echocardiographic examinations, the heart rhythm during exercise, measurements of serum cardiac troponin I (cTn<sub>I</sub>) before and after exercise, and the so-called stress echo immediately after work.

Echocardiography after the stress of exercise can be used in an attempt to identify global and regional myocardial dysfunction.<sup>122,317,331,337</sup> This examination must occur within 2 to 3 minutes after high-intensity exercise and with the heart rate in excess of 100 beats/min. However, the optimal heart rates and the influence of rapidly decreasing heart rates on echocardiographic measurements such as shortening fraction require better definition. Dynamic changes can be viewed from the short axis tomograms, and prominent thickening of the ventricular septum and LV free wall identified from long axis images. Persistent abnormalities in regional myocardial contraction are suggestive of vascular disease with ischemia, preexistent myocardial fibrosis, or a localized conduction disturbance. LV shortening fraction and LV fractional area change (two estimates of LV systolic function) are commonly measured during stress echocardiography. It is important to scrutinize multiple segments across the entire shortening area of the LV, because errors in cursor placement (e.g., too dorsal) or inconsistent orientation of the M-mode cursor placement between examinations can produce misleading results. Other methods used for stress echocardiographic assessment of LV function are the manual tracking of endocardial motion and subjective evaluation of regional wall motion. Newer echocardiographic modalities, including tissue Doppler imaging

and 2D strain (2D speckle tracking) imaging, may have some advantages over conventional methods and could prove useful for quantitative assessment of regional and global LV function during stress echocardiography (CC Schwarzwald, unpublished observations), but more data and standardizations are needed before methods can be widely accepted.

Undoubtedly, CV disorders can be induced or worsened by the stress of exercise, and the likelihood of detecting disease is increased. However, the assessment is challenging because physiologic variability is also magnified. The immediate postexercise period involves rapidly changing autonomic traffic<sup>420,429,430</sup> that can result in confusing ECG and echocardiographic findings.<sup>184,337</sup> The presence of significant respiratory disease and associated arterial hypoxemia also creates the potential for secondary rhythm disturbances, unrelated to primary cardiac disease.<sup>317</sup> Thus the reliability and overall sensitivity, specificity, and predictive values of the exercise test (as it pertains to detection of arrhythmia and organic heart disease) are incompletely defined for a number of reasons. The “standardized” exercise test may not be identical across equine medical centers, so it may be difficult to compare results. The examiner’s own reference for normal variation further qualifies the examination results. For example, the presence of isolated postexercise premature complexes may define the examination as *abnormal* for some<sup>317</sup> or *suspicious* or *uncertain* for others. Similarly, if the LV shortening fraction does not increase, but the LV fractional shortening area does, then one must ensure that the issue is not simply technical (i.e., cursor placement) as opposed to pathologic. Finally, the assessment of cardiac valve function after exercise or pharmacologic stress requires far better definition before any conclusions can be made.

Although the standardized treadmill examination is the most commonly used cardiac “stress test” at equine centers, some attention has been directed on performing *pharmacologic stress testing*. This examination involves increasing the heart rate and myocardial contractile force with dobutamine, either with or without atropine or glycopyrrolate, followed by echocardiographic assessment of ventricular contraction.<sup>332,413,418,423,431</sup> Pharmacologic stress echocardiography is used to identify regions of reduced myocardial perfusion or ischemic myocardial injury in human patients with coronary heart disease; the study is used in people who cannot perform physical exercise to stress the heart and increase myocardial oxygen demand.

Whether this form of stress testing should be used in horses is subject to debate. First, it must be emphasized that no compelling evidence from pathology studies indicates that horses develop significant coronary arterial disease. Admittedly, myocardial fibrosis is found in some horses at necropsy<sup>29,432</sup>; however, the pathogenesis or clinical relevance of these often-microscopic lesions is unresolved. In human patients, the diagnostic target is well-defined extramural coronary artery disease, and stress echocardiography generally predicts normal or abnormal findings at coronary arteriography. No evidence has been published at this time for a similar situation in horses, and this represents a major contextual issue when considering “stress echo” with either exercise- or pharmacologic-induced cardiac work. Furthermore, pharmacologic stress testing may not achieve the identical exercise endpoints in terms of heart rate or altered vascular resistances. The combination of dobutamine and atropine involves the use of proarrhythmic drugs,<sup>413</sup> making the heart rhythm assessment (a pivotal

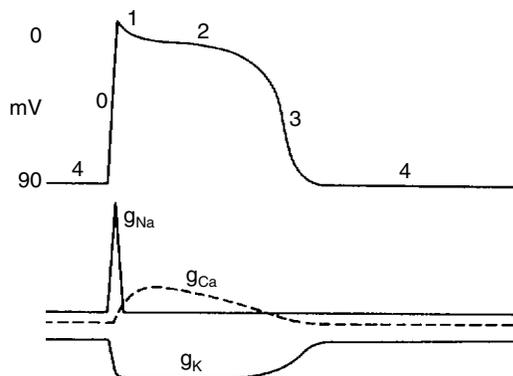

component of the exercise test) quite problematic. Pharmacologic stress testing does not provide an opportunity for dynamic assessment of the gait and airways.<sup>417</sup> Lastly, assessment of left heart valve function is complicated by changes in systemic ABP that may develop during drug-induced tachycardia (but have been poorly characterized in studies thus far.) Thus although pharmacologic stress testing carries the benefit of not requiring a treadmill, a number of outstanding issues must be addressed before this examination can be advocated for wider use.

## ELECTROCARDIOGRAPHY

### NORMAL CARDIAC CELL ELECTRICAL ACTIVITY

Cardiomyocytes are excitable and capable of responding to electrical stimuli regardless of extrinsic innervation. Specialized cardiac tissues such as those in the SA node and the His-Purkinje system demonstrate spontaneous depolarization and can serve as pacemakers for the heart. The electrical processes responsible for the ECG are caused by ion fluxes across the cell membrane (Figure 10-14).<sup>73,76,77</sup> A general understanding of cellular activity, generation, and spread of the cardiac electrical impulse; effects of autonomic innervation; and electrocardiographic lead systems is required to interpret the equine ECG.

The partially selective nature of the cardiac cell membrane and the presence of various cell membrane pumps leads to an unequal partitioning of ions across the cell membrane.<sup>73</sup> This results in very high potassium and relatively low sodium concentrations intracellularly when compared with the extracellular fluid. Other ions including chloride and magnesium (but most notably calcium) are important to cellular electrical activity. Calcium also is essential for contraction of the cardiomyocytes. Sudden changes in cardiac cell membrane permeability or conductance to sodium, calcium, potassium, and chloride are responsible for the processes of depolarization, muscular contraction, and repolarization (see Figure 10-14). Serum electrolyte concentration, acid-base status, autonomic traffic, myocardial perfusion and oxygenation, heart disease, and drugs, in turn, affect these processes. The basic processes of cell depolarization, calcium influx, and cell repolarization form the basis for, respectively, the P and QRS complexes of the ECG, myocardial contraction, and the ST-T wave of the ECG.

**FIGURE 10-14** The cardiac action potential. The diagram demonstrates the phases of depolarization and repolarization, as well as membrane conductance ( $g$ ) to important ions (see the text for details). (From Berne RM, Levy MN: Cardiovascular physiology, St Louis, 1986, CV Mosby.)

The resting membrane potential is determined primarily by the partitioning of potassium ions and proteins across the cell membrane and the relative impermeability of the membrane to sodium. *Depolarization* of atrial and ventricular myocytes and Purkinje fibers is caused by the rapid influx of extracellular sodium into the cell.<sup>76,77</sup> This current is represented by phase 0 of the cardiac cell action potential recording. Normal cardiac tissues depolarize in this manner conduct electrical impulses at high velocity. In contrast, the cells of the SA and AV nodes, as well as ischemic cells, demonstrate less negative diastolic membrane potentials. Nodal cells depend on a slow-inward current of depolarization that is carried mainly by calcium ions across the transient and long-lasting calcium channels. In ischemic cells, because of the less negative resting potential, some sodium channels remain in the inactivated state and thus are unavailable for activation and membrane depolarization during phase 0. Therefore cells in the SA node, AV node, and ischemic tissue conduct electrical impulses very slowly and can be involved in blocks, abnormal automatic mechanisms, or re-entrant pathways that promote cardiac arrhythmias. Anti-arrhythmic drugs and calcium channel blockers act differently on tissues that are “fast” versus “slow” current dependent (see Cardiac Arrhythmias later in this chapter).

The influx of extracellular calcium into the cell during the *plateau phase* (phase 2) of the action potential triggers the release of intracellular calcium from the sarcoplasmic reticulum. Increases in cytosolic calcium cause myocardial contraction. Hypoxia, acidosis, anesthetics, and many other drugs can affect myocardial contractility by interfering with calcium entry into cells, with the release of calcium from the sarcoplasmic reticulum, or with the binding of calcium to contractile filaments.<sup>73,76,104</sup> Conversely, digitalis glycosides and dobutamine increase calcium influx and myocardial contractility.

Cellular *repolarization* is initiated by decreases in the cell membrane conductance to sodium and to calcium coincident with increased conductance to potassium. As intracellular potassium moves out of the cell, along its concentration gradient, phase 3 of the cardiac action potential occurs. Repolarization is complex, involves a number of ion currents,<sup>433</sup> and is affected by genetics and by drugs such as quinidine or amiodarone. Sympathetic stimulation may activate currents that facilitate repolarization at higher heart rates, explaining the shortening of the action potential under sympathetic drive. Paradoxically, vagotonia also enhances repolarization by opening potassium channels, an effect that is very prominent in the atria and may predispose to development of AF. Hypoxia and abnormalities in serum potassium or calcium also alter repolarization. Hyperkalemia accelerates repolarization and shortens the ST-T wave of the ECG. This occurs because hyperkalemia *increases* membrane permeability to potassium and the high intracellular potassium (exceeding 100 mmol/L) is more than adequate to drive potassium out of the cell (because extracellular potassium rarely exceeds 10 mmol/L).

Spontaneous depolarization or automaticity is a property of select cardiac tissues. Such activity is most prominent in the SA node but may also be encountered in cells around the AV node and in the His-Purkinje network. Normal automaticity is observed in these cells during phase 4 of the cardiac action potential. Spontaneous *pacemaker activity* is generated in normal pacemaker tissues by the background inward sodium current and a time-related decrease in membrane permeability to potassium ion efflux, as well as a transient inward calcium current.<sup>76</sup> Once membrane threshold is reached, ion flow across the

**FIGURE 10-15** A normal equine base-apex lead electrocardiogram (ECG) (25 mm/sec; 1 cm = 1 mV). The waveforms are indicated. The normal P wave in this lead is positive and notched (bifid), and a depression occurs in the baseline after the P wave that indicates atrial repolarization (Ta wave). The QRS complex often lacks an R wave in this lead (QS complex). The T wave is labile and may be negative, biphasic, or positive. Increases in heart rate or sympathetic tone usually lead to positive T waves in this lead.

long-lasting calcium channels (“slow current”) predominates and leads to cell depolarization (phase 0). Spontaneous depolarization is modified markedly by autonomic traffic. Vagal activity opens potassium channels and hyperpolarizes the membrane, depressing automaticity. With sympathetic stimulation or membrane hyperpolarization, the depolarizing funny current ( $I_f$ ), becomes activated, enhancing pacemaker activity.

Autonomic innervation has profound effects on electrical activity<sup>9,189,434</sup> but is not distributed equally through the heart. The right and left vagus have preferential innervation to SA and AV nodes, and parasympathetic traffic is more extensive in supraventricular than ventricular myocardium. Sympathetic activity derived from paired ganglia is also not bilaterally symmetrical but does innervate both atria and ventricles extensively. Parasympathetic activity depresses SA nodal activity, enhances intra-atrial conduction by shortening atrial action potential duration, and slows AV nodal conduction. Conversely, sympathetic efferent traffic increases heart rate and shortens AV conduction time.<sup>76</sup> Sympathetic activity also increases cellular excitability, predisposes to some cardiac arrhythmias, and increases myocardial oxygen consumption by augmenting the heart rate, force of myocardial contraction, and myocardial wall tension. Parasympathetic efferent traffic dominates in the resting, standing horse and frequently fluctuates with changes in BP. The pronounced sinus arrhythmia, SA block, and second-degree AV block so often encountered in the normal horse is caused by changing vagal tone and serves to regulate ABP at rest (see Figure 10-6).<sup>71</sup>

Depression of normal SA automaticity or increased activity in other tissues in the atria, Purkinje system, or in cells around the AV node may lead to an abnormal or “ectopic” cardiac rhythm. This situation is often observed in healthy horses under general anesthesia. When the principal abnormality resides in depression of SA node function or blockage of the impulse in the AV node, the slow discharge of a subsidiary pacemaker is termed an *escape* mechanism. The purpose of these latent cardiac pacemakers is to rescue the heart from extreme bradycardia or asystole. However, drugs, inflammatory mediators, abnormal sympathetic activity, electrolyte disturbances, or ischemia also can enhance ectopic pacemakers abnormally, leading to *ectopic* rhythms that manifest as premature complexes or tachycardias. Additional abnormal electrophysiologic mechanisms, including abnormal automaticity in tissues other than nodal and conduction tissues (i.e., ischemic myocardium), after depolarizations, and re-entry account for the development of other arrhythmias.

## GENESIS OF THE ELECTROCARDIOGRAM

The SA node is located near the right auricle; therefore initial cardiac muscle depolarization crosses the RA (see Figure 10-3). Activation waves spread through the atrial myocardial cells to the LA and also in the direction of the AV node. Specialized atrial muscle cells comprising internodal pathways and Bachman’s bundle facilitate transmission of current across the atria.<sup>8,435</sup> These specialized pathways—as well as the SA node—are relatively resistant to high serum potassium concentrations and may function during hyperkalemia to cause a sinoventricular rhythm, even while normal atrial myocytes are inexcitable (atrial standstill).

Conduction continues across the AV tissues by first entering the AV node. Current transmission across the AV nodal cells is especially slow because this tissue depends on inward calcium currents and is subject to physiologic blockade from vagal efferent traffic.<sup>192</sup> Conduction proceeds at a greater velocity through the bundle of His and bundle branches. Propagation of the impulse through the ventricles is enhanced by a rapidly conducting Purkinje system that penetrates relatively completely through the ventricular myocardium.<sup>6,7</sup>

The ECG graphs the time-voltage activity of the heart. The average electrical potential generated by the heart muscle is recorded throughout the phases of the cardiac cycle with time displayed along the x-axis and electrical potential inscribed vertically (Figure 10-15). The normal waveforms are the P wave (atrial depolarization), the PR (or PQ) interval that is due mostly to slow AV nodal conduction, the QRS complex (ventricular depolarization), and the ST-T wave (ventricular repolarization). A prominent atrial repolarization wave (Ta wave) is often noted in the PR segment of the equine ECG, particularly at faster heart rates. The QT interval represents total electrical activation-repolarization time.

## CLINICAL ELECTROCARDIOGRAPHY

The clinical application of electrocardiography to the horse has been studied extensively.\* The principles of recording and interpreting the equine ECG are similar to those used for humans, dogs, and other species.<sup>111,445</sup> The lead systems used are identical, although some modified leads, such as the base to apex lead, are most useful for monitoring the cardiac rhythm. A number of semiorthogonal lead systems have been evaluated experimentally but are rarely used in clinical practice. The modified Einthoven’s lead system, consisting of leads frontal planes I, II, III,  $a_{VR}$ ,  $a_{VL}$ , and  $a_{VF}$ , and the precordial lead  $V_{10}$ , is quite applicable for ECG studies of horses (Box 10-7). The base-apex lead or chest leads are most often used for rhythm analysis.

The value of continuous, ambulatory (Holter) ECG monitoring is obvious for identification of infrequent rhythm disturbances, quantifying the severity of an arrhythmia, or objectively evaluating drug therapy (Figure 10-16). In one study it was observed that many horses that were historically and clinically without evidence of cardiac disease had supraventricular or (less often) ventricular arrhythmias on Holter ECG.<sup>359</sup> Ambulatory monitoring can be performed with contact electrodes using a bipolar lead system similar to that used for the equine heart rate monitors. Electrodes are

\*References 1, 4, 6-8, 11, 30, 33, 35, 40, 43, 72, 77, 111, 188, 194, 195, 336, 344, 360, 436-470.

## Base-apex monitor lead

Positive electrode over the left apex compared with  
the negative electrode over the right jugular furrow

## Precordial V leads

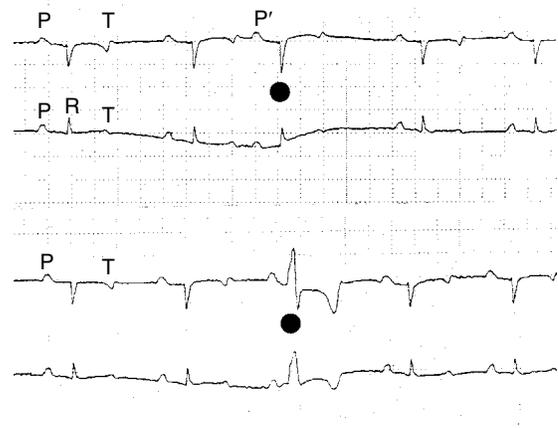

Positive electrode over the selected precordial site;  
–the lead is named based on the location of the  
exploring (V or C) electrodeLead V<sub>3</sub>: near the left apexLead V10: over the dorsal spinous processes (inter-  
scapular)

The most common method of obtaining the base-apex lead is to place the left foreleg electrode over the left apex, the right foreleg electrode over the jugular furrow (or at the top of the right scapular spine), and select lead I on the electrocardiograph. This lead is an excellent choice to monitor the cardiac rhythm. Precordial leads other than V10 (over the dorsal spine) are not commonly used.

usually placed over the left saddle area and sternum and are kept moist and in contact with the horse using a surcingle and padding material. This type of continuous 24-hour rhythm monitor can be quite useful to evaluate the horse with a history of syncope or an arrhythmia, but in which an arrhythmia cannot be induced during resting, exercise, and postexercise ECG examinations. An alternative is an ECG event recorder that continuously records the rhythm and stores the ECG after an observed event, such as a sudden fall. These event recorders can be worn for longer periods of time.

Telemetry-based ECG recordings are commonly used in exercise testing (see Exercise Testing) and in monitoring of critical patients in hospital settings.<sup>317,415</sup> The lead systems used are often similar to those used for Holter ECG recordings; however, the degree of artifact that occurs during exercise is considerable. Those interested in consistent recordings must experiment with various electrode positions and lead systems.

The orientation, amplitude, and duration of the ECG waveforms depend on many factors, including the age of the horse,<sup>348,464</sup> the lead examined, the size of the cardiac chambers, the degree of training, and even the phase of ventilation.<sup>439,440</sup> The principal use of the ECG is to diagnose the heart rhythm, because in horses this examination is insensitive for detecting cardiomegaly, especially in horses with mild to moderate heart enlargement. A normal ECG does not exclude heart disease;

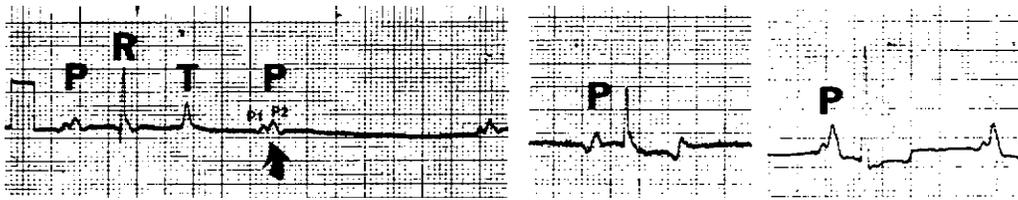

**FIGURE 10-16** Examples of extrasystoles. Atrial (P' at top) and ventricular (bottom) extrasystoles in a mare with heart failure, sinus tachycardia, and premature beats. The recordings are from a 24-hour tape-recorded (Holter) electrocardiogram (ECG). Two transthoracic leads recorded simultaneously. The waveforms are indicated. The dark circles indicate the premature complexes. The P-R interval of the APC is longer because of physiologic refractoriness in the atrioventricular node. The ventricular ectopic follows the sinus P wave (late diastolic) but discharges the ventricle before the sinus impulse can cause a normal QRS complex. The T wave of the ventricular extrasystole is abnormal (secondary T wave change). Paper speed is 25 mm/sec.

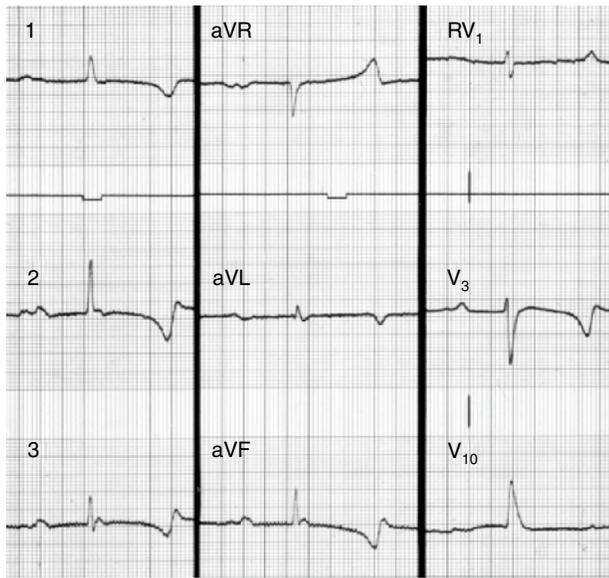

moreover, the ECG is not a test of myocardial function. A systematic approach to ECG analysis should be undertaken and compared with reference values (Table 10-4).

Atrial depolarization generates the P wave. Normal activation proceeds from right-to-left and cranial to caudal, leading to positive P waves in left-right lead I and also in craniocaudal leads II and aV<sub>F</sub>.<sup>8,11</sup> The normal P wave is notched or bifid; however, single peaked, diphasic, and polyphasic P waves may be encountered in normal horses. A negative/positive P wave is often recorded if the focus of pacemaker activity shifts to the caudal RA near the coronary sinus (Figure 10-17). The initial peak of the common bifid P wave is reportedly caused by depolarization of the middle and caudal one third of the RA.<sup>6</sup> The second peak represents activation of the atrial septum and the medial surface of the LA. The P wave peaks can be subdivided with P<sub>1</sub> reported to be as high as 0.25 mV (mean of 0.14) and the second peak, P<sub>2</sub>, reported to be as high as 0.5 mV (mean of 0.28).<sup>445</sup> Even subtle differences exist among breeds of horses. The P wave morphology can change cyclically with waxing and waning of vagal tone during sinus arrhythmia. During tachycardia, the P wave shortens, becomes more peaked, and is followed by a prominent atrial repolarization (T<sub>a</sub>) wave that deviates the P-Q segment downwards. Such features make the diagnosis of atrial enlargement by electrocardiography very difficult.

The time required for conduction across the AV node and His-Purkinje system is estimated by measuring the P-R interval. Because physiologic AV block is so common, significant variation exists in the P-R interval, even within the same horse; thus normal maximal values for the P-R interval are difficult to state. Values that persistently exceed 0.5 seconds are probably abnormal. Variation in the P-R interval is not usually related to changes in ventilation<sup>42</sup> but is often correlated with changes in BP and baroreceptor activation.<sup>71</sup>

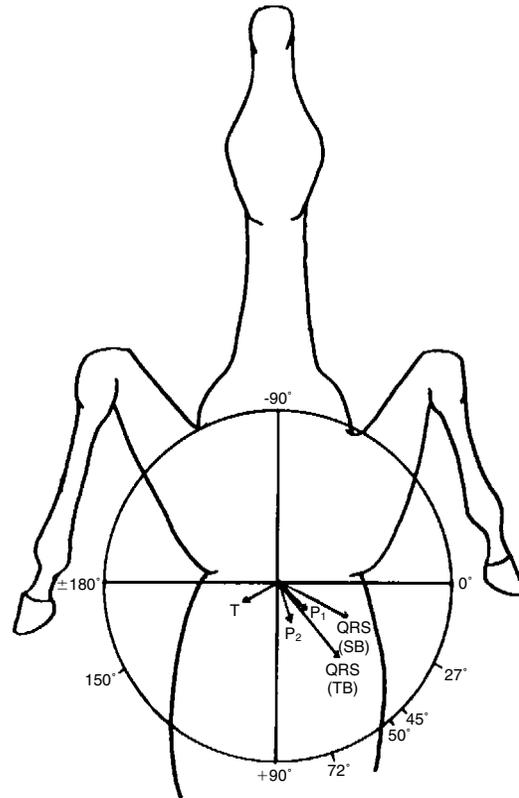

**FIGURE 10-17** P waves of the horse are demonstrated. On the left is a normal, bifid P wave morphology with two distinct peaks (designated as *P1* and *P2*) and also a physiologic second-degree atrioventricular block (*arrow*). The center panel demonstrates a negative/positive P wave of coronary sinus origin. This is a normal variation. The right panel shows increased amplitude P waves recorded in a horse after conversion from atrial fibrillation (AF). The second peak is particularly large and may indicate atrial enlargement; however, such voltage criteria correlate poorly with cardiomegaly in horses. Echocardiography is a more accurate method for evaluating atrial size. Lead 2 paper speed is 25 mm/sec.

**FIGURE 10-18** Multiple lead recordings in a normal horse. The varying configuration of the P-QRS-T complexes across the leads is notable.

The morphology of the QRS complex is variable. The relatively complete penetration of the conduction system into the free walls of the ventricle causes these chambers to be activated simultaneously with a burst of depolarization, which cancels much of the divergent electromotive forces.<sup>6,7</sup> Consequently, the normal electrical axis may vary and the amplitude of the QRS complex can be quite small in the frontal plane leads. A substantial dorsally oriented vector causes a prominent positive terminal deflection in lead *V10*, while the (– electrode) right base to (+ electrode) left apex lead exhibits a prominent S wave (see [Figures 10-15](#) and [10-18](#)). The normal slur in the ST segment makes determination of QRS duration difficult in many horses.<sup>35,471</sup> The mean amplitude for the R wave in lead II for normal racehorses is about 0.8 to 1.1 mV.\* Clinical experience suggests that R wave amplitudes exceeding 2.2 mV in lead II or 1.7 mV in lead I are often abnormal. However, occasionally the R wave amplitude in a normal horse exceeds even these limits.

\*References 1, 4, 111, 360, 445, 446, 467.

**FIGURE 10-19** Diagram of the normal frontal plane lead axis. The predominant vectors for the QRS complex in Standardbred (SB) and Thoroughbred (TB) horses are indicated. The orientation of the two components of the normal P wave (*P1* and *P2*; see [Figure 10-17](#)) differ slightly. (From Fregin GF: The cardiovascular system. In Mansmann RA, McAllister ES, Pratt PW, editors: Equine medicine and surgery, Santa Barbara, CA, 1982, American Veterinary Publications.)

The frontal plane leads can be inspected to estimate the mean electrical axis of depolarization, the “average” wave of depolarization ([Figure 10-19](#)). This determination is usually reported by direction, using a quadrant orientation (i.e., right or left, craniad or caudad), or is stated in degrees (e.g., lead I is 0 degrees, lead II is 60 degrees, lead aVF is 90 degrees, lead III is 120 degrees, lead aVR is minus 150 degrees, and lead aVL is minus 30 degrees). The general direction of the QRS axis can be quickly estimated by surveying the height

TABLE 10-4

**Electrocardiography: Approximate Limits for Normal Frontal Plane Leads**

Variable	Maximal Value	Comments
Heart rate	44-50 beats/min	Resting mature horses; higher in foals, colts, and ponies
Cardiac rhythm	—	Sinus mechanisms, sinus arrhythmia, vagal-induced first- and second-degree atrioventricular block*
P wave	0.16 seconds	Atrial repolarization (Ta wave) possibly making measurement difficult
P-R interval	0.48 seconds	Varies; longer when vagal tone is high
QRS complex	0.14 seconds	May vary with the size of the heart (often longer in the base-apex lead)
QT interval	0.575 seconds	Inversely related to the heart rate
R wave lead I	0.85 mV	
R wave leads II, aV <sub>F</sub>	2.3 mV	
Frontal axis	0-100 degrees	Axis variable in foals and yearlings

\*When evaluating the electrocardiographic rhythm, one should consider the following points:

Technical aspects: paper speed, calibration, and lead(s)

Artifacts: electric, motion, twitching, and muscle tremor

Heart rate per minute: atrial and ventricular

Cardiac rhythm: atrial, atrioventricular conduction sequence, and ventricular conduction

Arrhythmias

Site or chamber of abnormal impulse formation, myocardial fibrillation, or conduction disturbance

Rate of abnormal impulse formation

Conduction of abnormal impulses

Patterns or repeating cycles

P wave: morphology, duration, amplitude, and variation

P-R interval: duration, variation, and conduction block (of P wave)

QRS: morphology, duration, and amplitude

Frontal plane mean electric axis

ST segment: depression or elevation

T wave: changes in morphology or size; QT interval

Miscellaneous: electrical alternans, synchronous diaphragmatic contraction

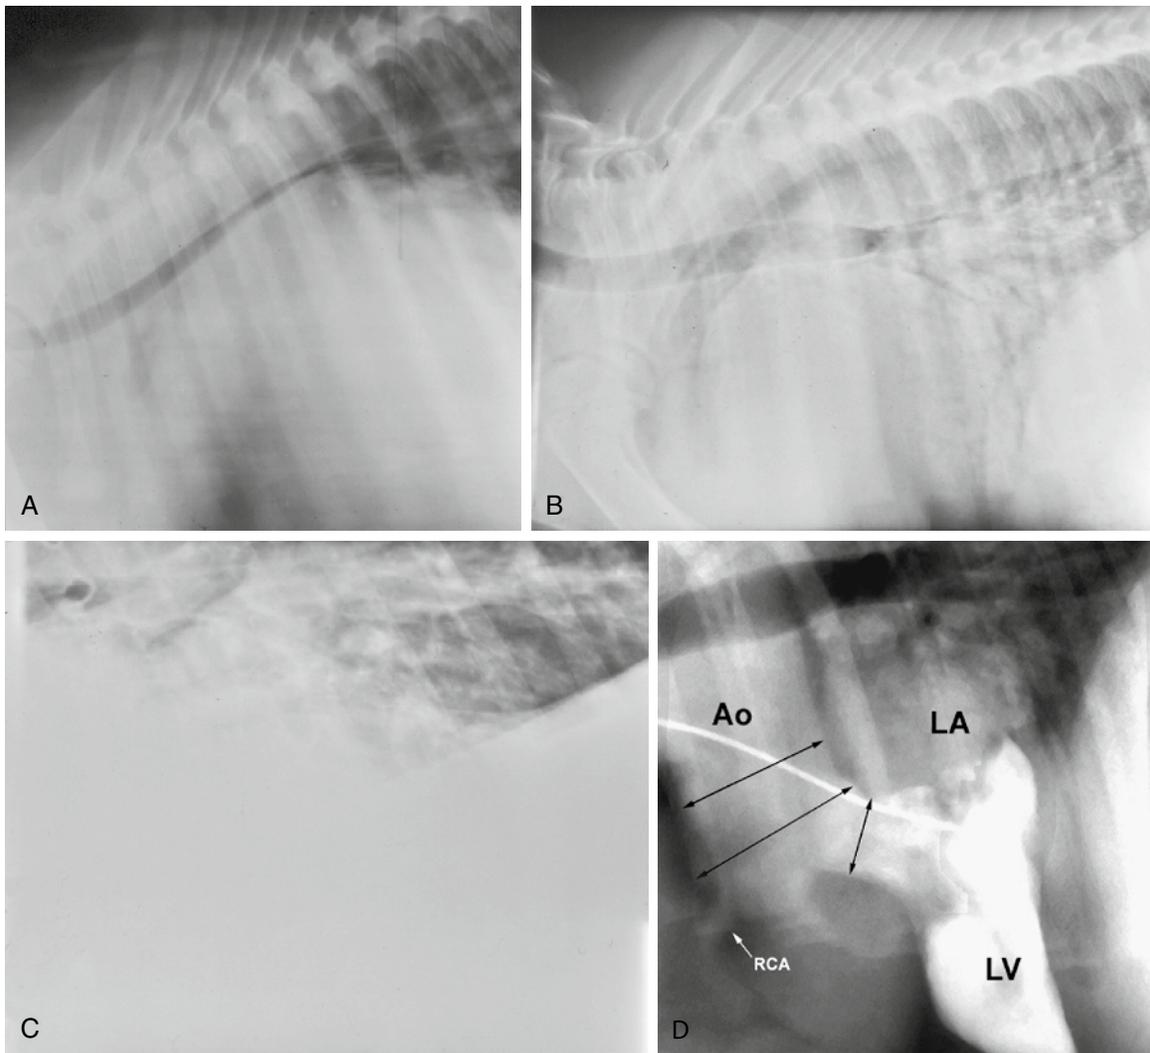

of the R waves in the frontal leads and selecting the lead with the greatest net-positive QRS complex. The axis in foals and yearlings is variable and frequently oriented cranial, whereas the frontal axis in most mature horses is directed left-caudad. Abnormal axis deviations have been observed with cardiomegaly, cor pulmonale, conduction disturbances, and electrolyte imbalance.<sup>467</sup>

After ventricular activation, repolarization of the ventricles is recorded. This period is measured from the end of the QRS complex (the "J point") and extends to the end of the T wave.<sup>35,451,472</sup> The T wave vector is most often directed toward the right caudal quadrant, resulting in a positive T wave in lead III and a negative or isoelectric T wave in lead I in resting horses.<sup>445</sup> Although some clinical surveys have suggested that abnormalities of the ST-T indicate cardiac dysfunction in performance animals, marked deviation of the ST segment and increased amplitude of the T wave are anticipated in healthy horses during exercise or even with excitement-induced tachycardia. No compelling evidence indicates that T wave abnormalities can be interpreted consistently. Progressive J point or ST segment deviation in the horse with hypovolemia or shock may indicate myocardial ischemia, whereas enlargement of the T wave may develop with myocardial hypoxia or hyperkalemia. Diagnosis and management of cardiac arrhythmias are discussed later in this chapter.

## THORACIC RADIOGRAPHY

There are significant limitations to the use of thoracic radiography for evaluation of the equine heart related to the large size of the mature horse and the ability to obtain only a standing lateral thoracic radiograph in all except the smallest foals.<sup>113</sup> While recumbent lateral and, on occasion, ventrodorsal or dorsoventral projections can be obtained on neonatal foals, the stress of restraint or requirement for heavy sedation can make such positioning contraindicated. Thoracic radiographs may be useful to identify areas of pulmonary or pleural disease and assist in the differential diagnosis of respiratory problems.

Gross changes in cardiac size and shape may be detected in a lateral thoracic radiograph of a foal or horse with significant cardiomegaly.<sup>113,342,473-475</sup> A normal thoracic radiograph does not necessarily indicate that the heart is normal in size. Mild to moderate increases in the size of the cardiac chambers may go undetected, particularly in adult horses. Generalized enlargement of the cardiac silhouette is observed in cases of significant pericardial effusion or with CHF (Figure 10-20). Dorsal displacement of the trachea may be detected in some horses with LA and LV enlargement. In some horses with LA enlargement, the caudodorsal border of the cardiac silhouette bulges caudally. Increased contact between the ventral border

**FIGURE 10-20** Thoracic radiography. **A**, Significant cardiomegaly in a Quarter Horse foal with complex congenital heart disease, including multiple ventricular septal defects (VSDs). **B**, Cardiomegaly and alveolar pulmonary edema in a filly with mitral regurgitation (MR) and left-sided congestive heart failure (CHF). **C**, Increased pulmonary density and pleural effusion in a Standardbred gelding with atrial fibrillation (AF), atrioventricular valvular regurgitation, myocardial failure, and biventricular CHF. **D**, Angiogram obtained from an Arabian foal with pulmonary atresia and a large VSD (pseudo-truncus arteriosus). Contrast medium was injected in the left ventricle (LV), and this medium opacifies a dilated, overriding aorta. Right-to-left shunting across the VSD results in dilution of contrast medium. The right arrow shows the subaortic LV outflow tract; the widened aorta is delineated by the arrows at the left. Ao, Aorta; LA, left atrium; LV, left ventricle; RCA, right coronary artery.

of the heart and the sternum may be detected with RV enlargement but is usually difficult to appreciate. A 50% decrease in the spinotracheal angle (the angle between the dorsal border of the trachea and the ventral border of the adjacent thoracic vertebrae) was demonstrated in young horses with cardiomegaly because of congenital cardiac disease.<sup>113</sup>

Evaluation of the pulmonary vasculature and pulmonary parenchyma is also difficult and very dependent on radiographic technique. Enlarged pulmonary vessels associated with pulmonary overcirculation can occasionally be observed in left-to-right shunts; the opposite is also true in congenital right-to-left shunts. Pulmonary edema causes generalized increased radiopacity, particularly in the hilar regions; the characteristic air bronchograms are more readily identified there when alveolar edema is present.

Angiography is only practical in foals less than about 115 kg and usually requires general anesthesia, which may be contraindicated in the foal with a severely compromised CV system. Both selective and nonselective positive contrast angiograms have been performed in foals and adult horses (see Figure 10-20, D),<sup>156,473,476</sup> but these techniques have been almost exclusively replaced by echocardiography and Doppler studies.

Nuclear medicine imaging has been developed in some equine referral institutions and has been used to assess cardiac function. First-pass nuclear angiography permits the visualization of the cardiac chambers during sequential phases of the cardiac cycle.<sup>113</sup> Application of first-pass studies may be useful for identification of cardiac shunting, but again, this diagnosis is more simply attained by echocardiography.

## ECHOCARDIOGRAPHY

Ultrasound is the mechanical vibration of sound waves within a medium at frequencies greater than 20,000 c/s. These inaudible sound waves follow the laws of optics, can be transmitted through tissue, and can also be refracted and reflected. This last property permits the clinician to image the heart and other organs.<sup>477</sup> Echocardiography is the application of ultrasound diagnostics to the heart. When combined with Doppler studies,<sup>478</sup> transthoracic echocardiography has evolved to become the most important diagnostic study currently available for evaluation of the equine heart.\* Transesophageal echocardiography (TEE) has been used in horses,<sup>234,235,285</sup> but (except in foals) it requires specially made endoscope-mounted transducers and is only practical in anesthetized or heavily sedated horses because of the fragile (and expensive) nature of the TEE probe.

Successful examination of the equine heart requires the use of crystals that vibrate at frequencies between 1.5 to 5.0 MHz, a detailed knowledge of ultrasound anatomy, thorough appreciation of equine cardiac diseases, and technical skills with imaging and instrumentation. Ultimately, a thorough echocardiographic examination yields information about the presence and nature of heart lesions, the size of the heart and great vessels, ventricular function, valvular function, blood flow, and the relevant hemodynamics of a cardiac lesion. Examination findings are relatively consistent when performed by experienced examiners, but day-to-day, subject, and examiner variation can be significant (>10%) for some variables and must be considered when performing serial examinations.<sup>303,307,308,518</sup>

The essential principle of echocardiography is straightforward: when ultrasound is directed into the chest and toward the heart, some of the sound energy reflects back to the transducer. This occurs because tissue interfaces with different acoustic impedance, such as muscle, collagen and blood, are encountered by the echobeam and ultrasound is reflected from these tissue interfaces. A hand-held transducer acts to both send and receive ultrasound.<sup>486,520</sup> The echocardiograph computer is capable of determining the spatial orientation and distance of the returning echoes, processing the signals, and displaying an image of the heart. The image is usually displayed, by convention, with that part of the heart closest to the transducer at the top of the display and adjacent to the transducer artifact. Two imaging modalities, the M-mode and 2D (B-mode or cross-sectional) formats, are in widespread use in equine practices. When Doppler studies or contrast echocardiography is added, blood flow can be detected relative to the 2D and M-mode images (Box 10-8; Figures 10-5 and 10-21 to 10-24).<sup>149,303</sup> M-mode, 2D, and Doppler studies can be used to quantify heart size and mass,<sup>49,50,481</sup> as well as estimate ventricular function. The influence of training on cardiac size can be assessed.<sup>102,515,516</sup> The technique also can be applied to assess the fetal heart.<sup>521</sup>

The M-mode echocardiogram is a single-crystal ice pick image of the heart (see Figures 10-5 and 10-22).<sup>13,14,53,522</sup> The movement of the cardiac structures (vertical axis) is displayed

over time along the horizontal axis. The ECG can be recorded to provide a timing reference if desired, and the depth of the cardiac structures from the transducer (y-axis) is displayed in centimeters. Visualization of the characteristic movements of cardiac structures permits the experienced viewer to evaluate and quantify cardiac anatomy and function (see Figure 10-21). The high sampling rate of the M-mode study makes it excellent for visualizing rapidly vibrating structures, such as the oscillating mitral leaflet in AR.<sup>138</sup>

The 2D echocardiogram generates a cardiac field by mechanically or electrically sweeping one or more piezoelectric crystals across the heart.\* In conventional transthoracic echocardiography, the operator hand-directs the imaging probe to achieve a suitable tomographic plane. The pie-shaped image obtained has both depth and breadth but has no significant thickness. Accordingly, different image planes must be used to interrogate the three-dimensional (3D) heart. These imaging planes are designated *long-axis* (sagittal), *short axis* (coronal), *apical* (when the transducer is near the left apex), and *angled* (hybrid) views. Apical images are difficult to obtain except in foals.

The 2D field is constantly updated to visualize cardiac motion in real time, and this is done at typical sampling rates of 20 to 40 frames/sec, with the update rate inversely related to penetration depth and angle of field. Fully digital echocardiographs can display much faster frame rates, often exceeding 60 frames/sec. In most cases the 2D study is watched in “real time” and also recorded digitally or on videotape for subsequent playback and analysis. Human interpretation is generally limited to 32 frames/sec so that recordings made at higher frame rates require slow-motion playback for detailed analysis. 2D echocardiography allows assessment of cardiac anatomy, detection of macroscopic structural lesions, subjective evaluation and measurement of chamber and vessel dimensions, and evaluation of LA and LV function.

Doppler echocardiography relies on the Doppler principle to measure the direction and velocity of red blood cells (RBCs) in the heart (see Figures 10-24 and 10-5).\* In Doppler echocardiography, a portion of the ultrasound emitted by the transducer strikes moving RBCs. These targets cause ultrasound to be reflected back to the transducer. Because the RBCs constitute a moving “source” of (reflected) ultrasound, the returning sound waves attain a frequency that is slightly different from that originally transmitted (the “carrier frequency”). When the echocardiograph unit records the Doppler frequency shift, calculation of RBC velocity and direction relative to the transducer is possible. The information is displayed as a Doppler spectrum showing time along the horizontal axis, flow direction relative to the transducer as above (toward) or below (away from) a zero baseline, and calculated RBC velocity along the y-axis. Thus pulsed Doppler methods measure direction and velocity of RBCs within a discrete area of the heart or circulation. Disturbed flow, as might be recorded across a regurgitant orifice or VSD, results in a high-velocity and broadened-velocity spectrum.

Color-coded Doppler imaging is a more refined example of pulsed-wave technology, whereby flow toward the transducer is coded in red and flow away is represented in blue. Calculated velocity is displayed in relative shades of these colors,

## BOX 10-8

## INTERPRETATION OF ECHOCARDIOGRAPHIC AND DOPPLER STUDIES

**General Principles of Interpretation**

- Evaluate the electrocardiogram relative to cardiac motion and cardiac rhythm disturbances; arrhythmias can alter measures of ventricular function, cause aortic valvular regurgitation, and alter flow and pressure gradients.
- Remember that persistent tachyarrhythmias can lead to reversible form of dilated cardiomyopathy (tachycardia-induced cardiomyopathy).
- Determine the initial image planes needed for examination based on clinical examination and your standard operating procedures.
- Identify the general situs of the heart and cardiac structures; identify the atria, ventricles, cardiac septa, great vessels, and cardiac valves.
- Note any dilation, attenuation, or absence of the aorta or pulmonary artery and identify their origins and relationships to the atrioventricular valves and to the ventricles.
- Note the presence of unanticipated or lack of expected structures.
- Identify pleural effusion.
- Rule out extrapericardial mass lesions of the lung or thorax.

**Pericardium and Pericardial Space**

- Rule out pericardial effusion and pericardial mass lesion.
- Mixed echoic effusions or shaggy tags may indicate highly cellular or inflammatory effusate.
- In pericardial effusion: Identify diastolic collapse of the right atrium or right ventricle indicating cardiac tamponade or a large bilateral pleural effusion; protracted collapse or ventricular or atrial inversion are more reliable signs of tamponade. Exuberant swinging of heart may be seen.
- In pericardial effusion: Identify any heart-related lesions using multiple complementary planes.
- If there is concern about constrictive pericardial disease, evaluate the motion of the ventricular septum (for accentuated flutter or “septal bounce”) and perform Doppler studies of the left and right ventricular inlets; large E-waves with abrupt termination of filling may be observed; evaluate the effects of ventilation because marked variation may be observed in E-waves; tissue Doppler may also be instructive in cases of constrictive disease.

**Left Atrium, Pulmonary Veins, and Atrial Septum**

- Identify pulmonary veins and pulmonary venous entry.
- Examine for attenuation or small size: Rule out volume depletion, right-to-left shunt, or low cardiac output.
- Examine for enlargement or rounding/turgid appearance: rule out left-to-right shunt, mitral valve disease, left ventricular systolic or diastolic failure, chronic arrhythmia (e.g., atrial fibrillation).
- Measure left atrial diameter and/or left atrial area by 2D imaging.
- Examine the atrial septum for abnormal bowing to the left or right atrium (high atrial pressure).

- Examine the atrial septum for septal defects or patent foramen ovale (perform Doppler and “bubble” contrast studies if necessary).
- Examine the blood pool for spontaneous contrast.
- Examine the atrioventricular groove for dilated vascular structure: Rule out dilated coronary sinus and left cranial vena cava.
- 2D Echocardiography and tissue Doppler can be used to evaluate atrial wall motion and function.

**Mitral Valve**

- Identify two valve leaflets and cusps in long and short axis planes; if evidence of mitral regurgitation, also examine mitral valve from left caudal imaging windows in two or more imaging planes.
- Observe motion during cardiac cycle by 2D and M-mode echocardiogram.
- Examine the support apparatus (chordae tendineae, papillary muscles).
- Increased valve echogenicity: Rule out degenerative thickening, valvulitis, vegetation (infective endocarditis), malformation (rare).
- Cleft or common septal leaflet: Rule out endocardial cushion defect/primum atrial septal defect (rare defects).
- M-mode: Reduced diastolic (E-F) slope: decreased transvalvular flow.
- Lack of diastolic separation or increased mitral E point to septal distance: Rule out aortic regurgitation (regurgitant jet impinging on the valve); left ventricular dilation with left ventricular failure (reduced transmitral flow), or mitral stenosis/tethering (rare defects or acquired from endocarditis).
- Prolapse of mitral leaflet into left atrium: Rule out degenerative disease, elongated or ruptured chordae tendineae, lesion of papillary muscle.
- Flail leaflet: Rule out ruptured chordae tendineae or avulsion of papillary muscle.
- Double line of mitral closure (mobile): Rule out ruptured chordae tendineae (flail leaflet).
- Diastolic mitral valve fluttering: Rule out aortic regurgitation.
- Systolic mitral fluttering: Rule out mitral regurgitation (musical).
- Chaotic valve motion: Rule out arrhythmia (atrial flutter, premature ventricular complexes); ruptured chordae tendineae.
- Premature (diastolic) closure: Rule out severe semilunar valve insufficiency, long P-R interval, or atrioventricular block.
- Delayed (systolic) closure (B-shoulder): rule out left ventricular failure and elevated atrial pressure.
- Systolic anterior motion of the mitral valve (systolic anterior motion, systolic mitral-septal contact): rule out dynamic left ventricular outflow tract obstruction due to valve malformation, subaortic stenosis, volume depletion, pulmonic stenosis, or hypertrophic or infiltrative cardiomyopathy (all very rare).

## BOX 10-8

## INTERPRETATION OF ECHOCARDIOGRAPHIC AND DOPPLER STUDIES—cont'd

- Doppler studies can be used to interrogate the mitral valve for regurgitation or abnormal flow; multiple planes should be obtained including short-axis images at the level of the left atrium immediately dorsal to the mitral valve.
- Mitral regurgitation is common. Eccentric jets are often observed. Do not confuse “backflow” color noise with true regurgitation. Horses can develop mid-to-late systolic mitral regurgitation (as with mitral prolapse). Multiple jets of mitral regurgitation are common.
- Always time flow events of mitral regurgitation (color M-mode and spectral Doppler); do not misdiagnose diastolic mitral regurgitation. Do not overemphasize receiving chamber color coding in mitral regurgitation because red blood cell entrainment and a “spray effect” can result in overestimation of mitral regurgitation severity, whereas wall-hugging jets underestimate severity of mitral regurgitation. Attempt to measure jet width at origin and correlate to left atrial and left ventricular chamber size.

**Left Ventricle**

- Evaluate from long and short axis tomograms; inspect contour and walls; dorsal septum is normally slightly thicker than left ventricle free wall.
- Echogenic smoke/contrast: Some spontaneous contrast may be normal; rule out low output states, bradycardia, systemic inflammation (?).
- Evaluate left ventricle dimensions (internal dimensions, thickness of interventricular septum and free wall) and left ventricle systolic function (fractional shortening, ejection fraction) using M-mode or 2D imaging.
- Left ventricle dilation: Rule out causes of volume overload or left ventricle failure: mitral or aortic valvular regurgitation, dilated cardiomyopathy, myocarditis, left-to-right shunt, persistent tachyarrhythmia.
- Left ventricle wall thinning: Rule out infarct, prior myocarditis, congenital aneurysm (rare).
- Left ventricle wall thickening: Consider “athletic heart”; rule out pseudohypertrophy from volume depletion, infiltrative cardiomyopathy (amyloid), myocarditis, chronic systemic hypertension, or left ventricle outflow obstruction (very rare).
- Hyperkinesis of left ventricle: Rule out mitral or aortic insufficiency, bradycardia, sympathetic stimulation.
- Hypokinesis or dyskinesis of the left ventricle: Rule out cardiomyopathy or other myocardial disease, ischemia, infarct, arrhythmia, regional wall infiltration, or myocarditis.
- Hyperechoic myocardium or subendocardium: Rule out recurrent ischemia, fibrosis, infiltration, infarction, myocarditis, amyloidosis.
- Tissue Doppler and 2D strain (2D speckle imaging) may be used to evaluate global and regional left ventricle function; transmitral flow can be obtained but is limited with respect to evaluation of left ventricle diastolic function

**Left Ventricular Outlet, Aortic Valve, and Aorta**

- Identify aortic valve leaflets and motion during cardiac cycle: Identify abnormal leaflet morphology (e.g., thickenings, fenestrations) or motion. Examine in both long-axis and short-axis image planes to see all leaflets.
- Thickened leaflets: diffuse or nodular: Rule out degeneration, endocarditis.
- Prolapse of aortic valve into the left ventricle: Rule out degenerative semilunar valve disease (common), ventricular septal defect, or bacterial endocarditis with torn leaflet.
- Diastolic fluttering of the aortic valve: Rule out aortic insufficiency.
- Systolic fluttering or the aortic valve: normal or high flow state.
- Lack of systolic separation: Rule out low cardiac output, arrhythmia, stenosis (rare).
- Decreased aortic diameter: low cardiac output, hypotension.
- Aortic dilation: Rules out aortic regurgitation, tetralogy of Fallot, pulmonary artery atresia, truncus arteriosus, patent ductus arteriosus (rare).
- Aortic sinus of Valsalva aneurysm: focal dilation or ballooning of affected sinus: Evaluate for rupture into ventricular septum or right atrium.
- Doppler studies may be used to identify blood flow patterns in the left ventricle outflow tract, aortic regurgitation, paramembranous ventricular septal defect, and rare case of aortic stenosis. Doppler studies also can identify abnormal blood flow paths in rare cases of aortic sinus ruptured into the heart.

**Ventricular Septum**

- Septal hyperkinesis: as per the left ventricle.
- Septal hypokinesis: as per left ventricle; also rule out right ventricular pressure or volume overload.
- Paradoxical ventricular septal motion: rule out moderate to severe right ventricular volume overload such as atrial septal defect, severe tricuspid regurgitation, severe pulmonary hypertension with tricuspid regurgitation.
- Flat ventricular septum: rule out right ventricular volume overload (diastolic flattening) or right ventricular pressure overload (systolic flattening).
- Exaggerated and disparate ventricular filling rates with diastolic septal fluttering: Rule out constrictive pericardial disease.
- Examine for ventricular septal defects in both long-axis and short-axis image planes (perform Doppler studies if necessary).
- Echocardiogram drop-out or discontinuity of the ventricular septum: Rule out ventricular septal defect (peri/paramembranous adjacent to right/noncoronary cusps of the aortic valve and septal leaflet of tricuspid valve; inlet septal ventricular septal defect (ventral to tricuspid valve); muscular or trabecular ventricular

## BOX 10-8

## INTERPRETATION OF ECHOCARDIOGRAPHIC AND DOPPLER STUDIES—cont'd

septal defect; subpulmonic ventricular septal defect (also termed outlet, suprasternal, subarterial, or doubly committed ventricular septal defect; directly underneath pulmonic and aortic valves); tetralogy of Fallot; pulmonary artery atresia; truncus arteriosus, or a false defect caused by angle of the ascending aorta or aortic dilation.

- Malalignment of the ventricular septum and anterior aortic root: examine for tetralogy of Fallot, malalignment type ventricular septal defect.
- Examine for dissection or “track” that may suggest rupture of the aorta into the ventricular septum with subsequent fistula.
- High-frequency fluttering of the ventricular septum: Rule out aortic regurgitation.
- Doppler studies, especially color Doppler, are useful for recognizing ventricular septal defects; continuous wave Doppler should be used to measure velocity across shunts to evaluate for “restrictive” versus unrestrictive septal defects. High velocity flow across a ventricular septal defect (>4.75 m/s) generally suggests a restrictive defect more likely to be well tolerated.

**Right Atrium and Atrial Septum**

- Examine for attenuation: If small, rule out volume depletion, external compression, or mass lesion impairing venous return.
- Examine for enlargement: If enlarged, rule out tricuspid regurgitation, tricuspid stenosis or atresia (rare), right heart failure, atrial septal defect, moderate to severe anemia or chronic arrhythmia.
- Examine the atrial septum for abnormal bowing into the left or right atrium (high atrial pressure).
- Examine the atrial septum for septal defects or patent foramen ovale (double mobile lines in foals).
- Doppler studies can be used to identify atrial septal defect, but streaming of normal flow patterns (i.e., caudal vena cava flow) is confusing.
- “Bubble studies” (by injecting agitated normal saline into the jugular vein) should be used to identify right-to-left shunting of blood. Caution: Similar to Doppler studies, streaming of normal blood from the caudal vena cava may produce negative contrast in the right atrium, falsely suggesting left-to-right shunting of blood.

**Tricuspid Valve**

- Identify valve leaflets and cusps in long- and short-axis image planes.
- Observe motion during cardiac cycle.
- Identify support apparatus (chordae tendineae, papillary muscles).
- Increased valve echogenicity: Rule out degenerative thickening, vegetation, malformation, thrombus on valve.
- Common septal leaflet: Rule out endocardial cushion defect/primum atrial septal defect (rare).

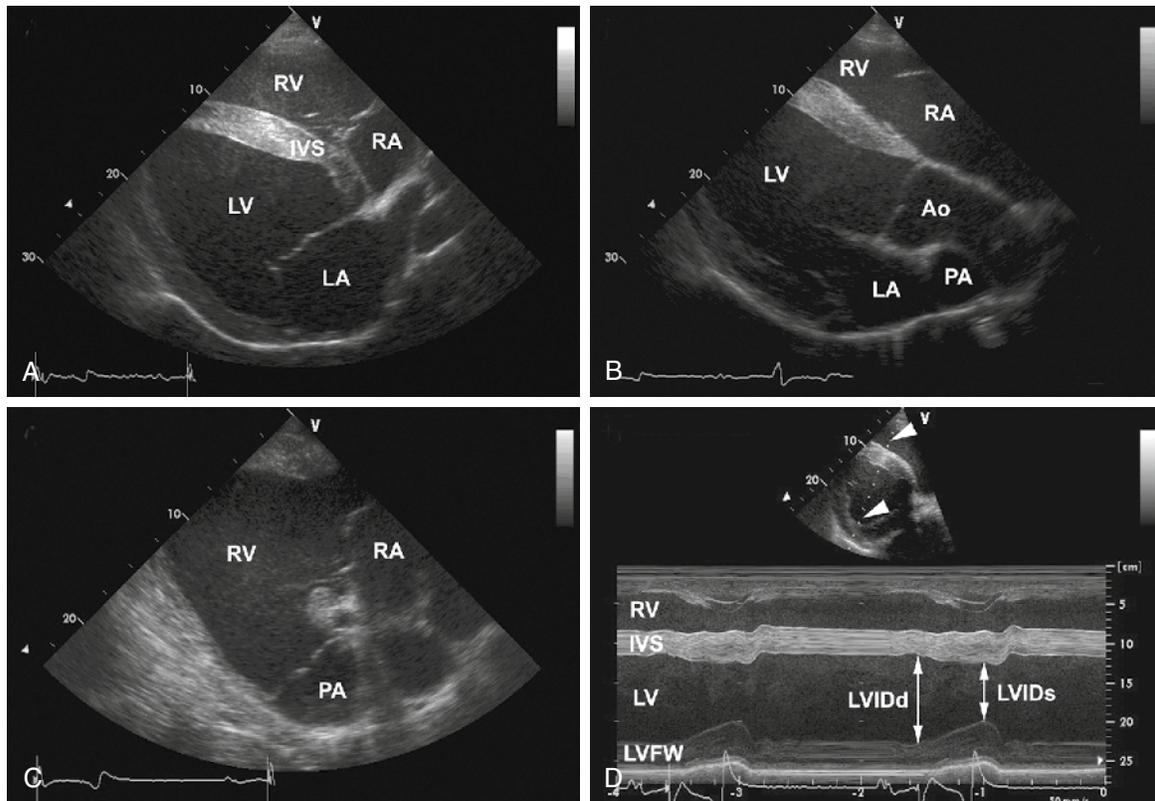

- Flail leaflet: Rule out ruptured chordae tendineae or avulsion of papillary muscle; rule out infective endocarditis.
- Chaotic valve motion: Rule out arrhythmia, ruptured chordae tendineae.
- Premature (diastolic) closure: Rule out severe pulmonic insufficiency, long P-R interval, or atrioventricular block.
- Doppler studies can interrogate the tricuspid valve for abnormal flow or regurgitation; most horses have some small jets of tricuspid regurgitation by color Doppler evaluation; use color M-mode and spectral Doppler to evaluate timing and peak velocity. High velocity tricuspid regurgitation (>3 m/s): Also rule out pulmonary hypertension, large ventricular septal defect, right ventricular outflow obstruction.

**Right Ventricle**

- Dilation: Rule out severe tricuspid insufficiency, chronic right ventricular pressure overload, biventricular congestive heart failure, atrial septal defect, large ventricular septal defect, severe pulmonary insufficiency, persistent tachyarrhythmia.
- Hypertrophy: Rule out large (unrestrictive) ventricular septal defect, pulmonary hypertension, pulmonic stenosis (rare), tetralogy of Fallot (rare), or complex congenital heart disease.
- Midventricular bands: Rule out double chambered right ventricle (examine for ventricular septal defect); remember that the right ventricular moderator band can be very prominent in horses.
- Hyperechoic tissue: Rule out myocardial fibrosis.

**Right Ventricular Outlet, Pulmonary Valve, and Pulmonary Artery**

- Identify valve leaflets and motion during cardiac cycle; if pulmonary valve lesion is suspected, also interrogate from a left cranial transducer position.
- Thick, fused, or hypoplastic leaflets: Rule out congenital stenosis or dysplasia (rare).
- Diastolic fluttering of pulmonic valve: Rule out valvular insufficiency.
- Systolic fluttering of pulmonic valve: normal or high flow state.
- Lack of systolic separation of the pulmonic valve: Rule out low cardiac output, arrhythmia, stenosis.
- Pulmonary artery, absence or attenuation: Rule out pulmonary atresia or pulmonary artery hypoplasia.
- Pulmonary artery, dilation of: Rule out pulmonary hypertension, left-to-right shunt, poststenotic dilation of pulmonic stenosis (rare); rupture of the aorta into the right heart or pulmonary artery (rare).
- Doppler studies can be used to identify abnormal flow in the pulmonary artery, including the rare pulmonic stenosis (high velocity), increased velocity flow from a left-to-right shunt, and patent ductus arteriosus in equine neonates. Pulmonary regurgitation is normal; high velocity pulmonary regurgitation indicates pulmonary hypertension.

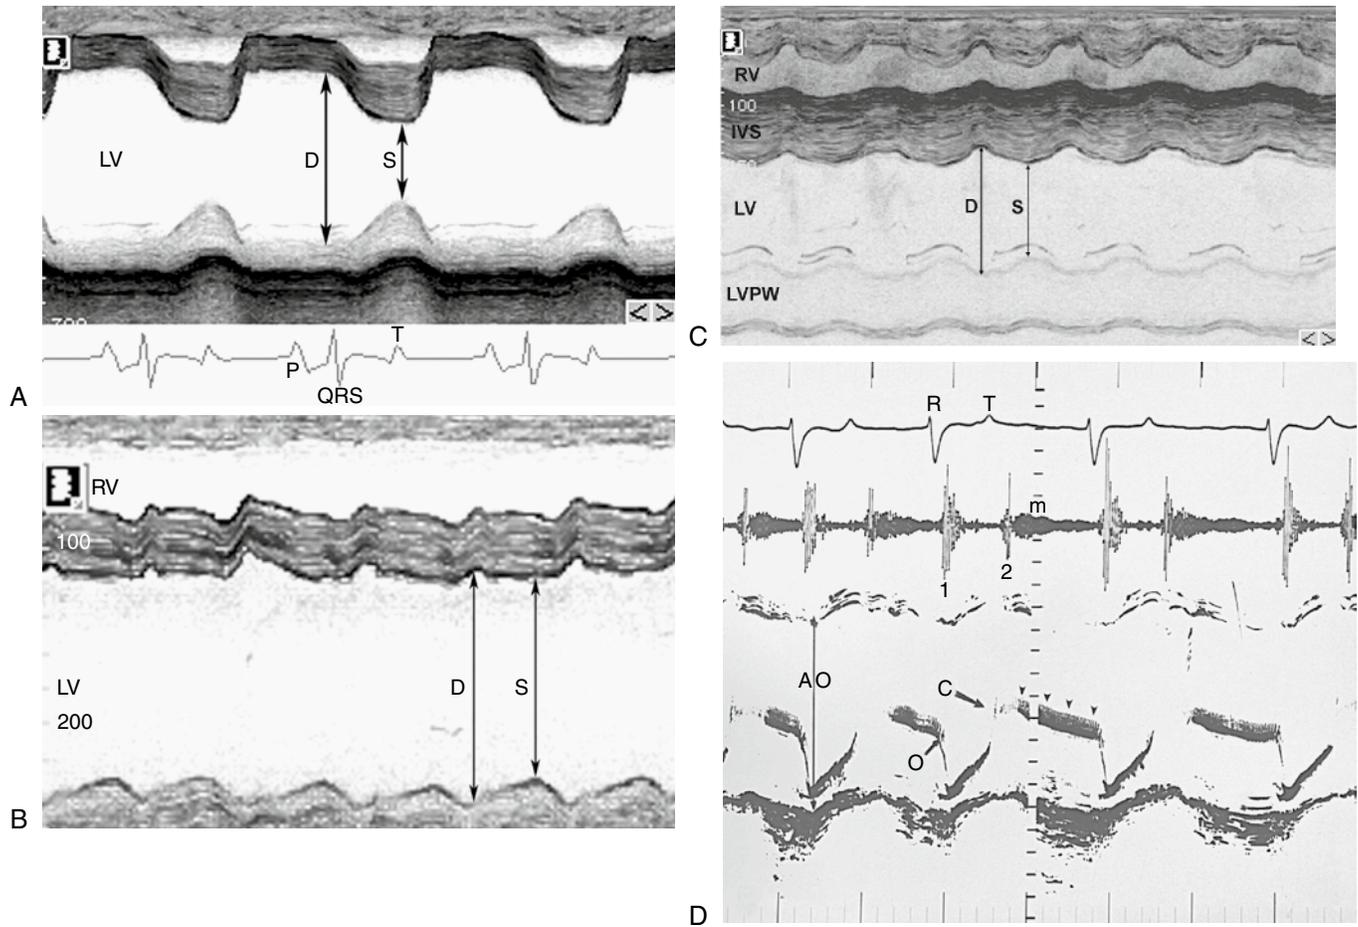

**FIGURE 10-21** Two-dimensional (2D) echocardiograms obtained from the right side of the chest. An ECG is recorded simultaneously for timing. **A**, Four-chamber view. **B**, Left-ventricular outflow tract view. **C**, Right-ventricular inflow and outflow tract view. These images, recorded in a right-parasternal long-axis view, allow subjective assessment of cardiac structures and myocardial function and measurement of selected cardiac dimensions. **D**, M-mode echocardiogram of the normal left ventricle (LV) performed in a right-parasternal short-axis view at the level of the chordae tendineae. The myocardial wall motion (*y*-axis) along the cursor line (*arrowheads*) is displayed over time (*x*-axis). An ECG is recorded simultaneously for timing. This view allows subjective assessment of right- and left-ventricular dimensions and left-ventricular systolic function, measurement of the left-ventricular internal dimensions in systole and diastole, and calculation of the left-ventricular fractional shortening (percentage of change in the internal dimension;  $FS = [LVIDd - LVIDs]/LVIDd \times 100$ ). The latter provides an index of systolic left-ventricular function. LV, Left ventricle; LA, left atrium; RV, right ventricle; RA, right atrium; IVS, interventricular septum; Ao, aorta; PA, pulmonary artery; LVFW, left-ventricular free wall; LVIDd, left-ventricular internal diameter at end diastole; LVIDs, left-ventricular internal diameter at peak systole. (From Schwarzwald CC, Bonagura JD, Muir WW: The cardiovascular system. In Muir WW, Hubbell JAE, editors: Equine anesthesia: monitoring and emergency therapy, ed 2, St Louis, 2009, WB Saunders.)

and green or yellow are added to the flow mapping to identify “turbulence.” Color-coding permits superimposition of flow information onto the 2D or M-mode image (see Figure 10-24). Although substantial technical challenges exist in terms of penetration and frame rate, color-Doppler imaging is useful in horses because a large area of the heart can be screened for flow disturbances. For example, it is much easier to find a jet of MR using color Doppler imaging than with other Doppler methods. A pivotal limitation of color Doppler regards temporal resolution. Depending on the system used, the frame rates of interrogation can be very slow (often <10/sec). Thus it is *mandatory to time flow events* using either spectral Doppler or by invoking the M-mode cursor and recording the event by color-M-mode echocardiography. In many cases, the color M-mode examination is simpler and provides excellent temporal resolution, reducing interpretation errors. This timing of blood flow prevents the clinician from misinterpreting normal

“backflow” signals related to valve closure or diagnosing a diastolic flow event as systolic.

Pulsed-wave spectral and color Doppler techniques can provide accurate information about the location of flow disturbances but cannot measure high-velocity flow faithfully. High-velocity flow is encountered as RBCs are ejected from high- to lower-pressure zones across incompetent valves, stenotic valves, and intra- and extracardiac shunts (provided that there is a pressure difference across the defect). In general, once velocities exceed about 2.5 m/sec in either direction, part of the returning signal is displayed in the incorrect direction. This problem is called *signal aliasing*<sup>257</sup> (see Figure 10-24). To quantify high-velocity flow, a third modality must be invoked, either high pulse repetition frequency Doppler or continuous wave Doppler. Continuous wave Doppler has virtually unlimited ability to record very high velocity but does not provide the spatial discrimination found in pulsed-wave Doppler modalities.

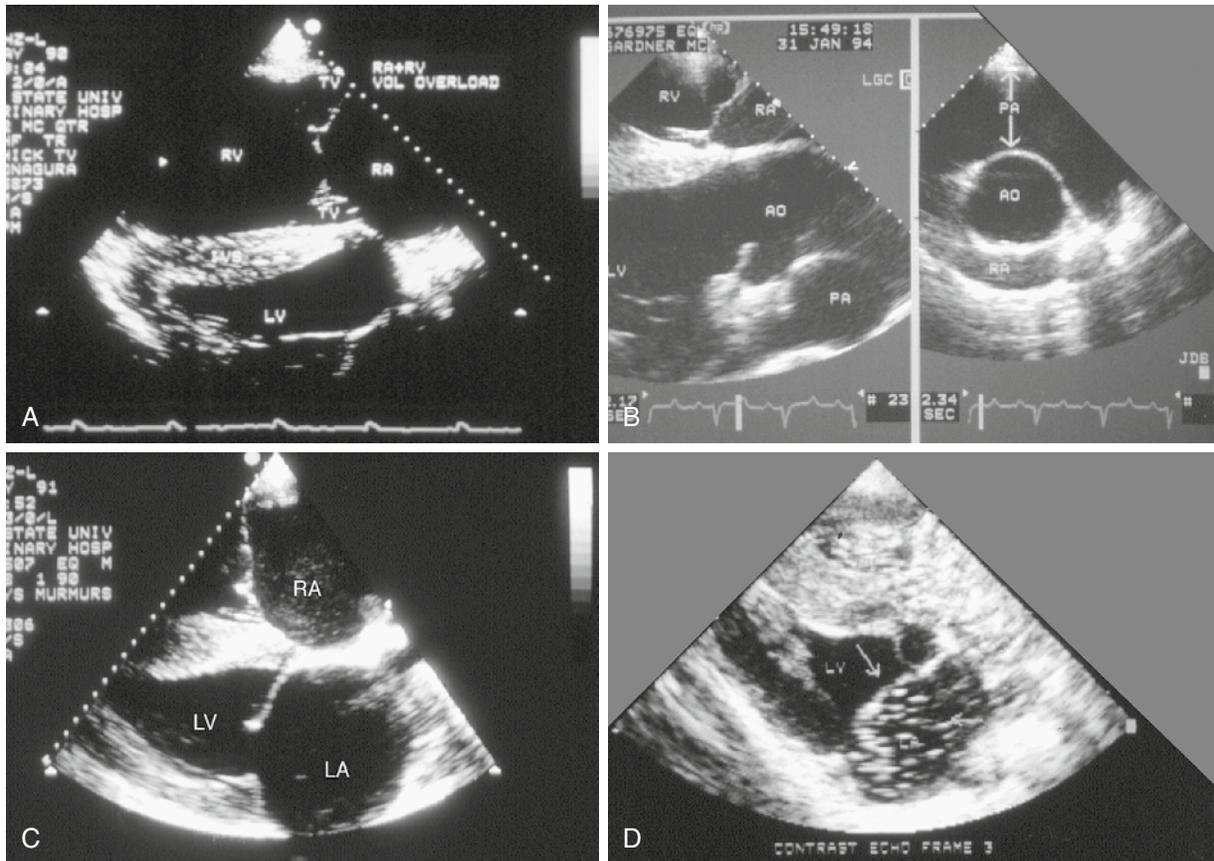

**FIGURE 10-22** M-mode echocardiography. **A**, M-mode tracing demonstrating a hyperdynamic left ventricle (LV) in a horse with acute mitral regurgitation (MR). The significant change in LV dimensions from diastole (D) to systole (S) is notable and is typical of volume overloading with preserved ventricular function. Furthermore, the reduced resistance to ejection of blood into the left atrium (LA) enhances ventricular shortening. Depth calibration in millimeters is shown on the left. **B**, Recording through the ventricles demonstrating decreased contractility with a reduced LV shortening fraction. This pattern of contraction can be caused by myocarditis, myocardial injury (e.g., monensin), idiopathic dilated cardiomyopathy, chronic volume overload, protracted ventricular tachycardia (VT), or administration of negative inotropic drugs. Depth calibration in millimeters is shown on the left (RV, right ventricle). **C**, M-mode echocardiogram across the ventricles recorded from a horse with cardiac amyloidosis. Global LV systolic function is mildly reduced. The IVS and LVPW are thickened. The IVS also appears hyperechoic relative to the RV wall. The LVPW in the far field is less echogenic owing to attenuation of echoes in the far field. The right ventricle (RV) contained spontaneous echocontrast. Depth calibration in millimeters is shown on the left (RV, right ventricle; IVS, interventricular septum; LV, left ventricle; LVPW, left ventricular peripheral wall). **D**, Recording from a horse with aortic regurgitation (AR) and atrial fibrillation (AF), demonstrating fine diastolic fluttering of an aortic valve leaflet (*small arrows*). The aortic root (AO), valve opening (O), and valve closing (C) are indicated. The murmur (*m*) of AR is evident in the previous phonocardiogram. First (1) and second (2) heart sounds are labeled. Diastolic fluttering of the mitral valve (most common), aortic valve, ventricular septum, or walls of the aortic root may be observed in horses with this hemodynamic abnormality. The M-mode sampling rate (approximately 1000 pulses/sec) is ideal for detecting these high-frequency events.

Accurate recording of flow disturbances can provide qualitative and quantitative information about the severity of a lesion (see discussion later in this chapter). Furthermore, the pressure difference between the source and the sink of a high-velocity jet can be estimated by the modified Bernoulli equation, in which pressure drop in mm Hg equals  $4V^2$  (where maximal velocity,  $V$ , is measured in m/sec by continuous wave Doppler). If, for example, a peak velocity

of 4.8 m/sec is recorded across a VSD, and if the systolic systemic ABP is determined noninvasively to be 125 mm Hg, then the estimated RV systolic pressure would be calculated as follows:

$$\begin{aligned} \text{Pressure drop} &= 4 \times 4.82^2 = 92 \text{ mm Hg} \\ \text{Estimated LV systolic pressure} &= 125 \text{ mm Hg} \\ \text{Estimated RV systolic pressure} &= 125 - 92 = 33 \text{ mm Hg} \end{aligned}$$

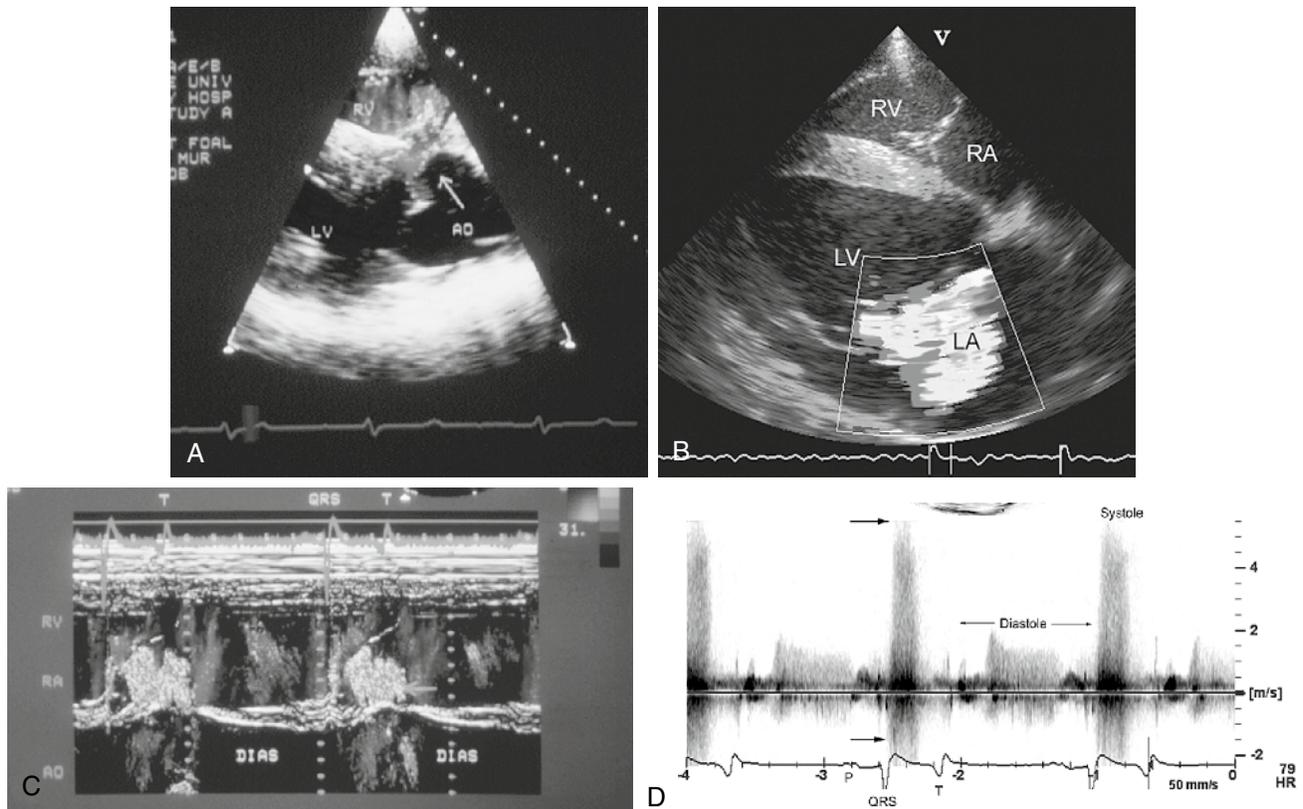

**FIGURE 10-23** Two-dimensional (2D) echocardiograms. **A**, Long-axis image from the right thorax in a 12-year-old Quarter Horse gelding demonstrating significant right ventricular (RV) and right atrial (RA) dilation after tricuspid regurgitation (TR) and elevated pulmonary artery pressure. In this case a tumor that obstructed flow in the main pulmonary artery caused the pulmonary hypertension. The ventricular septum is flat and bulges slightly into the left ventricle (LV). **B**, Images of the ascending aorta and pulmonary artery obtained from the right hemithorax (*left panel*) and left cranial hemithorax. An evaluation of the pulmonary artery diameter relative to the aorta is useful when identifying pulmonary hypertension. **C**, Biatrial dilation in a Thoroughbred colt with mitral regurgitation (MR), pulmonary hypertension, atrial fibrillation (AF), and congestive heart failure (CHF). Both atria are rounded and appear turgid. The cause of mitral disease in this case was idiopathic lymphocytic-plasmacytic mitral valvulitis (RA, right atrium; LV, left ventricle; LA, left atrium). **D**, Contrast echocardiogram demonstrating right-to-left shunting at the level of the foramen ovale in a foal with severe respiratory disease. The saline generates echocontrast, opacifies the right atrium (RA) and right ventricle (RV), and visibly fills the left atrium (LA) (*arrows*), although the LV has not yet been opacified. This technique is easy and practical for demonstrating right-to-left shunts across the cardiac septa.

These findings indicate a restrictive septal defect, a lesion unlikely to cause difficulties for the horse except at highest levels of performance.

A similar quantitative approach is used to estimate the presence or absence of pulmonary hypertension when TR is identified in the absence of RV outflow tract obstruction (i.e., PA ejection velocity of <1.5 m/sec). Assuming the jet can be interrogated at nearly parallel to flow, peak regurgitant velocities exceeding 3.5 m/sec are suggestive of elevated PA systolic pressure. For this calculation, peak RA pressure must be estimated (around 10 mm Hg in horses without CHF). For example, a peak regurgitant velocity of 3.8 m/sec would result in calculated pressure drop from RV to RA of  $(3.8)^2 \times 4$  or 58 mm Hg. When the RA pressure estimate (10 mm Hg) is added, estimated PA systolic pressure is 68 mm Hg. In cases of right-sided CHF, the RA pressure can be assumed to be at least 20 mm Hg or more or can be accurately measured by a catheter.

Advanced methods for assessing heart function by echocardiography includes measurement of various timing intervals of blood flow or tissue movements by Doppler methods. For example, systolic time intervals of aortic blood flow can be recorded from the aortic flow signal and may provide insight regarding LV function or changes related to valvular heart disease.<sup>46,237</sup> More advanced methods record longitudinal and radial tissue velocities by pulsed and color Doppler methods, or they assess of myocardial deformation (strain) by computer analysis of tissue movements (2D strain or 2D speckle tracking).<sup>525,526</sup> Strain and strain rate can be measured in longitudinal, radial, and circumferential planes and may provide more sensitive methods for assessing regional or global myocardial function. An additional application is measurement of atrial function using tissue velocities or time intervals.<sup>244</sup>

Echocardiography is most useful in the evaluation of congenital heart disease, heart murmurs, pericardial diseases,

**FIGURE 10-24** A to C, Black-and-white representations of color Doppler echocardiograms demonstrating mapping of blood through the heart. **A**, Perimembranous ventricular septal defect (VSD) in a foal (*arrow*). The flow pattern was coded red and aliased as the velocity increased across the defect. **B**, Wide spray of mitral regurgitation (MR) with flow moving from left ventricle (LV) into the left atrium (LA) in a horse with mitral valve prolapse (RV, right ventricle; RA, right atrium). **C**, Color M-mode study from a horse with tricuspid regurgitation (TR). The bright systolic flow pattern, following the QRS of the electrocardiogram (ECG), was mapped as turbulence in the color study. This is an excellent method for timing abnormal flow events. **D**, Example of continuous wave (CW) spectral Doppler echocardiogram obtained from a horse with a VSD and mild aortic regurgitation (AR). Time and the ECG waveforms are shown along the x-axis and velocity of flow along the y-axis with a meters per second scale (m/sec). Direction of flow relative to the transducer is also shown; flow toward the transducer is displayed as a positive signal (relative to the zero velocity baseline) and away from the transducer as a negative signal. A low-velocity flow pattern is evident in diastole related to diastolic shunting across the VSD, aortic regurgitant flow moving across the cursor line "off angle" (with parallel alignment, the AR velocity would be higher [i.e., >3.75 m/sec]), or contaminated tricuspid flow. In systole a high positive velocity signal is recorded (>5 m/sec) compatible with a small (restrictive) left-to-right shunting VSD. However, the maximum velocity is not evident because the signal reaches the upper limit of the velocity scale (*arrow*). The negative signal (*lower arrow*) is either an aliased signal (if antialiasing filters are off) or VSD turbulence in the other direction. Moving the baseline down or increasing the velocity scale would have allowed for faithful recording of the peak velocity. (Note: For color images of color Doppler echocardiograms, see case examples included on the DVD.)

heart failure, and cardiac arrhythmias. Ultrasound can also identify other lesions of the lung, pleural space, or mediastinum that may masquerade as heart disease.<sup>100,527</sup> The source of a pathologic cardiac murmur, the size and function of the heart, and the overall influence of a cardiac lesion can be accurately determined by a complete echocardiographic and Doppler examination. A normal echocardiogram and Doppler study in a horse with a cardiac murmur is a favorable finding, suggesting a functional basis for the murmur. Conversely, identification of an abnormal flow pattern with associated cardiomegaly or abnormal ventricular function may indicate a high risk or limitation for work. As with all diagnostic

studies, there can be ambiguous results, particularly regarding the tricuspid valve, because physiologic TR, silent to auscultation, is detectable by Doppler studies in many clinically normal horses. Contrast echocardiography,<sup>528</sup> whereby saline is used to delineate the path of blood flow, is especially useful for the detection of right-to-left shunts in foals, including patent foramen ovale (see [Figure 10-23, D](#)). Reference values for ventricular chamber size, wall thickness, and LV shortening fraction have been published,<sup>51,231,252,303-305,502</sup> and some representative data<sup>252,303</sup> are given in [Table 10-5](#). Sedation can affect echocardiographic studies, mainly by altering sympathetic tone, ventricular loading, and subsequently LV size

This summary is intended to serve as a general guide for assessment of some of the most commonly used echocardiographic indices of cardiac dimensions and cardiac function in horses. Individual measurements may differ depending on echocardiographic techniques and breed, age, and athletic condition of the animal.

SD, Standard deviation; THB, Thoroughbred; STB, Standardbred; N, number of horses; MM, M-mode; PWD, Pulsed-wave Doppler.

and function.<sup>529</sup> Clinical applications of echocardiography are illustrated later in this chapter.

## INTRAVASCULAR PRESSURES AND CARDIAC CATHETERIZATION

A large body of literature is derived from catheterization studies of the healthy standing, exercising, and anesthetized horse and pony along with limited catheterization data derived from horses with heart disease.\* Normal published data relate in part to population and study methods; accordingly, reference ranges vary considerably and have been summarized recently.<sup>77</sup> Normal values also depend on the head and body positions of the horse, the influence of administered tranquilizers, sedatives, or anesthetic agents, and the size of the animal. Hemodynamic variables that can be measured or calculated by catheterization techniques include systolic, diastolic, and mean BP in the systemic and pulmonary circulations; PA occlusion (or pulmonary capillary wedge) pressure; central venous pressure; intracardiac pressures; CO; systemic and pulmonary vascular resistances; and arteriovenous oxygen difference.

Cardiac catheterization in the clinical setting has largely been replaced by Doppler echocardiography. However, indications for right heart catheterization persist, especially when accurate measurement of PA pressure is needed, the origin of pulmonary hypertension cannot be determined, or the diagnosis of occult constrictive pericardial disease is entertained. Knowledge of the general principles of hemodynamics and catheterization data in health and disease creates a useful framework for understanding clinical assessment of the CV system.

Pressures on the left side of the circulation include systemic arterial, LV, and LA pressures. Measurement of ABP has been described previously. Systemic arterial pressure is related in a directly positive manner to LV systolic function, impedance to blood flow in the aorta, systemic vascular resistance, and heart rate. Systolic pressures in the aorta and LV in the standing horse generally peak at approximately 110 to 130 mm Hg (with individual variation). Diastolic aortic pressure is usually near 75 mm Hg. An increase in heart rate as small as 10 beats/min can increase systemic BP by 20 mm Hg (or greater than these values). A peak systolic pressure gradient between the LV and central aorta indicates an obstruction to LV outflow, a very rare condition in horses. LV diastolic pressure reflects diastolic ventricular function and filling pressures, as well as ventricular emptying during systole. The diastolic pressure most often reported is the end diastolic pressure (typically 12 to 24 mm Hg in standing animals), which is higher than the early (often subatmospheric) minimal diastolic LV pressure. Horses and ponies have higher ventricular end diastolic pressures than do either human beings or dogs.<sup>21,24,246,540</sup> Exercise increases both LA and ventricular end diastolic pressures.\* Pathologic elevation of resting LV end diastolic pressure indicates either reduced myocardial contractility, ventricular failure, LV volume overload (large VSD, MR, or AR), myocardial infiltration (lymphoma, amyloid), pericardial constraint, or increased ventricular wall stiffness. LA pressure is rarely measured directly,

but can be estimated by a pulmonary capillary wedge pressure as described follows.

A right heart catheterization is easily performed in most horses using a percutaneous technique involving placement of an 8-French introducer sheath and a 7-French balloon-tipped (Swan-Ganz) catheter of 110 to 120 cm in length. Pressures within the RA, RV, and PA can be obtained by advancing the catheter slowly from the jugular vein into a lobar branch of the PA. This is typically guided by pressure measurements and often with 2D ultrasound imaging. It may be possible to inflate the balloon tip briefly to occlude PA flow and “wedge” the distal catheter tip. This pulmonary capillary wedge pressure can be used to estimate the LV filling pressures of the pulmonary veins and LA.\*

Mean RA and central venous pressures estimate the pressures filling the RV and are influenced by plasma volume, venomotor tone, body position, and heart function. Central venous pressure is typically about 5 to 10 mm Hg but increases significantly in recumbent horses, especially during general anesthesia. Values frequently double from the standing preanesthetic measurement, and central venous pressure determinations of 20 mm Hg are not uncommon.<sup>538,554</sup> A single measurement of the central venous pressure or of pressure in the RA is difficult to interpret unless the value is severely elevated. Trends are most important in assessment of plasma volume status and cardiac function. Markedly elevated RA pressures are observed with cardiac tamponade, constrictive pericardial disease (along with an abrupt y descent; see Figure 10-4, A), and in right-sided CHF. The x descent of the RA pressure waveform may be replaced by a positive c-v wave in the setting of severe TR; this pressure wave corresponds to a prominent jugular pulsation observed during inspection of the neck.

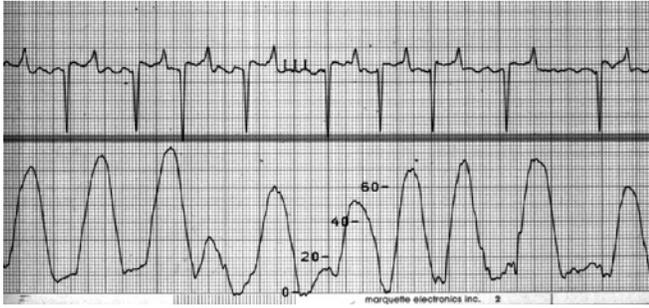

The peak RV systolic pressure is lower than that of the LV and is usually around 40 mm Hg (to up to 60 mm Hg) in standing horses. A small gradient (usually 10 to 15 mm Hg) may be measured between the ventricular apex and proximal pulmonary artery during systole in normal animals and relates in part to gravitational influences. RV end diastolic pressure is usually between 10 and 14 mm Hg, but values as high as 20 to 28 mm Hg have been reported. Hydrostatic effects can influence the RA and the RV end diastolic pressure if the horse's head is raised or lowered.<sup>385</sup> As with the LV, depression of contractility reduces the rate of systolic pressure development (dp/dt).<sup>309</sup> Elevated RV systolic pressure is recorded in pulmonary hypertension from any cause, with a large VSD, and with RV outflow obstruction as with pulmonic stenosis, tetralogy of Fallot, or obstructive pulmonary valve vegetation.<sup>135</sup> Pathologic elevations in RV diastolic pressure are encountered with pericardial disease, pulmonary hypertension, severe right-sided valvular disease, and CHF (Figure 10-25).

Pulmonary artery pressures in standing mature horses are considerably lower than values recorded from the aorta because of the lower resistance encountered in the pulmonary vascular tree. Mean PA pressure is higher in the newborn foal and decreases significantly during the first 2 weeks of life as pulmonary arteriolar resistance falls.<sup>265</sup> Average PA pressure in healthy horses and ponies is approximately 35 to 45 mm Hg in systole (but can be higher or lower depending on CO). Diastolic PA pressures are lower, approximately 20 to 30 mm Hg, but again showing some variation. Pulmonary pressures

\*References 265, 312, 406, 497, 536, 553.

**FIGURE 10-25** Recording of intravascular pressure during cardiac catheterization. Right ventricular (RV) pressure recordings from a Thoroughbred yearling with atrial fibrillation (AF), pulmonary hypertension, and biventricular congestive heart failure (CHF). The pressure waveforms vary because of ventilation and the arrhythmia. Peak pressures exceed 70 mm Hg. In the absence of pulmonic stenosis or a large ventricular septal defect (VSD), this indicates pulmonary hypertension. The ventricular end diastolic pressure also is elevated and is compatible with heart failure.

increase dramatically with increased CO as encountered during sinus tachycardia or with exercise.<sup>390,406,532,536,553</sup> The pressure that must be developed in the PA depends not only on pulmonary arteriolar resistance but also (unlike the systemic circulation) on the pulmonary capillary resistance and on the compliance and pressure in the LA. Pulmonary disease can influence these variables; for example, alveolar hypoxia and acidosis can induce reactive vasoconstriction, raising PA pressures.<sup>555</sup> This reaction may be particularly important in newborn foals where vascular resistance is already high.<sup>265</sup>

LV function also directly influences PA pressure because elevation of LA and pulmonary venous pressure places a direct burden on the PA and RV.<sup>246</sup> LV failure generally leads to secondary pulmonary hypertension that can be very severe, with systolic pressures exceeding 100 mm Hg. Presumably, other factors such as reactive vasoconstriction or anatomic changes in the pulmonary vascular tree must develop as a consequence of elevated LA pressures to sustain such high pressures at rest. In other cases the cause of pulmonary hypertension may not be evident.<sup>556</sup> Accordingly, elevated PA pressures must be assessed in light of heart rate, pulmonary wedge, LA or LV end diastolic pressure,<sup>309,310</sup> and CO. When PA pressure is increased, RV systolic pressure is also elevated to meet the pressure load. If pulmonary hypertension is chronic, then right-sided cardiac enlargement, TR, and right-sided heart failure can ensue.

The origin of pulmonary hypertension generally can be determined by conducting a thorough cardiorespiratory examination that includes echocardiographic and Doppler assessment of the left and right sides of the hearts. However, catheterization of the PA under sedation and local anesthesia can be instructive in confusing cases, especially if left-sided heart failure cannot be excluded. The pulmonary occlusion or wedge pressure estimates LV filling pressure and should approximate LV end diastolic pressure, provided that no obstructions are noted in the pulmonary veins or across the mitral valve. The PA diastolic pressure also can estimate PA wedge pressure provided that heart rate is normal and pulmonary vascular resistance is not increased. Increases in pulmonary capillary wedge pressure (or pulmonary diastolic pressure) are measured during exercise as LA pressure increases,<sup>239,312,553</sup> in left-sided

CHF,<sup>310,497</sup> with severe MR,<sup>311</sup> and in some horses with AF.<sup>313</sup> Overinfusion of crystalloid solutions or marked depression of LV function are other causes of elevated pulmonary capillary wedge pressure; conversely, the wedge pressure is reduced in hypovolemia. When pulmonary hypertension is not caused by left heart failure, a near-normal wedge pressure is recorded in the setting of elevated PA diastolic pressure. This indicates increased vascular resistance across the small arteries because of pulmonary vasoconstriction or pulmonary vascular lesions. One caveat is that a pressure gradient between the PA diastolic and pulmonary capillary wedge pressures may be observed in normal horses in the setting of resting tachycardia.

CO is the volume of blood pumped by the left (or right) ventricle in 1 minute. This can be divided by body weight or surface area to calculate the cardiac index. The CO can be measured by thermodilution techniques, lithium dilution, arteriovenous oxygen difference (Fick methodology), 2D echocardiographic and Doppler studies, and other methods.\* Determination of CO is most often done clinically when monitoring the effects of anesthetic agents or during fluid and drug therapy of the circulation in critical care situations wherein CO relates to tissue oxygen delivery. Reported values for cardiac index in standing horses or ponies are approximately 72 to 88 ml/min/kg. Noninvasive estimation of CO can be achieved using transthoracic 2D and Doppler echocardiographic methods, but (at least in adult horses) these estimates of CO are neither accurate nor reliable. In one study of foals, volumetric measurements by 2D echocardiography provided better estimates of CO than Doppler echocardiography.<sup>275</sup> The mixed venous (pulmonary artery) oxygen content (ml oxygen/dl blood) can be used as an indirect estimate of CO. As CO increases, the tissues extract less oxygen from each aliquot of blood; consequently, the venous oxygen content increases.<sup>267</sup> As CO decreases, the tissue extraction of oxygen increases, the oxygen content decreases, and the systemic-venous oxygen difference widens. Mixed venous samples obtained from PA catheters are probably superior to venous samples obtained from either the jugular or peripheral veins.<sup>462</sup>

Systemic and pulmonary vascular resistances strongly influence the mean pressures in their respective vascular systems. Vasoconstriction increases ABP. However, resistances cannot be measured directly in the intact animal and are generally calculated using a variation of Poiseuille's or Ohm's laws. The general formula for calculation of static vascular resistance is as follows:

$$\text{Vascular resistance} = (\text{mean arterial pressure} - \text{mean atrial pressure}) / \text{CO}$$

where CO is measured in liters per minute. The pressures used are mean aortic pressure and mean RA pressure for calculation of systemic vascular resistance and mean PA pressure and mean pulmonary wedge pressure for calculation of pulmonary vascular resistance. Correction values may be added to convert resistance to centimeter-gram-second (cgs) units.<sup>561</sup> Normal systemic vascular resistance in horses averages about 265 dynes-s-cm<sup>-5</sup>.<sup>5,77</sup> Pulmonary vascular resistance should be about one fifth of the systemic value, but reported values vary more widely. Inasmuch as mean arterial pressure is similar between horses of different sizes, calculated vascular resistance is normally higher in smaller horses and ponies. Mechanisms

\*References 260, 261, 265-267, 272-280, 282, 284, 285, 532, 534, 535, 551, 557-560.

that increase systemic vascular resistance include sympathetic activation, activation of the renin-angiotensin system, and the release of other vasoactive hormones into the blood, including arginine vasopressin (antidiuretic hormone) and epinephrine.<sup>73</sup> The pulmonary vascular resistance is tied to pulmonary vascular anatomy, age, total lung capillary resistance, LA pressure, and degree of pulmonary vascular constriction. The latter is controlled by the tension of alveolar oxygen and local mediators, including nitric oxide and endothelin.

## LABORATORY STUDIES

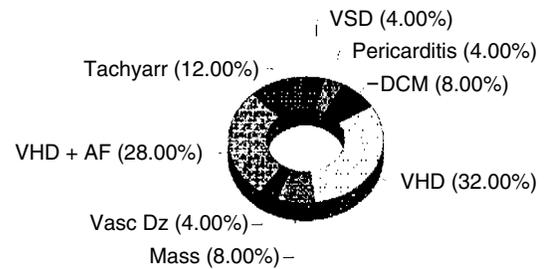

CV disorders may develop as a consequence of systemic or metabolic diseases such as electrolyte disturbances or septicemia. Conversely, circulatory failure or CV infections may alter routine laboratory tests. Prerenal azotemia and electrolyte disturbances (hyponatremia, hypokalemia, hypomagnesemia) may be detected in the horse with CHF, especially after diuretic therapy. Myocardial enzymes or troponins may be released in the circulation from primary or secondary cardiac muscle injury,<sup>562</sup> as might occur with hypotension, ischemia, or myocardial infarction. Increased cTn<sub>i</sub> is often used as a biomarker for recent myocardial injury,<sup>563,564</sup> and this test can be obtained from most commercial laboratories. Elevated concentrations in a horse with an arrhythmia may indicate ongoing myocardial injury or myocarditis. Increased serum cTn<sub>i</sub> also can be identified in horses after endurance races but does not necessarily indicate underlying structural heart disease.<sup>563</sup> Natriuretic peptides are released in the blood in response to a variety of stimuli, including myocardial stretch because of volume overload and increases in intracardiac pressures. Plasma atrial natriuretic peptide (ANP) concentrations may be elevated in horses with cardiac disease, particularly in the presence of LA enlargement or LA dysfunction (Schwarzwaldd CC, unpublished observations). To date, the use of ANP as a cardiac biomarker is limited to experimental settings, and more work is to be done to elucidate its clinical value in horses with heart disease.

An overview of the laboratory studies useful in assessment and management of CV diseases is found in [Box 10-4](#). A complete blood count (CBC) and fibrinogen, biochemical profile, and urinalysis are indicated in horses with arrhythmias, heart failure, or when clinical evidence suggests endocarditis, pericarditis, vasculitis, or pleural effusion. Additional studies including blood cultures, blood gas tensions, oxygen saturation, other electrolytes (e.g., magnesium), cytology and culture of pericardial effusates, and myocardial isoenzymes of CK are indicated in selected cases. Monitoring of serum or plasma drug concentrations, especially quinidine and digoxin, are appropriate when these drugs are administered. Further application of these studies is discussed under specific diseases.

## CONGESTIVE HEART FAILURE

### CAUSES OF HEART FAILURE

Heart failure is a clinical syndrome characterized by cardiac disease, limited CO in the setting of normal to high venous pressures, increased neurohormonal activity, renal sodium retention, accumulation of edema in tissues, and transudation of fluid into serous body cavities. The neurohormonal and renal abnormalities that characterize heart failure have not been extensively studied in horses but are probably similar to those reported in other species.<sup>76,105</sup> The most sensitive sign of heart failure is impaired

**FIGURE 10-26** Graph demonstrating the overall causes of congestive heart failure (CHF) in 25 horses at a referral teaching hospital as a percentage of the total number of cases of equine CHF. *Tachyarr*, Tachyarrhythmia; *VSD*, ventricular septal defect; *DCM*, dilated cardiomyopathy; *VHD*, valvular heart disease; *Mass*, mass lesion; *Vasc Dz*, vascular disease; *VHD + AF*, valvular heart disease and atrial fibrillation. (Data from Ohio State University Veterinary Hospital.)

exercise capacity, but this is hardly specific in horses. The most characteristic clinical features of heart failure are increased venous pressures and fluid accumulation. The typical horse with cardiac failure is recognized in the overtly congested phase termed *CHF*.

Most cardiac lesions in horses are insufficient to cause CHF, and this syndrome is not common in equine practice. Nevertheless, CHF does develop in foals and mature horses as a consequence of diverse disorders, including congenital malformation, severe degenerative valvular disease, valvulitis, bacterial endocarditis, dilated cardiomyopathy, myocarditis, myocardial necrosis, pericardial disease, vascular rupture, pulmonary hypertension, artery obstruction, or persistent tachyarrhythmia.<sup>112,564,565</sup> The most common cause of CHF in horses is valvular heart disease—often complicated by AF ([Figure 10-26](#)). In addition to structural lesions of the heart and blood vessels, primary electrical disturbances, particularly sustained AV dissociation caused by intractable junctional or VT, can reduce myocardial function, decrease CO, and lead to CHF.<sup>566</sup> This is especially likely when the heart rate exceeds 100 beats/min for many days. Resolution of CHF in such cases may be possible if antiarrhythmic therapy is successful.

## CLINICAL RECOGNITION OF HEART FAILURE

Congestive heart failure may develop suddenly or gradually. Peracute heart failure can occur after rupture of mitral valve chordae tendineae or consequent to acute endocarditis of a heart valve. Rapid multiform ventricular tachycardia can also result in the sudden development of congestive heart failure. Heart failure may progress rapidly in a foal with a large VSD as the pulmonary vascular resistance falls in the weeks after birth. Chronic valvular regurgitation can, after many years, lead to CHF; although only a small number of horses with degenerative valvular disease develop CHF.<sup>567</sup> Some lesions, which might otherwise be well tolerated, can cause heart failure if increased demands for CO develop. Examples include strenuous work, severe anemia, or persistent fever. Pregnancy is another example: the volume expansion and increased demands for CO in the latter stages of gestation may precipitate CHF in a mare with previously compensated heart disease. Development of AF in a horse with underlying structural disease, such as severe mitral or AR, can precipitate CHF.<sup>568,569</sup> Such cases are distinguished from the more typical case of AF by the presence of persistent, resting tachycardia and identification of structural lesions and cardiomegaly during echocardiography.

The clinical features of CHF are easily recognized,<sup>399</sup> but determination of the underlying cause of heart disease may be more difficult. The cause can be established if careful auscultation is combined with echocardiography, ECG, laboratory tests, and ultrasound examination of other body cavities.\* Presenting clinical signs can vary but often include exercise intolerance, poor recovery after exercise, weight loss, coughing, tachypnea, ventral edema, and often colic-like signs.

The clinical features of right-sided CHF include resting tachycardia and prominent third (ventricular) sound along with generalized ventral, preputial, pectoral, and limb edema. Isolated limb edema, which is so common in hospitalized horses, is not a sign of CHF. Nor does ventral edema in the absence of generalized venous distention suggest a diagnosis of CHF. This finding should prompt consideration of other disorders including hypoproteinemia, vasculitis or severe pleural or abdominal effusion, or causes of generalized fluid retention. Scrutiny of the jugular and other superficial veins generally makes the recognition of right-sided CHF straightforward, because affected horses demonstrate elevated venous pressure and pathologic jugular pulses and filling (see [Figures 10-12 and 10-13](#)). The most common causes of “isolated” right-sided CHF are tricuspid or pulmonic valve lesions as with valvular endocarditis, diffuse pulmonary vascular disease, and pericardial disease. In most cases a prominent murmur of TR will be evident over the right thorax. When pulmonary hypertension underlies right-sided failure, the tricuspid murmur may be especially loud and the pulmonic component of the second heart sound tympanic. Because right-sided heart failure often develops consequent to pulmonary hypertension caused by left heart failure, left-sided murmurs are not uncommon. Another common association of right-sided CHF is persistent cardiac arrhythmia, such as AF, superimposed on structural heart disease of any form. Horses with long-standing uniform ventricular tachycardia can also present with right-sided heart failure. Cranial mediastinal lymphosarcoma and cranial thoracic masses including large pulmonary abscesses must be distinguished from RV failure.<sup>100,581</sup> Differential diagnosis is facilitated by examination with 2D echocardiography and thoracic ultrasonography.

The recognition of isolated left-sided heart failure, which causes pulmonary venous congestion and pulmonary edema, is more difficult in horses. In these cases, heart sounds and murmurs may be difficult to identify owing to loud airway sounds or even pulmonary crackles. If a cardiac murmur is present but missed, then an erroneous diagnosis of pneumonia may be entertained. Again, resting tachycardia and loud third heart sound are typical in these cases, and echocardiographic examination of the horse will be particularly useful. Typical findings in acute left-sided CHF are dilatation and rounding of the LA and ventricle, dilation of pulmonary veins, and often dilatation of the PA caused by pulmonary hypertension. A small aortic root may be evident, associated with low cardiac output. Careful examination may demonstrate anatomic lesions of the aortic root, ventricular septum, left heart valves, or chordae tendineae. Fulminant left-sided CHF can lead to coughing and expectoration of edema—a grave sign in most horses.

Biventricular CHF is most commonly observed when severe left sided disease results in chronic CHF and is complicated by AF. The clinical signs of advanced biventricular heart failure include

resting tachycardia (usually >60 beats/min), loud ventricular filling sound, subcutaneous edema, tachypnea (from pulmonary edema or pleural effusion), varying amounts of ascites and pleural effusion, a small pericardial effusion, jugular distention, and abnormal jugular pulsations. Chronic biventricular CHF is frequently characterized by lethargy and also by loss of body condition. In most cases there will be one or more cardiac murmurs on the left typical of mitral or aortic valvular regurgitation and a murmur of TR on the right. Infrequently biventricular CHF is the result of congenital heart disease such as a VSD.

It is important to understand that *chronic* left-sided CHF in the horse is likely to cause interstitial lung edema and pulmonary hypertension. The magnitude of pulmonary hypertension is often impressive, with systolic PA pressures exceeding 80 mm Hg in many cases. The mechanisms by which the lung accommodates such severe and chronic elevations in pulmonary venous pressures without development of alveolar edema is speculative. It is likely that pulmonary arterial resistance increases, possibly related to remodeling in pulmonary arteries from chronic elevation of LA pressure. Chronic pulmonary hypertension also leads to RV dilatation and TR, which limits CO and predisposes to right-sided CHF. Furthermore, generalized fluid retention is a characteristic of chronic CHF in most species, and this retained fluid is generally pooled in the skin, pleural space, and peritoneal cavity.

Thus the clinician should anticipate signs of right-sided CHF even when the primary cardiac lesion is located on the left side of the heart. Clinical findings of severe pulmonary hypertension caused by left-sided CHF include a loud, tympanic, pulmonary component of the second heart sound (heard cranioventral to the aortic valve area), a systolic murmur and jugular pulse of tricuspid insufficiency, and dilatation of the PA, which can be identified by 2D echocardiography. Thoracic radiographs may demonstrate increased pulmonary vascularity, pulmonary infiltration near the hilus, pleural effusion, and rounding or enlargement of the cardiac silhouette. Further scrutiny of the echocardiogram identifies LA dilatation and lesions affecting the LV and usually the mitral valve, aortic valve, or the aorta. Doppler echocardiography can document abnormal flow patterns such as valvular regurgitation and predict PA pressures (using the Bernoulli relationship discussed previously). An ECG is needed to evaluate cardiac arrhythmias.

## THErapy FOR CONGESTIVE HEART FAILURE

Therapy for CHF is realistic for potentially reversible disorders such as pericarditis or sustained ventricular tachyarrhythmia. It may also be feasible for valuable breeding stallions and mares, mares that develop CHF during gestation, or horses and ponies kept as pets.<sup>146,399,582</sup> Before therapy can commence, an accurate diagnosis is needed. For example, pericardiocentesis (not cardiac drugs) would be appropriate initial management of cardiac tamponade; thereafter, surgical drainage of the effusion (using drainage tubes) or a pericardiectomy could be considered.<sup>86,87,94,583,584</sup> Antibiotics would be essential in the treatment of bacterial endocarditis or infective pericarditis. Sustained junctional and ventricular tachyarrhythmias may lead to low CO and a potentially reversible dilated cardiomyopathy. Antiarrhythmic therapy with quinidine, magnesium sulfate solution, lidocaine, procainamide, propafenone, or amiodarone may be effective for treatment of some of these arrhythmias, and with resumption of normal rhythm, CHF may be reversed.

Furosemide<sup>294,572,585-587</sup> is administered to horses with CHF not associated with cardiac tamponade. The dosage initially

\*References 87, 88, 105, 109, 112, 137, 146-148, 152, 186, 294, 299, 300, 309, 342, 504, 556, 565, 568-569, 570-580.

should be directed to mobilize edema and prevent its recurrence, and 1 to 2 mg/kg IV boluses are given to effect, whereby the higher or more frequent doses may be required when renal function is impaired.<sup>588</sup> Bolus administration may be followed by constant-rate infusion when profound diuresis is needed (Table 10-6). Respiratory effort should improve when pulmonary edema is evident. Short-term therapy with nasal oxygen, if available, also may be useful for horses with respiratory distress. Volume depletion, azotemia, and electrolyte imbalances are the most common adverse effects. Renal function should be followed and the dosage controlled to minimize prerenal azotemia. Diuretic therapy may eventually be discontinued in some horses, but others will require once- or twice-daily administration on the farm to prevent fluid retention.

Digoxin therapy is indicated for CHF not associated with pericardial disease or serious ventricular ectopy and is particularly beneficial when concurrent AF is superimposed on structural valvular heart disease. Treatment is initiated by the IV route, with most (450 to 550 kg) horses receiving a total dose of about 1 mg IV (see Table 10-6). The reported elimination half-life of digoxin has not been consistent (7.2 to 28 hours) and probably relates to the clinical state of the animals studied.\* Long-term digoxin therapy involves once or twice daily oral administration, usually mixed with molasses and some grain. As expected, oral doses of digoxin are relatively higher because of lower bioavailability (20%).<sup>300</sup> Chronic digoxin therapy is monitored by measuring the serum digoxin concentration (drawn between 8 to 12 hours after the previous dose). Target therapeutic values range between 0.8 to 1.5 ng/ml (1-1.5 nmol/L), depending on the time of the blood sample, and drug therapy achieving these levels is usually well tolerated in terms of appetite and heart rhythm. Periodic cardiac examinations, measurements of serum biochemistries (creatinine, electrolytes), and recordings of ECG rhythm strips are warranted during any long-term course of therapy.

Limited published experience is available regarding use of vasodilators and ACE inhibitors in horses with CHF. Hydralazine<sup>268</sup> might be considered in the initial management of severe MR caused by ruptured chordae tendineae or endocarditis, because systemic arterial dilatation can reduce the mitral regurgitant fraction. ACE inhibitors decrease renal sodium and water reabsorption, reduce volume overload, blunt the mechanisms leading to diuretic resistance, cause vasodilation, decrease in myocardial oxygen demand, and are considered cardioprotective by decreasing myocardial remodeling and fibrosis. In humans, ACE inhibitors have been shown to reduce mortality in heart failure. However, the benefits of ACE inhibitors have not been well studied in equine heart failure. Limited data are available in horses regarding enalapril,<sup>315,591,592</sup> ramipril,<sup>593</sup> and quinapril.<sup>594</sup> Although effective intravenously, oral enalapril did not significantly reduce ACE activity after oral administration. Ramipril administered at 200 µg/kg orally (PO) daily reduced indirect BP in healthy horses in an uncontrolled study, and this drug also has been used to treat CHF.<sup>595</sup> An open-label clinical study of quinapril in horses with MR but without CHF showed some evidence for increased stroke volume and reduced regurgitation fraction.<sup>594</sup> Most ACE inhibitors are contraindicated in humans during pregnancy. Therefore until appropriately studied, all

ACE inhibitors should be considered as contraindicated in pregnant mares because of potential ill effects on the fetus.

For horses with cardiomyopathy or valvular disease, or in pregnant mares with CHF, the development of AF may precipitate CHF. Furosemide and digoxin can effectively control CHF in many of these cases. All ACE inhibitors should be considered as contraindicated in pregnant mares because of potential ill effects on the fetus. Quinidine is also generally contraindicated in such cases, although horses may sometimes convert to sinus rhythm after the resolution of CHF by medical therapy. Reasonable long-term control of CHF may be achieved in some of chronic CHF, thus permitting a comfortable existence for the horse and—in the case of breeding animals—continued reproductive service.

Prognosis in CHF is at best guarded when irreversible structural heart disease is the cause of failure; thus the long-term outcome for life is poor. Of course, the horse with CHF requires rest to reduce demands on the heart and should never be worked or ridden owing to the risk of PA rupture, syncope, or fatal arrhythmia. Valuable horses may be used for breeding with great caution, but the stallion in CHF poses some risks for the handler, and pregnant mares are likely to be difficult to control in the later stages of gestation related to the volume expansion that accompanies the latter stages of pregnancy. Embryo transfer and freezing of semen are alternative approaches for valuable animals in CHF.

## ☞ CONGENITAL HEART DISEASE

The prevalence of congenital heart disease in the overall equine population is unknown. In one survey of causes for neonatal death or euthanasia in 608 cases, the prevalence of congenital heart disease was 3.5%.<sup>160</sup> Congenital heart disease is often considered when a foal, weanling, or immature horse is identified with a prominent cardiac murmur, cyanosis, or signs of CHF.<sup>365</sup> A wide variety of cardiac malformations have been identified.\* Theoretically, a great number of cardiac malformations could occur, including anomalies of (1) venous drainage, (2) atrial situs or septation, (3) atrioventricular connection, (4) atrial or ventricular development (including formation of the two atrioventricular valves), (5) ventricular outflow tracts, (6) semilunar valves, and (7) great vessels.<sup>623,624</sup> Furthermore, abnormal segmental connections might occur leading to “discordance” in the path of systemic or pulmonary venous return relative to the pulmonary artery or aorta. These abnormalities include transposition of the great vessels and double-outlet ventricle, wherein both great vessels exit the RV or LV cavity. However, practically speaking, the most common cardiac malformations in horses involve shunting of blood at the atrial or ventricular levels.

Although some defects are lethal to the neonate, other malformations are compatible with life but limit performance or reproductive value. Most cardiac malformations involve shunting of blood, with the VSD most often recognized (Figures 10-27 to 10-29). Isolated malformations leading to valvular stenosis or incompetence are uncommon. Rare lesions such as double-outlet RV,<sup>598</sup> transposition of the great vessels,<sup>157,165,625</sup> aorticopulmonary septal defect,<sup>626</sup> bicuspid pulmonary valve, pulmonary stenosis,<sup>168</sup> persistent fetal circulation,<sup>627</sup> hypoplastic left heart syndrome,<sup>158,159</sup> subaortic stenosis,<sup>607</sup> mitral valve malformation,<sup>510,628</sup>

TABLE 10-6

Drug Therapy of Heart Disease			
Drug	Dose Recommendations	Comments—Therapeutic Drug Monitoring—Adverse/Toxic Effects	Indications (I) Contraindications (CI)
<b>ANTIARRHYTHMICS</b>			
<i>SODIUM CHANNEL BLOCKER (CLASS I<sub>A</sub>)</i>			
Quinidine sulfate (PO) or gluconate (IV)	22 mg/kg quinidine sulfate PO by NGT q2h for 4 (-6) doses until converted, adverse or toxic effects, or plasma quinidine concentration > 4 µg/ml. Do not exceed 6 doses PO q2h.  Continue q6h until converted, adverse or toxic effects, or total dose of 180 mg/kg.  1-2.2 mg/kg quinidine gluconate IV q10min or 0.1-0.22 mg/kg/min CRI up to 12 (-24*) mg/kg total dose (*Caution: Can result in severe adverse effects!)	IV administration for AF of recent onset (< 2 weeks) without underlying structural heart disease or AF occurring during anesthesia.  PO administration preferred for long-standing AF (> 2-4 weeks).  Therapeutic drug monitoring: Therapeutic range: 2-5 µg/ml [6.2-15.4 µmol/L] 1-2 h after PO administration.  Adverse effects: Commonly depression, diarrhea, colic, nasal mucosal swelling, and ataxia; rarely: paraphimosis, urticaria, and laminitis. Cardiovascular effects include acceleration of AV conduction and tachycardia (most common), prolonged QRS and QT interval, VT or torsades de pointes, hypotension, negative inotropism, exacerbation of heart failure, cardiovascular collapse, sudden death.	I: AF, SVT (ventricular arrhythmias)  CI: Ventricular tachyarrhythmias, torsades de pointes, untreated heart failure, preexisting prolonged QRS or QT interval, complete AV block, digitalis intoxication.  Use with caution in patients with uncorrected hypokalemia, hypomagnesemia, hypoxia, or acid-base disorders.
Procainamide	25-35 mg/kg PO q8h  1 mg/kg/min IV, up to 20 mg/kg total dose	Adverse effects: Hypotension, QRS and QT prolongation, negative inotropism, arrhythmias, GI and neurologic disorders. Similar but generally less severe than with quinidine.	I: Ventricular and supraventricular arrhythmias  CI: See quinidine
<i>SODIUM CHANNEL BLOCKER (CLASS I<sub>B</sub>)</i>			
Lidocaine	0.25-0.5 mg/kg slow IV, repeat in 5-10 min to effect, up to 1.5 mg/kg total dose; followed by 0.03-0.05 mg/kg/min CRI	Adverse effects: Low incidence at therapeutic doses. Occasionally depression and muscle fasciculations. Overdoses may lead to ataxia, CNS excitement, seizures, hypotension, VT, collapse, and sudden death.	I: Ventricular arrhythmias, (potentially vagally sustained AF)  CI: SA, AV, or intraventricular block, bradycardia.  Caution with hypovolemia, liver disease, shock, and heart failure.
Phenytoin	20 mg/kg PO q12h for 3-4 doses or until signs of sedation, followed by 10-15 mg/kg PO q12 maintenance dose  5-10 mg/kg IV, followed by 1-5 mg/kg IM q12h or 10-15 mg/kg PO q12h	Maintenance dose varies considerably.  Therapeutic drug monitoring: Therapeutic range 5-10 µg/ml [19.8-39.6 µmol/L].  Adverse effects: Sedation, lip and facial twitching, gait deficits, excitation seizures, arrhythmias. Hepatotoxicity with chronic therapy. Hypotension and respiratory depression at high doses.	I: Digoxin-induced arrhythmias, other ventricular arrhythmias  CI: SA or AV block, sinus bradycardia

Continued

TABLE 10-6

Drug Therapy of Heart Disease—cont'd			
Drug	Dose Recommendations	Comments—Therapeutic Drug Monitoring—Adverse/Toxic Effects	Indications (I) Contraindications (CI)
<i>SODIUM CHANNEL BLOCKER (CLASS I<sub>c</sub>)</i>			
Flecainide	1-2 mg/kg IV, infused at a rate of 0.2 mg/kg/min  4 mg/kg PO q2h for 4-6 doses, followed by 4 mg/kg PO q4h; adjust dose intervals if signs of toxicity occur.	Use with caution.  Not generally recommended for treatment of AF. May not be effective for chronic AF.  Adverse effects: Depression, colic, neurologic signs, negative inotropism, QRS and QT prolongation, severe ventricular arrhythmias, sudden death	I: Acute AF, supraventricular and ventricular arrhythmias resistant to other treatments  CI: Structural heart disease, heart failure, SA or AV node dysfunction
Propafenone	0.5-2.0 mg/kg in 5% dextrose slowly IV over 10-15 min  2 mg/kg PO q8h	Can be used for IV or PO control of serious ventricular arrhythmias. IV formulation not available in U.S.A.  Adverse effects: GI and neurologic disorders, bronchospasm, negative inotropism, exacerbation of heart failure, AV block, QRS and QT prolongation, arrhythmias	I: Supraventricular and ventricular arrhythmias resistant to other treatments  CI: Structural heart disease, heart failure, SA or AV node dysfunction
<i>β-ADRENOCEPTOR BLOCKER (CLASS II)</i>			
Propranolol	0.03-0.16 mg/kg slow IV q12h  0.38-0.78 mg/kg PO q8h	Unspecific β <sub>1</sub> /β <sub>2</sub> -blocker.  Variable oral bioavailability.  Dosage should be individually adjusted.  Adverse effects: Depression, lethargy, weakness, bradycardia, AV block, hypotension, negative inotropism, exacerbation of heart failure, bronchoconstriction (aggravation of recurrent airway obstruction)	I: SVT and AF (rate control, often in combination with digoxin), catecholamine-induced arrhythmias, unresponsive supraventricular and ventricular arrhythmias  CI: Bradycardia, high-degree AV block, untreated heart failure, bronchopulmonary disease
<i>POTASSIUM CHANNEL BLOCKER (CLASS III)</i>			
Amiodarone	5 mg/kg/h IV for 1 h, followed by 0.83 mg/kg/h for 23h, and subsequently 1.9 mg/kg/h for 30h or to effect	Also class I, II, and IV effects.  Poor and variable oral bioavailability, long half-life (16 days).  Adverse reactions: Hindlimb weakness, weight shifting, torsades de pointes (supposedly low incidence), SA and AV nodal inhibition, bradycardia, hypotension. Prolonged treatment may affect lungs, liver, heart, thyroid gland, GI tract, eyes, skin, and nerves.	I: AF, ventricular arrhythmias (not investigated)  CI: Sinus node dysfunction, bradycardia, AV block, cardiogenic shock
Bretylium tosylate	3-5 mg/kg IV, repeat up to 10 mg/kg	Also indirect anti-adrenergic effects  Adverse effects: Excitement, GI disorders, hypotension, tachycardia, arrhythmias	I: Refractory, life-threatening ventricular tachycardia, ventricular fibrillation
<i>CALCIUM CHANNEL BLOCKER (CLASS IV)</i>			
Diltiazem	0.125 mg/kg over 2 min IV, repeated every 10 minutes to effect, up to 1.25 mg/kg total dose	Titrate to effect. Use diltiazem doses > 0.5-1.0 mg/kg with caution.  Adverse effects of class IV drugs: Hypotension, tachycardia, sinus arrhythmia, bradycardia, sinus arrest, high-grade AV block, negative inotropism, exacerbation of heart failure (unless secondary to SVT or AF with rapid ventricular response rate)	I: Supraventricular arrhythmias (ventricular rate control in AF and interruption of SA/AV nodal-dependent SVT)  CI: Hypotension, bradycardia, SA or AV block, ventricular systolic dysfunction, severe heart failure, cardiogenic shock, β-blocker
Verapamil	0.025-0.05 mg/kg IV q30min, up to 0.2 mg/kg total dose		

TABLE 10-6

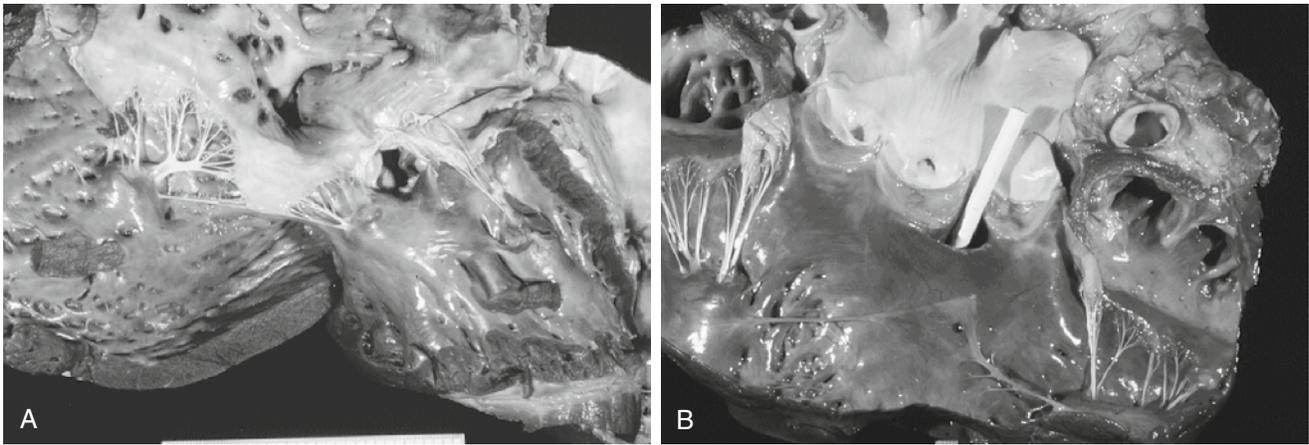

Drug Therapy of Heart Disease—cont'd			
Drug	Dose Recommendations	Comments—Therapeutic Drug Monitoring—Adverse/Toxic Effects	Indications (I) Contraindications (CI)
<i>PHYSIOLOGIC CALCIUM CHANNEL BLOCKER, ACTIVATOR OF MEMBRANE NA<sup>+</sup>/K<sup>+</sup>-ATPASE</i>			
Magnesium sulfate	2-6 mg/kg/min IV to effect, up to 55 (-100) mg/kg total dose	Adverse effects: Overdoses (rare) may lead to CNS depressant effects, weakness, trembling, bradycardia, hypotension. Very high doses lead to neuromuscular blockade with respiratory depression and cardiac arrest.	I: Ventricular arrhythmias (especially for quinine induced and other causes of torsades de pointes and refractory VT), hypomagnesemia associated with cardiovascular disease CI: Bradycardia, SA and AV block, renal failure
<b>DIGITALIS GLYCOSIDES</b>			
Digoxin	IV loading dose: 0.0022 mg/kg IV q12h, for 2 doses IV maintenance dose: 0.0022 mg/kg IV q24h PO maintenance dose: 0.011 mg/kg PO q12h	Therapeutic drug monitoring: Peak (1-2h) and trough (12h) concentrations at steady state should fall within 0.8-1.2 (2.0) ng/ml [1-1.5 (2.6) nmol/L]. Adverse effects: Depression, anorexia, colic, diarrhea, sinus bradycardia, AV block, supraventricular and ventricular arrhythmias (bigeminy)	I: Heart failure, ventricular rate control in SVT or AF CI: AV block, diastolic ventricular dysfunction, preexisting digitalis toxicity, myocarditis, ventricular arrhythmias
<b>ADRENERGIC (SYMPATHOMIMETIC) AGENTS</b>			
<i>INOTROPES</i>			
Dopamine	1-5 µg/kg/min CRI, titrate to effect or adverse reactions	β <sub>1</sub> -Adrenergic, also dose-dependent dopaminergic and α <sub>1</sub> -adrenergic Adverse reactions: Tachycardia, ventricular arrhythmias, vasoconstriction and hypertension can occur at doses > 4-5 µg/kg/min	I: Hypotension, acute heart failure, cardiogenic shock, noncardiogenic shock (after adequate fluid loading), sinus arrest, bradycardia, high-grade or complete AV block, vagally induced bradyarrhythmias
Dobutamine	1-5 µg/kg/min CRI, titrate to effect or adverse reactions	β <sub>1</sub> -Adrenergic, also β <sub>2</sub> - and α <sub>1</sub> -adrenergic. Preferred over dopamine. Adverse reactions: Tachycardia, ventricular arrhythmias, vasoconstriction	CI: Ventricular arrhythmias, tachycardia, atrial fibrillation (risk of severe tachycardia because of accelerated AV conduction)
Epinephrine	0.01-0.05 mg/kg IV 0.1-0.5 mg/kg IT Note different concentrations: 1:1,000 = 1 mg/ml 1:10,000 = 0.1 mg/ml	β-Adrenergic, α <sub>1</sub> -adrenergic at higher doses Adverse effects: Tremor, excitability, arrhythmias, ventricular fibrillation. Overdoses can lead to hypertension, arrhythmias, renal failure, pulmonary edema, cerebral hemorrhage.	I: Ventricular asystole, cardiopulmonary resuscitation CI: Nonanaphylactic shock, arrhythmias, hypertension
<i>VASOPRESSORS</i>			
Norepinephrine	0.05-1 µg/kg/min CRI, titrate to effect	α <sub>1</sub> -adrenergic. Norepinephrine also exerts some β <sub>1</sub> -adrenergic effects.	I: Hypotension and shock associated with excessive peripheral vasodilation (i.e., septic or endotoxemic shock, quinidine toxicity; after adequate volume loading)
Phenylephrine	0.1-1 µg/kg/min CRI, titrate to effect	Usually administered in conjunction with fluid therapy and dobutamine. Adverse effects of vasopressors: Hypertension, reflex bradycardia, reduction in cardiac output because of increased afterload, CNS effects (excitement, restlessness), rarely arrhythmias. Overdosage can lead to seizures, ventricular arrhythmias, cerebral hemorrhage	CI: Hypertension, bradycardia, poor cardiac output, cardiac disease, ventricular tachycardia

TABLE 10-6

<b>Drug Therapy of Heart Disease—cont'd</b>			
<b>Drug</b>	<b>Dose Recommendations</b>	<b>Comments—Therapeutic Drug Monitoring—Adverse/Toxic Effects</b>	<b>Indications (I) Contraindications (CI)</b>
<b>ANTICHOLINERGIC (VAGOLYTIC) AGENTS</b>			
Atropine	0.01-0.02 mg/kg IV, IM	Adverse effects: Constipation, ileus, colic, bradycardia (initially or at very low doses), tachycardia, arrhythmias, CNS effects (stimulation, drowsiness, ataxia, seizures, respiratory depression). Glycopyrrolate is slightly less arrhythmogenic and rarely results in CNS effects	I: Vagally induced bradyarrhythmias, sinus bradycardia, sinus arrest, high-grade or complete AV block CI: Tachycardia, tachyarrhythmias, heart failure, GI disease, colic
Glycopyrrolate	0.005-0.01 mg/kg IV		
<b>ANGIOTENSIN-CONVERTING-ENZYME (ACE) INHIBITORS</b>			
Enalapril	0.5 mg/kg PO q12h	Optimal doses and efficacy unknown	I: Cardiovascular protection in cases with AR or MR, treatment of heart failure CI: Severe renal failure, hyperkalemia, hypotension
Quinapril	0.25 mg/kg PO q24h	Adverse effects: Cough, impairment of renal function, hypotension, hyperkalemia	
Ramipril	0.05-0.2 mg/kg PO q24h		
<b>VASODILATORS AND INODILATORS</b>			
Nitroglycerine	5-20 µg/kg/min CRI, titrate to effect	Venous vasodilator (preload reducer). Tolerance with long-term treatment (12-24h). Adverse effects: Severe hypotension, reflex tachycardia, weakness	I: Acute management of CHF CI: Hypotension, hypovolemia
Hydralazine	0.5-1.5 mg/kg PO q12h 0.5 mg/kg IV	Arterial vasodilator (afterload reducer) Adverse effects: Transient weakness, lethargy, hypotension, tachycardia, sodium/water retention (unless given with diuretics)	I: CHF, mitral regurgitation CI: Hypotension, hypovolemia, severe renal disease
Milrinone	0.2 µg/kg IV bolus, followed by 10 µg/kg/min CRI 0.5-1.0 mg/kg PO q12h	Phosphodiesterase inhibitor (inodilator) Adverse effects: Arrhythmias, hypotension, tachycardia, accelerated AV conduction	I: Acute management of CHF CI: Normal or low filling pressures, severe renal failure
<b>DIURETICS</b>			
Furosemide	Initial dose for CHF: 1.0-3.0 mg/kg IV or IM q8-12h as needed to produce diuretic effect Alternatively: 0.12 mg/kg IV bolus, followed by 0.12 mg/kg/h CRI Maintenance dose: 1 mg/kg IV or IM q12h	Start at higher/more frequent doses and reduce to minimal effective dose. Oral administration may be ineffective due to inconsistent bioavailability. Adverse effects: At high doses risk of hypovolemia, renal failure, electrolyte and acid-base imbalances	I: Congestive heart failure, edema CI: Dehydration, severe electrolyte disturbances

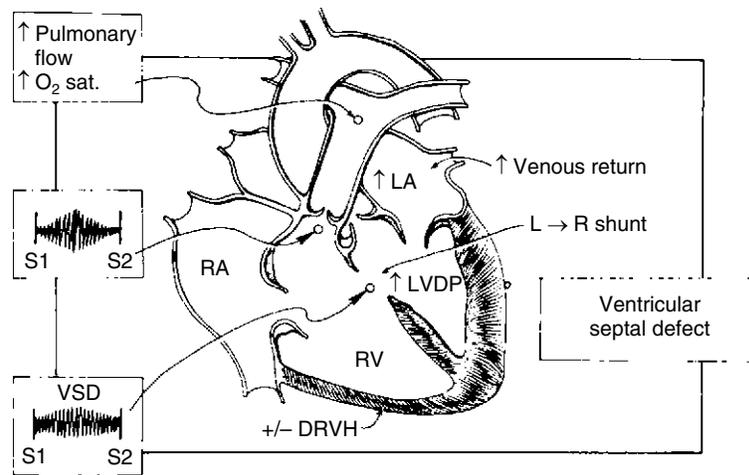

AF, Atrial flutter/fibrillation; AR, aortic regurgitation; AV, atrioventricular; CHF, congestive heart failure; CNS, central nervous system; CRI, constant-rate infusion; GI, gastrointestinal; HF, heart failure; IM, intramuscular; IT, intratracheal; IV, intravenous; MR, mitral regurgitation; NGT, nasogastric tube; PO, oral; RAAS, renin-angiotensin-aldosterone system; SA, sinoatrial; SVT, supraventricular tachycardia; VT, ventricular tachycardia.

**FIGURE 10-27** Pathologic evaluation of ventricular septal defects (VSDs). **A**, Opened right ventricle (RV) from a mare demonstrating a perimembranous septal defect opening just beneath the septal leaflet of the tricuspid valve. Aortic valve cusps are visible through the defect. Congestive heart failure (CHF) occurred late in life, after the development of atrial fibrillation (AF). **B**, A large VSD in a horse. A probe runs through the defect. The dorsal location immediately beneath the right and the noncoronary cusps of the aortic valve are notable. Ostia of both coronary arteries are also evident.

**FIGURE 10-28** Echocardiograms demonstrating ventricular septal defects (VSDs). **A**, This subaortic VSD is not evident from the long-axis image (*left panel*) but is visible in the short-axis tomogram (*arrows*). This Quarter Horse gelding also had pulmonic stenosis. The elevated right ventricular (RV) pressures have led to significant RV enlargement with bulging of the septum toward the left ventricle (LV). **B**, Malalignment and a perimembranous septal defect associated with prolapse of an aortic valve leaflet across the defect (*arrow*) (RVW, Right ventricular wall). **C**, Continuous wave Doppler study recorded from a foal with a small, restrictive VSD. The maximal velocity of nearly 6 m/sec (*arrow*) predicts a pressure difference of up to 144 mm Hg between left and right ventricles.

endocardial fibroelastosis,<sup>61,629</sup> total anomalous pulmonary venous return,<sup>630</sup> and aortic origin of the pulmonary artery have been reported but will not be discussed further. Some of the more frequently recognized defects<sup>342</sup> are described following.

## PATHOGENESIS OF CONGENITAL HEART DISEASE

The underlying genetic or other causative factors responsible for cardiac malformations in horses have not been studied. Potential but unproven causes include drugs, viral infection, environmental toxins, and nutritional disorders. Cardiac morphogenesis is complicated, but it is helpful to understand elementary aspects of cardiac development, especially as these pertain to CHD.<sup>631</sup> Among the fundamentals are septation of the atria, the anatomic components forming the ventricular septum, separation of the great vessels, and the normal fetal circulation.

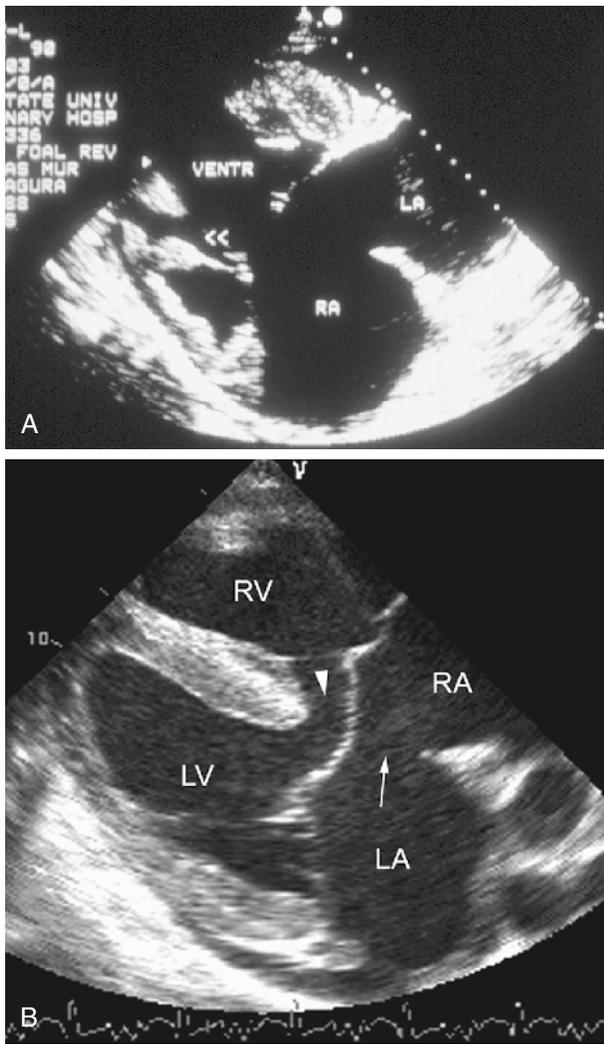

The right and left atria are separated by incorporation of the right horn of the sinus venosus and through development and fusion of two prominent membranes: septum primum and septum secundum. The endocardial cushions close the gap between the atrial and ventricular septa. These tissues also contribute to the atrioventricular septum, the septal segment spanning the point of mitral valve septal insertion on the left to the tricuspid valve insertion on the right. The foramen ovale, a normal atrial structure, is located approximately in the middle of the atrial septum, continues almost directly from the entry of the caudal vena cava, and creates a passageway for blood to flow from RA to LA in the normal fetus. The equine foramen ovale resembles a fenestrated finger cot and can be observed echocardiographically as a mobile septal membrane even in healthy, full-term foals. This interatrial path may persist in foals with pulmonary hypertension and elevated RA pressures. Failure of normal development can lead to an ASD, which is typically designated by the location of the defective membrane (Figure 10-30).

The ventricular septum is a complicated partition that includes a small membranous portion located opposite the aortic root and craniodorsal to the tricuspid valve, an inlet septum immediately below the septal tricuspid leaflet, an apically

located muscular or trabecular septum, and a dorsal outflow segment that separates the subaortic and the subpulmonic infundibulum. The ventral atrial septum connects to the dorsal ventricular septum by growth and differentiation of endocardial cushions. These swellings also form major parts of the atrioventricular valves. Insufficient development of any of these embryonic components can lead to a VSD, the most common cardiac malformation in horses. Defective differentiation of the endocardial cushions causes various combinations of an ostium primum (ventral) ASD, an inlet VSD, malformation of the atrioventricular valves, or common atrium with a single atrioventricular valve.

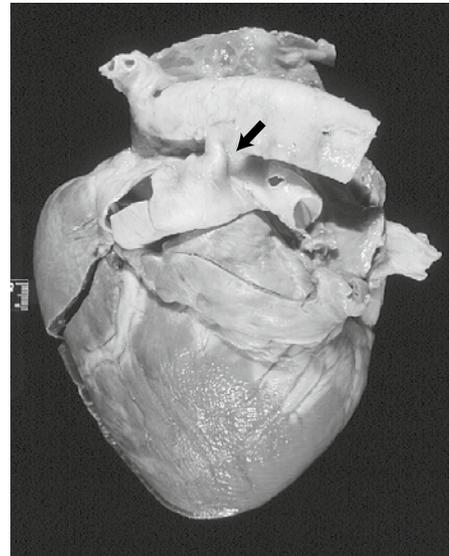

The aorta and pulmonary artery begin as a single vessel in the conus arteriosus. This common trunk or truncus arteriosus is eventually partitioned by migration of the conus and development of the conotruncal and spiral septa. Twisting of the spiral septum produces appropriate alignment (concordance) of the great vessels with their respective ventricular chambers. The descending aorta and pulmonary artery are connected by the ductus arteriosus, which carries fetal blood from pulmonary artery to descending aorta. Maldevelopment of conotruncal or spiral septal tissues leads to complicated congenital heart defects in the horse, including persistent truncus arteriosus,<sup>632</sup> double-outlet RV,<sup>598</sup> transposition of the great vessels,<sup>157,165,625</sup> and aorticpulmonary septal defect.<sup>626</sup> Persistence of the right aortic arch<sup>633,634</sup> and persistent PDA are both rare in horses (Figure 10-31).

There are two fetal circulations: one serving the embryo and the other communicating with the placenta. Functionally, two right-to-left shunts are present: one across the foramen ovale and the other across the ductus arteriosus. The fetal lungs are collapsed, pulmonary vascular resistance is high, and pulmonary blood flow is minimal. Desaturated blood returning from the fetal tissues is collected in the cardinal venous system and enters the sinus venosus and RA. This blood is largely earmarked for the RV and pulmonary artery. Most pulmonary arterial flow is diverted through the ductus arteriosus to the descending aorta and placenta where it is oxygenated. Well-saturated blood returning across the umbilical veins is delivered by the caudal vena cava to the RA, where it preferentially crosses the foramen ovale to enter the LA, LV, and ascending aorta. These patterns change dramatically with foaling. As the

**FIGURE 10-30** **A**, Echocardiogram demonstrating a primum atrial septal defect (ASD) in a foal with complex congenital heart disease that included a common (*left*) ventricle, rudimentary (*right*) ventricle, and double-outlet ventricle. The septal defect is evident between the four cardiac chambers. The dorsal secundum septum (*right*) is present, as well as the apical ventricular septum (*left*). **B**, Long axis image from a foal with a complete endocardial cushion defect. The primum ASD is evident in the ventral atrial septum (*arrow*), and an inlet ventricular septal defect (VSD) component (*arrowhead*) is observed below the closed common (or straddling) atrioventricular valve. Normal mitral and tricuspid septal leaflets would insert into the septum at slightly different levels (with tricuspid septal leaflet inserting more ventrally than the mitral septal leaflet).

lungs expand, pulmonary vascular resistance falls, and pulmonary blood flow increases. The resultant increase in LA pressure functionally closes the foramen ovale within the first 24 to 48 hours of life. Similarly, inhibition of local prostaglandins leads to functional closure of the ductus arteriosus within 72 hours in most full-term foals. Persistence of the right-to-left shunts, especially at the level of the foramen ovale, can occur in premature foals or those suffering from severe pulmonary disease with associated pulmonary hypertension. In these cases, shunting across the foramen ovale represents an additional mechanism for arterial desaturation and tissue hypoxia.

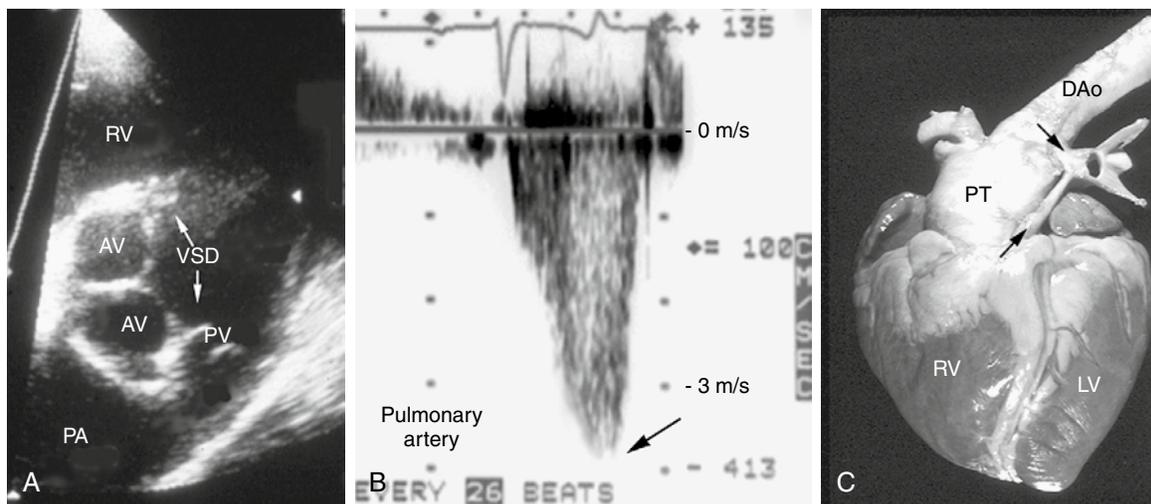

**FIGURE 10-31** A postmortem demonstration of the ductus arteriosus (*arrow*) between the descending aorta and the pulmonary artery in a foal with complex congenital heart disease.

### CLINICAL PATHOPHYSIOLOGY OF SHUNTS

Fundamental to understanding of cardiac malformations is an appreciation of shunt physiology and the responses of the heart and circulation to a shunt.<sup>596</sup> Shunting can be defined as an abnormal deviation of blood flow between systemic (left) and pulmonary (right) circulations. Shunting can be left-to-right, right-to-left, and bidirectional. Systemic to pulmonary (left-to-right) shunting is the expected consequence of an ASD, VSD, PDA, so long as systemic pressures and resistances exceed those on the right side and no stenosis limits PA flow. Even in cases of abnormal ventricular-arterial development, as with persistent truncus arteriosus, double-outlet RV, or univentricular heart, the clinical findings of a left-to-right shunt may predominate unless obstruction to blood flow or elevated pulmonary vascular resistance is seen.

The actual shunt volume carried to the lungs depends on the caliber (or “restrictive” nature) of the lesion orifice and the relative vascular resistances between systemic and pulmonary circulations. Shunting may not be significant for some weeks after foaling because pulmonary vascular resistance is relatively high and systemic arterial and LV pressures are relatively low. Eventually left-to-right shunts increase pulmonary arterial flow and augment pulmonary venous return. Small shunts are easily handled at the expense of mild left-sided dilation and hypertrophy. When the pulmonary to systemic flow ratio ( $Q_p:Q_s$ ) exceeds about 1.8:1, the shunt is usually considered clinically significant and the consequences are obvious volume overload of the LA and LV. The greater the shunt volume, the higher is the potential for left-sided or biventricular CHF from ventricular dysfunction. Pulmonary hypertension can occur in the setting of left-to-right shunting from combinations of increased PA flow, lesions in the small pulmonary arteries, and LV failure. Thus consequences of significant left-to-right shunting may include any of the following: exercise intolerance, tachypnea, pulmonary edema, respiratory distress, pulmonary hypertension, AF, pleural effusion, jugular venous distension, or ventral edema. The foal may be smaller than

**FIGURE 10-32** Phonocardiograms of cardiac murmurs caused by valvular heart disease. **A**, A holosystolic murmur of mitral regurgitation in a horse with chronic valvular degeneration. **B**, A variable, late systolic murmur of mitral regurgitation related to mitral valve prolapse. The murmur has a crescendo and peaks at end systole (arrow). Heart sounds are indicated. The murmur obscures the second sound. **C**, A holodiastolic, vibratory murmur of aortic regurgitation with presystolic accentuation. The accentuation probably is related to atrial contraction, altered ventricular volume and pressure, and an incremental increase in regurgitant volume. (From Bonagura JD: Congenital heart disease. In Robinson N, editor: Current therapy in equine practice, ed 5, Philadelphia, WB Saunders.)

expected and may have a history of antibiotic therapy for presumed bouts of “pneumonia.”

Right-to-left shunting produces a different clinical presentation. When a shunt is complicated by a right-sided obstruction downstream from the defect, right-to-left shunting will develop once right-sided pressures exceed those on the left. This can occur in a foal with tricuspid valve atresia and ASD or with pulmonary valve atresia and VSD. Conversely, elevated right-sided resistance can develop more chronically from pulmonary vascular disease. For example, a large left-to-right shunt can induce medial hypertrophy and intimal thickening of small pulmonary arteries that elevates pulmonary vascular resistance. Though very uncommon, the resultant pulmonary hypertension may become severe and reverse the shunt to right-to-left (Eisenmenger’s physiology). In these cases the left heart chambers are small and RV is hypertrophied to generate systemic BP.

The entrance of desaturated blood into the left side of the circulation causes arterial hypoxemia with potential consequences of tissue hypoxia, cyanosis, exercise intolerance, mild to moderate polycythemia, hyperviscosity of blood, and stunting of growth. CHF is rare, but sudden death can occur, presumably from arrhythmia. The degrees of hypoxemia and cyanosis in a right-to-left shunt depend on overall pulmonary blood flow and the degree of blood mixing between the circulations. Thus if pulmonary flow is markedly diminished, as with tricuspid atresia, then severe cyanosis is likely. However, effects of right-to-left shunting can be mitigated by overall increases in pulmonary blood flow as with truncus arteriosus or double-outlet RV without pulmonary obstruction. These lesions cause less hypoxemia because the volume of oxygenated blood reaching the LV is increased. The location or “commitment” of a VSD relative to the subaortic or subpulmonic region also influences clinical signs because oxygenated blood from the LV can actually stream preferentially through a VSD into the aorta. In these situations, cyanosis related to any mixing of blood in the RV may be negligible and the clinical condition predominated by

left-sided or biventricular CHF. If the increased pulmonary flow is sufficient to minimize arterial hypoxemia but not create heart failure, then survival even beyond 5 years of age is possible.

## VENTRICULAR SEPTAL DEFECTS

Ventricular septal defect is the most important CHD of horses.\* A genetic basis is likely in the Arabian breed, and Welsh Mountain ponies also appear to be predisposed to VSD. In the authors’ experience, VSD is also encountered regularly in Standardbred horses and in Quarterhorses. The VSD often accompanies more complicated heart malformations.

The location of a VSD depends on the embryogenesis of the lesion and influences the designation and even the clinical manifestations of the defect. The nomenclature of VSDs is confusing but can be remembered by considering the main components of the normal ventricular septum (see Figures 10-27 to 10-29). In most cases, a VSD is located dorsally (“high”) on the ventricular septum, below the right and noncoronary cusp of the aortic valve on the left side, craniodorsal to the septal tricuspid leaflet on the right, and encompassing or contiguous with the fibrous part of the ventricular septum.<sup>504</sup> Such defects are generally termed *perimembranous*, *membranous*, or perhaps more correctly, *paramembranous*. Most of these holes are also “subcrystal” because the VSD is located caudoventral to the supraventricular crest separating the RV inlet from the outlet. However, a very large paramembranous defect also can extend under the tricuspid valve toward the inlet septum or advance across the supraventricular crest toward the outlet septum. The (conotruncal-) septal defects associated with tetralogy of Fallot (Figure 10-32) and with pulmonary atresia are usually very large, and they fall into the latter appellation. Sometimes the aortic

\*References 131, 145, 151, 157, 162, 165, 479, 482, 504, 513, 528, 576, 596, 602, 608, 614-617.

root is displaced ventrocranially and straddles the defect, creating a “malalignment” VSD. This is characteristic of the tetralogy of Fallot, but it also can be seen with large, isolated paramembranous defects. Malalignment is clinically significant because the right or noncoronary cusp of the aortic valve is likely to prolapse into the defect leading to AR (see Figure 10-28, B). A less common location for a VSD is immediately ventral to the septal tricuspid valve within the muscular septum. Such “inlet” VSDs are typical of a complete endocardial cushion defect and commonly related to a primum ASD, common atrioventricular valve leaflet, or persistent atrioventricular canal, which creates a gap between all four cardiac chambers (see Figure 10-30, B).<sup>635</sup> A subaortic VSD that communicates with the outlet portion of the ventricular septum directly below the pulmonary valve is variably termed a *subarterial*, *outlet*, *supracristal*, *subpulmonic*, or *doubly committed* VSD. This lesion also places the aortic valve at risk for prolapse. Finally, apical muscular (trabecular) defects or multiple VSDs are rare, but they have been observed in horses. Some of these are small, whereas others have been enormous.

Many VSDs close spontaneously in people, but whether or not this is common in horses is unknown. However, the flow across a VSD can be diminished by imposition of a cardiac valve. For example the rim, or even a major portion of a VSD, may be occluded by fibrotic tissue that ensnares the septal tricuspid leaflet, rendering the defect functionally smaller and possibly creating a hyperechoic aneurysm on the right septal surface. Large defects associated with malalignment of the ascending aorta to the upper border of the remaining septum are often associated with prolapse of an aortic valve leaflet (or of the aortic root) into the defect. Aortic prolapse can effectively close even a large VSD but at the risk of permitting chronic aortic valve insufficiency over time.<sup>504</sup>

The pathophysiology of the uncomplicated VSD is that of a left-to-right shunt as described previously (see Figure 10-29). Much of the shunt volume pumped by the LV is ejected immediately into the PA. As pulmonary flow increases, increased venous return to the LA and LV is noted, causing LV dilation and hypertrophy that can be recognized by echocardiography. Thus the left (not the right) ventricle performs most of the extra volume work. This is made more severe if aortic valve prolapse with AR is seen or if MR develops owing to LV enlargement. If the shunt is large and pulmonary arteriolar resistance does not increase significantly, then LV failure can develop. This is most likely to occur early in life, as the high fetal pulmonary vascular resistance declines, but late cases of CHF (with AF) also have been observed. The degree of RV hypertrophy and enlargement varies, depending on the location and size of the septal defect and pulmonary vascular resistance. Large nonrestrictive defects create a functional common chamber, allowing ventricular pressures to equilibrate and leading to marked RV hypertrophy, as well as pulmonary hypertension.

The clinical features of VSD are variable.<sup>504,596</sup> Clinical signs may be absent and the defect identified as an incidental finding. A mature horse may be presented for poor performance or with AF. Foals may be symptomatic for pulmonary edema or biventricular heart failure. Most commonly, a murmur is detected incidentally during the physical examination for another problem or during a prepurchase examination (see Figure 10-10, B). Because most defects communicate near the tricuspid valve, the most consistent physical examination finding is a harsh, holosystolic murmur that is loudest just below the tricuspid valve region and above the right sternal border. A slightly less intense ejection murmur because of increased flow across the RV outlet is usually evident over the left base. The second heart

sound may be split more widely than normal, owing to disparate ventricular ejection times; the pulmonic component of  $S_2$  will be tympanic if pulmonary hypertension is noted. In contrast the murmur of a subarterial (subpulmonic or supracristal) VSD is loudest over the left cranial base as the high velocity flow enters the main PA. When VSD is associated with complex cardiac malformation, the murmur is likely to be loud over each side of the thorax. The severity of the defect cannot be judged based on murmur intensity. In some cases, a small defect may be quite loud; whereas, a large, less restrictive defect may cause a murmur related entirely to the increased flow (relative pulmonic stenosis). A holodiastolic murmur of AR indicates prolapse of an aortic cusp and the likelihood that the lesion is relatively large. Substantial AR is associated with a hyperdynamic arterial pulse. If significant LV volume overload occurs, then the mitral valve may become incompetent and a holosystolic murmur of MR may be evident over the left apex. The rare trabecular (muscular) VSD may also create a systolic murmur over the left or right apex. The VSD associated with pulmonary atresia or persistent truncus arteriosus may not create a substantial murmur, but the increased flow through the dilated single vessel usually generates a loud ejection murmur over each side of the chest. If significant cardiomegaly develops, then atrial and ventricular premature complexes, or even AF, may be recognized.

Diagnostic studies are needed to confirm the lesion and determine the severity. The performance history is a useful overall indicator of effect, and the horse with an excellent work history is unlikely to have a large defect. The ECG is unreliable for diagnosing cardiomegaly in horses but is indicated in the setting of an arrhythmia. Thoracic radiography can be useful in foals to demonstrate cardiomegaly (see Figure 10-20, A), the pulmonary circulation, the lungs, and the pleural space; 2D echocardiography and color Doppler imaging establish the diagnosis.<sup>478</sup> M-mode studies and spectral Doppler examinations are useful for assessing the hemodynamic burden of the defect.

The VSD is delineated successfully using 2D echocardiography in almost every case, provided sufficient imaging planes are obtained (see Figures 10-24 and 10-28). It is important to collect long axis images of the LV outflow tract and aortic valve, as well as a short axis images at the level of the LV outflow tract, at and just ventral to the aortic leaflets. The typical paramembranous defect appears under the aortic valve and adjacent to the septal leaflet of the tricuspid valve. A true defect is characterized by a relatively echogenic tissue interface; whereas, an area of false echo dropout tends to be gradual. Most defects can be imaged in orthogonal (long axis/short axis) planes. The ostium of the right coronary artery of the horse is relatively large and may be confused with a subarterial (supracristal) VSD in short axis image planes. It also should be noted that a true inlet VSD of an endocardial cushion defect located immediately ventral to the septal tricuspid valve might not be easily seen in standard planes. Tipped or oblique views that show both atrioventricular valves may be required. Similarly, finding a muscular, apical, or small subarterial defect requires more imaging experience and is greatly assisted by color Doppler studies.

Attempts should be made to identify the largest diameter of the defect in complementary planes and compare this with the size of the aortic root, because orifice size is an important prognostic factor. While there are limitations to 2D sizing of the VSD, a defect exceeding 2.5 cm in diameter or a VSD/aortic root diameter of greater than 0.4 identifies a large defect with greater likelihood of clinical signs. Furthermore, 2D or M-mode evidence of left-sided cardiac dilatation, RV enlargement, or marked dilation

of the main PA suggests a hemodynamically significant VSD and one more likely to affect performance or survival.

Identification of shunting across a VSD is confirmed using color Doppler studies. There will typically be high-velocity, turbulent flow entering the RV during systole with low velocity, uniform color shunting noted during diastole. Color Doppler imaging is extremely helpful for identifying a very small VSD or one with an atypical location. AR is identified in some horses, and the regurgitant flow is often directed into the VSD resulting in high-velocity diastolic shunting. Continuous wave Doppler is used to estimate the pressure difference between the two ventricles, because velocity (in m/sec) is proportional to the instantaneous pressure difference across the ventricles (by the modified Bernoulli equation:  $\Delta P = 4V^2$ ; see Figures 10-24, D, and 10-28, C). A relatively small VSD is "restrictive" to flow, and the peak shunt velocity will generally exceed 4.5 m/sec, assuming proper alignment to shunt flow. In the setting of pulmonary hypertension, pulmonic stenosis, or systemic hypotension, the velocity of left-to-right shunting will be lower; when pulmonary hypertension is present, a TR jet of greater than 3.5 m/sec may be identified.

Potential outcomes of the isolated VSD include the following: (1) tolerance of the lesion; (2) partial or complete closure of a VSD by adherence of the septal tricuspid leaflet, fibrous tissue, RV hypertrophy, or aortic valve prolapse; (3) progressive AR, (4) AF; (5) left-sided or biventricular CHF, (6) pulmonary hypertension (with left-to-right shunting); or (7) reversal of the shunt with development of arterial hypoxemia and cyanosis. The last situation would be caused by either severe pulmonary vascular disease (Eisenmenger's physiology) or fibromuscular obstruction in the RV outlet leading to subpulmonic stenosis. The horse with a relatively small-diameter paramembranous defect, high-velocity left-to-right shunt, mild cardiomegaly, relatively normal RV cavity, and normal heart rhythm probably has a restrictive VSD that will be well tolerated. Most of these animals can perform sufficiently in the show ring, as hunter-jumpers, or even as endurance horses or racehorses. Large defects that are associated with echocardiographic evidence of moderate to severe cardiomegaly, RV hypertrophy, aortic root prolapse, or Doppler evidence of pulmonary hypertension are prone to complications and carry a less favorable prognosis for performance or life regardless of current clinical signs.

Definitive therapy for VSD involves cardiopulmonary bypass surgery and is impractical. Surgical banding of the PA elevates RV pressures and reduces left-to-right shunting; however, this procedure also limits CO and is not advised. New "hybrid" procedures involving catheter devices delivered by a transventricular approach and guided by epicardial echocardiography are now possible, although perhaps not practical. Medical management of CHF or of arrhythmias associated with CHD can be considered. However, even if the response to treatment is good, then the horse should not be used. In the authors' view, breeding of affected animals generally should be discouraged, especially in Arabian horses.

### ATRIAL SEPTAL DEFECTS

Atrial septal defects, including endocardial cushion defects, are quite uncommon in foals.\* As indicated earlier, an ASD may involve different portions of the atrial septum and is more likely

to be observed with complex congenital cardiac defects, particularly with tricuspid or pulmonary atresia. An isolated ASD may be clinically insignificant, with no significant murmur or clinical signs. Moderate to good exercise capacity may be expected because left-to-right shunting decreases as the systemic to pulmonary vascular resistance ratio declines with exercise. In the case of a large ASD, left-to-right shunting leads to right-sided volume overload and pulmonary overcirculation and potentially to pulmonary vascular injury. Large defects are visible echocardiographically (see Figure 10-30, A), and Doppler echocardiography can confirm the direction of the shunt and estimate its severity. AF has been observed in conjunction with ASD.

Complete endocardial cushion defects are rarely seen but are serious, usually leading to CHF or AF at an early age. Components of this defect typically include a large ASD involving the primum and the atrioventricular septa, a common atrioventricular valve leaflet, and often an inlet VSD (see Figure 10-30, B). The ventricles may be partitioned normally, unequally with one rudimentary ventricular chamber, or not at all, creating a single ventricle. In the most severe cases, there is a common atrioventricular canal, a single common atrioventricular valve, and a single ventricle from which both great vessels exit. The clinical signs of a complete endocardial cushion defect are variable. The foal with two ventricles and an unobstructed outlet to the pulmonary arteries will be hemodynamically similar to one with a large VSD. When a common ventricle is present, varying degrees of cyanosis may be observed. A systolic murmur is typical and may reflect flow across the VSD, ventricular outflow, or atrioventricular valve regurgitation. A 2D echocardiogram can reveal the lesions, and Doppler echocardiography can reveal the intracardiac shunts and AV valvular regurgitation. CHF may supervene, and the prognosis is poor.

### PATENT DUCTUS ARTERIOSUS

Patent ductus arteriosus is rare as an isolated congenital cardiac defect in foals and is detected most frequently in combination with other, more complex malformations (see Figure 10-31).\* The ductus arteriosus is a fetal vessel, derived from the left sixth aortic arch, which permits shunting from the PA to the descending aorta in the fetus. At birth the ductus arteriosus normally constricts, in response to increased local oxygen tension and inhibition of prostaglandins. It is functionally closed 72 hours after birth in the vast majority of foals. If the ductus arteriosus does not close, then a left-to-right shunt from the aorta to PA occurs. Although there may be some hereditary predisposition to PDA in other species, this lesion is so rare as an isolated congenital defect that this is not a significant concern. Premature foals, foals with persistent pulmonary hypertension, and foals whose dams have been given prostaglandin inhibitors may be more susceptible to the development of a PDA.

The clinical signs depend on the magnitude of the shunting through the PDA, which is determined by ductal diameter and vascular resistance in the pulmonary circulation. Physical examination findings (with a left-to-right PDA) include a continuous machinery murmur and thrill, usually loudest over the main PA (craniodorsal to the aortic valve area), and bounding arterial pulses. Differential diagnosis includes other systemic to pulmonary shunts in association with complex congenital heart disease.

\*References 131, 159, 161, 163, 513, 528, 578.

\*References 156, 159, 165, 168, 265, 367, 575, 597, 601.

Echocardiography will reveal volume overload of the PA, LA, and LV. The severity of these findings depends on the magnitude of the shunt. Direct visualization of the PDA is not always possible by 2D echocardiography, because overlying lung may obscure the ductus arteriosus. Ductal flow is best identified from the left cranial thorax by Doppler echocardiographic examination of the main PA that reveals continuous, high-velocity, turbulent flow directed toward the pulmonary valve. Cardiac enlargement and increased pulmonary vascularity may be detected in neonatal foals with a PDA, as well as radiographic evidence of pulmonary edema if the foal has developed CHF. Cardiac catheterization reveals elevated PA and capillary wedge pressures and increased PA oxygen saturation. The heart should be evaluated carefully for other congenital cardiac defects before surgical or catheter-based intervention is considered, because complex cardiac malformations are likely in a foal with PDA. Late complications of this lesion include rupture of the PA.

### TETRALOGY OF FALLOT

The tetralogy of Fallot is one of the more common congenital cardiac anomalies in foals responsible for right-to-left shunting, arterial desaturation, and cyanosis.<sup>156,162,167,528</sup> The four lesions are large paramembranous outlet VSD, RV outflow tract obstruction, cranial and rightward (dextro-) positioning of the aorta with overriding of the septal defect, and RV hypertrophy. Outflow obstruction can be the result of subvalvular fibromuscular obstruction, valvular pulmonic stenosis, or hypoplasia of the PA. Ventricular hypertrophy is caused by RV outflow obstruction and the large, unrestrictive, VSD that functionally creates a “common ventricle.” Blood leaves the heart along the path of least resistance such that pulmonary flow depends on the severity of RV outflow tract stenosis. As previously discussed, the degree of cyanosis and severity of clinical signs depends on the volume of blood traversing the lungs. In some horses, a PDA is also present (pentalogy of Fallot), and this defect reduces signs by increasing pulmonary flow, left heart filling, and systemic arterial hemoglobin saturation.

Affected foals are usually smaller than normal, lethargic, and intolerant of exercise. Cyanosis is most evident after activity and is variably present at rest. Arterial blood gas analysis demonstrates hypoxemia with normal or reduced partial pressure of carbon dioxide ( $P_{aCO_2}$ ). Auscultation is typically characterized by a loud systolic murmur over the pulmonic valve area on the left side caused by (sub-) pulmonic stenosis. The second heart sound is usually unremarkable. Although polycythemia can be significant, it is usually mild, even when arterial oxygen tensions fall to 50 to 70 mm Hg.

Echocardiographic evaluation is diagnostic and reveals a large, unrestrictive VSD, RV outflow tract obstruction, malalignment and overriding of the aortic root, and RV hypertrophy (see Figure 10-32). Shunting can be identified by color Doppler or saline contrast echocardiography initiated by injection of agitated saline into the jugular vein. Both studies will demonstrate a right-to-left or bidirectional shunt. Conventional spectral Doppler studies can be used to delineate the shunt (typically bidirectional, low-velocity flow of <2 m/sec) and RV outflow obstruction (high-velocity flow exceeding 4 m/sec).

Although it is possible for horses to live for a number of years with tetralogy of Fallot, most affected animals are humanely destroyed because of the poor prognosis for life. Affected horses should not be used or bred if they survive to maturity. Tetralogy of Fallot must be distinguished from other

causes of cyanotic heart conditions, including tricuspid atresia, pulmonary atresia with VSD, D-transposition of the great vessels, and double-outlet RV with pulmonary stenosis.

### PULMONARY ATRESIA WITH VENTRICULAR SEPTAL DEFECT

Pulmonary atresia with VSD is rare, having been observed most often in Arabian foals (see Figure 10-32, C).<sup>156,616,621,636</sup> This malformation represents the exaggerated form of tetralogy of Fallot, with these findings: (1) the RV outlet does not connect into the pulmonary artery, (2) the RV hypertrophied, (3) a large malalignment VSD is present (in most cases), and (4) the fetal truncus arteriosus has been partitioned so unequally that the aorta is markedly dilated and the pulmonary trunk atretic or severely hypoplastic. Without careful ultrasound studies (or necropsy dissection) of the pulmonary circulation, the dilated aorta can be mistaken for a persistent truncus arteriosus, hence the moniker *pseudotruncus arteriosus*. Owing to the atretic pulmonary valve, pulmonary blood flow must be derived either from a PDA or the aorta. In the latter instance, the systemic collaterals are usually from bronchial arteries. Pulmonary atresia with intact ventricular septum has been diagnosed rarely.<sup>622</sup>

The diagnosis of pulmonary atresia is usually stimulated by clinical findings of cyanosis, cardiac murmur, and stunting in a foal or weanling. Diagnosis is confirmed by echocardiography. Careful imaging can identify the main lesions outlined previously. Of diagnostic importance is the inability to identify the pulmonary valve in the rudimentary RV outflow tract (though a small pouch may be seen). Careful ultrasound examination of the ascending aorta and aortic arch from the right and left sides of the thorax will fail to reveal a normal origin for the pulmonary trunk or an origin of the PA directly from a truncus arteriosus. The bifurcation of the PA may be found from a cranial imaging position, and continuous flow into that vessel documented by Doppler echocardiography suggests that pulmonary blood flow is derived from the ductus arteriosus or a collateral systemic artery.

### TRUNCUS ARTERIOSUS

The failure of the fetal truncus arteriosus to partition into the aorta and PA represents a rare anomaly of the equine heart.<sup>164,615</sup> In this condition the fetal truncus never partitions and both ventricles continue to develop, communicating with the truncus arteriosus across a large malalignment type VSD. Systemic, coronary, and PA flows each arise from the truncus, which is guarded by a truncal valve (that can be incompetent or stenotic). Pulmonary blood flow originates from one or more pulmonary arteries connected directly to the truncus arteriosus (types I, II, III truncus) or indirectly from systemic to pulmonary collateral vessels (type IV truncus in older nomenclatures).

The pathophysiology and clinical findings of this malformation depend largely on the magnitude of pulmonary blood flow. If the PA origins are not stenotic and if pulmonary vascular resistance remains relatively low, then the clinical condition resembles a left-to-right shunt, except for right-to-left mixing of blood across the VSD. However, the degree of arterial hypoxemia may not be severe and cyanosis may not be obvious. Conversely, high pulmonary vascular resistance or obstruction to flow at the truncal origin of the PA is associated with arterial desaturation and findings similar to pulmonary atresia.

Clinical examination usually indicates a systolic cardiac murmur. The mucous membranes may be pink or cyanotic. If marked left-to-right shunting is noted, then CHF may occur. With careful ultrasound examination, the truncus and origin of the pulmonary arteries may be identified, allowing the condition to be distinguished from pulmonary atresia with VSD. Furthermore in some cases an abnormal truncal valve (with four leaflets) may be evident, further supporting the diagnosis. Management is best accomplished by consultation with a cardiac specialist.

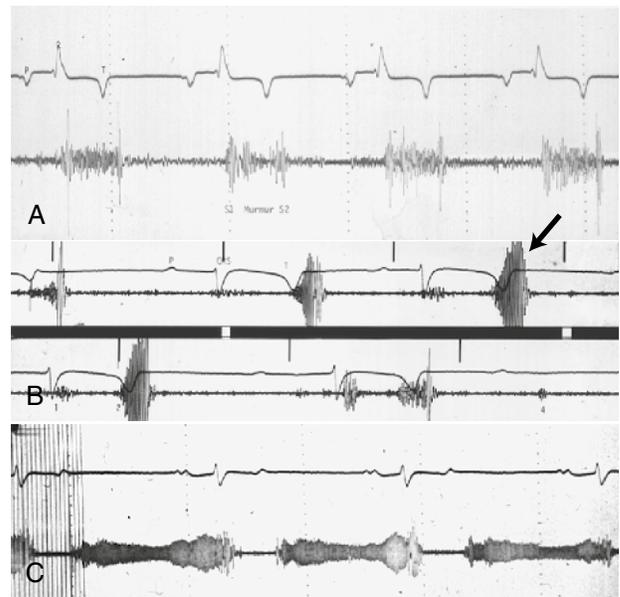

### TRICUSPID ATRESIA

Another differential diagnosis for cyanotic heart disease is atresia of the tricuspid valve.<sup>151,156,163, 165,636-638</sup> This malformation dictates right-to-left shunting of systemic venous blood at the atrial level. The atrial shunt may be across a true ASD or a patent foramen ovale. Because all venous return must mix in the LA, this malformation generally causes marked hypoxemia with cyanosis. Affected foals rarely survive to weanling age unless there is a left-to-right shunting VSD into a functional RV outflow tract that provides good pulmonary flow. Otherwise, pulmonary flow must come from a ductus arteriosus or systemic collaterals (e.g., bronchial arteries). Most foals are stunted, nurse poorly, and exhibit severe exercise intolerance and cyanosis at rest. Arterial oxygen tension can be very low (40 to 60 mm Hg). Echocardiography reveals a markedly dilated RA and coronary sinus, atretic tricuspid valve, and rudimentary RV (larger if a functional left-to-right shunting VSD exists). Atrial shunting that allows systemic venous return to empty into the LA must be observed. Abnormal flow patterns can be verified by contrast or color Doppler echocardiography. Prognosis is grave.

## ACQUIRED VALVULAR HEART DISEASE

Healthy cardiac valves maintain normal antegrade flow in the heart and prevent significant regurgitation of blood. Diseased cardiac valves, which can be stenotic or incompetent, limit CO and place an increased workload on the heart. Stenotic valvular lesions in horses are typically congenital in nature and are extremely rare.<sup>126,156,157,168</sup> However, acquired valvular regurgitation (also called *valvular insufficiency* or *valvular incompetency*) is very common.\* The majority of valvular diseases in horses are degenerative in nature or related to high-level training.† Infective (bacterial) endocarditis, ruptured chordae tendineae, and inflammatory valvulitis are infrequent causes of valvular dysfunction. Box 10-2 summarizes important causes of valvular dysfunction. Degenerative valvular disease and infective endocarditis are the valvular problems most often encountered by the equine practitioner (and the focus of this section).

The clinical significance of a valvular lesion depends largely on the severity of regurgitation across the valve. It is clear that many horses adapt to trivial or mild valvular regurgitation with no apparent consequence on performance.<sup>643</sup> The severity of valvular regurgitation is related to the dynamic cross-sectional area of the regurgitant orifice, the pressure gradient driving blood across the valve, and the time allowed for

**FIGURE 10-33** Phonocardiograms of cardiac murmurs caused by valvular heart disease. **A**, A holosystolic murmur of mitral regurgitation (MR) in a horse with chronic valvular degeneration. **B**, A variable, late systolic murmur of MR related to mitral valve prolapse. The murmur has a crescendo and peaks at end systole (arrow). Heart sounds are indicated. The murmur obscures the second sound. **C**, A holodiastolic, vibratory murmur of aortic regurgitation (AR) with presystolic accentuation. The accentuation probably is related to atrial contraction, altered ventricular volume and pressure, and an incremental increase in regurgitant volume.

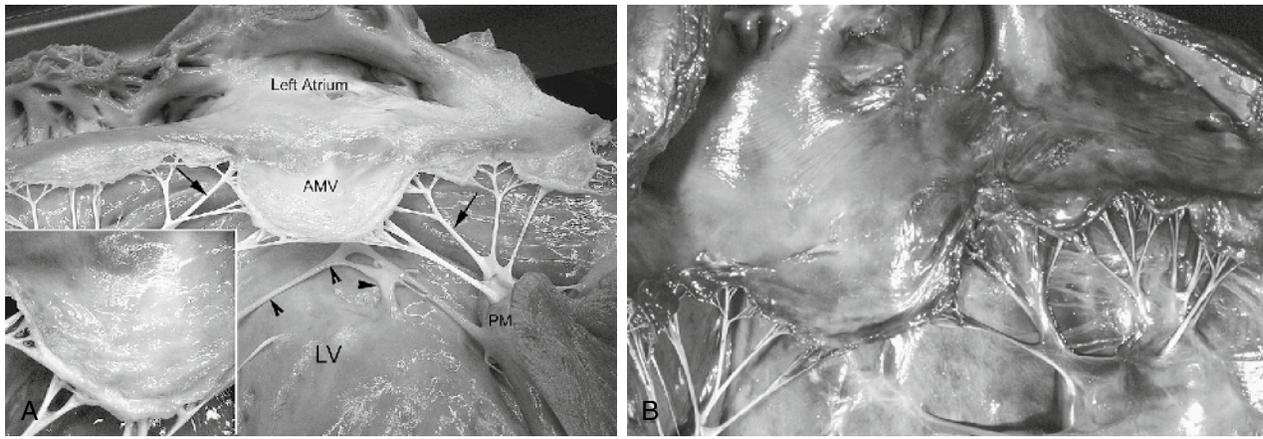

regurgitation, because not all incompetent valves leak throughout systole or diastole. Regardless of the volume, the movement of blood from a high to low pressure chamber is associated with a high-velocity jet that is proportional to the pressure drop between source and sink. The production of high-velocity jets leads to disturbed flow (with turbulence) and in many cases an audible cardiac murmur, the hallmark clinical feature of valvular heart disease (see Figures 10-10 and 10-22, D; Figure 10-33).

Valvular incompetency may be diagnosed by auscultation or with Doppler echocardiography.<sup>129,354,509</sup> Doppler studies are highly sensitive for identification of valvular incompetency and represent the gold standard for identification of valvular dysfunction. However, many horses with normal auscultation findings also demonstrate valvular regurgitation by Doppler examination. Most cardiologists consider these “silent” valvular leaks as normal,<sup>354</sup> especially when observed on the right side of the heart. Even on the left side, silent regurgitation is often observed by color Doppler examination.

Some of these flow signals are brief, representing “backflow” or valve closure signals; these are easily misinterpreted unless carefully timed by spectral Doppler or color M-mode examinations. Certainly some cases of silent regurgitation represent the earliest signs of degenerative valvular disease. However, there is no clinical benefit to screening horses by Doppler, and the approach is neither practical nor predictive of future outcome. Thus cardiac auscultation remains the most clinically important method for identifying *significant* valvular disease. Echocardiography including Doppler studies is used to verify the source of a pathologic murmur, identify heart lesions responsible, assess ventricular function, and quantify the degree of cardiac remodeling that has developed in response to the

†References 31, 90, 91, 109, 125, 135, 138, 139, 142-144, 147, 148, 169, 170, 172-178, 185, 509, 642.

**FIGURE 10-34** **A**, Postmortem images from a horse with mitral regurgitation (MR) and congestive heart failure (CHF) caused by severe degenerative valvular disease. The left ventricle (LV) is opened and the septal or anterior mitral valve leaflet (AMV) is shown. The free edges of the valve or cusps are slightly thickened for an equine valve. The body of the valve is very irregular and thick, changes most evident when viewed in close-up (see inset at lower left). The cut surface of a papillary muscle (PM) and intact chordal attachments to the valves are evident (*arrows*). The arrowheads (*left*) point to the LV moderator band or trabeculae septomarginalis, part of electrical conduction system. Myxomatous degeneration of the valve was evident on histopathology. The cause was unknown. **B**, Chronic suppurative valvulitis caused by chronic endocarditis has led to scarring, thickening, and distortion of the mitral valve. This horse developed severe left-sided CHF. Noninfective valvulitis also is recognized sporadically in horses, particularly in younger animals.

lesion. It is also emphasized that there is no echocardiographic or Doppler correlate to the functional ejection murmur.

Although examiners usually discount “silent” regurgitation, the clinical significance of *audible* valvular regurgitation also must be placed in context. For example, examination of high-performance athletes will demonstrate murmurs of tricuspid, mitral, or aortic valvular insufficiency in many of these horses. These findings are readily verifiable by Doppler imaging. In one study of 2-year-olds,<sup>509</sup> the prevalence of tricuspid and mitral regurgitant murmurs increased significantly over a 9-month training period to an incidence of 25.5% and 21.8%, respectively. The causes of these changes and the interpretation of these findings are problematic, especially when referenced to the clinical benchmark of “normal.” It is possible that high-level training induces changes in ventricular geometry or in valvular thickness related to CV work, elevations of BP during training, or other factors. Nevertheless, whether these murmurs are actually “normal” or not, it is clear that the *clinical importance* of a regurgitant murmur in a horse must be interpreted with caution and certainly with the perspective of clinical and imaging findings.

The most practical evaluations for assessing the significance of a heart murmur are the work history, physical examination findings, and echocardiography. Other studies such as electrocardiography and exercise testing provide further information by which to judge the importance of a murmur. As a general rule, significant regurgitant murmurs tend to be loud and long. However, the intensity of an insufficiency murmur is related not only to the regurgitant volume but also to the driving pressures of blood and the physical characteristics of the thorax. Therefore although the examiner can grade the intensity of a heart murmur (see earlier in this chapter), it is not possible to grade the severity of regurgitation by auscultation alone. Relatively loud murmurs may be associated with regurgitant volumes that are inconsequential to an individual horse, especially when the murmur is high-pitched, vibratory, or musical in quality. Thus

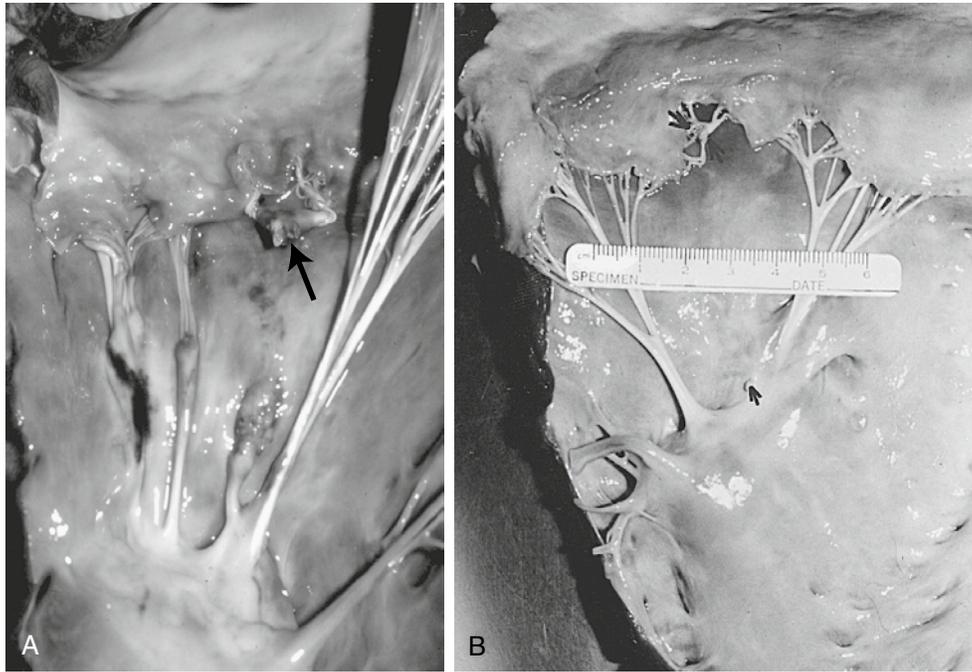

although clinically significant valvular heart disease is best *identified* by auscultation (see [Tables 10-2](#) and [10-3](#)), the *clinical relevance* of a valvular regurgitation must be assessed in other ways.\* This approach is emphasized as follows.

## MITRAL REGURGITATION

Mitral regurgitation is one of the more common murmurs detected in horses. The etiopathologic basis of mitral valve incompetency may involve any of the following: high-level training, degenerative thickening, idiopathic disease, prolapse of the valve, ruptured chordae tendineae, bacterial endocarditis, noninfective valvulitis, primary or ischemic myocardial disease, and congenital malformation of the valve ([Figures 10-34](#) and [10-35](#)).† Degenerative, fibrotic thickening of the mitral valve has been observed at necropsy in mature horses and is probably the basis for most cases of mild to moderate MR, including those with “normal” 2D echocardiographic imaging. The basis of mitral valve prolapse is uncertain but could involve connective tissue disease of the leaflets, stretched chorda tendineae, minor chordal ruptures, or injury to a papillary muscle. Ruptured mitral valve chordae tendineae with flail mitral leaflet can occur in animals of any age, including foals. Chordal ruptures, which often involve the accessory mitral cusps, may lead to severe MR with fulminant CHF. Necropsy findings in these cases often show degenerative thickening of the ruptured strand; rarely endocarditis is involved. Although uncommon, infective endocarditis can lead to ulceration, vegetation, or chordal injury and substantial MR (see later). The authors have observed MR because of severe mitral

\*References 129, 130, 145, 278, 346, 354, 509.

†References 4, 38, 45, 48, 77, 109, 111, 124, 125, 128, 130, 132, 136, 138, 139, 141, 143, 144, 147, 148, 186, 366, 483.

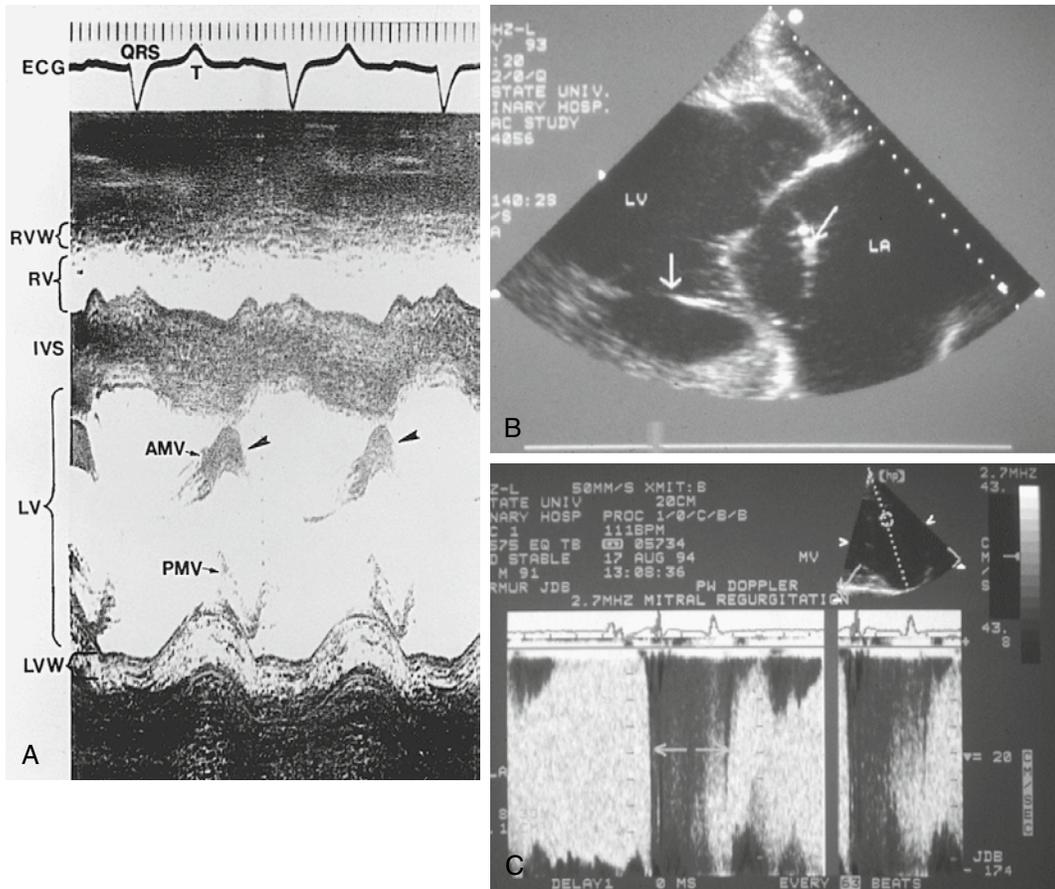

**FIGURE 10-35** Rupture of the mitral valve chordae tendineae. **A**, Acute rupture of a chorda tendinea in a horse with lymphocytic plasmacytic valvulitis. The flail mitral cusp actually has twisted because of loss of support (*arrow*). The ventral portion of the tear is obvious adjacent to intact chords. **B**, Chronic rupture of a chorda tendinea in a horse. The contraction of the scarred segments (*arrow*) is notable.

scarring and thickening in young and mature horses. The cause of these lesions is unknown, but the nonsuppurative valvulitis identified might be related to an immune-mediated process. Cardiomyopathy, myocarditis, or myocardial infarction can lead to valvular insufficiency through dilatation of the mitral annulus or loss of papillary muscle support.

The *clinical presentation* of the horse with MR varies. MR is often an incidental finding detected during a routine examination. In other situations MR may be identified in a horse with suboptimal performance or overt clinical signs of heart failure. As indicated previously, relatively soft murmurs of MR are very common in high-performance horses.<sup>509</sup> When MR is only mild to moderate, significant LA dilatation and LV volume overload are not evident, LA pressure (as estimated by pulmonary capillary wedge pressures) increases little compared with healthy controls,<sup>311</sup> and the horse often performs satisfactorily. Two recent retrospective studies also suggest a good long-term prognosis for cases of mild MR in sport and pleasure horses<sup>567</sup> and in middle-aged to older horses and ponies<sup>643</sup> with left-sided valvular regurgitation. With moderate to severe MR, clinical signs are more likely, including poor performance, exercise-induced pulmonary hemorrhage, or overt CHF. Tolerance of the lesion depends largely on whether the horse is used for vigorous work. Some horses with MR also develop AF, which can further impair CO. When a murmur of MR is identified within the setting of fever, weight loss, polyarthritis, or systemic inflammation, infective endocarditis should be considered. MR related to chordal rupture is a rare but well-recognized cause of CHF, including peracute disease with fulminating pulmonary edema (see [Figure 10-11](#)). Chronic, hemodynamically significant MR from any cause can lead to pulmonary hypertension, AF, and biventricular CHF, with clinical signs of right-sided CHF dominating the clinical presentation (see earlier in this chapter).<sup>48,109</sup>

The *physical examination* of the horse with MR typically reveals a grade 2 to 5 (of a possible 6) holosystolic or pansystolic murmur. The murmur is detected most intensely at or dorsal to the palpable left apical impulse and over the mitral valve area (see [Figure 10-8](#)). Quite often the murmur is loud at the aortic valve, probably related to the proximity of the septal leaflet to the aortic valve or to cranial projection of the regurgitant jet. Loud MR murmurs often project quite dorsally and to the right. The typical murmur of MR is long (holosystolic or pansystolic), extending into the second sound.<sup>38</sup> This timing may cause the listener to misinterpret the third sound as the second, thus preventing a full appreciation of the significance of the murmur. When the third sound is very loud, the clinician should consider significant volume overload or increased LV diastolic pressure. Because many horses with MR also have concomitant TR, echocardiographic examination and Doppler studies may be needed to differentiate bilateral AV valve insufficiency from isolated MR with radiation to the right. Finally, AF or premature beats can modify the murmur of MR.

Two variants of holosystolic MR murmur are the protomesosystolic decrescendo murmur and the mid-to-late systolic crescendo murmur. A decrescendo murmur may be detected with mild MR because coaptation of the leaflets can occur as the ventricular volume decreases during late systole. This type of murmur can be easily confused with a functional ejection murmur, unless the point of maximal murmur intensity is centered near the left apex. Conversely, severe MR with CHF could conceivably cause a decrescendo murmur because atrial and ventricular pressures may equilibrate in late systole. However, this is not a common finding and would be associated with CHF. The other variant of MR is the mid-to-late systolic crescendo murmur (see [Figure 10-33, B](#)). Presumably this murmur is caused by mitral valve prolapse as it starts *after* the LV

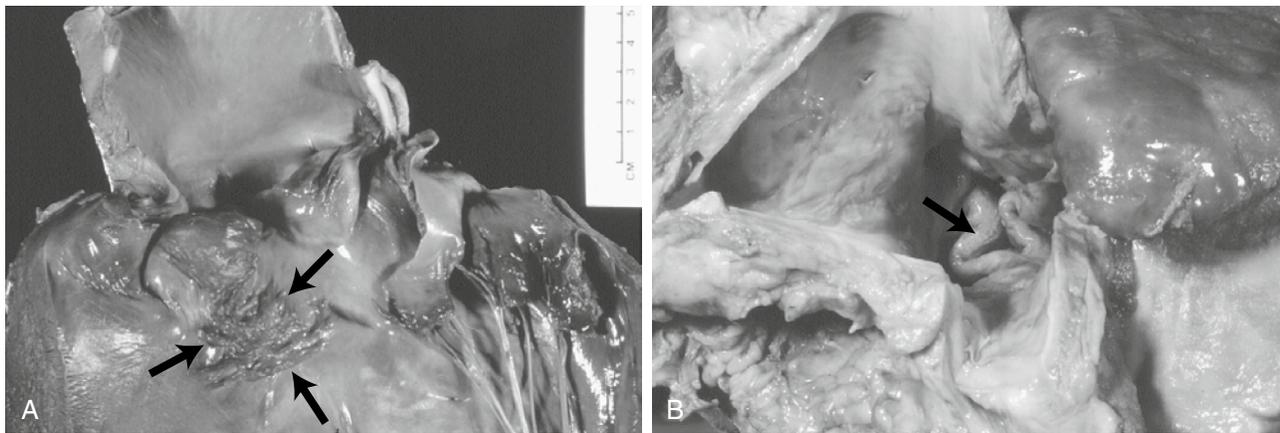

**FIGURE 10-36** Echocardiograms recorded from horses with mitral regurgitation (MR). **A**, M-mode study demonstrating significant thickening of the anterior mitral valve (AMV) leaflet (arrows). This would be compatible with endocarditis or severe valvulitis (RVW, right ventricular wall; RV, right ventricle; IVS, intraventricular septum; LV, left ventricle; LVW, left ventricular wall). **B**, Flail mitral leaflet (right arrow) in a horse with multiple chordae ruptures. The prolapsed portion of the mitral valve forms a curved echodense line in the dilated left atrium (LA), whereas the other valve portions are to the left of this echocardiogram. A normal chord is evident (left arrow). **C**, Pulsed-wave Doppler study recorded from the LA demonstrating a turbulent, high-velocity, aliased systolic jet of MR in a Thoroughbred horse. The duration of the event is shown (arrows).

has begun ejection. Decreasing LV volume predisposes to leaflet prolapse and initiates midsystolic regurgitation that builds through the second heart sound. The resultant murmur can be harsh or musical, and the novice often confuses this flow event with an early diastolic murmur.

Both *echocardiography* and *Doppler examinations* play a pivotal role in the assessment of the horse with MR\* (Figure 10-36); they are indicated to examine the valve anatomy; estimate the severity of MR; measure the size of the atria, ventricles, and great vessels; and quantify LV systolic function. The underlying cause of MR may be obvious from the echocardiographic examination. Mild to moderate valvular thickening, although admittedly subjective, is compatible with degeneration or non-bacterial valvulitis. Prolapse of the mitral valve cusps has been observed in horses with MR, but the limits of “normal” prolapse require further definition. Lesions caused by vegetative endocarditis cause the valves to appear irregularly thickened or shortened. In cases of acute endocarditis, evidence of valve

thrombus can be seen; a high frame rate, real-time examination may show oscillation of this tissue. Small, focal lesions are more commonly observed on the atrial surface of the valve (see Figure 10-43, B). In chronic endocarditis, the valve may be more echodense or even appear calcified. Chordal rupture is recognized by observing chaotic flutter of a mitral structure (a flail leaflet), prolapse of a large portion of the valve into the atrium, or the contracted chordal remnant flipping into the atrium during systole (see Figure 10-36). High-frequency systolic vibrations of the mitral valve may be seen on the M-mode study in horses with a musical murmur of MR. Pulsed or continuous wave or color-Doppler studies can identify the mitral regurgitant jet (see Figure 10-36). The Doppler examination should be performed from both right- and the left-sided thoracic windows. High-velocity or turbulent jets may be difficult to find without a complete and thorough examination of the mitral valve that involves multiple image planes. When color-flow Doppler demonstrates both a wide *origin* of the regurgitant jet and a pattern of diffuse distribution of turbulence deep into the LA, the likelihood of hemodynamically significant MR is greater. Quantitation of cardiac size is instrumental in assessing

\*References 129, 130, 354, 505, 509, 510.

**FIGURE 10-37** Postmortem lesions of aortic regurgitation (AR; see also Figure 10-41, B). **A**, A segment of the left ventricular (LV) outflow tract and the ascending aorta. Linear bands are evident on the two valves shown, and a large jet lesion also is visible below the valves (*between the arrows*). The lesion is typical in aged horses. **B**, The aortic valve (*arrow*) viewed from the ascending aorta. Noninfective valvulitis and scarring have caused severe thickening.

severity. With severe MR and LV volume overload, rounding of the LV apex and increased end diastolic dimension will occur. Global LV function may appear normal to exuberant because ventricular preload is increased and afterload decreased in severe MR. However, when MR is both severe and chronic, or if the underlying basis for MR is cardiomyopathy, then the ventricular shortening fraction is normal to decreased. The LA often assumes a more circular, almost turgid, appearance when MR is hemodynamically important, and the 2D echocardiographic measure of internal atrial dimension often exceeds 13.5 to 14.5 cm. With acute or chronic MR, the lobar and main PA may be dilated as a consequence of pulmonary hypertension, presumably related to increased LA pressure, interstitial lung edema, vascular remodeling, or other factors.

The prognosis for horses with MR is variable and, as discussed earlier, is related to clinical findings, work history, and results of echocardiographic studies. Abnormalities observed during echocardiography, including lesions of the mitral valve leaflets, the degree of LA and LV volume overloading, global LV function, and Doppler findings, should be considered when formulating the prognosis. Certainly, when MR is associated with CHF, AF, endocarditis, chordal rupture, marked cardiomegaly, severe valvular thickening, dilated cardiomyopathy, or pulmonary hypertension, the prognosis for life and performance is poor. The detection of PA dilatation indicates significant pulmonary hypertension and the low but concrete possibility of PA rupture associated with exercise. Fortunately, the vast majority of horses with MR appear to perform very well, indicating that MR in most cases is not clinically important.<sup>567</sup> Whether progressive exercise intolerance will develop in a particular case depends on the horse's use and on the progression of the underlying lesion. Generally, when MR is caused by valve degeneration and the heart size is normal, the progression is gradual, the prognosis for life is favorable, and performance is maintained. When MR is detected in an untrained colt or filly, the prognosis is less encouraging. The presence of even mild to moderate cardiac dilatation in a case of MR recommends a more guarded prognosis, although this assessment is best made by serial examinations. The significance of trivial to mild MR in the high performance horse or racehorse is uncertain. In some animals, treadmill exercise is normal, whereas others may demonstrate a higher heart rate for a given level of

work than might otherwise be expected. The latter finding may be suggestive of a cardiac limitation to performance.

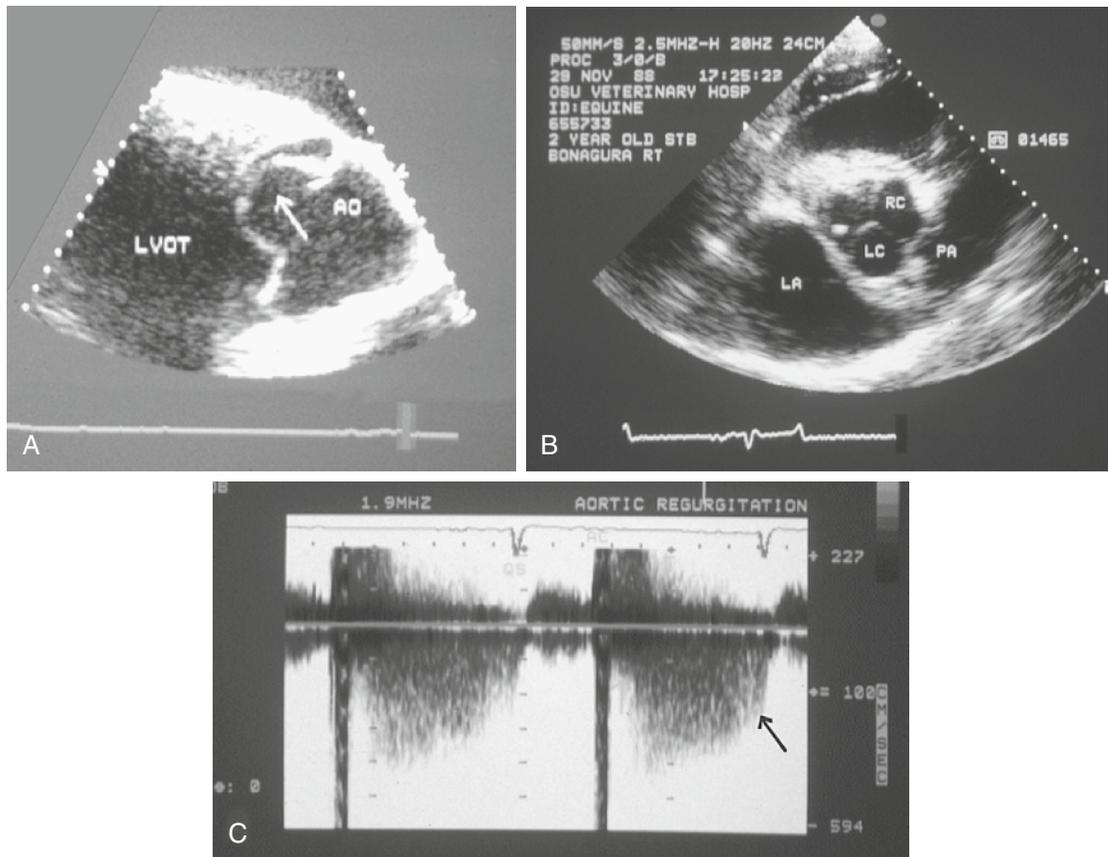

Regardless of cause or the severity of the condition, the horse diagnosed with MR merits follow-up examinations at least yearly, if not more often, to evaluate progression of the hemodynamic burden and to detect the development of CHF, pulmonary hypertension, or cardiac arrhythmias. Treatment of MR involves management of complications such as heart failure, endocarditis, or arrhythmias. These topics are covered elsewhere in this chapter.

## AORTIC REGURGITATION

Aortic regurgitation is a common valvular insufficiency. Degeneration of the aortic valve is by far the most common reason for AR.\* The degenerative nodular lesions and fibrous bands responsible for AR in older horses have been well described by Bishop, Cole, and Smetzer<sup>5</sup> (Figure 10-37, A). Prolapse of the aortic valve is a common echocardiographic finding and probably represents another manifestation of connective tissue degeneration affecting the valve. Small fenestrations of the valve also have been identified at necropsy but have uncertain clinical significance. Other potential causes of AR in horses include infective endocarditis, congenital valvular disease, VSD (see earlier in this chapter), noninfective valvulitis, and ruptured aortic sinus aneurysm.

In most cases, AR is an incidental finding encountered during a routine physical, prepurchase, or insurance examination. Most horses with this murmur are older than 10 years of age, and the murmur is especially common in aged horses, a testament to the degenerative nature of the lesion. Careful auscultation in a quiet area may identify a very soft diastolic murmur in a younger horse. Silent AR may also be considered physiologic or trivial, and it is not uncommon to identify a trivial jet of AR by Doppler studies in horses with no identifiable diastolic murmur.<sup>354</sup> When a loud murmur of AR is identified in a younger animal, a complete echocardiographic

\*References 4, 18, 77, 111, 125, 127, 130, 136, 138, 139, 141, 142, 366, 496, 614, 640.

**FIGURE 10-38** Echocardiograms recorded from horses with aortic regurgitation (AR; see also Figure 10-22, D). **A**, Aortic valve prolapse (arrow) in a 12-year-old Standardbred gelding. **B**, A well-circumscribed, echodense “bead” on the noncoronary cusp of the aortic valve in a 2-year-old Standardbred colt may represent a congenital or acquired lesion. This short-axis image plane is recorded across the base of the heart. **C**, Continuous wave Doppler recording from the same horse as in **A** demonstrates a turbulent diastolic signal that ends at the QRS complex (arrow). LC/RC, Left/right coronary cusps of the aortic valve in short axis; PA, pulmonary artery; LA, left atrium.

examination is warranted. Poor performance is an infrequent presenting complaint in horses with AR, because most will continue at their prior performance level, provided that no other clinical or cardiac abnormalities are present. Intermittent fevers, weight loss, or lameness should prompt consideration of endocarditis. CHF is infrequently observed in conjunction with isolated AR but may develop in the horses when AR occurs in combination with MR or AF.

Clinically important AR is identified by cardiac auscultation, which reveals a holodiastolic murmur, with the point of maximal intensity over the aortic valve area, and strong radiation to the right and toward the left cardiac apex in many instances. The murmur may vary greatly in intensity and character. The quality is typically harsh and decrescendo with a blowing nature (see Figure 10-10, C), but presystolic accentuation may be noted (see Figure 10-33, C). The character can be vibratory, musical, cooing, buzzing, or “dive bomber” in quality. A precordial thrill is palpable over the aortic valve area when the murmur is loud. A variant of the typical AR murmur is that associated with rupture of an aortic sinus into the RA, ventricular septum, or pulmonary artery. An aortic-cardiac fistula leads to a holodiastolic or continuous murmur that is louder over the right side of the thorax. However, in the majority of horses with an aortic-cardiac fistula, a continuous

machinery type of murmur is detected. The quality of the arterial pulses is a good indicator of the severity of the isolated AR.<sup>138</sup> Bounding arterial pulses indicate significant LV volume overload and moderate to severe AR. A systolic ejection murmur is often present (particularly when the regurgitant volume is large) and is explained by ejection of a large stroke volume across the aortic valve. It should be emphasized that no evidence for anatomic stenosis as the result of degenerative aortic valve disease has been published.

A complete echocardiographic examination including Doppler echocardiography is useful for further evaluation of horses with AR, particularly when the arterial pulse is abnormal or cardiac-related clinical signs are suspected.\* The most common abnormality observed by 2D echocardiography is mild valvular thickening in association with prolapse of one or more aortic leaflets (Figure 10-38). These findings are compatible with degenerative valvular disease. The aortic valve may flutter or vibrate. The 2D examination also assists with the differential diagnosis. In cases of endocarditis, the leaflets may appear thickened, irregular, and more highly echogenic. The valve may appear to oscillate if fresh thrombus is noted

\*References 84, 130, 136, 138, 139, 141, 142, 152, 496, 501, 504.

within the vegetation. Other rare 2D echocardiographic findings related to AR include fenestrations of the aortic valve leaflets, flail aortic leaflet, aortic sinus aneurysm, and aortic root prolapse into a VSD. Dilatation of the aortic root (exceeding 10 cm) may be observed in some horses with AR.

The traditional M-mode examination in horses with AR is still useful. LV volume overload that develops with AR increases ventricular internal diameter at end diastole, increases shortening fraction, and decreased free wall thickness. An exaggerated or swinging septal motion on 2D or M-mode examination represents another subjective observation of volume overload. If myocardial failure develops, then the end systolic dimension may be increased, despite normal shortening fraction. Inspection of the mitral valve often reveals high-frequency diastolic vibrations of the anterior (septal) leaflet related to an eccentric high-velocity AR jet directed across the LV outflow tract to the left and caudally. Similar vibrations may also be detected on the intraventricular septum when the regurgitant jet is oriented in a right or cranial direction. High-frequency fluttering of the aortic valve leaflets or aortic walls is more common in horses with musical or vibratory murmurs. Increased mitral valve E-point septal separation can indicate the regurgitant jet is impinging on the valve or herald LV dilatation and failure. In the latter case, other markers of severe insufficiency will be evident, including ventricular dilatation, rounding of the LV apex, and a wide origin jet of AR on Doppler studies. Premature (pre-systolic) mitral closure is an uncommon but ominous finding of severe AR with elevated ventricular end diastolic pressure.

The flow disturbance of AR is confirmed by Doppler studies. The Doppler examination shows one or more central or eccentric diastolic jets of AR. The timing of the flow disturbance should be verified by spectral Doppler or color M-mode studies. Assessing the severity of AR by Doppler studies is rife with pitfalls, and the examiner should use multiple 2D, M-mode, and Doppler findings to assess severity. Importantly, a wide jet area in the LV outflow tract does not always indicate severe AR. The finding of a small, central perivalvular jet, with a small cross-sectional area, suggests trivial AR. Often these leaks are confined to mid-to-late diastole. Conversely, a strong spectral signal, holodiastolic timing, and wide-origin color Doppler signal suggests more significant regurgitation. Examination of the short axis jet area in cross-sectional studies of the aortic root is especially instructive because a wide ventricular spray is often associated with a small origin jet (this suggests mild AR). The CW Doppler spectrum can be assessed for a short pressure half-time (steep AR slope), which indicates LV diastolic pressure is rapidly increasing and that AR is severe. However, the examiner must be certain the ultrasound beam has remained in good alignment with the regurgitant jet before this assessment can be made.

The clinical significance and prognosis of AR is most accurately based on the history, physical examination, and echocardiogram. Because most cases of AR are associated with a slow degeneration of the aortic valve leaflets, and this occurs in older horses without other cardiac problems, the prognosis for life and performance is usually good. Such animals typically have minimal echocardiographic abnormalities or only mild echocardiographic signs of volume overload. Epidemiologic studies suggest that in general AR is mild in most cases and not an independent predictor of survival<sup>643</sup>; however, the occasional case is encountered with moderate to severe AR. The findings of flail aortic valve leaflet, endocarditis, or echo markers of moderate to severe volume overload or myocardial failure indicate a poor prognosis for life and

performance. Ventricular dilatation can predispose to ventricular arrhythmias. Therefore an exercising ECG and exercise test should be obtained in performance horses with significant AR to determine if the horse remains safe to ride. A Holter ECG can be considered as a potential test in older, valuable animals to rule out ventricular ectopy. Follow-up clinical and echocardiographic examinations are indicated for the horse with moderate to severe AR. The development of secondary MR, AF, ventricular arrhythmias, CHF or sudden death should be anticipated in horses with severe volume overload.

## TRICUSPID REGURGITATION

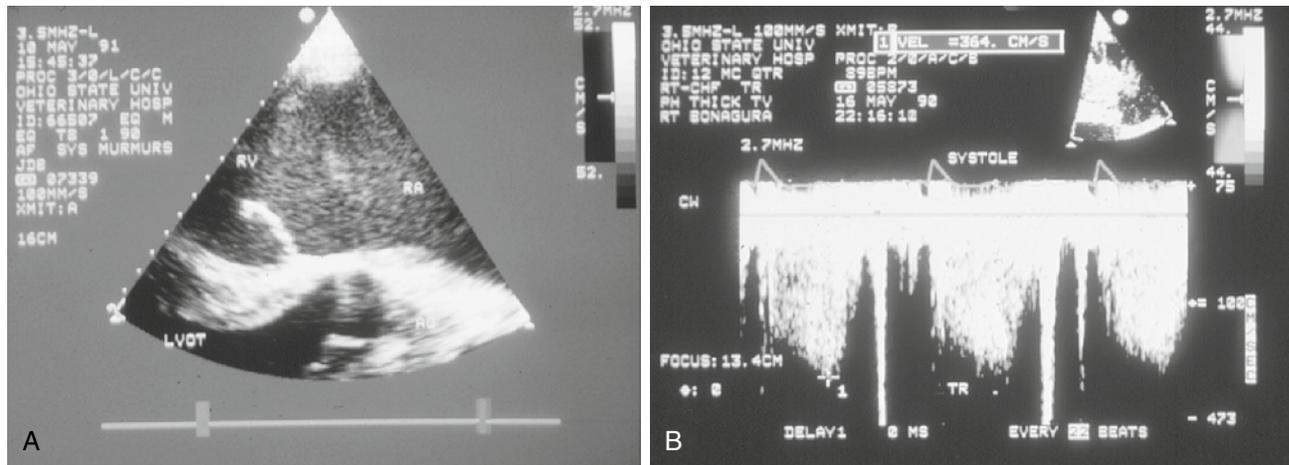

Tricuspid regurgitation might be the most frequently detected flow disturbance and murmur in the horse,\* although little information confirms the etiopathogenesis of this condition aside from speculation that it might be related to recurrent physiologic pulmonary hypertension of high-intensity exercise. The prevalence and color of Doppler severity of TR increases with age, training, and subtle increases in RV size.<sup>185</sup> The anatomic basis of tricuspid valve incompetency can be any of the following lesions: idiopathic, degenerative thickening, prolapse, noninfective tricuspid valvulitis, bacterial endocarditis, pulmonary hypertension (including left-sided failure), ruptured chordae tendineae, myocardial disease with secondary cardiomegaly, chronic tachyarrhythmia, and congenital malformation of the valve. TR is common in horses of racing age<sup>509</sup>; however, the anatomic correlate to this incompetency is uncertain. Degenerative, fibrotic thickening of the tricuspid valve in mature horses may lead to mild to moderate TR. When compared with the mitral condition, ruptured tricuspid valve chordae tendineae are uncommon<sup>639</sup> and better tolerated unless associated with endocarditis. The tricuspid valve can be infected by bacteria, and in some cases is secondary to an injudicious or septic jugular venipunctures or catheterization. Pulmonary hypertension, cardiomyopathy, and myocarditis can lead to secondary dilatation of the tricuspid annulus or alteration of papillary muscle support, permitting valvular insufficiency. Tricuspid malformation does occur but seems more commonly associated with stenosis or atresia of the valve<sup>†</sup> (see earlier discussion in this chapter).

A soft, grade 2 to 3 systolic murmur of TR is most often an incidental finding detected during a routine examination. The murmur becomes more problematic when it is loud, or is identified in a horse that is performing poorly. Many horses with TR race well; therefore the clinician should first exclude other likely reasons for poor performance before incriminating the tricuspid valve. Of course, if chronic hemodynamically significant TR has developed, then peak work effort will suffer and even right-sided CHF may develop. The latter situation is very uncommon unless the TR is severe, related to pulmonary hypertension or infective endocarditis, or complicated by AF. Prominent jugular pulses (giant c-v waves) are typical of horses with TR associated with CHF.

Auscultation of the horse with TR typically reveals a grade 2 to 5 holosystolic murmur with the point of maximal intensity over the right hemithorax at the tricuspid valve area. The murmur can be holosystolic, decrescendo, or mid-to-late systolic.

\*References 4, 77, 111, 125, 130, 149, 179, 180, 182, 184, 230, 354, 639, 644.

†References 151, 156, 161-163, 165, 366, 637, 638.

**FIGURE 10-39** Echocardiograms from horses with tricuspid regurgitation (TR; see also Figure 10-24, C). **A**, Two-dimensional (2D) echocardiogram demonstrating probable valve thickening, significant right atrial (RA) distention, and spontaneous RA contrast in a horse with severe TR, atrial fibrillation (AF), and congestive heart failure (CHF) (1-cm calibrations at the left of the sector; LVOT, left ventricular outflow tract). **B**, Continuous wave Doppler recording of a high-velocity TR jet from a horse with TR caused by pulmonary artery obstruction as the result of a mass lesion. The high velocity of regurgitation (>3.6 m/sec) indicates that elevated right ventricular (RV) pressure is driving the regurgitant jet. In this case the high pressure is caused by supravalvular pulmonary stenosis resulting from the tumor. TR jets associated with normal RV pressures are typically less than 3.0 m/sec.

Although the timing and intensity may at times remind the examiner of a functional murmur, the location of greatest murmur intensity argues against that possibility. The murmur usually radiates dorsally and, if loud, to the extreme left cranio-ventral thorax. The intensity of the TR murmur in many cases does correlate well to the regurgitant volume, but loudness also depends on PA and RV systolic pressures. In general, a grade 4 or louder murmur is anticipated when there is moderate to severe TR or when TR is related to pulmonary hypertension. AF or atrial premature beats are present in some horses with TR, particularly when the RA is dilated or the regurgitant jet is large.

Echocardiographic examinations of the tricuspid valve (Figure 10-39) are typically performed from the right side of the thorax, because the tricuspid valve and RV inlet are closer to the right thoracic wall. However, an extreme left cranial transducer location with caudal angulation also can be successful for examining the tricuspid valve. Because a number of potential reasons for tricuspid incompetency must be considered, careful attention must be directed to the valve and its support apparatus, the size of the PA, and the left side of the heart. In the vast majority of cases, a clear-cut lesion of the tricuspid valve leaflet is not evident. Valve thickening, prolapse, vegetations, chordal rupture, regurgitation secondary to RV dilatation, and pulmonary hypertension usually can be diagnosed or excluded with careful imaging. As with MR, moderate to severe TR leads to RA and RV volume overload; however, it is more difficult to quantify these chamber volumes owing to their complex geometry.<sup>185</sup>

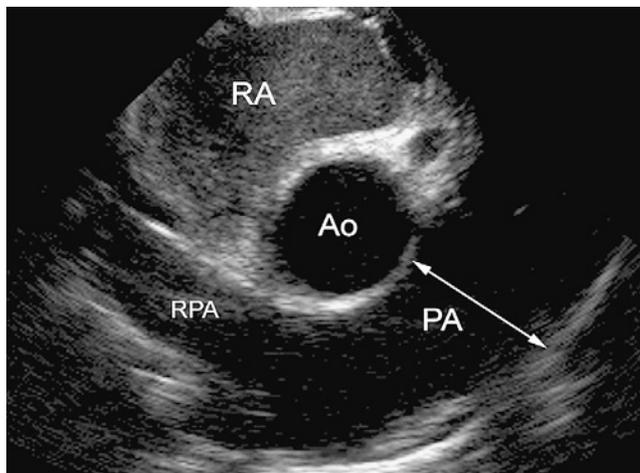

Doppler studies can identify the tricuspid regurgitant jet. In trivial or “silent” TR, this jet is typically very narrow at the origin and directed at the aorta. However, when the jet is wide at its origin, or projects centrally or laterally into the RA, cardiomegaly is more likely to be present and the heart should be examined carefully. The RV (and PA) systolic pressure can be estimated by faithfully recording the peak jet velocity. This requires the

examiner to align the continuous wave Doppler cursor parallel to regurgitant flow and may demand a ventral or dorsal placement of the transducer with steep beam angulation. When the jet velocity is less than 2.5 m/sec, pulmonary hypertension is not present. Jets exceeding 3.2 to 3.4 m/sec are indicative of pulmonary hypertension—provided that no RV outflow obstruction or VSD are identified (see Figure 10-39, B). The identification of pulmonary hypertension should prompt careful examination of the left heart, because the main cardiac lesion may be centered over the mitral valve, aortic valve, or LV cavity and the right heart changes simply a secondary consequence.

The prognosis for horses with TR is generally very favorable. A soft murmur of TR in a trained athlete is disregarded as clinically insignificant; although, defining such a disturbance as “functional” would be imprecise in the opinion of the authors. The presence of TR is more likely to cause concern if right-sided cardiomegaly, pulmonary hypertension, or AF is evident. Visualization of a vegetation or chordal rupture would indicate a poor prognosis for performance and a guarded prognosis for life. The width of the regurgitant jet at its origin, recent performance history, and results of exercise testing are useful in developing a prognosis for life and future work. The affect of exercise and the associated pulmonary hypertension on the volume of TR may become better understood with the increased use of exercise testing and postexercise echocardiography.<sup>184</sup> When TR is judged to be moderate or severe, periodic re-examinations are indicated to follow the progression of the lesion and to detect cardiomegaly or cardiac arrhythmias if they develop.

## PULMONARY INSUFFICIENCY

Trivial and clinically silent, physiologic pulmonic insufficiency can often be detected by Doppler studies; however, this is a normal finding.<sup>130,149,230,354</sup> Clinically significant pulmonic insufficiency is rare and occurs most frequently

**FIGURE 10-40** Right cranial echocardiogram with the aorta (Ao) in short axis demonstrating a dilated pulmonary artery (PA). The cause was pulmonary hypertension after left-sided congestive heart failure (CHF). RA, Right atrium (with spontaneous contrast in cavity); RPA, right branch of the pulmonary artery.

with pulmonary hypertension associated with left-sided heart failure. Infective endocarditis, congenital abnormalities of the valve leaflets (bicuspid or quadricuspid valve), and rupture of the pulmonary valve are rare causes of pulmonic insufficiency.<sup>135,137</sup> Murmurs of pulmonic regurgitation are usually undetectable unless the regurgitant volume is large or is driven by pulmonary hypertension; however, the regurgitant flow can be easily identified using pulsed-wave and color-flow Doppler echocardiography. Dilatation of the PA may be detected echocardiographically when pulmonic insufficiency is caused by pulmonary hypertension (Figure 10-40).

When severe pulmonic regurgitation does develop, it is generally a consequence of left-sided heart failure with pulmonary hypertension and accompanied by clinical signs of biventricular failure. Signs of right-sided CHF typically stem from the combination of pulmonary hypertension, pulmonic regurgitation, RV volume overload, and TR. If a murmur of pulmonic regurgitation is detected, then it is usually holodiastolic and a decrescendo murmur, with the point of maximal intensity at the pulmonic valve area, radiating toward the right cardiac apex. The prognosis for life and performance is usually poor in these cases.

## INFECTIVE ENDOCARDITIS

Infective (bacterial) endocarditis is caused by invasion of the heart valves or endocardium by bacteria. Endocarditis is not common in horses but occurs sporadically in most populations.\*

Horses of any age can be affected, although the pathogenesis may differ in younger animals or in those that are immunosuppressed. In one report, the mean age of affected horses was 2.1 years.<sup>179</sup> Numerous bacteria have been associated with bacterial endocarditis. The offending microorganism likely depends on the environment, portal of entry (e.g.,

gastrointestinal tract, skin, lung, oral cavity, joint, surgical wound, or IV catheter), and the effects of prior antimicrobial therapy that may select for resistant strains. *Streptococcus* spp., *Actinobacillus equuli*, and *Pasteurella* spp. have been isolated most frequently. *Rhodococcus equi*, *Candida parapsilosis*, *Erysipelothrix rhusiopathiae*, meningococci, *Staphylococcus aureus*, and other organisms (e.g., aspergillosis) have also been isolated.

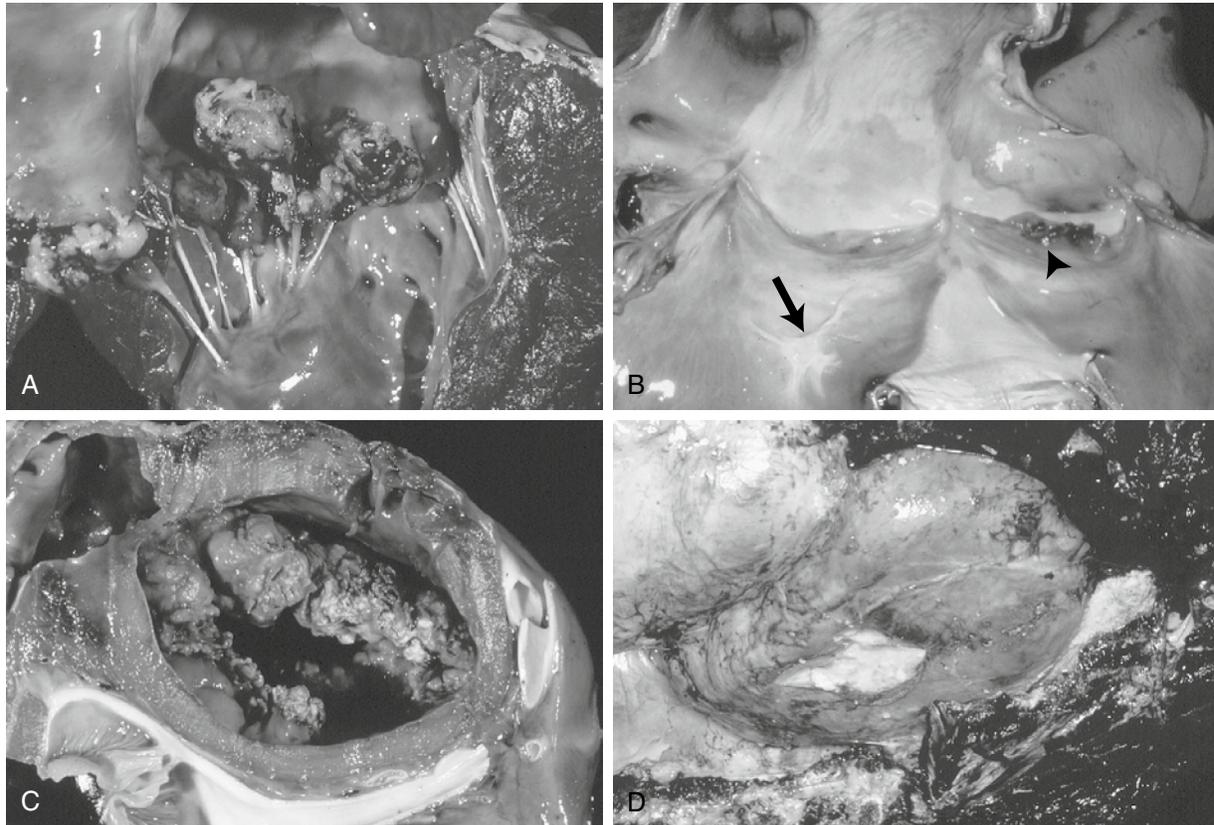

The pathogenesis involves bacterial invasion from the bloodstream and colonization of the heart valve or endocardial surfaces. Bacteremia is a prerequisite for development of this condition. Direct invasion of a previously normal valve by virulent bacteria, or in the context of overwhelming sepsis, represents the most likely pathogenic mechanism involved in foals with infective endocarditis. Disruption of the endocardial surface by jet lesions associated with congenital intracardiac shunts may also predispose to endocarditis, although this mechanism is not well established in horses. Preexisting valvular heart disease with endocardial changes or high-velocity jets may represent risk factors for bacterial colonization in older horses, but again this is completely unproven.

The most common sites of infective endocarditis are the aortic and mitral valves, although endocarditis lesions have been reported on all cardiac valves. Mural and chordal endocarditis lesions have also been reported but occur much less frequently. The combination of bacterial injury, exposure of valve collagen, thrombosis, and host leukocyte response contributes to development of the vegetation (Figure 10-41), which consists microscopically of bacteria, platelets, fibrin, leukocytes, and varying degrees of granulation or fibrosis. Bacteria may not be evident at necropsy, especially if antimicrobial therapy has sterilized the vegetation.

The pathophysiology of endocarditis in horses is probably similar to that in other species. A host response, as well as the primary cardiac lesions, contributes to the morbidity of this disease. Cardiac manifestations include valvular injury leading to regurgitation, chordal rupture, or rarely to stenosis; secondary cardiomegaly; myocarditis from extension of the infection or through coronary embolization; myocardial infarction if emboli are shed to the coronary arteries; arrhythmias from cardiomegaly, myocarditis, or infarction; and myocardial depression from bacteremia. Recurrent or chronic bacteremia, and hence fever, is characteristic of endocarditis. Metastatic infection, distant thrombosis and infarction, and immune-mediated host responses can occur. Distant infection or immune complex disease can lead to multisystemic clinical signs, including polyarthritis, osteomyelitis, vasculitis, or nephritis. Right-sided thrombi can lead to pulmonary thrombi, abscessation of the lungs, or both (see Figure 10-41).<sup>135,169</sup>

Clinical features of endocarditis are variable.<sup>179</sup> Affected horses usually have a history of intermittent fever, weight loss, depression, anorexia, lethargy, and often intermittent lameness (Figure 10-42). Synovial distension may be noted. A predisposing condition or a concurrent infection may be evident, including jugular vein thrombophlebitis, strangles, septic joint, or an abscess. In most horses no history of previous illness or evidence of concurrent infection is identified. The physical examination often reveals fever, and some horses may be tachypneic. The fever is often intermittent. Murmurs of mitral or aortic valvular insufficiency are most commonly detected; those of TR are less common. Systolic murmurs caused by valve destruction must be differentiated from the physiologic flow murmurs that are heard so often in febrile horses. Murmurs of valvular stenosis may also be detected with

\*References 4, 31, 77, 90, 109, 111, 125, 135, 138, 139, 142-144, 147, 148, 169, 170, 172-180.

**FIGURE 10-41** Bacterial endocarditis: postmortem lesions. **A**, Severe mitral valve endocarditis in a yearling. **B**, Focal aortic valve endocarditis is evident in this view of the left ventricular (LV) outlet and the ascending aorta. The septal mitral leaflet is at the lower right, and a jet lesion (*arrow*) is visible in the LV outflow tract. Above the mitral leaflet, in the center of the left coronary cusp, is a raised, irregular vegetation (*arrowhead*) that caused aortic regurgitation (AR). **C**, Tricuspid valve vegetation in a weanling. Although less common than mitral or aortic vegetations, right-sided endocarditis is a definite risk in horses, particularly in animals subjected to repeated jugular venous catheterization. **D**, A lung abscess in a horse after pulmonary valve endocarditis. The center of the abscess is incised and reveals caseous exudate. Systemic embolization and metastatic infection are recognized complications of valvular infections.

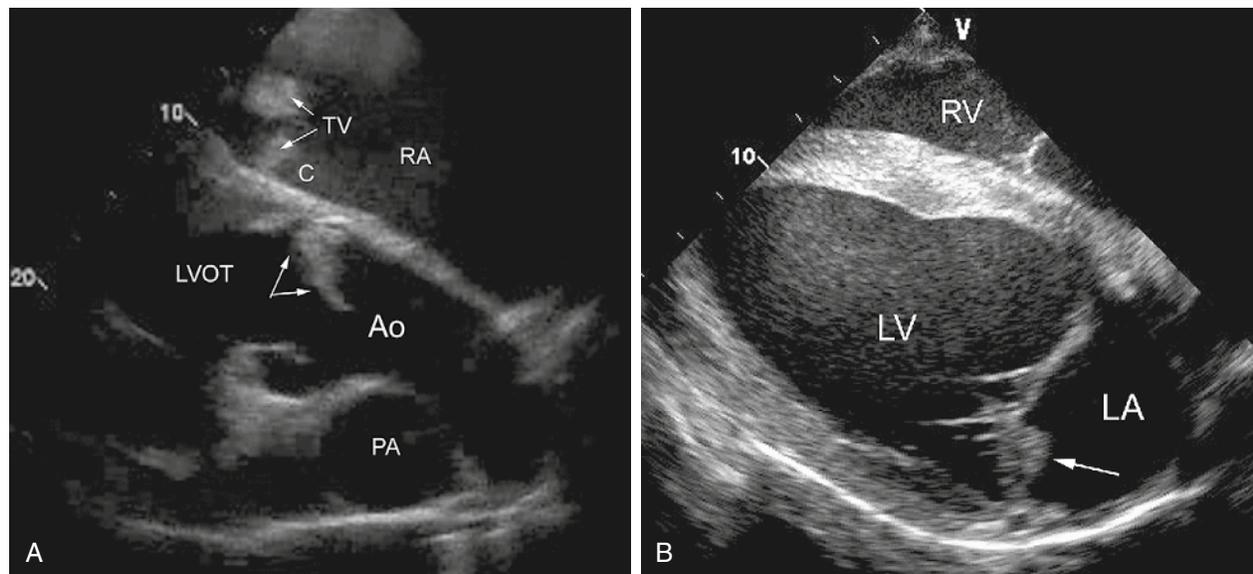

bacterial endocarditis but occur rarely.<sup>135</sup> Some horses with bacterial endocarditis have no auscultable murmur initially. The quality or intensity of the murmur may change over a number of days. AF, atrial or ventricular premature depolarizations, and VT have been observed with endocarditis.<sup>109,174</sup>

Laboratory studies obtained from horses with infective endocarditis may reveal anemia (of chronic inflammatory disease), hyperproteinemia (hyperglobulinemia with hypoalbuminemia), elevated fibrinogen, and leukocytosis with a mature neutrophilia.<sup>179</sup> Multiple blood cultures should be performed when bacterial endocarditis is suspected. The result of blood cultures may be negative, however, particularly after antimicrobial therapy. A positive blood culture may be more likely if multiple samples are drawn at different times of the day during or near febrile episodes. Antibiotic removal system media might also be of value when culturing blood from horses that have received antibiotics recently, and it can be helpful to consult with a clinical microbiologist regarding optimal broth media used for blood culturing.

Diagnosis of infective endocarditis may be definitive in the setting of a compatible clinical history with positive blood

**FIGURE 10-42** Weight loss, loss of condition, and ventral edema in this weanling with endocarditis and right-sided congestive heart failure (CHF; see also Figure 10-41, C).

**FIGURE 10-43** **A**, Right parasternal long axis two-dimensional (2D) image from a horse with infective endocarditis affecting multiple valves. Marked thickening of the tricuspid valve (TV) is evident, with spontaneous contrast (C) surrounding the valve. The right leaflet of the aortic valve is markedly thickened (arrows) between the left ventricular outflow tract (LVOT) and ascending aorta (Ao). Pulmonary artery (PA) and right atrium (RA) are seen in the far and near fields. **B**, Focal vegetation (arrow) is observed on a closed mitral valve in a long-axis image from the right thorax (RV, right ventricle; LA, left atrium; LV, left ventricle).

cultures or clear echocardiographic demonstration of a vegetation. In the absence of these, the relative likelihood of endocarditis is based on combinations of clinical findings and laboratory tests. Major and minor diagnostic criteria (Duke criteria) have been used for assessment of human patients,<sup>645</sup> and these principles are probably applicable to horses. Endocarditis should be considered in any horse that presents with a fever of unknown origin and one or more of the aforementioned clinical signs, particularly in association with synovial distension and lameness. Endocarditis becomes more likely when the cause of fever cannot be isolated to another body system and concurrent cardiac disease is identified. The diagnosis is confirmed with positive blood cultures in the setting of compatible clinical findings or by echocardiographic detection of vegetative lesions on the valve leaflets or endocardial surface (Figure 10-43).

Vegetative lesions usually appear echocardiographically as thickened, echogenic to hyperechoic masses with irregular or “shaggy” edges. The valve leaflet often demonstrates diffuse thickening as well. Discrete lesions are generally on the valve surface facing the normal path of blood flow. The typical endocarditis lesion adheres to the valvular endocardium (and therefore moves with the valve). When a fresh thrombus is attached to the vegetation, an oscillatory appearance may be evident with high frame rate, real-time imaging. Chronic lesions may contract, calcify, or develop a smooth contour. Rupture of the chordae tendineae or avulsion of a valve leaflet may also be detected echocardiographically, and this complication is not uncommon in mitral or tricuspid valve endocarditis. Pulsed-wave and color-flow Doppler echocardiography can be used to confirm that the valve is incompetent or (rarely) stenotic. Valvular regurgitation often progresses because of continued damage to the valve leaflets associated with ongoing bacterial infection or subsequent to fibrosis or calcification associated with a bacteriologic cure.

Early diagnosis and aggressive, prolonged treatment are important for successful treatment of infective endocarditis. Treatment should consist of high levels of bactericidal antibiotics, ideally based on culture and sensitivity patterns of blood culture isolates. Initial therapy should be broad spectrum, until the results of the blood culture are known or when a positive blood culture cannot be obtained. IV therapy is preferred in the initial stages of treatment. Drugs that penetrate fibrin well, particularly potassium penicillin (22,000 to 44,000 IU/kg, IV every 6 hours), are reasonable initial choices because bacteria may be sequestered in fibrin and may be unavailable to leukocytes. To extend the antimicrobial spectrum, penicillin is usually combined with gentamicin sulfate (6.6 mg/kg, IV every 24 hours) or amikacin sulfate (10 mg/kg, IV every 24 hours for adults; 25 mg/kg, IV every 24 hours for foals). Erythromycin estolate (25 mg/kg, PO every 6 to 12 hours) combined with rifampin (5 to 10 mg/kg, PO every 12 hours) may be useful in some cases. Nonsteroidal anti-inflammatory drugs (NSAIDs) (flunixin meglumine 1.1 mg/kg, IV every 12 hours) may be beneficial to reduce systemic and local inflammatory reactions. Aspirin (10 mg/kg, PO every 24 to 48 hours) and heparin (sodium heparin 40 IU/kg, SC every 8-12 hours; Fragmin 50 IU/kg, SC every 24 hours; or enoxaparin 40 IU/kg, SC every 24 hours) are used by some clinicians to prevent platelet adhesion, diminish growth of the vegetation, and reduce the risk of thrombotic complications, although the benefits of antithrombotic therapy are uncertain.

With effective antimicrobial therapy, the fever should resolve within 5 to 7 days. Response to treatment should be assessed by repeated examinations, including clinical assessment, laboratory analyses, and serial echocardiograms. Therapy should extend to at least 4 to 8 weeks or until body temperature, plasma fibrinogen concentration, and leukocyte counts have been normal for at least 2 weeks. The duration and type of

long-term therapy depend on various factors, and the bacterial isolate, clinical response, cost, and potential toxicosis of the antimicrobial therapy must all be weighed in these decisions.

The expectation for long-term survival is poor in most cases of infective endocarditis causing severe valvular injury. Even in the absence of significant valvular regurgitation, difficulty may occur in achieving a bacteriologic cure, or valvular damage may progress as the vegetation heals and scars the valve. Although some horses have been treated successfully for endocarditis,<sup>31,172,174</sup> the prognosis for long-term use relative to athletic performance or breeding is low. The absence of an obvious echocardiographic lesion or signs of systemic inflammatory response creates a more favorable situation, provided that a bacteriologic cure can be obtained. Progressive cardiomegaly, CHF, rupture of the PA, development of AF, and sudden death have been reported in horses affected with endocarditis. Accordingly, periodic follow-up examination, including echocardiograms, should be performed in successfully treated cases.

## PERICARDIAL DISEASE

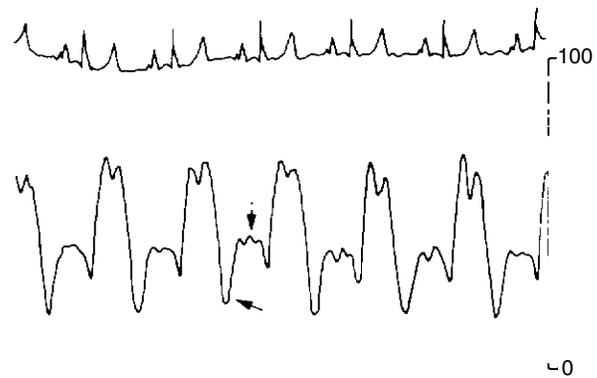

Pericardial diseases occur uncommonly and are usually associated with pericardial effusion and fibrinous pericarditis.\*

Pericarditis and pericardial effusion may be idiopathic, bacterial, viral, fungal, or traumatic in origin or associated with cardiac or pericardial neoplasia. Mesothelioma and lymphosarcoma are the most common neoplasms affecting the pericardium in horses. Pericardial hernias have also been seen but are rare. Not all cases of pericarditis are septic, but an infectious cause should be assumed until proven otherwise. *Streptococcus* spp. have most frequently been reported with pericarditis, but *Actinobacillus equi*, *Pseudomonas aeruginosa*, *Pasteurella* spp., *Corynebacterium* spp., *Mycoplasma* spp., and other microorganisms have been isolated.<sup>87,94,96,652,654</sup> Equine influenza and equine viral arteritis have been associated with fibrinous pericarditis (as well as abortion). Sterile inflammatory and eosinophilic effusates have been recognized, and an outbreak of pericarditis centered in Kentucky was attributed to a caterpillar vector<sup>97</sup> (see Figure 10-45, A). However, *Actinobacillus* spp. were the principal isolates obtained from necropsy and clinical cases.<sup>95</sup> External thoracic trauma or penetration by a gastric foreign body may lead to bacterial inoculation of the pericardial space.<sup>646,649,650</sup> The pathogenesis of noninfective pericarditis is unknown but might be immune mediated in some situations.<sup>94</sup>

The pathophysiology of pericardial disease in most cases is ascribed to impaired cardiac filling caused by either external compression (cardiac tamponade) or pericardial constriction. Typically, marked elevation is seen in the venous, atrial, and ventricular end diastolic pressures (Figure 10-44). Occasionally a mass lesion compresses the heart or obstructs venous drainage or ventricular outflow and mimics findings of pericardial disease. Other clinical signs may be referable to the underlying cause as with infection or neoplasia.

Reduced cardiac filling despite increases in ventricular filling pressures characterizes the clinical syndrome of pericardial effusion with tamponade. In acute cases, reduced ABP may be noted; chronically, BP is normal but signs of right-sided CHF are evident. The history usually includes systemic signs

Right ventricular pressure curve

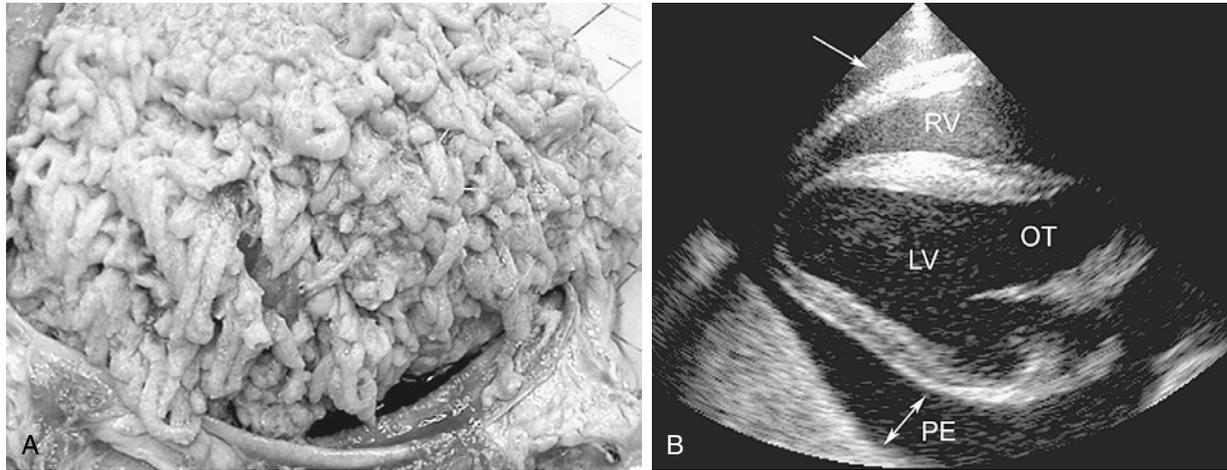

**FIGURE 10-44** Pressure tracing demonstrating elevated right ventricular (RV) end diastolic pressure in a horse with constrictive pericarditis and heart failure. A quick rise occurs from the nadir of pressure (lower arrow) to a plateau (upper arrow), which is typical of constrictive disease and ventricular filling that is limited to early diastole.

of illness, such as fever, lethargy, depression, anorexia, tachypnea, ventral edema, colic, and weight loss. A recent history of an upper or lower respiratory tract infection is not uncommon. Physical examination abnormalities include various combinations of tachycardia, fever, pericardial friction rub, muffled heart sounds, tachypnea, pleural effusion, jugular and generalized venous distention, ventral edema, thready pulses, and ascites. ABP may be decreased in cardiac tamponade and a pronounced inspiratory fall in BP (pulsus paradoxicus) may be identified by palpation of the pulse or through careful measurement of ABP. In chronic disease BP is normal, owing to fluid retention, elevated venous pressures, vasoconstriction, and tachycardia.

Laboratory studies are contributory to the diagnosis. Clinical laboratory abnormalities are not specific, but the most frequently detected abnormalities include anemia, hyperproteinemia, hyperfibrinogenemia, and a neutrophilic leukocytosis. Other hematologic abnormalities may be observed related to inflammation, CHF, or organ hypoperfusion. Thoracic radiographs usually reveal a globoid cardiac silhouette or pleural effusion and may reveal interstitial pulmonary infiltrates and enlarged pulmonary vessels. The ECG usually demonstrates decreased amplitude of the QRS complexes. If the effusion is large and the heart is swinging, then electrical alternans may be observed. Pericarditis may elevate the ST segment in multiple leads, but this change may occur simply as a result of tachycardia. Sinus tachycardia is typical, but ventricular or APCs may be detected.

The echocardiographic examination is diagnostic, demonstrating an anechoic or hypoechoic fluid space between the pericardium and epicardial surface of the heart (Figure 10-45, B), while excluding an extracardiac mass lesion, which can mimic pericardial disease.<sup>100</sup> Fibrin tags frequently are evident on the parietal and visceral pericardial surfaces. Findings of protracted diastolic collapse of the RV or systolic collapse of the RA are compatible with a clinical diagnosis of cardiac tamponade. Inflammatory processes may eventually lead to adhesions between the parietal and visceral pericardial layers, causing constrictive pericarditis with minimal or no obvious effusion. Associated pleural effusion is a

\*References 4, 80-84, 86-95, 100, 125, 583, 584, 646-653.

**FIGURE 10-45** **A**, Considerably proliferative epicardial reaction in a horse with idiopathic, fibrinopurulent pericarditis. The heart is covered by a layer of organizing fibrin and inflammatory debris creating a shaggy appearance typical of inflammatory pericarditis. **B**, Two-dimensional (2D) long-axis echocardiogram from another horse demonstrating a moderate pericardial effusion. The effusion (*PE*) appears more prominent behind the left ventricle (*LV*) but is also evident (*arrow*) cranial to the right ventricle (*RV*) (*OT*, left ventricular outflow tract).

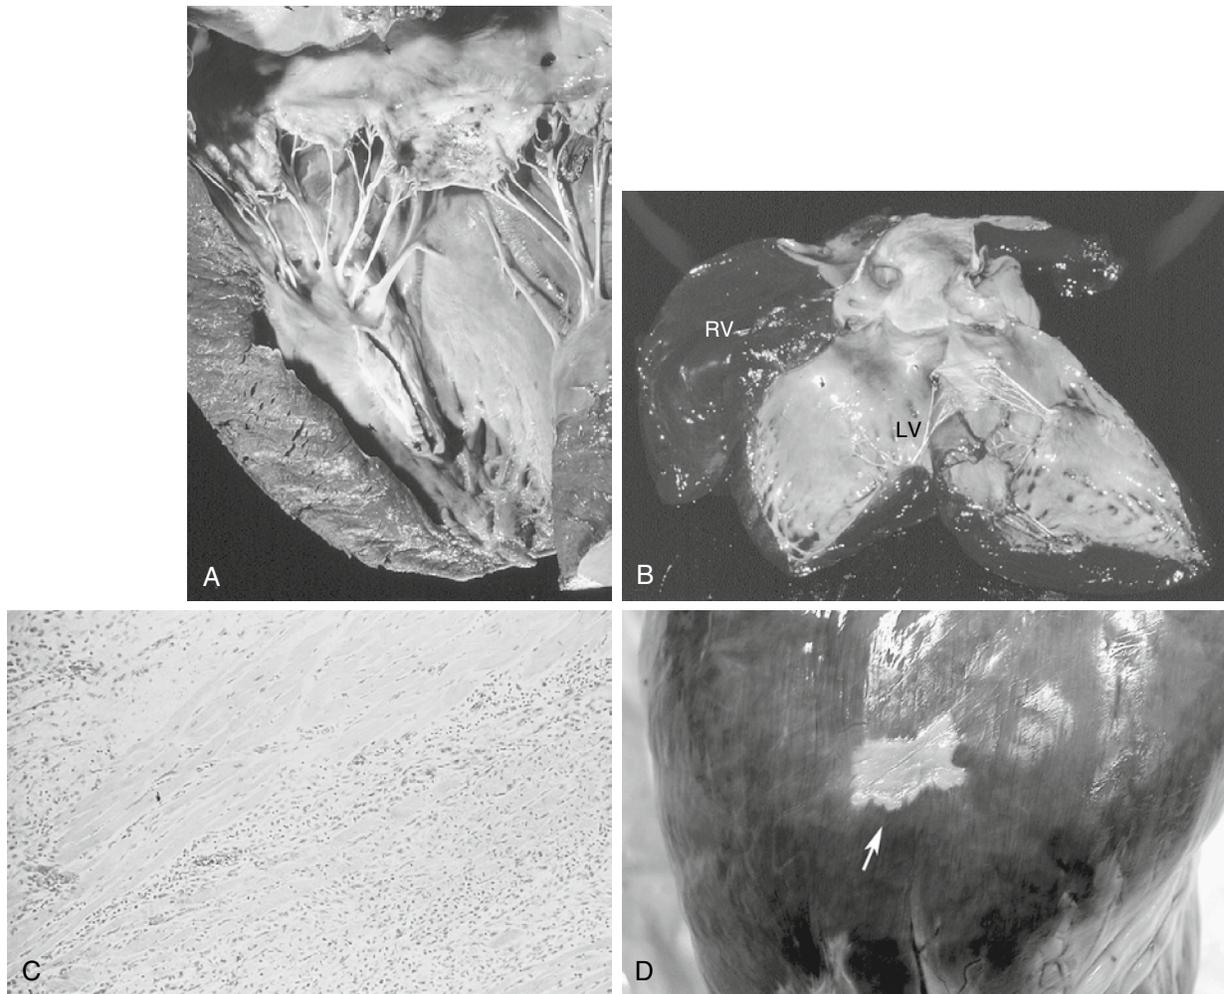

common ultrasound finding. Echocardiographic diagnosis of constrictive disease without effusion is more challenging, but typically reveals thickened pericardium, atrial dilatation, systemic venous dilation, exuberant movement of the ventricular septum, and exaggerated inspiratory filling of the heart as documented by pulsed-wave Doppler studies. In some cases right-sided heart catheterization is needed to establish the diagnosis. Typical findings are increased central venous pressure, elevated RV diastolic pressure, and possibly by a diastolic dip and plateau appearance to the RV waveform (see Figure 10-44).<sup>86</sup>

Cytologic evaluation of the pericardial effusion is essential to distinguish septic, aseptic, or neoplastic pericardial effusion. Fluid can be obtained in the course of needle pericardiocentesis or during the placement of an indwelling tube for pericardial lavage and drainage. Bacterial culture and sensitivity of the aspirated fluid should be performed so that antimicrobial therapy can be guided in cases of septic pericarditis.

The treatment of pericardial diseases varies, depending on the cause and clinical situation. Even when signs of right-sided CHF dominate the clinical picture, the use of furosemide is generally contraindicated, because aggressive diuresis results in lowered filling pressures, reduced ventricular filling, decreased CO, and possibly syncope. Instead, pericardiocentesis or catheter drainage should be considered as first-line therapeutic procedure in all cases of pericardial effusion with cardiac tamponade. Because the development of cardiac tamponade depends not only on the volume of pericardial fluid but also on the rate at which it accumulates, the clinician's urgency should be guided by BP, clinical signs, magnitude of pleural effusion, and echocardiographic evidence of cardiac tamponade. Tamponade is an indication for immediate drainage of the pericardial sac. Echocardiography can be used to localize a site for pericardiocentesis and choose an appropriate length of needle, catheter, or drainage tube. Pericardiocentesis should be performed after locally anesthetizing the intercostal muscles and pleura, and inserting an intravenous catheter to provide intravenous access should it be necessary.

Electrocardiographic monitoring should be performed continuously during the procedure to monitor for cardiac puncture or in case ventricular arrhythmias develop. Pericardiocentesis is usually performed within the left fifth intercostal space, above the level of the lateral thoracic vein, although it can also be performed at the right hemithorax. Drainage is achieved using a large-bore catheter, teat cannula, or chest tube; the latter is recommended for repeated drainage and lavage of the pericardial sac and is most successful for aggressive management of septic or idiopathic fibrinous pericarditis. After insertion of an indwelling catheter, local therapy is administered that includes pericardial lavage and direct instillation of antimicrobials and possibly anticoagulants such as heparin. Combined with systemic antimicrobials, this therapy has been effective in the treatment of septic pericarditis.<sup>583</sup> Pericardial lavage should be continued for several days, until little accumulation of pericardial fluid (<1 L over 12 hours) is seen, clinical signs have improved, and the cytologic character of the fluid becomes less inflammatory. Initially, broad spectrum antibiotics should be used; the antibiotic regimen should then be adapted according to the results of bacterial cultures and antibiotic sensitivity patterns. NSAIDs are indicated to fight inflammation and to reduce the risk of constrictive pericarditis. If the cytologic analysis and culture are negative for bacteria, then anti-inflammatory doses of dexamethasone may be used for treatment of idiopathic, nonseptic, effusive pericarditis.<sup>87,94</sup> Exudative pericarditis may not respond in all cases to conservative treatment or even to drainage. Surgery is a rarely used option for treatment of pericardial disease but would be most appropriate for constrictive or constrictive-effusive pericarditis.<sup>86</sup> Presumably, introduction of minimally invasive thoracoscopic surgical techniques to management of pericardial diseases in horses might prove useful.

The prognosis for survival and maintenance of performance in horses affected by pericardial disease is guarded. The prognosis for cardiac or pericardial neoplasia is quite poor. Caution also must be expressed regarding inflammatory

**FIGURE 10-46** Myocardial diseases. **A**, An opened left ventricle (LV) revealing a (incised) large, oval area of subendocardial and myocardial fibrosis in a mare. No causative agent was found. **B**, Significant LV dilation and subendocardial fibrosis in a horse with idiopathic dilated cardiomyopathy. The white discoloration of the LV and left atrium (LA) may result from chronic distention or represent fibrosis after another injury. The opened right ventricle (RV) (to the left) is dilated but is not discolored. **C**, Myocardial lymphosarcoma. A substantial myocardial infiltration is evident in this photomicrograph. **D**, Close-up of the LV, subepicardial myocardial infarct (*arrow*) of undetermined cause.

pericarditis because the condition may become chronic, but very good results have been obtained in some reports.<sup>94</sup> The potential of eventual constrictive or fibrotic pericardial disease is also greatest with inflammatory pericardial conditions so that early success may be tempered by later complications of the disease.<sup>87</sup> The best prognosis of horses with fibrinous pericarditis is when treatment includes repeated drainage and lavage. Treated horses should be followed and re-evaluated by echocardiography.

## MYOCARDIAL DISEASE

Myocardial diseases are probably under-recognized in clinical practice, and few published reports regarding these disorders are available.\*

Certainly a potential exists for myocardial injury related to drugs, toxins (ionophore antibiotics, poisonous plants), ischemia, hypoxia, infective agents, parasite migration, heavy metals, trauma, relentless tachyarrhythmia, metabolic disease, or nutritional imbalance. Myocardial injury also can derive from extension of a preexisting infection (pericarditis, pericardial abscess, or endocarditis) or related to sepsis.<sup>665</sup> Infiltrative cardiomyopathies can occur consequent to neoplasia (melanoma, lipoma, lymphosarcoma, hemangiosarcoma, mesothelioma)<sup>666</sup> or the very rare amyloidosis<sup>667</sup> (Figure 10-46; see Box 10-2). Idiopathic, dilated cardiomyopathy also has been recognized in the horse. Tachyarrhythmias such as VT developing at a high rate (>160) can impair ventricular function and resolution of the rhythm disturbance may lead immediately to more normal LV function. A potentially reversible cardiomyopathy may accompany relentless ventricular or supraventricular tachycardia that has been present for days. Myocardial function in affected horses can only be assessed a number of days after conversion to sinus rhythm.

\*References 4, 28, 29, 77, 98, 106-108, 110, 111, 114, 115, 121, 125, 432, 604, 655-664.

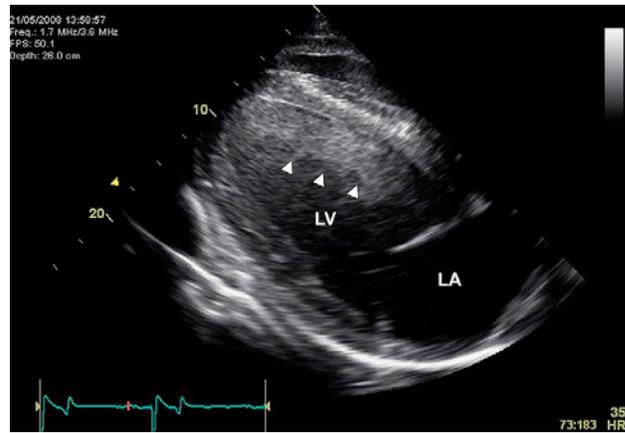

## CLINICAL FEATURES OF MYOCARDIAL DISEASES

The general manifestations of myocardial disease, regardless of the underlying injury, can be attributed to the following *pathophysiologic processes*: (1) reduced myocardial contractility and ventricular ejection fraction; (2) diastolic dysfunction with impaired ventricular filling; (3) mitral or tricuspid valve incompetency caused by cardiac dilatation or papillary muscle dysfunction; or (4) the development of arrhythmias. The overall cardiac disability engendered by myocardial disease varies greatly. Some horses have no detectable clinical signs; whereas, others demonstrate exercise intolerance, life-threatening arrhythmias, low-output CHF, or sudden death.

Persistent ventricular premature depolarizations or VT can be observed in horses with myocardial disease.<sup>562</sup> Atrial premature depolarizations, atrial tachycardia, or AF are more often primary electrical disturbances; although, these arrhythmias also can develop in horses with cardiomyopathies. Although it is tempting to diagnose “myocardial disease” in the setting of any cardiac rhythm disturbance, it should be appreciated that many rhythm abnormalities are “functional,” without a gross anatomic substrate. This point is especially germane to horses suffering from electrolyte or other metabolic imbalances, high sympathetic tone, sepsis or toxemia, hypoxemia, or ischemia. In horses examined for sudden death at a racetrack, gross or microscopic myocardial lesions were relatively uncommon finding as compared with pulmonary hemorrhage.<sup>69</sup>

The onset of clinical signs may lag behind the initial myocardial insult, especially in cases of myocarditis or chronic myocardial injury. For example, a horse that has apparently recovered from an illness may develop problems once rigorous training is begun. The trainer may complain that the horse is unable to achieve faster speeds or may stop or suddenly slow during hard training. The affected horse may take a long time to “cool out” after a workout. In more severe cases, marked exercise intolerance, weakness, ataxia, or even collapse may occur. Respiratory distress, pulmonary edema, cyanotic mucous membranes, prolonged capillary refill time, and a rapid thready pulse may be detected after exercise. In case of severe myocardial injury, signs such as fever, persistent tachycardia, arrhythmia, murmur, pulmonary or ventral edema, or respiratory distress may be observed. Sudden death may occur without premonitory signs.

Results of the *clinical examination* in horses with myocardial disease are inconsistent. Resting physical examination findings can be normal, or signs of heart disease may be evident. These can include persistent tachycardia, tachypnea, frequent premature beats, sustained arrhythmias, systolic murmurs of AV valvular insufficiency, or CHF. A postexercise examination often detects an abnormally rapid heart rate, which remains persistently high after exercise is discontinued. The ECG may demonstrate atrial or ventricular arrhythmias, and an exercise ECG typically records an inappropriately high heart rate for the level of work undertaken. Resting echocardiography usually reveals a low normal or unambiguously reduced ventricular shortening fraction. Depending on the type of myocardial disease, the (relative) LV wall thickness can be increased (i.e., infiltrative cardiomyopathy) or decreased (i.e., dilated cardiomyopathy; see Figure 10-22). Postexercise echocardiography may demonstrate a paradoxical reduction

**FIGURE 10-47** Spontaneous echo contrast (SEC), shown by arrowheads in the left ventricle (LV) of a 10-year-old Warmblood gelding with myocardial dysfunction. One can compare the LV density with the density within the left atrium (LA). A small amount of SEC is considered normal in horses, but marked increases in spontaneous contrast may be observed with very poor myocardial function. Bradycardia, low cardiac output (CO), rouleaux formation, systemic inflammation, and coagulation disorders are thought to contribute to this finding.

of LV shortening fraction or regional dysfunction characterized by LV wall motion abnormalities. Marked increases in LV or LA spontaneous contrast may be observed with very poor myocardial function, although this is not a specific finding (Figure 10-47). Abnormal areas of myocardial echogenicity have been observed; however, myocardial tissue characterization by echocardiography is not well established in horses, and gray scale also depends on technical factors.

Clinical laboratory tests can be useful in the identification of myocardial damage but may not necessarily distinguish myocarditis from myocardial cell injury induced by a toxin or by ischemia. Elevated plasma or serum myocardial fractions of CK (i.e., creatine kinase *MB fraction* [CK-MB]) or of lactate dehydrogenase (LDH; both LDH<sub>1</sub> and LDH<sub>2</sub>) suggest myocardial injury.<sup>309</sup> A more specific marker of myocardial is elevation of serum cTnI or troponin T.<sup>562,668-672</sup> Although normal values or mild elevations do not exclude cardiomyopathy or myocardial infiltration, elevated values point to recent cardiac muscle damage.

Diagnosis of myocardial disease requires clinical suspicion and integration of findings from clinical and laboratory examinations. Because of the extreme variability of findings, the presumptive diagnosis of myocardial disease can be made only after reviewing the history, physical examination, echocardiogram, ECG, and clinical laboratory tests. Definitive diagnosis of myocarditis requires transvenous endomyocardial biopsy, but this test is largely impractical and may not identify piecemeal inflammation, degeneration, infiltration, or necrosis.

Treatment of horses affected by myocardial disease is primarily supportive. Prognosis depends on the cause and severity of myocardial injury and the hemodynamic consequences of myocardial disease. All horses should be rested, preferably in a stall, until myocardial function, ECG, and serum troponin return to normal or at least remain stable for several weeks. A minimum rest of 1 month (and usually more) should be instituted before a horse is returned to work. Supplementation with vitamin E and selenium may be beneficial, particularly in cases with suspected nutritional deficiencies. Antiarrhythmic therapy

is administered when indicated for potentially life-threatening arrhythmias (see later in this chapter). Theoretically, an ACE inhibitor will reduce myocardial remodeling and unload the ventricle, assuming the drug can be sufficiently absorbed and biotransformed to an active state. When CHF has developed, digoxin and furosemide are prescribed as previously discussed in the section on CHF. Digitalization should be undertaken with caution in horses with ventricular extrasystoles because the arrhythmia may be aggravated, and it is not indicated in monensin toxicosis (see following discussion). If noninfective myocarditis is believed to be the cause of the arrhythmia or clinical signs, then corticosteroid therapy may be indicated, although its value is unsubstantiated. When the principal manifestation of myocardial disease is electrical (arrhythmias with otherwise normal myocardial function), the prognosis is fair to good for resolution of the arrhythmias. Horses with decreased myocardial function by echocardiography or those with CHF must be given a guarded prognosis for life and a poor prognosis for future performance. It is notable, however, that some horses with acute onset of CHF have recovered completely and returned to their prior performance levels. Such horses most likely suffered from acute myocarditis that resolved spontaneously or after anti-inflammatory therapy. Other horses may achieve a less spectacular recovery but still serve successfully as breeding animals.

## MYOCARDITIS

Myocardial inflammation, or myocarditis, is difficult to diagnose. The diagnosis is often entertained in horses with cardiac arrhythmias or abnormal myocardial function, particularly when cardiac signs occur after another illness and are associated with elevated cardiac isoenzymes and serum troponin I concentrations. Often the prior disorder is a viral, influenza type of condition or an infection caused by *Streptococcus* spp. It is logical that immune-mediated myocarditis is operative in these cases, but definitive cause-and-effect proof is lacking. Myocarditis may also follow parasitic migration, pericarditis, or infective endocarditis. Hematogenous spread to the heart may be another mechanism for myocarditis. Severe necrotizing myocarditis can lead to arrhythmias or to signs of myocardial dysfunction as discussed earlier. The signs, prognosis, and treatment of myocarditis are similar to that described in the preceding section.

## TOXIC INJURY OF THE MYOCARDIUM

A number of chemicals and plant toxins are potentially injurious to the myocardium. Ionophore antibiotics are among the most notorious causes of myocardial necrosis in horses.<sup>114-120</sup> Toxic myocardial injury also can occur after ingestion of white snake-root (*Eupatorium*), glycoside-containing Japanese yew plants (*Taxus* spp.), or cut oleander,<sup>673,674</sup> or also may occur from eating feed contaminated by *Epicauta* spp. (blister beetles), which contain the toxic element cantharidin.<sup>658,660,675</sup> Myocardial necrosis has also been observed after endotoxemia, particularly with clostridial infection, salmonellosis, and torsion of the large colon. Rattlesnake venom has been associated with cardiac injury and arrhythmias.<sup>676</sup>

Horses are uniquely sensitive to ionophore antibiotics, which are used as a coccidiostat in poultry production and as a growth promoter in cattle. Monensin toxicosis (>2 to 3 mg/kg) has occurred most frequently, but salinomycin (0.6 mg/kg or higher) and lasalocid (21.5 mg/kg or higher) also have caused myocardial injury and death in horses.<sup>677</sup> Ionophores react

with polar cations to form lipid-soluble complexes, leading to cation transport across myocardial cell membranes. Various ionophores demonstrate particular affinities for different cations, although lasalocid may complex with a variety of ions. Exposure of horses to the ionophore antibiotics usually stems from accidental contamination of equine feedstuffs at the mill or through accidental delivery of poultry or cattle feed to horses. In most outbreaks, a recently acquired ration was fed.

Clinical signs of horses with ionophore toxicity vary with the specific type, quantity, and concentration of ionophore ingested and the preexisting health and body condition of the exposed horses. A wide range of clinical signs has been observed by one of the authors in exposed horses ranging from none to clinical signs involving almost all body systems. Weakness, lethargy, depression, anorexia, ataxia, colic, diarrhea, profuse sweating, and recumbency have been seen. The cardiac findings are similar to those previously described for myocardial diseases. If sudden death occurs, it is usually within 12 to 36 hours of ingestion of the contaminated feed. A single dose may lead to death from cardiac arrhythmias before the development of myocardial necrosis.

A recent report indicates that sublethal toxicosis may be well tolerated by some but not all horses, and echocardiography and exercise testing may help to identify horses affected more severely.<sup>120</sup> Polyuria and hematuria are other signs that have been reported in ponies after ionophore exposure.

A diagnosis of ionophore toxicity is based on the detection of the ionophore in the feed or stomach contents of exposed horses. Various clinicopathologic abnormalities are observed with monensin toxicity, including decreased serum calcium, potassium, magnesium, and phosphorus, as well as increases in serum urea, creatinine, unconjugated bilirubin, aspartate aminotransferase (AST), and muscle enzymes. Elevated concentrations of serum cardiac troponin cTn<sub>i</sub> and isoenzyme patterns of CK and LDH have indicated cardiac, skeletal, and RBC damage. Elevated packed cell volume (PCV) and total solids have been associated with dehydration. Echocardiographic evaluation of affected horses has revealed marked decreases in shortening fraction with segmental wall motion abnormalities that range from mild to severe.

Prognostically, horses that exhibit decreased shortening fraction and dyskinesia shortly after exposure to monensin generally are unlikely to survive. Horses with mild decreases in shortening fraction survive and may be useful breeding animals, but most do not return to previous performance levels. Horses with normal echocardiograms typically survive and return to work at their previous levels. Postmortem findings range from no visible lesions to myocardial pallor and signs of CHF. Severe myocardial necrosis and fibrosis has been observed in horses with decreased shortening fraction or ventricular dyskinesia on echocardiography.

Treatment for affected horses is largely symptomatic (see previous discussion), unless very recent exposure is known. Vitamin E has been suggested to have a protective effect in other species and may be beneficial in affected horses. Digoxin and calcium channel blockers are contraindicated in acutely affected horses. If ingestion of the contaminated feedstuff is recent, then treatment with activated charcoal or mineral oil is indicated to reduce absorption of the ionophore. IV fluid and electrolyte replacement therapy may be indicated, as well as antiarrhythmic drugs, for any life-threatening arrhythmias. Stall rest in a quiet environment for up to 8 weeks after exposure is most important, because echocardiograms recorded after trivial exercise or

excitement can reveal residual disease characterized by marked decreases in fractional shortening and myocardial dyskinesia.

## DILATED CARDIOMYOPATHY

Idiopathic dilated cardiomyopathy is a disorder of the myocardium characterized by global reduction of LV systolic function that cannot be explained by valvular, vascular, coronary, or congenital heart disease. The inciting cause of dilated cardiomyopathy is generally undetermined, although myocarditis or prior toxic injury is often suspected. Relentless junctional or VT also can lead to a dilated cardiomyopathic state that is reversible with control of the tachyarrhythmia. The clinical signs of cardiomyopathy are similar to those described earlier for myocardial diseases. Echocardiography is diagnostic, revealing cardiomegaly with biatrial and biventricular dilatation and depressed shortening fraction (see Figure 10-22, B). Symptomatic therapy with digoxin and diuretics may temporarily stabilize CHF and lead to transient improvement, but most horses deteriorate in the 3 to 12 months after diagnosis and are humanely destroyed. Neither the history nor the postmortem examination reveals the cause, and generally only diffuse or multifocal myocardial degeneration, necrosis, and fibrosis are observed.

A form of dilated cardiomyopathy also can be caused by vitamin E and selenium deficiency and is observed primarily in fast-growing foals from mares with a marginal or deficient selenium status raised in selenium-deficient areas. Affected foals are usually younger than 6 months of age and experience an acute onset of weakness, recumbency, respiratory distress, pulmonary edema, tachycardia, murmurs, and arrhythmias. The prognosis for foals affected with the myocardial manifestations of white muscle disease is poor, and most die within 24 to 48 hours after the onset of clinical signs. Laboratory abnormalities in affected foals include marked elevations of CK (including the MB fraction in foals with myocardial involvement), AST, and LDH, as well as hyperkalemia, hyponatremia, and hypochloremia. Myoglobinuria may occur. Echocardiography demonstrates the severity of myocardial involvement. Whole blood selenium, RBC glutathione peroxidase, and vitamin-E levels may be helpful in the diagnosis; however, tissue samples provide a more accurate indication of selenium stores. Treatment with vitamin E and selenium might be successful, but typically the myocardial necrosis is extensive and incompatible with life. Postmortem findings reveal pale streaking of the myocardium with intramuscular edema, myodegeneration, myocardial necrosis, and fibrosis or calcification. Prevention of white muscle disease is important in selenium-deficient areas. Supplementation of pregnant mares should occur during gestation based on individual blood and tissue selenium levels and should be continued during lactation, because more selenium is passed to the foal through the milk than across the placenta.

## ☞ VASCULAR DISEASES

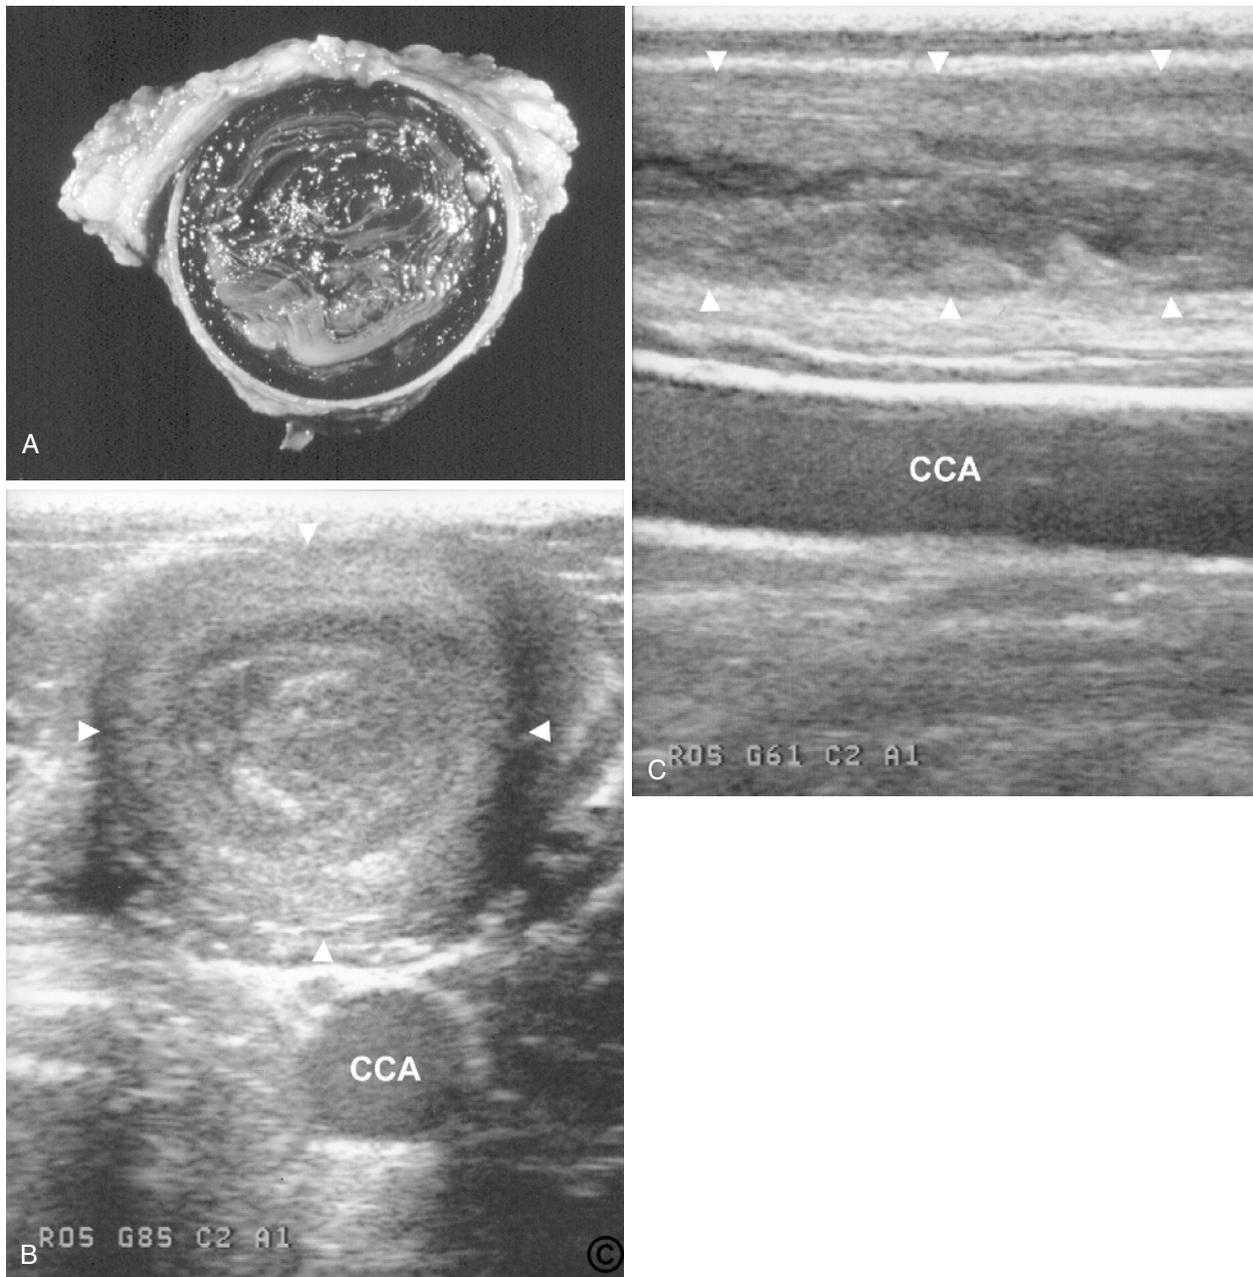

Acquired disorders of blood vessels include a variety of conditions, varying in cause and ranging from subclinical to devastating.\* Jugular vein thrombosis or thrombophlebitis is

probably the most common vascular problem encountered in clinical practice (Figure 10-48). Catheter embolization is observed periodically and has been amenable to surgical and percutaneous catheter retrieval.<sup>699,700</sup> Venous aneurysms,<sup>680</sup> vascular and lymphatic malformations, and angiomatous lesions are rare.<sup>612</sup> Rupture of the aorta or PA is usually a life-threatening event or leads to severe sequelae. Rupture of aortic sinus aneurysm into the ventricular septum or right heart chambers (Figures 10-49 and 10-50), aortic rupture into the pericardium, aortic aneurysms, and acquired aortic-pulmonary fistula have been reported.<sup>34,58,219,221,698</sup> Degenerative lesions (see Figure 10-50, A) including calcification may be observed in the aorta or PA.<sup>701</sup> Degenerative and calcific lesions affecting the bifurcation of the right and left pulmonary arteries also have been reported,<sup>702,703</sup> although the clinical importance of these is not well defined. Arteriosclerosis and arterial thrombosis may be caused by parasite migration in the mesenteric arteries<sup>704</sup> and possibly at the terminal aortic quadrifurcation (Figures 10-51 and 10-52). Aortic inflammation of unknown cause has been observed.<sup>508,513</sup> Rupture of the PA is a potential consequence of longstanding pulmonary hypertension and left heart failure. Arteriovenous communications occur rarely and may develop after vascular rupture or subsequent to growth of vascular tumors. Pulmonary vascular disease and associated hypertension may place a load on the RV, a condition called *cor pulmonale*. Although both acute and chronic airway obstruction can negatively affect right heart and overall cardiac function,<sup>555,705</sup> there is no compelling evidence to incriminate *cor pulmonale* as a common cause of clinically important heart disease in horses. Idiopathic pulmonary hypertension has been reported as a cause of AF in horses; however, left heart dysfunction was not completely excluded in the reported cases.<sup>62</sup> Tumors of the great arteries and veins are rare,<sup>612</sup> but neoplasms can compress or invade arteries and veins, including the PA and venae cavae. Mycotic disease within the guttural pouch is a well-recognized cause of arteritis and rupture of the affected arteries.

The echocardiographic observation of intravascular, spontaneous contrast within blood vessels and cardiac chambers has been suggested to indicate CV or rheologic disease,<sup>490,706</sup> as well as a normal phenomenon caused by rouleaux formation or platelet aggregates. This observation is common during ultrasound examinations and contrast may be observed in a variety of vessels, as well as in the heart (see Figure 10-47). Pronounced spontaneous echo contrast is especially likely when low flow rates exist as a result of bradycardia, arrhythmia, or myocardial failure, as well as when actual obstruction to blood flow in vessels is noted. Contrast is often prominent in valvular endocarditis. Lesions, thrombosis, or even venipuncture of the jugular vein can lead to spontaneous echo contrast in systemic veins and in blood flow entering the right side of the heart, often becoming more obvious if venous return suddenly increases. The identification of spontaneous contrast is also dependent on the operator with respect to transducer, gain, and gray-scale contrast settings. The clinical significance of isolated intravascular contrast cannot be stated with certainty; it has been observed in healthy horses, as well as those with CV disease.

Serious vascular disease often can be suspected from the clinical examination, although it may not be obvious until a catastrophic vessel rupture or fatal hemorrhage occurs. In general, significant *arterial* disease reduces perfusion to the

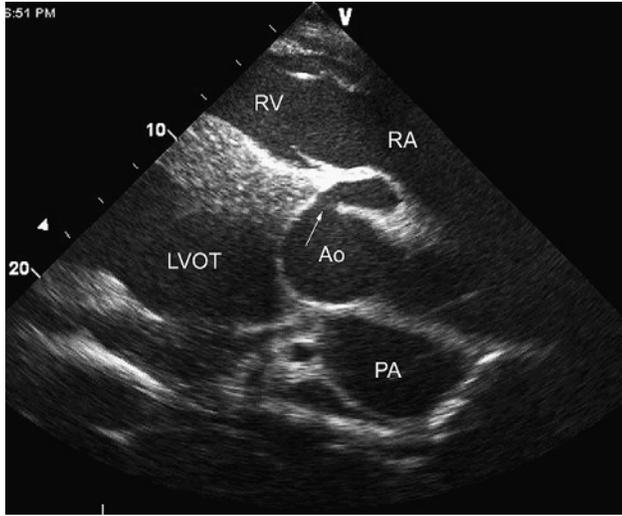

\*References 4, 34, 52, 55-58, 62, 64, 66, 103, 106-108, 111, 125, 137, 152, 171, 207, 218, 219, 221-228, 316, 364, 368, 396-398, 476, 489, 501, 506, 549, 597, 600, 612, 678, 679, 698.

**FIGURE 10-48** A, Postmortem specimen of a thrombosed jugular vein in cross-section. B and C, Ultrasonographic images obtained from a horse with jugular vein thrombosis in a cross-sectional (B) and a longitudinal (C) plane. The images show a mixed echogenic thrombus within the jugular vein (arrowheads). The common carotid artery (CCA) is displayed adjacent to the jugular vein. Residual blood flow through the affected area can be evaluated using duplex Doppler ultrasonography or newer vascular imaging technologies that directly visualize blood reflectors (e.g., red blood cells [RBCs]) in a gray-scale display (see DVD).

affected vascular bed, impairing tissue metabolism and function. If severe or complete, then ischemia may lead to tissue necrosis (infarction) and even perforation of a hollow organ. A bruit (auscultatory evidence of vascular narrowing or rupture) may be noted over the affected artery (or obvious hemorrhage if a superficial the vessel has ruptured). Ultrasound and Doppler examination can demonstrate serious arterial disease provided an acoustic window for examination is available.

Rarely angiography or nuclear scintigraphy is required to demonstrate arterial thrombosis or disruption. In major *venous* disease, the typical sign is swelling of soft tissues drained by the affected vessel. Palpable evidence of local inflammation and thrombosis may be found in superficial venous disease. Right-sided endocarditis, embolic pneumonia, and pulmonary embolism are potential consequences of systemic venous disease.

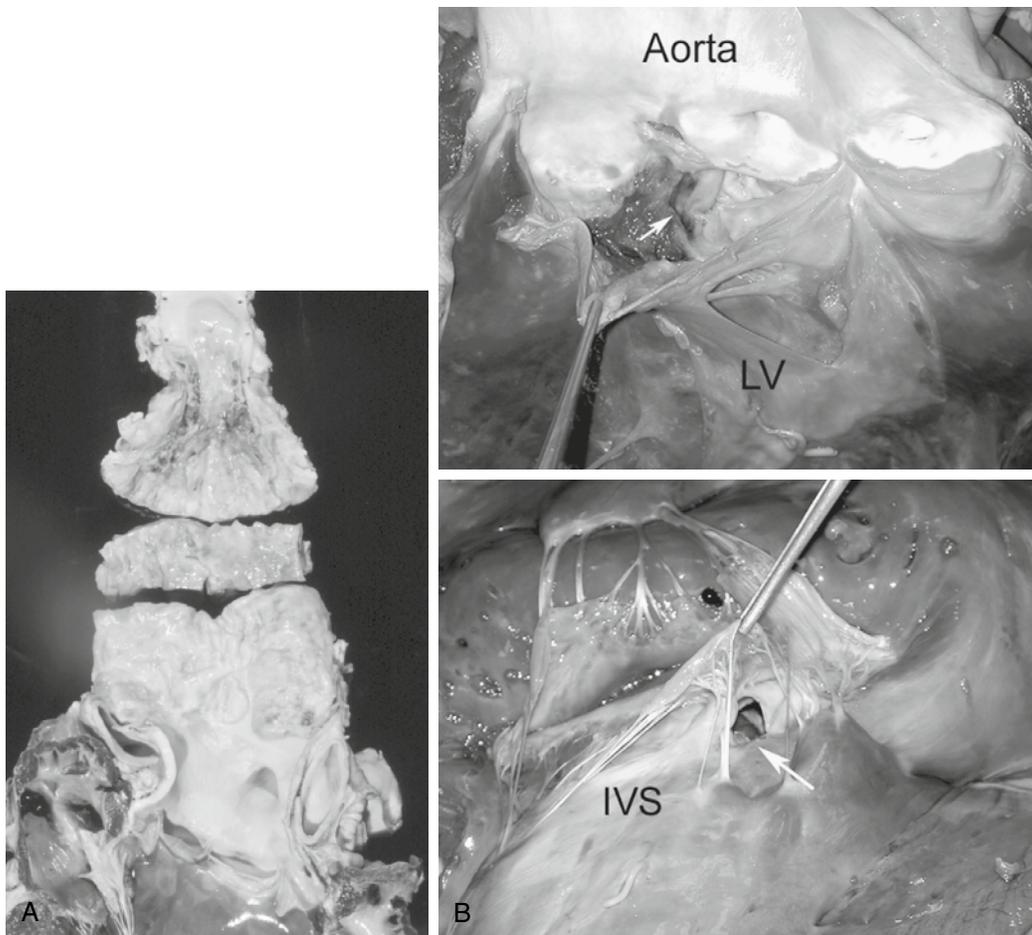

**FIGURE 10-49** Aortic to cardiac fistula. Off-angle long-axis image of the proximal aorta (Ao) shows the origin (arrow) of a ruptured sinus of Valsalva aneurysm. This channel communicated with the right atrium (RA) in another plane. The right ventricle (RV) and pulmonary artery (PA) are slightly dilated because of left-to-right shunting.

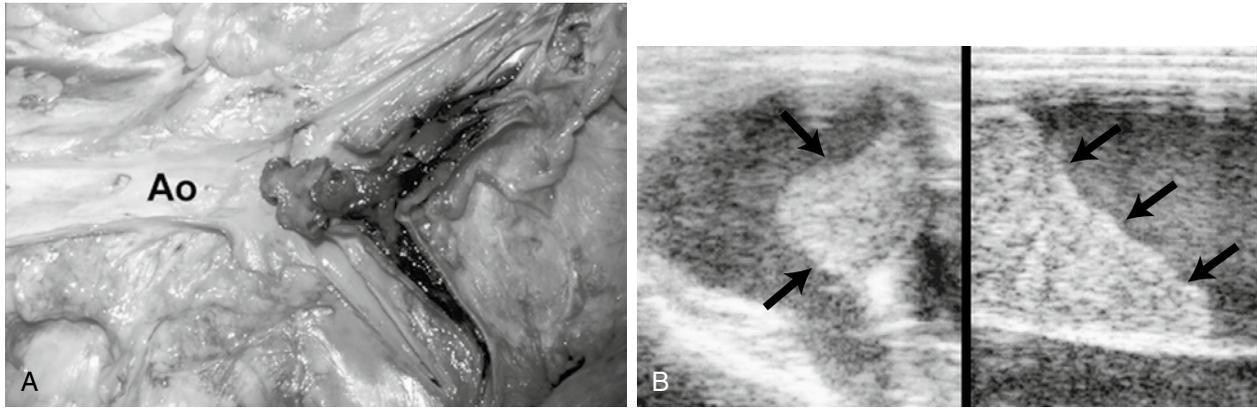

## THROMBOPHLEBITIS

Thrombophlebitis, the inflammation and thrombosis of a vein, is most commonly caused by IV catheterization or IV injection (see Figure 10-48).<sup>398,689</sup> The jugular veins are most often affected. Thrombosis can develop in the absence of preexisting vessel trauma subsequent to coagulation disorders. Clinical signs of phlebitis are straightforward, including swelling over the affected vein and pain on palpation of the involved tissues. Thrombotic occlusion results in distention of the veins and possibly subcutaneous edema adjacent to the affected area. Marked swelling, heat, and pain on palpation, combined with fever, hyperfibrinogenemia, or a neutrophilic leukocytosis, indicate infection of the thrombus.

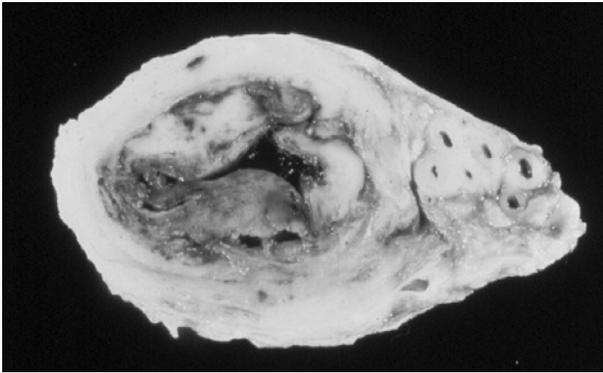

The diagnosis and assessment of thrombophlebitis is based on the detection of the previously described clinical signs and examination by duplex Doppler ultrasonography (see Figures 10-48, B and C). Imaging of the affected vein reveals filling of the lumen with an anechoic, hypoechoic, hyperechoic (if gas filled), or mixed echogenic material that partially or completely occludes the vessel. Ultrasonographic evaluation may also reveal thickening of the vessel wall, perivascular swelling, tracts extending from the vein to the subcutaneous tissues or

**FIGURE 10-50** Aortic disease. **A**, Severe atheromatous change with secondary *Streptococcus* spp. infection of the proximal aorta. The intimal and subintimal change begins just distal to the coronary ostia. Representative sections of the ascending aorta are shown. *Strongylus vulgaris* was not found. The most distal segment was necrotic and severely narrowed flow across the region. **B**, Dissecting lesion communicating the root of the aorta (top panel, arrow) to the right side of the heart across the intraventricular septum (IVS). The distorted tricuspid valve is retracted to demonstrate the lesion on the right (arrow).

**FIGURE 10-51** Aorto-iliac thrombosis. **A**, Postmortem image showing the thrombus in the terminal aorta (Ao) and the iliac arteries. **B**, Images obtained by rectal ultrasonographic examination in cross-sectional (left) and longitudinal (right) direction. The thrombus is evident as hyperechoic mass within the vessel (arrows).

**FIGURE 10-52** Verminous arteritis and thrombosis in the cranial mesenteric artery caused by *Strongylus vulgaris*.

skin, or subcutaneous abscesses. Cavitation in the center of a thrombus is suggestive of infection and represents a target for aspiration and bacterial culture. Stagnant or turbulent flow may be manifested by increased spontaneous venous contrast. Flow across the affected zone may be evaluated by contrast venography using agitated saline as a contrast agent, with pulsed-wave or color-coded Doppler studies, or with newer vascular imaging technologies that directly visualize blood reflectors (e.g., RBCs) in a gray-scale display. Venous drainage proximal and distal to the area of thrombosis also should be assessed, because collateral circulation may still enter the vein distally. A careful evaluation of the communicating large veins and of the heart should be performed in horses with infective thrombophlebitis. Bacterial endocarditis may develop secondary to embolization of infective thrombus or bacteremia.

Infections with multiple organisms should be anticipated in cases of infective thrombophlebitis, and high doses of broad spectrum antimicrobials should be administered until culture and sensitivity results of the aspirate are obtained. Metronidazole (15 mg/kg, PO every 6 hours, or 25 mg/kg, PO every 12 hours) should be considered if anaerobic infection is suspected. Flunixin meglumine (1 mg/kg every 12 hours) may be added to reduce inflammation. Local therapy including hot compresses and topical ichthammol (ammonium bituminosulfonate), NSAIDs (diclofenac sodium), heparinoids (chondroitin

polysulfate), or dimethyl sulfoxide may be helpful in the treatment of thrombophlebitis. If antimicrobial therapy is unsuccessful, then surgical resection of the affected tissue may be indicated. Recanalization of an affected vein often occurs and can be documented by Doppler or contrast ultrasound studies demonstrating blood flow between the vessel wall and the thrombus. Occasionally, loculation may be detected within the ends of the thrombus. Such loculation may result in persistent fibrous webs within the vein that restrict venous return. Venous stricture also may occur because of longstanding thrombophlebitis. Complete fibrous occlusion of the jugular vein may impede venous return from the head such that if adequate collateral circulation does not develop, impaired venous drainage of the head and neck may limit performance. Vascular surgery may be required to regain venous drainage. Alternatively, an expert in interventional radiology or medicine can be consulted regarding other options, such as intravascular stenting.

## AORTOILIAC THROMBOSIS

Aortoiliac thrombosis is an uncommon, but potentially serious, disorder. The gross appearance, histologic features, and clinical findings of this vaso-occlusive disorder have been reviewed extensively, and the interested reader is directed to these and other related reports.\*

The terminal aorta and the iliac arteries, including their proximal branches, are the focus of involvement in this disease. Vessels become partially to completely occluded by multifocal ingrowths of fibrous tissue, laminated thrombi, or fibrous plaques.<sup>222</sup> Histologic lesions include organized, fibrous connective tissue, hemosiderin-laden macrophages, irregular vascular channels, and disruption of the intima and internal elastic lamina. The lesions are generally devoid of fat. Arteriosclerotic and atherosclerotic aortic lesions have also been observed at other sites as well (see Figure 10-50, A). Suggested causes of these arterial disorders include *Strongylus vulgaris* infection, systemic infections, embolization, and vasculitis. No convincing evidence indicates that aortoiliac thrombosis is consistently caused by *Strongylus* spp. infection, and Azzie<sup>224,226</sup> has refuted this contention.

\*References 56, 222-227, 396, 397, 683, 690, 707-713.

Although aortoiliac thrombosis is uncommon, it can be associated with severe performance problems, including reproductive failure.<sup>690</sup> The typical features include exercise-associated, typically unilateral, hindlimb lameness, ataxia, or collapse.<sup>222,224,226,227</sup> Aortoiliac thrombosis has also been diagnosed as a cause of breeding failure in stallions.<sup>224,226,227</sup> Physical examination of an affected horse at rest may reveal weak metatarsal arterial pulses or delayed saphenous refill in the affected limb. The temperature of the limb in the resting animal is usually normal, unless complete arterial occlusion has occurred, in which case the limb is cold and painful and may become edematous. Exercise in affected animals results in an exercise-associated gait abnormality (lameness, ataxia, or weakness), with a decreased or absent metatarsal and digital pulse and delayed or absent saphenous refill. Claudication may cause the horse to become very uncomfortable and reluctant to bear weight on the affected limb. Marked hyperpnea, other signs of distress, and profuse, generalized sweating are often present with trembling of the affected limb. A rectal examination may reveal fremitus, a weak or absent pulse, or aneurysmal dilatation of the affected artery or arteries. These abnormalities may be more evident after exercise and may help to confirm the diagnosis.

The diagnosis can be confirmed by ultrasonographic evaluation of the terminal aorta and iliac arteries (see [Figure 10-51](#)), using a high-frequency (5 or 10 MHz) rectal transducer,<sup>223,225,397</sup> or by nuclear techniques.<sup>711,714</sup> Doppler studies may indicate abnormal blood flow in the femoral arteries.<sup>715</sup> Essential abnormalities include a hypoechoic to echogenic mass protruding into the arterial lumen. An estimation of the degree of obstruction can be made based on the percentage of the artery occluded. Many cases are longstanding, and hyperechoic areas, even tissues sufficiently echo-dense to cast acoustic shadows, may be imaged within the aortic or iliac thrombus (these findings suggest mature scar tissue and calcification).

The prognosis for this disorder is guarded. No controlled studies have evaluated therapy for this condition. A case survey<sup>709</sup> suggests no treatment consistently improves outcome, but potential benefit of surgical or catheter-based thrombectomy or anticoagulation should be considered. Various medical treatments have been reported including IV sodium gluconate, larvicidal dewormings, phenylbutazone, low molecular weight dextran, anticoagulants,<sup>713</sup> and a controlled exercise program. Ultrasound-guided balloon thrombectomy<sup>712</sup> has been successful in some cases but is probably most useful in cases of active thrombosis in which the obstruction can be partially relieved. Early diagnosis is essential if therapy is to be beneficial. Treatment is aimed at improving collateral circulation and preventing additional thrombus formation.

## PARASITIC INFECTION

The migrating larval forms, particularly L<sub>4</sub>, of *Strongylus vulgaris*, are known causes of arterial disease, particularly involving the aorta and the cranial mesenteric artery and its branches (see [Figure 10-52](#)). Lesions have been described as far forward as the bulbous aorta and the aortic sinuses in infected horses. Rounded fibrous plaques and mural thrombi have been reported in the thoracic and cranial abdominal aorta in 9.4% of horses examined immediately after death by Cranley and McCullagh.<sup>106</sup> These investigators reported a statistical association between the occurrence of proximal aortic

*S. vulgaris* lesions and the presence of focal ischemic lesions in the myocardium. They hypothesized that these lesions were consequent to microembolism from parasitic lesions. With the advent of ivermectin and other new anthelmintics, as well as aggressive deworming programs currently recommended by practicing veterinarians, heavy *S. vulgaris* larval migration damage occurs much less frequently. However, migration of *S. vulgaris* L<sub>4</sub> larvae must be considered in horses with poor deworming histories, high potential of exposure, high fecal egg counts, and palpable abnormalities on rectal examination, as well as when fremitus or aneurysmal dilatation of the aorta is found, particularly in the region of the cranial mesenteric artery or iliac system. An ultrasonographic evaluation of the cranial mesenteric artery is possible and can be used to confirm the diagnosis of thrombosis in these vessels.<sup>687,709</sup> Treatment should consist of larvicidal deworming, combined with a rigorous individual and environmental parasite control program.

## ARTERIOVENOUS FISTULAS

Arteriovenous fistulas occur uncommonly and are most often detected with large vascular tumors (hemangiomas, hemangiosarcomas) or as a rare congenital defect or post-traumatic sequelae.<sup>686,716</sup> Classic features include a continuous thrill and murmur over the affected area, localized edema, slowing of the heart rate after occlusion of the shunt, and signs of increased CO if the shunt flow is great. Clinically important fistulas are more likely to develop where large arteries and veins run in parallel, as with the jugular vein and carotid artery. A diagnosis can be made with Doppler ultrasound, including pulsed-wave and color-flow Doppler to demonstrate continuous and pulsatile flow from the artery, through the associated communication, into the distended veins. A complete CV examination should be performed because a large arteriovenous communication could lead to cardiac failure. Treatment depends on the underlying cause, and an experienced surgeon should be consulted. No treatment may be indicated with small, uncomplicated arteriovenous communications. Large vascular neoplasms are usually inoperable at the time when they are diagnosed or complicated by the possibility of metastasis.

## ARTERIAL RUPTURE

Rupture of the aorta or its branches or of the PA is reported sporadically. Rupture of the aortic root has been commonly reported in older breeding stallions but may also occur in older mares or in younger horses.<sup>58</sup> Rupture typically involves the right aortic sinus of Valsalva (see [Figures 10-49 and 10-50, B](#)). The aortic root can rupture into the RA, RV, intraventricular septum, or pericardial space.<sup>58,152,220,221</sup> Dystrophic changes in the media of the aorta have been reported, and the hypertension associated with breeding has been implicated as a cause of aortic root rupture. Aneurysms of the right sinus of Valsalva have also been reported and are related to congenital defects in the media of the aorta near the right aortic sinus. Rupture of the middle uterine artery can lead to fatal peripartum hemorrhage.<sup>218</sup> Ruptures of the extrapericardial aorta or other blood vessels leading to fatal hemorrhage or a systemic to pulmonary shunt have been reported.<sup>52,57-60,62,64-68</sup>

Rupture of an artery is often a catastrophic event, and most diagnoses are made at the necropsy floor. Antemortem diagnosis of an aortic sinus of Valsalva aneurysm is possible

by echocardiography. Aside from breeding, horses with diagnosed aortic aneurysms or aortocardiac fistulas should not be used for athletic endeavor, because rupture of the aneurysm could occur at any time. When aortic root rupture or rupture of a sinus of Valsalva aneurysm communicates with the RA or RV, right-sided heart failure can occur. Rupture of the more distal aorta into the pulmonary artery also can occur.<sup>34</sup> These types of fistulas typically cause a continuous heart murmur. Cardiac arrhythmias (usually VT) may also develop, especially if dissection progresses into the intraventricular septum.<sup>220</sup> The prognosis for life in these horses is generally guarded, depending on the site and size of the communication. Some horses survive, and others may require supportive treatment for CHF.

Pulmonary artery rupture is most often caused by chronic pulmonary hypertension and PA dilatation. This is most commonly detected in conjunction with severe MR and pulmonary hypertension. The potential for PA rupture should be considered whenever a large dilated main PA or left and right PA is detected echocardiographically. Affected horses should be considered unsafe for riding or driving and should not be used, except for breeding, because of the possibility of sudden death. Focal medial calcification of the PA is not uncommon at necropsy<sup>506,703</sup> but is of uncertain clinical significance.

## ☞ CARDIAC ARRHYTHMIAS

Cardiac arrhythmias are disturbances in heart rate, rhythm, or conduction and can be classified based on atrial and ventricular rate, anatomic origin of the impulse, method of impulse formation, and conduction sequence. A wide variety of cardiac arrhythmias have been recognized.<sup>566,717</sup> Of principal concern to the clinician are the hemodynamic consequences of arrhythmias (reduced pressure, flow, perfusion) and the potential for further electrical instability (myocardial fibrillation, sudden death).

The electrophysiologic basis of cardiac arrhythmias is not discussed in this section; however, other sections of the chapter provide information regarding abnormal automaticity, re-entry, and other mechanisms of arrhythmogenesis. Cardiac arrhythmias are classified based on the anatomic origin of the manifest ECG mechanism (Box 10-9). The reader should be aware that some arrhythmias, especially those originating in the AV junction, may mimic either atrial rhythm disturbances or “high” ventricular rhythms. For purposes of this discussion, the authors have elected to distinguish *atrial* from *junctional*; however, the term *supraventricular* may also be applied to these rhythm disturbances.

The clinical evaluation of the horse with an arrhythmia is reviewed in Box 10-10. Routine electrocardiography, clinical chemistry, hematology, echocardiography, exercising electrocardiography, postexercise electrocardiography, and continuous 24-hour electrocardiographic (Holter) monitoring can all play a role in the complete evaluation of a horse suspected of having intermittent cardiac arrhythmias. These points are discussed further following.

### SINUS RHYTHMS

A number of physiologic sinus rhythms are recognized. These can be explained by the effects of autonomic nervous system traffic on the SA node (Figure 10-53). Normal horses at rest demonstrate vagal-mediated sinus bradycardia, sinus arrhythmia, sinus block, and sinus arrest; however, fear or a sudden stimulus may provoke sympathetically driven sinus tachycardia. Exercise leads to pronounced sinus tachycardia, with

### CARDIAC RHYTHMS OF THE HORSE

#### Sinus Mechanisms\*

- Normal sinus rhythm
- Sinus arrhythmia
- Sinoatrial block or arrest
- Sinus bradycardia
- Sinus tachycardia

#### Atrial Rhythm Disturbances

- Atrial escape complexes†
- Atrial premature complexes
- Atrial tachycardia: nonsustained and sustained
- Atrial flutter
- Atrial fibrillation
- Reentrant supraventricular tachycardia

#### Junctional Rhythm Disturbances

- Junctional escape complexes†
- Junctional escape rhythm† (idio nodal rhythm)
- Junctional premature complexes
- Junctional (“nodal”) tachycardia
- Re-entrant supraventricular tachycardia

#### Ventricular Rhythm Disturbances

- Ventricular escape complexes†
- Ventricular escape rhythm† (idioventricular rhythm)
- Ventricular premature complexes
- Accelerated ventricular rhythm (idioventricular tachycardia)
- Ventricular tachycardia
- Ventricular flutter
- Ventricular fibrillation

#### Conduction Disturbances

- Sinoatrial block\*
- Atrial standstill (hyperkalemia)
- Atrioventricular blocks: first degree,\* second degree,\* third degree (complete)
- Ventricular pre-excitation

\*Generally physiologic.

†Escape complexes develop following another rhythm disturbance.

heart rates often exceeding 200 beats/min. AV conduction, as a general rule, tends to follow sinus activity. During sinus tachycardia, the P-R interval shortens, whereas during periods of progressive sinus node slowing, the P-R interval generally prolongs. Mobitz type I second-degree AV block (Wenckebach periodicity) often follows a progressive prolongation of the P-R interval. Sinus rate and AV conduction usually change in parallel; however, some horses appear to control BP during high sinus tachycardia by blocking impulses in the AV node. Second-degree AV block is more likely in a standing horse, in a horse that has suddenly stopped submaximal exercise, or after a brief surge of sinus tachycardia in an anxious animal.

Sinus rate and rhythm should be carefully monitored in the critically ill or anesthetized horse because heart rate is a major determinant of CO and ABP (see Figure 10-4, B). Sedative drugs and anesthetics can cause sinus bradycardia or sinus

## BOX 10-10

EVALUATION OF THE HORSE WITH A  
CARDIAC ARRHYTHMIA

- General medical history, past illnesses, past and current medications
- Work history and exercise tolerance
- General physical examination
- Physical examination: evidence of congestive heart failure
  - Subcutaneous edema
  - Jugular venous distention and pulsations
  - Pulmonary edema
  - Pleural and peritoneal effusion
  - Weight loss, poor condition
- Auscultation of the heart
  - Assessment of heart sounds (rhythm, third heart sound)
  - Assessment of heart murmurs
- Resting electrocardiogram
  - Heart rate and cardiac rhythm
  - Analysis of P-QRS-T waveforms
- Postexercise electrocardiogram
- Exercise (or treadmill) electrocardiogram
- Clinical laboratory studies
  - Complete blood count (rule out anemia, infection)
  - Blood culture (in cases of suspected endocarditis)
  - Serum electrolytes (particularly potassium and possibly magnesium)
  - Serum biochemical tests (especially renal function)
  - Skeletal muscle enzymes (cardiac isoenzymes)
  - Serum troponin concentration
  - Red blood cell potassium
  - Fractional excretion of potassium
- Echocardiogram/Doppler echocardiogram
  - Examine for cardiomegaly or reduced myocardial function
  - Identify predisposing cardiac lesions and abnormal flow
- Serum/plasma concentrations of cardioactive drugs
  - Serum digoxin concentration
  - Plasma quinidine concentration
- Response to medications

(Modified from Bonagura JD: Clinical evaluation and management of heart disease, *Equine Vet Educ* 2:31–37, 1990.)

arrest. Anesthetic drugs, hypoxia, traction on an abdominal viscus, ocular manipulation, hypothermia, increased intracranial pressure, and hypertension can depress sinus node function. Concurrent depression of the sinus node with stimulation of latent pacemakers in the coronary sinus or AV junction can lead to ectopic rhythms in the anesthetized horse. Conversely, an increasing sinus rate may indicate inadequate depth of anesthesia, pain, hypotension, hypovolemia, hypercarbia and hypoxemia, anemia, endotoxemia or sepsis, pyrexia, systemic inflammatory response syndrome (SIRS), anaphylaxis, or excessive catecholamine administration. Specific therapy for sinus tachycardia is rarely required because it represents a physiologic response to stress. However, when sinus tachycardia is identified, the cause must be sought and treated as appropriate.

Sinus bradycardia is generally a benign rhythm in standing horses; however, when encountered during sedation or anesthesia, this rhythm can lead to hypotension. Treatment of symptomatic sinus bradycardia can include the infusion of catecholamines (dobutamine, dopamine, epinephrine) or the administration of anticholinergic drugs (atropine, glycopyrrolate). Dopamine or dobutamine can be infused to increase heart rate, contractility, and ABP; however, reflex AV block may develop in some horses.<sup>209,213,236,294</sup> Excessive administration of catecholamines causes sinus tachycardia and ectopic beats. Anticholinergic drugs may not be effective in the setting of anesthetic-induced depression of SA function, particularly if vagal efferent traffic is low. Gastrointestinal complications including ileus and colic may develop after anticholinergic drug therapy; thus it should not be chosen for trivial rate problems.

### ATRIAL ARRHYTHMIAS

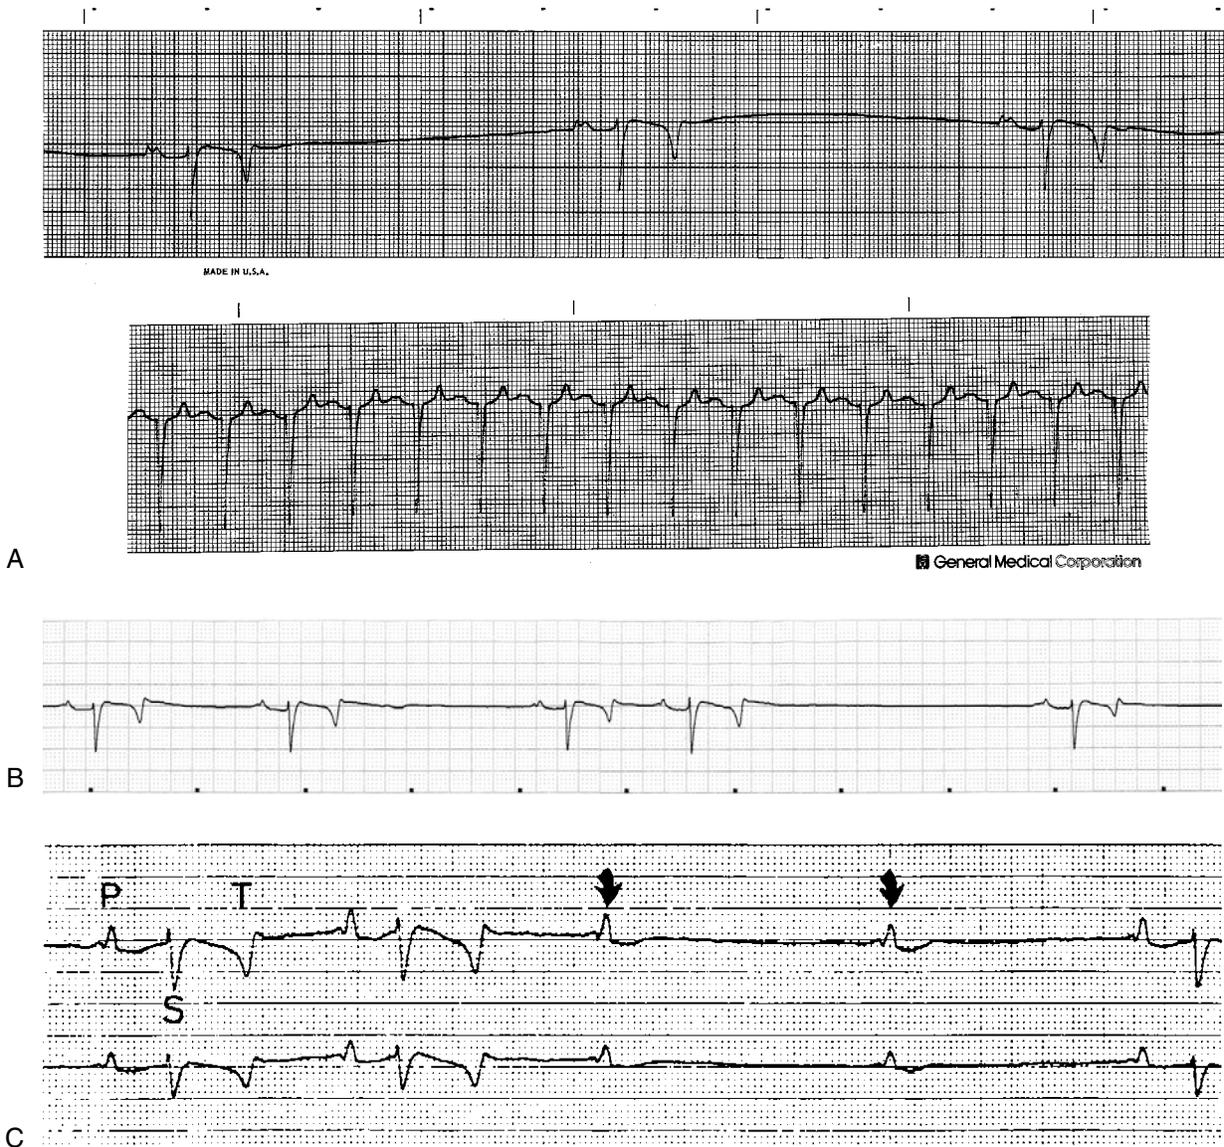

Rhythms originating in the atria are common. These disturbances often develop as functional disorders with no overt structural cardiac lesion. Autonomic imbalance (including high sympathetic activity or high vagal tone), hypokalemia, drugs (catecholamines, anesthetics), infections, fever, anemia, hypoxia, and colic can be associated with APCs. Atrial rhythm disturbances are also very common in the setting of structural lesions of the heart valves, myocardium, and pericardium. Cardiac conditions known to predispose to atrial arrhythmias include mitral or tricuspid insufficiency, endocarditis, myocarditis, cardiac (atrial) enlargement, myocardial fibrosis, and myocardial ischemia. APCs can precipitate sustained atrial arrhythmias, including atrial tachycardia, atrial flutter, and AF. The large size of the equine atria and the frequent presence of microscopic atrial fibrotic lesions likely predispose the horse to these sustained arrhythmias. The high resting vagal tone present in most horses serves to shorten the duration of the action potential of atrial myocytes and also facilitates development of sustained atrial tachyarrhythmias, which probably depend on re-entry.

Atrial arrhythmias are the most common abnormal rhythms detected in horses (Figures 10-54 and 10-55).<sup>\*</sup> APCs are the least complex of these rhythm disturbances; these can be clinically insignificant or associated with exercise intolerance or other signs of cardiac disease. In contrast, atrial tachycardia, atrial flutter, and AF are more likely to become clinically important. The overall importance of APCs is often difficult to ascertain. Routine ECG rhythm strips recorded from over 950 horses and interpreted by one of the authors indicated that atrial arrhythmias, overall, were present in less than 3% of the horses studied. However, when clinically normal horses were examined by Holter monitor, APCs were recorded in 28% of the horses. Thus it appears that the incidence of atrial arrhythmias depends not only on the population examined but also on the methods used for identification. These rhythm disturbances should be assessed in light of other clinical findings.

### ATRIAL PREMATURE COMPLEXES

Atrial premature complexes are detected by auscultation and are documented by an ECG. Auscultation usually reveals a regular sinus rhythm that is interrupted by an obviously

<sup>\*</sup>References 2, 33, 39, 42, 46, 55, 109, 134, 140, 174, 190, 191, 193, 195, 201, 293, 363, 469, 495, 546, 556, 568, 574, 576, 578, 718-731.

**FIGURE 10-53** Sinus rhythms. **A**, Sinus bradycardia (*top*) and tachycardia (*bottom*). Base-apex lead recorded at 25 mm/sec. Whereas two consecutively blocked P-waves are considered normal on a 24-hour ECG, these phenomenon are observed infrequently (in approximately 1% of normal horses). **B**, Sinus arrhythmia with sinus arrest/sinus block recorded at 25 mm/sec paper speed. **C**, Sinus arrhythmia with second-degree atrioventricular block (*arrows*). An ambulatory electrocardiogram (ECG) is shown; transthoracic leads recorded at 25 mm/sec. Whereas two consecutively blocked P-waves are considered normal on a 24-hour ECG, these phenomena are observed infrequently (in approximately 1% of normal horses).

premature beat or—in case of a blocked APC—by an abnormal pause. Premature atrial contractions may be fully interpolated (continuation of the regular sinus rhythm after the premature atrial contraction is noted), or a pause may occur (if the sinus node is reset or the premature complex is nonconducted). The ECG is characterized by a premature (usually narrow) QRS complex, which is preceded by an abnormal, premature P wave (P' [P prime wave]) that is often buried within the preceding T wave. If the impulse arrives in the AV node before complete repolarization, then the P-R interval is longer than normal (physiologic first-degree AV block). If the ectopic P' wave is nonconducted (physiologic second-degree AV block), then a pause will be evident in the ventricular rhythm (see [Figure 10-54](#)). Premature atrial impulses can also be conducted aberrantly

through the ventricle as a result of incomplete repolarization or persistent refractoriness of ventricular conducting tissues; this causes the QRS-T complex to be wider than normal or atypical in configuration. Care must be taken not to overdiagnose APCs. Sinus arrhythmia and sinus bradycardia often lead to variations in the P-P intervals, and often a “wandering atrial pacemaker” gradually alters the P wave morphology. Exercise or excitement will abolish such physiologic rhythms.

APCs, as a general rule, are more likely to be clinically significant in the following circumstances: When they (1) are frequent at rest, (2) associated with runs of atrial tachycardia, (3) related to poor performance (if other causes are excluded), (4) precipitate paroxysmal atrial flutter or fibrillation, or (5) develop in conjunction with structural cardiac disease.

**FIGURE 10-54** Electrocardiograms (ECGs) with atrial rhythm disturbances (recorded at 25mm/sec). **A**, Premature atrial complexes (*arrows*). The premature P waves of different morphology, the slightly prolonged P-R interval indicating atrioventricular nodal refractoriness, and the normal-appearing QRS complex indicating a supraventricular origin are notable. A slight conduction aberrancy is evident in the second premature QRS complex (see also Figure 10-16). **B**, Premature atrial complexes occurring during the QT interval of the preceding complexes. The first premature complex is nonconducted (*arrow*), the second premature complex is conducted with first-degree AV block (*arrowheads*). **C**, Sustained atrial tachycardias. The top picture shows atrial tachycardia with rapid, regular P waves (*P*) and a variable ventricular rate response to conducted P waves. The base-apex lead recorded at 25 mm/sec. The lower trace shows atrial flutter (*F*) with variable ventricular response (*S*). Lead 3 recorded at 25 mm/sec.

Documentation of atrial arrhythmias *during* exercise may be critical for determining if paroxysmal atrial tachycardia or fibrillation is likely to be the cause of poor performance.<sup>428</sup> Clinical judgment must be used; however, because supraventricular premature complexes are most likely to occur in the immediate postexercise period, probably associated with autonomic imbalance. If these postexercise arrhythmias are not associated with clinical signs and are not detected during exercise, then they are unlikely to be clinically significant. Cardiac rhythm monitoring during exercise may be necessary to be certain.

Isolated APCs generally are not treated. The hemodynamic consequences of these rhythm disturbances are minor, unless sustained abnormal activity develops. Consideration of antiarrhythmic therapy might be appropriate if frequent atrial extrasystoles are documented to precipitate

AF. Unfortunately, neither quinidine nor procainamide are practical for chronic use, and the effectiveness of other antiarrhythmics including digoxin has not been established for this indication. Maintenance of normal serum potassium and magnesium may be important in suppressing atrial ectopic activity. In cases of suspected myocarditis, anti-inflammatory doses of dexamethasone might be considered as empiric therapy with consideration of adverse effects of such treatment.

#### ATRIAL TACHYCARDIA

Atrial tachycardia can be defined as a series of ectopic APCs. Atrial tachycardia may be sustained or nonsustained (paroxysmal) and is generally precipitated by a single APC. The atrial rate is rapid and regular; however, because ectopic P waves can

be blocked physiologically in the AV node, an irregular ventricular rate response often results (see Figure 10-54, C). Atrial rates of 120 to 300 beats/min are typical in horses with sustained atrial tachycardia. At lower atrial rates, 2:1 AV conduction may yield a regular, relentless heart rate. At the higher atrial rates, the rhythm may be indistinguishable from atrial flutter. Differentiation of atrial tachycardia from flutter may not be critical because both arrhythmias seem to carry the same clinical significance and are treated in the same general way. Sustained atrial tachycardia is most often recognized during treatment of horses with quinidine sulfate. Before conversion of AF to sinus rhythm, atrial tachycardia may be observed (see Figure 10-55, A); thus in this setting, rhythm indicates a partial therapeutic effect of quinidine on the atrial myocardium. When this atrial tachycardia occurs as an isolated finding, structural or underlying myocardial disease should be suspected and the horse should be considered predisposed to the development or recurrence of AF. Treatment is the same as that described for AF. If the ventricular response rate is especially rapid (>120 beats/min), then consideration can be given to administration of either digoxin to block AV nodal conduction or possibly to diltiazem if digoxin is ineffective (see Table 10-6). ABP should be monitored carefully if diltiazem is administered.<sup>243,732,733</sup>

### ATRIAL FLUTTER

Isolated atrial flutter is probably less common than atrial tachycardia and represents a form of atrial circuit movement or macroreentry. The clinical circumstances and assessment of this rhythm disturbance are identical to those of atrial tachycardia. The ECG in atrial flutter is characterized by a very rapid, abnormal, but regular atrial activity that is usually manifested as a “saw-toothed” ECG baseline. The atrial frequency often exceeds 300 beats/min. The RR intervals are usually irregular because of variable AV conduction, and fewer QRS and T complexes than flutter waves exist (see Figure 10-54, C). The ventricular rate depends on the refractory period of the AV node and on the strength of the atrial stimulus. Atrial flutter often alternates with AF in horses, creating so-called flutter-fibrillation. Treatment is similar to that for AF.

### ATRIAL FIBRILLATION

Atrial fibrillation is the most common atrial arrhythmia associated with poor performance and exercise intolerance.\* AF is most common in adult horses and has been reported infrequently in foals, weanlings, yearlings, or ponies. Several reports indicate a higher incidence in Standardbreds, draft horses, and Warmblood horses compared with the general hospital population.

CO at rest is normal in most horses with AF<sup>546</sup>; however, maximal CO during exercise is limited because the atrial contribution to filling is most important at higher heart rates. As expected, exercise intolerance is most common in high-performance horses (e.g., racehorses, advanced combined training horses, polo ponies, and some Grand Prix jumpers) and less common in show hunters and in pleasure, dressage, and endurance horses. The high LA pressures present in

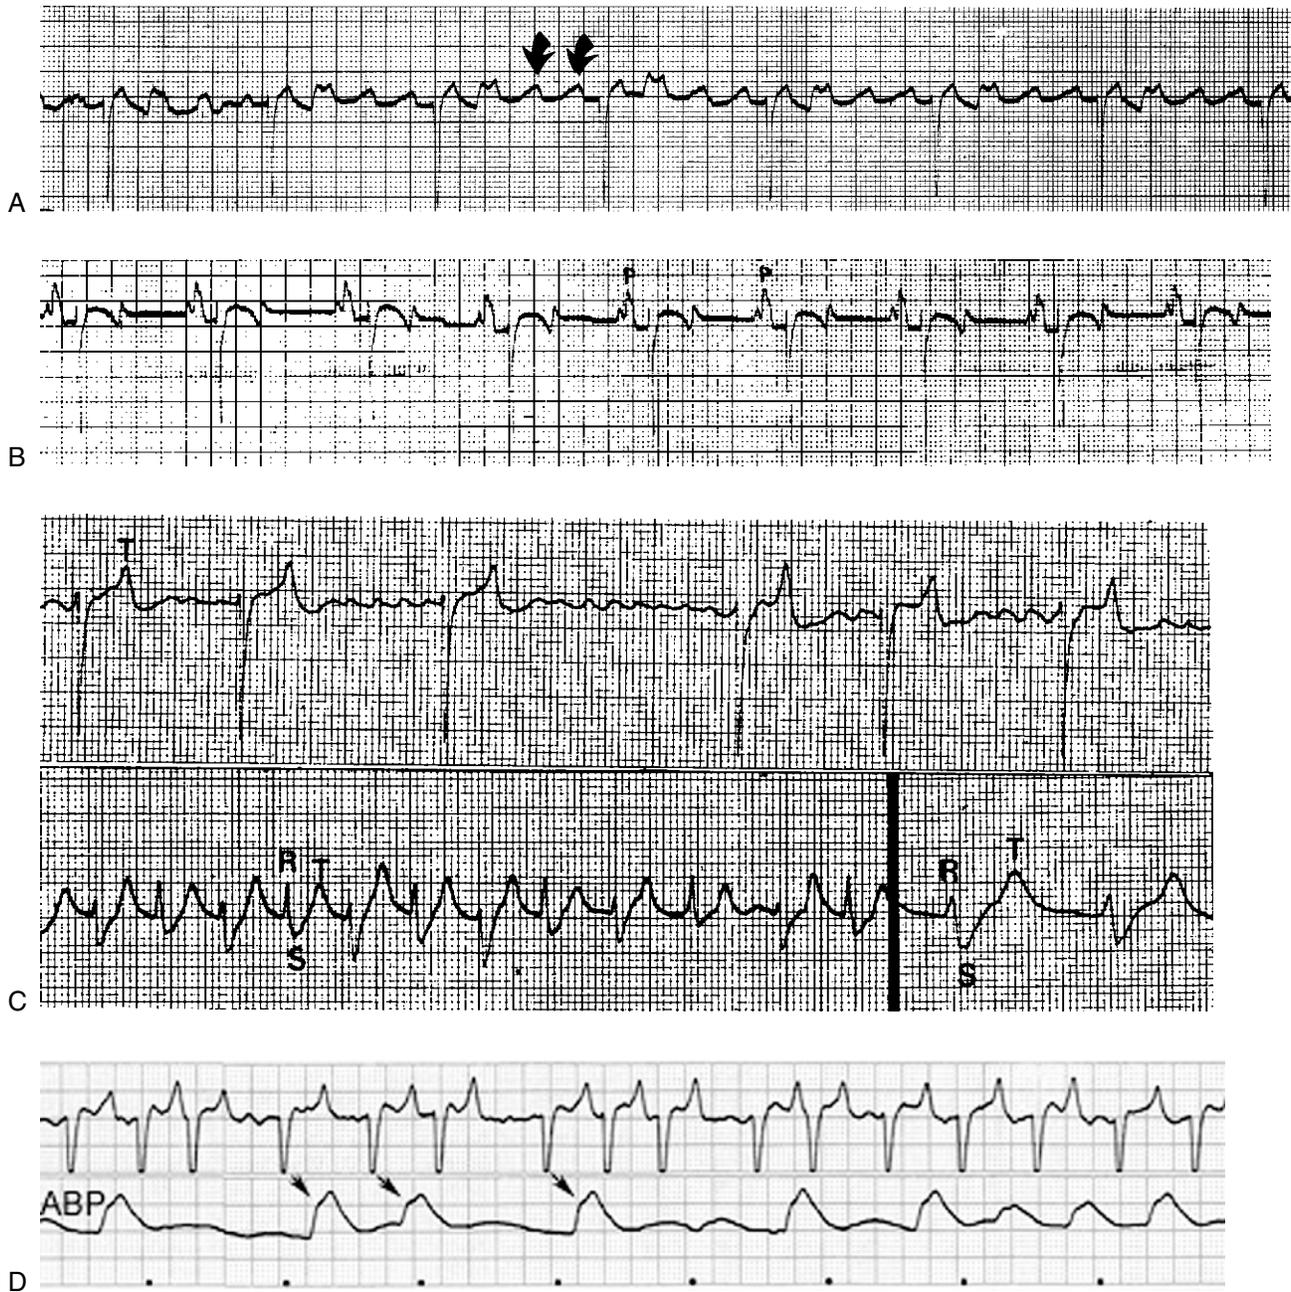

heavily exercising horses<sup>240,553</sup> is further exacerbated by the loss of active atrial transport function<sup>313</sup> and may contribute to exercise intolerance or other associated signs. Exercise-induced pulmonary hemorrhage, respiratory distress, CHF, ataxia or collapse, and myopathy have all been reported with AF; conversely, the arrhythmia is often detected as an incidental finding in horses with no overt signs.<sup>363</sup>

AF can be acute or chronic, and it can be paroxysmal, persistent, or permanent. Paroxysmal AF is often associated with a single episode of poor performance, with the horse often decelerating suddenly during a race. The arrhythmia usually disappears spontaneously within 24 to 48 hours. Paroxysmal AF may be associated with transient potassium depletion, particularly in horses treated with furosemide or bicarbonate solutions, and it is most often unrelated to other clinical or echocardiographic abnormalities of cardiac disease (lone AF). Although less common than paroxysmal AF, both persistent and permanent AF are easier to diagnose (persistent AF terminates after treatment, whereas permanent AF is sustained and resistant to therapy). Many horses with sustained AF have no other evidence of significant underlying cardiac disease when examined by physical examination and echocardiography. However, ultrastructural and functional myocardial pathology may be present, predisposing to AF. Furthermore, AF can induce atrial electrical, structural, and functional remodeling that may be responsible for the self-perpetuating, progressive, and recurrent nature of AF.<sup>242,244,740</sup> These remodeling changes are more likely to be reversible if AF is treated promptly. Recurrent episodes of AF are not uncommon and are more likely in the presence of concurrent structural or functional cardiac disease.

Horses with AF generally have a normal resting heart rate, although the rate decreases (and stroke volume tends to increase) after successful conversion of AF to normal sinus rhythm.<sup>741</sup> The presence of resting tachycardia in a horse with AF should give the clinician pause to consider intercurrent cardiac lesions or a disorder that increases sympathetic tone such as pain, anemia, fever, or infection. A number of factors interact in the prognosis of a horse with AF. Of these, the presence of CHF represents the overall worst prognostic indicator and is invariably associated with resting tachycardia. Severe structural heart disease, recurrent bouts of AF, long-standing AF, and failure to convert with therapeutic serum concentrations of quinidine represent negative prognostic factors inasmuch as affected horses can be more difficult to convert to sinus rhythm or more likely to revert back to AF even when therapy is successful.

The diagnosis of AF is initiated by recognition of an irregularly irregular heart rhythm, variable intensity heart sounds, and an absent fourth heart sound during cardiac auscultation. Arterial pulses vary in intensity, and pulse deficits may be present, especially when the ventricular rate is high (see Figure 10-55, D). The ECG is characterized by an absence of P waves; instead, fibrillation or *f* waves are seen in the baseline. These *f* waves may be coarse (large) or fine (small), and the number of atrial impulses per minute cannot be easily counted but usually exceeds 500 per minute. The QRS-T complexes are normal in morphology and duration, but ventricular rate response is quite irregular, although periodicity may be observed infrequently.<sup>191</sup> As for all atrial tachyarrhythmias, the ultimate ventricular rate response (and examination heart rate) depends on the refractory period of the AV node and the frequency and strength of the atrial stimuli. In the otherwise healthy horse in AF, vagal tone will be high and sympathetic tone

\*References 2, 33, 39, 42, 46, 55, 109, 134, 140, 146, 174, 190, 191, 193, 201, 293, 361-363, 427, 428, 469, 495, 546, 556, 568, 574, 576, 578, 580, 718, 719, 721-731, 734-739.

**FIGURE 10-55** Atrial arrhythmias. **A** and **B**, Successful conversion of atrial fibrillation (AF) using a combination of digoxin and quinidine (see text for details). **A**, Incomplete conversion of AF to atrial tachycardia with rapid, regular atrial activity (*arrows*). **B**, Conversion to normal sinus rhythm during combination therapy. Notice the high amplitude of the second part of the P wave, indicating possible atrial enlargement. **C**, Quinidine toxicosis can be manifested as abnormalities on the electrocardiogram (ECG). In this horse, AF (*top*; base-apex lead recorded at 25 mm/sec) was not converted. The lower recording shows persistent AF with a rapid atrioventricular conduction response, electrical alternans, and widening of the QRS complex (lead 2 recorded at 25 mm/sec; *right panel*, at 50 mm/sec). The rapid rate response is related to the vagolytic effect of quinidine. The electrical alternans is common with regular supraventricular tachycardias with rapid ventricular response rates; this finding indicates varying conduction into the ventricle. The widened QRS is a sign of quinidine toxicosis. An idiosyncratic reaction leading to polymorphous ventricular tachycardia (VT) also has been recognized (see Figure 10-59). **D**, Hemodynamic consequences of increasing ventricular response rate in AF. The short QRS-QRS intervals do not generate effective arterial pulsations recorded in the arterial blood pressure (ABP) tracing, which is related to inadequate ventricular filling time during short cycles. Pulse deficits are detectable by physical examination.

low when standing; consequently, the ventricular rate will be close to normal or slightly increased. If sympathetic activity is increased for any reason, or if vagal activity is blocked (as occurs with quinidine sulfate therapy), then the ventricular rate response will increase as the AV nodal refractory period shortens. This explains the clinician's simple, but very useful, dependence on measuring pretreatment, resting heart rate in horses with AF.<sup>363,574</sup> Because the horse with structural heart disease will be more likely to require sympathetic support to maintain CO and ABP, persistent resting tachycardia, higher than 60 to 70 beats/min, indicates underlying cardiac disease and is associated with a poorer prognosis.

Laboratory studies in horses with AF are usually normal. Infrequently, a horse is found to have low serum potassium, fractional excretion of potassium, or RBC potassium. Chest radiographs are usually normal unless there is concurrent pulmonary disease. Thoracic radiography is not a high-yield procedure in horses without signs of lung disease or structural heart disease. The echocardiogram is usually normal, unless concurrent valvular or ventricular myocardial disease is noted. It is not uncommon for an otherwise normal horse to demonstrate a slightly reduced LV shortening fraction (usually in the 24% to 32% range), which returns to normal once the horse has been converted to sinus rhythm.<sup>495,731</sup> This decrease in fractional shortening is probably multifactorial in origin, probably related in part to decreased preload from loss of the atrial contribution to ventricular filling and irregular cardiac cycle. Doppler studies are useful in evaluating horses with concurrent valvular disease.

The most common treatment for AF involves conversion to normal sinus rhythm, unless concurrent CHF is noted or the horse is aged and therapy is deemed of little benefit. Conversion of AF to sinus rhythm can be accomplished using a number of drugs or through electrocardioversion, generally delivered by intracardiac catheters.<sup>628,742-748</sup> No prospective study has compared the two methods, and both quinidine and electrocardioversion are generally safe and effective treatments. Quinidine sulfate is the standard drug against which other drug treatments should be compared, although this agent is becoming more difficult to obtain in some countries. Quinidine cardioversion of AF is successful in many horses, and a number of different treatment plans can be followed (see Table 10-6).<sup>319,717,739</sup> The use of other drugs including flecainide,<sup>738,749-753</sup> propafenone,<sup>754</sup> and amiodarone<sup>755-758</sup> may be considered in unresponsive cases or when quinidine cannot be tolerated or obtained (see following). As a general principle, when AF occurs in the setting of CHF, the treatments should be aimed at controlling CHF and resting heart rate with furosemide, digoxin, and possibly an ACE inhibitor, as opposed to conversion back to sinus rhythm.

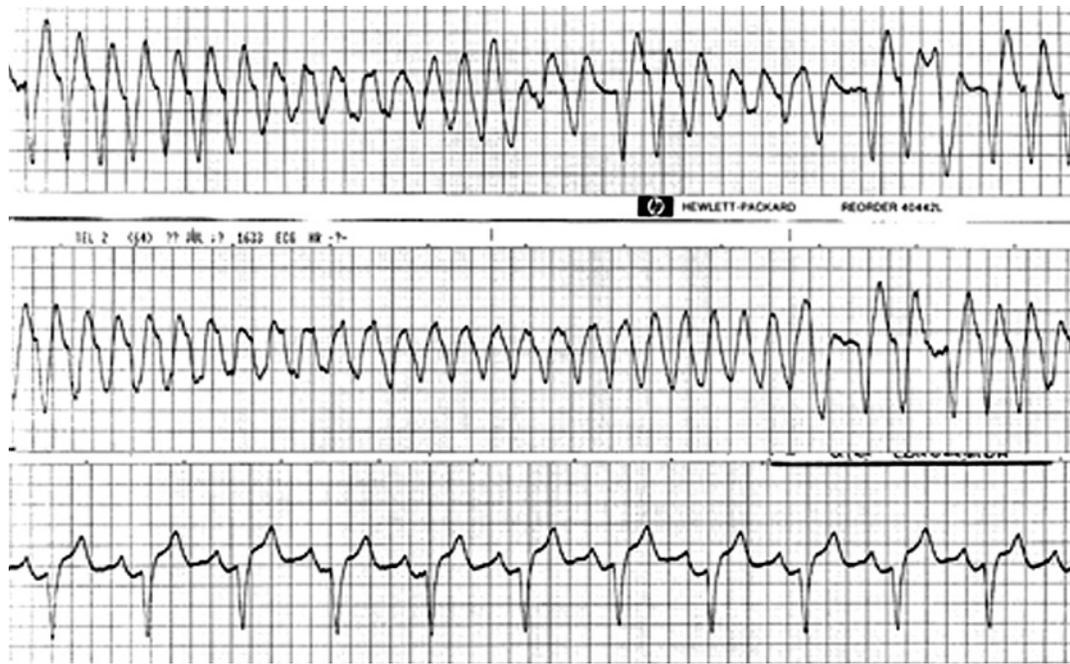

Based on the work of Reef, Levitan, and Spencer,<sup>574</sup> an excellent prognosis for quinidine conversion (>95% conversion rate) may be given for horses with heart rates of less than or equal to 60 beats/min, murmurs less than or equal to grade 3/6, and AF lasting less than 4 months. Recurrences affect approximately 25% of these horses. Quinidine conversion to sinus rhythm represents the standard therapy for most equine practices and has been used for the longest period of time. In general the use of other drugs (e.g., flecainide, amiodarone) is considered mainly for cases of resistant or recurrent AF or in situations in which quinidine or electrocardioversion are unavailable. In a study of electrocardioversion, the results were also very positive with a greater than 98% conversion rate (71 of 72 episodes in 63 horses).<sup>747</sup> Horses with longer duration of AF or significant structural cardiac disease may be

more difficult to convert to sinus rhythm using quinidine or electrocardioversion, and they are more likely to have a higher recurrence rate independent of the treatment modality.

### QUINIDINE THERAPY OF ATRIAL FIBRILLATION

Quinidine is typically administered by nasogastric tube because of its irrigating effects on the mucous membranes (see Table 10-6). Intravenous quinidine gluconate can be successful in conversion of horses with AF of recent onset or when nasogastric delivery is not feasible,<sup>727</sup> but failure to respond does not predict the response to oral treatment. Many successful approaches have been used to convert AF in horses, and the clinician should appreciate that the mean quinidine elimination half-life after an oral 10-g dose is about 6.7 hours.<sup>294,759</sup> One treatment approach for AF involves administration of a loading dose of 22 mg/kg quinidine sulfate by nasogastric tube every 2 hours for two to four doses, followed by every 6 hours dosing until the horse converts or develops initial signs of toxicosis. Aggressive every-2-hours dosing exceeding 88 to 132 mg/kg is especially likely to induce adverse effects. Therapeutic plasma quinidine concentrations for conversion from AF to sinus rhythm are 2 to 5 µg/ml (6.2 to 15.4 µmol/L) and should be measured if a horse fails to convert after an appropriate dosing regimen. If conversion to sinus rhythm has not occurred after 24 hours of therapy, then digoxin at 0.0055 to 0.011 mg/kg orally twice a day may be added to the treatment regimen for 24 to 48 hours. As in other species, a digoxin-quinidine interaction occurs that can effectively double the serum concentration of digoxin.<sup>760</sup> Thus combination therapy beyond 24 hours should be continued only with drug level monitoring of the serum digoxin (see Table 10-6) and consideration of using the lower end of the digoxin dosage range. Even horses that do not convert on the "standard" administration regimen may convert after the combined use of quinidine with digoxin. The value of using such a treatment plan every 6 hours is that steady-state levels are reached, sufficient time elapses to attain myocardial concentrations, and quinidine toxicity is less frequent when compared with the every-2-hour regimen. When prolonged treatment over more than 12 to 24 hours is necessary, adequate hydration and electrolyte balance (particularly potassium and magnesium) must be ensured by oral or IV administration of crystalloid solutions, because most horses undergoing oral quinidine treatment will become depressed and inappetent, will show reduced water intake, and may develop mild diarrhea.

Careful clinical and continuous electrocardiographic monitoring should be performed on horses with AF during conversion to sinus rhythm. The QRS duration should be monitored and compared with the pretreatment QRS duration before each additional treatment is administered. Prolongation of the QRS duration to greater than 25% of the pretreatment value is an indication of quinidine toxicity and should prompt discontinuation of therapy. The simplest ECG change is an acceleration of AV nodal conduction related to the vagolytic effect of quinidine (see Figure 10-55, C). Rapid supraventricular tachycardias with ventricular rate responses of up to 300 beats/min have been seen in several horses receiving quinidine sulfate. These horses have been treated with IV digoxin at 0.002 mg/kg to slow the ventricular response rate, IV replacement fluids to improve perfusion, IV sodium bicarbonate at 1 mEq/kg to reverse the sodium channel blocking effects of quinidine (probably by a combined effect of increasing extracellular sodium concentration and alkalinization,

**FIGURE 10-56** Polymorphous ventricular tachycardia (VT) after administration of quinidine sulfate for attempted conversion of atrial fibrillation (AF). In this case, normal sinus rhythm was established (lower tracing) after treatment with lidocaine, bicarbonate (to reverse sodium channel–blocking effects of quinidine), and phenylephrine (administered to maintain arterial blood pressure [ABP]).

leading to increased protein binding of quinidine and decreased extracellular concentrations of ionized calcium), and if needed, a phenylephrine drip to restore BP if critical hypotension develops. Ventricular arrhythmias (torsades de pointes, multiform VT, and ventricular premature complexes) have also been detected with quinidine toxicosis (Figure 10-56). Intravenous sodium bicarbonate is also indicated in these horses to bind free-circulating quinidine, whereas IV magnesium sulfate (up to 25 g in a 450- to 500-kg horse) is the treatment of choice for quinidine-induced ventricular arrhythmias (see Table 10-6). Lidocaine HCl may also be used if needed, starting with an IV bolus of 0.5 to 1.5 mg/kg, IV slowly. Conversely, administration of digoxin is contraindicated in horses with ventricular arrhythmias induced by quinidine.

Clinical markers of quinidine toxicosis include ataxia, colic, and nasal edema causing upper respiratory tract stridor. Most toxic reactions to quinidine sulfate are associated with higher plasma concentrations of the drug (>5 µg/ml) and can be avoided with careful clinical and electrocardiographic monitoring. Some of the adverse effects of quinidine administration, particularly polymorphic VT, are likely an idiosyncratic reaction. These adverse effects should prompt discontinuation of therapy or altering treatment intervals. Depression and paraphimosis occur in most horses treated with quinidine but disappear with the discontinuation of the drug. Diarrhea often develops with the administration of higher doses of quinidine, but this sign also disappears with discontinuation of the drug. Convulsions, hypotension because of vasodilation, CHF, laminitis, urticaria, and sudden death have rarely been reported with quinidine sulfate administration. A ventricular rate response in excess of 100 beats/min is an adverse reaction that may be more common in nervous horses or those prone to the vagolytic effects of quinidine. These horses may benefit from administration of

digoxin to blunt the ventricular rate response, particularly if no other signs of quinidine toxicosis or elevated plasma concentration are present. If an increased ventricular response rate is anticipated, then one may even consider pretreatment with digoxin before initiation of quinidine therapy. Alternatively, diltiazem could be used for ventricular rate control, provided that BP can be closely monitored (see Table 10-6). However, the clinical experience with the use of diltiazem is limited, and doses should be carefully titrated to effect.

#### OTHER DRUGS FOR ATRIAL FIBRILLATION

Other drugs have been studied recently for treatment of AF in horses. Amiodarone administered as a constant-rate infusion has been used successfully for treating experimentally induced and natural AF in horses, but it cannot be recommended as a first-line therapy at this time.<sup>755,757,758</sup> Flecainide, a class Ic antiarrhythmic drug, may become more widely used if quinidine becomes unavailable. Although IV administration was generally ineffective at a dose of 2 to 3 mg/kg,<sup>753</sup> oral administration has demonstrated some success. Pharmacokinetics of flecainide have been studied in horses, and it has been successfully administered for treatment of AF, including recurrent AF.<sup>738,749-753</sup> The drug can be dissolved in water and delivered orally or by nasogastric tube. The approximate dosage is 4 to 6 mg/kg PO at intervals of 2 to 4 hours. Like quinidine, flecainide can prolong the QRS complex and become proarrhythmic, so the ECG must be carefully monitored from the first dose. Appreciation of the overall adverse effect profile of the drug in horses will require more clinical experience. IV propafenone also has been suggested for conversion of chronic AF,<sup>754,761</sup> but it has recently been shown to be ineffective at a dose of 2 mg/kg IV in horses with naturally occurring (and with pacing-induced) AF. Therefore the current knowledge

does not support the use of this class Ic antiarrhythmic drug for treatment of AF.

### ELECTROCARDIOVERSION OF ATRIAL FIBRILLATION

Electrical cardioversion of AF to sinus rhythm has been used at a number of referral centers as either the primary method of treatment or for management of horses that respond adversely or inadequately to quinidine therapy. As stated previously, electrocardioversion is very effective therapy, especially for AF of recent onset, but it requires special equipment and trained personnel. The procedure involves percutaneous placement of two specialized electrode catheters transvenously, with one catheter tip located within the left PA and the other within the RA cavity. Catheter placement is done under sedation and local anesthesia. The catheters are guided by pressure monitoring through the catheter lumen and 2D echocardiographic imaging (Figure 10-57). Radiography is used to verify the placement of the catheters either before or preferably after induction of general anesthesia. Although the catheters can be placed under local anesthesia, electrical cardioversion is very painful and must be performed under general anesthesia with the horse well padded because the shock results in a sudden jolt of the body and limbs.

The specific procedure used for cardioversion is beyond the scope of this textbook but has been well described in several studies.<sup>743-747</sup> In these reports, cardioversion was achieved with a mean energy level of 160 J. Experience indicates that some horses require higher energy doses, sometimes exceeding 300 J, and as with quinidine, not all cases result in conversion. The complications associated with electrocardioversion appear to be quite low but are finite related to general anesthesia or electrical shock. A case of transient complete AV block has been reported.<sup>762</sup>

### FOLLOW-UP CARE

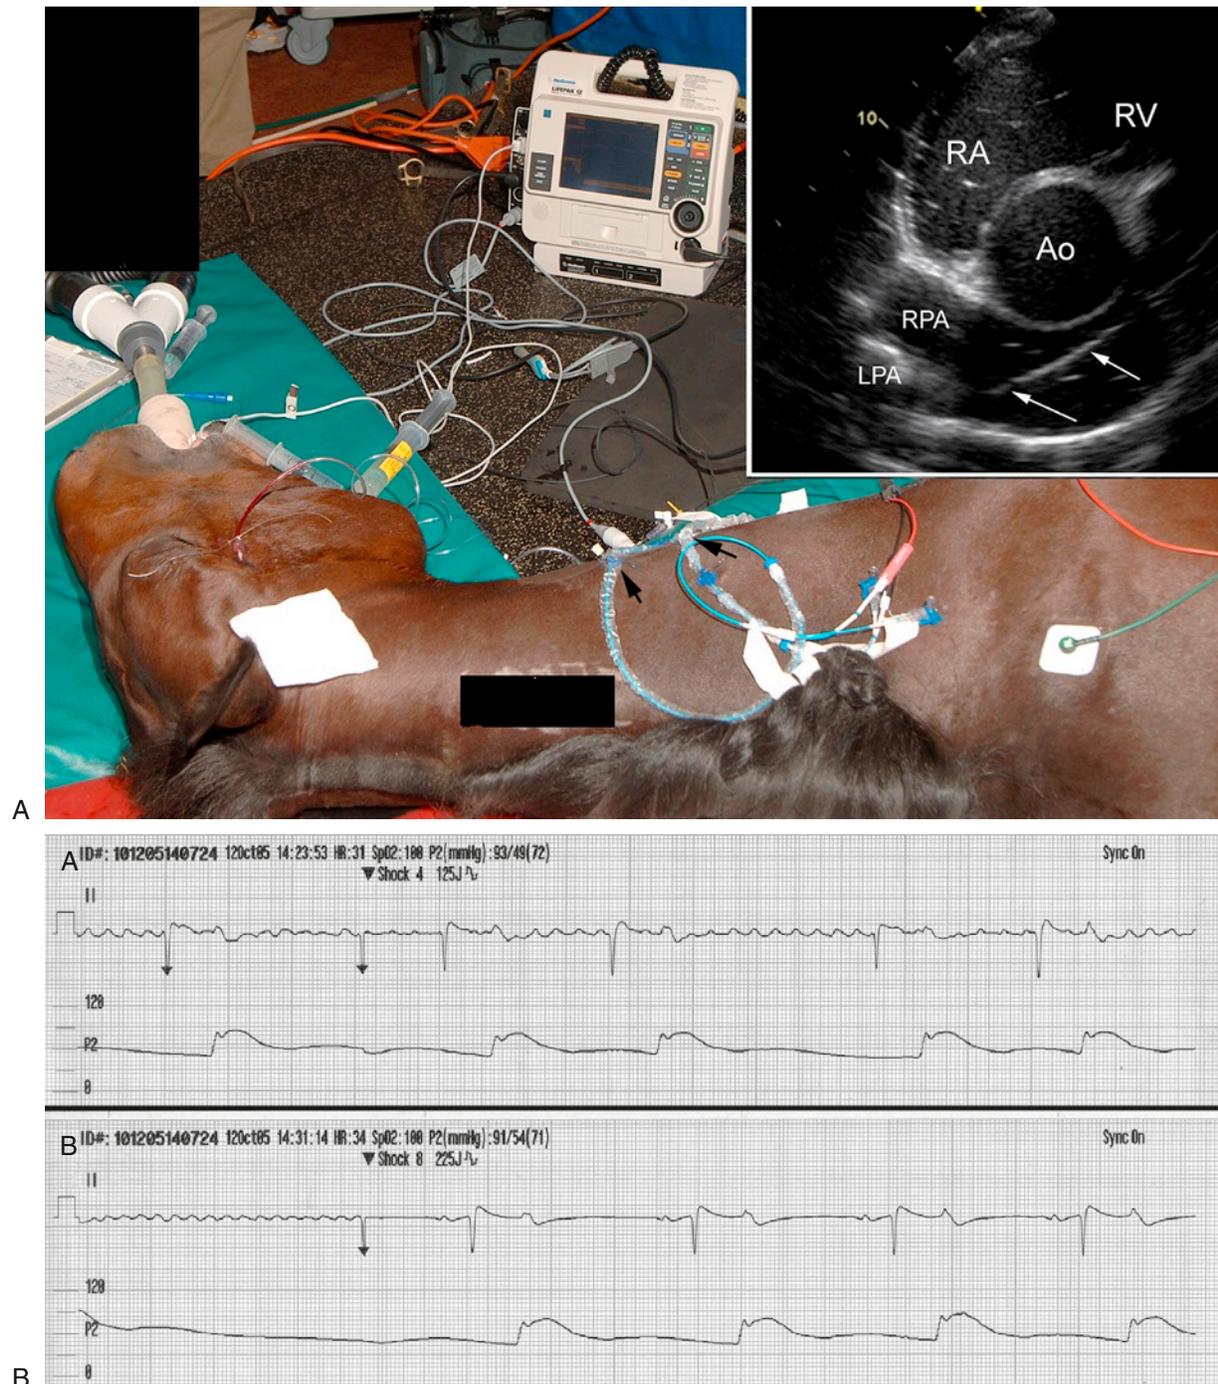

Horses can usually be returned to training within 24 to 48 hours after conversion. However, persistent sinus tachycardia, recurrent APCs (as detected by follow-up 24-hour Holter ECG), or persistent LV or LA dysfunction (as detected by follow-up echocardiography)<sup>740</sup> observed after successful conversion of AF to normal sinus rhythm may indicate subtle myocardial disease or AF-induced atrial remodeling. In addition, it may potentially indicate a higher risk of recurrent AF (although this contention has not been proven so far). These horses should probably be given more time to recover if possible (i.e., 1 to 2 weeks). Conversion of horses with AF generally results in a return to their previous performance level.<sup>363,574</sup> The exception is the horse with persistent LV dysfunction whose functional status will be improved following conversion to sinus rhythm, but whose performance will be less than its previous best. Horses with repeated episodes of AF are often converted numerous times with quinidine sulfate or electrocardioversion. Most horses that experience a recurrence of AF do so within 1 year of initial conversion, but much longer intervals have occurred between episodes of AF in some horses. If the duration of sinus rhythm becomes shorter, then repeated treatments may no longer be practical and a career change may be indicated. Some horses eventually become refractory to drug or electrical cardioversion, probably because of progressive atrial fibrosis or underlying myocardial disease. However, in the absence of significant, detectable cardiac disease, horses with persistent or permanent AF may still be used at lower levels of exercise (as long as the expected level of performance can be achieved), or they can be kept as breeding animals or pasture horses.

## JUNCTIONAL AND VENTRICULAR ARRHYTHMIAS

Cardiac arrhythmias that originate within the AV conducting tissues, the ventricular specialized conducting tissues, or myocardium are classified as *junctional* (AV nodal or bundle of His) or *ventricular* in origin. Unlike sinus or atrial arrhythmias, these arrhythmias are not preceded by a conducted P wave. When sustained, junctional and ventricular rhythms often lead to dissociation between the SA (P wave) activity and that of the ventricle (QRS-T), resulting in AV dissociation.<sup>447</sup> In these cases an independent atrial rhythm is superimposed on the ectopic rhythm (see Figure 10-58, C and D). AV dissociation in these cases develops because the premature AV junctional or ventricular depolarization causes interference to the conduction of normal SA impulses. It is important to note that escape rhythms (see following) also cause AV dissociation. Therefore *AV dissociation* is a purely descriptive term of an ECG finding and neither characterizes the type and pathophysiologic mechanism of the arrhythmia nor determines the therapeutic approach.

With sustained junctional or VTs, P waves may be identified that are not conducted and therefore not consistently associated with a QRS complex (see Figure 10-58). Some of these P waves may be buried in the ectopic QRS-T complexes (especially at higher rates of ventricular activation), making their identification difficult. The use of ECG calipers helps determining the P-P interval and can greatly facilitate the identification of P waves. Occasionally, atrial impulses may be normally conducted, leading to capture beats or fusion beats. *Capture beats* are characterized by a normal P-QRS-T configuration, resulting from normal ventricular activation occurring before the ectopic focus discharges (see Figure 10-58, D). *Fusion beats* are seen when both the conducted impulse and an ectopic impulse cause simultaneous ventricular activation. The QRS-T morphology of a fusion beat represents the summation of a normal and an ectopic beat (see Figure 10-58, C).

It may be difficult to distinguish between junctional and ventricular arrhythmias and to determine the exact location of the abnormal impulse formation. The differentiation of junctional and ventricular rhythms can sometimes be made by inspection of the QRS complex. Junctional impulses are more likely to result in a narrow, relatively normal-appearing QRS complex with normal initial activation and electrical axis, because they originate above the ventricular myocardium. Complexes of ventricular origin, by contrast, are conducted abnormally and more slowly, resulting in a widened QRS, an abnormal QRS orientation, and abnormal T waves. However, junctional tachycardias also may be conducted aberrantly, resulting in a bizarre and wide QRS complex. When sustained, both types of rhythms cause AV dissociation with an independent atrial rhythm superimposed on the ectopic ventricular rhythm. Advanced echocardiographic methods that identify the sequence of ventricular activation may be of some value in distinguishing ventricular origin complexes from those starting above the ventricle and using the normal conduction system. The former are more likely to demonstrate ventricular dyssynchrony, characterized by wider dispersion of activation of different parts of the ventricles. Advanced electrophysiologic studies might also be applied to this differentiation.

**FIGURE 10-57** **A**, Electrocadioversion procedure in a Thoroughbred horse. The horse is under general anesthesia. Two specialized electrode catheters (*arrows*) were previously placed percutaneously under local anesthesia into the right atrium (RA) and left pulmonary artery under guidance from two-dimensional (2D) echocardiography and intravascular pressure monitoring. The biphasic cardioverter (*top*, center of image) is connected to the catheters and is used to deliver the synchronized cardioversion shock, as well as monitor electrocardiogram (ECG) rhythm, invasive blood pressure (BP), and pulse oximetry. *Inset*: 2D image showing short axis image at base of heart. The catheter inserted into the left pulmonary artery (LPA) is indicated (*arrows*) (RA, right atrium; RV, right ventricle; Ao, aorta; RPA, right pulmonary artery). **B**, Transvenous electrical cardioversion for treatment of atrial fibrillation (AF) in a 2-year-old Standardbred racehorse under general anesthesia. A surface ECG (25 mm/sec) and an arterial blood pressure (ABP) tracing are displayed. The QRS complexes are automatically detected by the defibrillator unit and marked by small triangles. Biphasic electrical shocks (*larger triangles on top*) are applied at increasing energy levels. Delivery of the shocks is synchronized to the QRS complex to avoid the vulnerable period (T wave) and prevent induction of ventricular arrhythmias. **(A)** Unsuccessful attempt at an energy level of 125J. **(B)** Successful cardioversion at an energy level of 225J. Immediately after the shock, the baseline flattens and normal sinus rhythm resumes. No further treatment is required at this point. (From Schwarzwald CC, Bonagura JD, Muir WW: The cardiovascular system. In Muir WW, Hubbell JAE, editors: Equine anesthesia: monitoring and emergency therapy, ed 2, St Louis, 2009, WB Saunders.)

## JUNCTIONAL ARRHYTHMIAS

Junctional complexes that arise early relative to the normal cardiac cycle are designated as *premature junctional complexes*. These complexes may occur as single or repetitive events and can resemble ectopic rhythms that might originate in the atria. Repetitive ectopic complexes that occur in short bursts or runs are termed *nonsustained* or *paroxysmal junctional tachycardias*. *Sustained junctional tachycardias* may also occur and can lead to CHF.

The clinical significance of an occasional junctional premature complex is difficult to ascertain. Persistent or repetitive junctional or ventricular rhythms are indicative of heart disease, systemic disease, or a drug-induced abnormality of cardiac rhythm. The best management choice is uncertain inasmuch as some junctional rhythms behave more like atrial tachyarrhythmias, whereas others cause AV dissociation and appear to act like ventricular ectopic impulses. Because the mechanism responsible for junctional tachycardias can be either abnormal automaticity or re-entry (circuit) movement using the AV node, empiric therapy is usually required to control sustained arrhythmias. If obvious AV dissociation is noted, then lidocaine, quinidine, or procainamide would seem reasonable choices (see Table 10-6). If the mechanism is uncertain but is clearly supraventricular, then IV digoxin or IV diltiazem may either silence the rhythm or slow the rate.

## ESCAPE RHYTHMS

The normal heart contains potential cardiac pacemakers within the AV junctional and ventricular specialized tissues. These potential pacemakers may become manifest during periods of sinus bradycardia or AV block, creating *escape complexes* or *escape rhythms* (see Figure 10-60, B). Escape rhythms are characterized by slow ventricular rates, often in the realm of 15 to 25 beats/min. Specific antiarrhythmic drug suppression of escape rhythms is generally not necessary and is contraindicated because these rhythms serve as rescue mechanisms for the heart. Instead, management of escape rhythms should be aimed at resolving the underlying cause of sinus bradycardia or AV block.

## ACCELERATED IDIONODAL (IDIOVENTRICULAR) RHYTHMS

Occasionally, the subsidiary nodal or ventricular pacemakers may be enhanced and discharge at a rate that is equal to or slightly above the SA rate (usually between 60 and 80 beats/min). The resulting rhythm is commonly referred to as *accelerated idionodal (idioventricular) rhythm* or *slow VT* (see Figure 10-58, C). Conditions that favor the development of these rhythms include gastrointestinal disease (possibly because of a combination of endotoxemia, autonomic imbalance, acid-base disturbances, and electrolyte abnormalities)<sup>450</sup> and administration of anesthetics or catecholamines. When the independent atrial and ventricular pacemaker foci discharge at similar rates, the P waves may appear to “march in and out” of the QRS complex. This phenomenon is called *isorhythmic AV dissociation* and is occasionally observed in adult horses during inhalation anesthesia. Accelerated idioventricular rhythms are often quite regular and may be misdiagnosed as sinus tachycardia on auscultation or palpation of peripheral pulses. Persistent, unexplained mild to moderate tachycardia should therefore prompt an electrocardiographic examination to ascertain a correct rhythm diagnosis. However, accelerated idioventricular rhythms generally are of little clinical (electrophysiologic and hemodynamic) significance and resolve spontaneously

with appropriate treatment of potential underlying conditions and reduction of anesthetic dosages. Electrolyte supplementation (potassium, magnesium) and correction of fluid deficits and acid-base disturbances may be beneficial. Lidocaine (see Table 10-6) is sometimes administered as an intraoperative adjunct to general anesthesia, or it is used as an analgesic and prokinetic drug in the management of postoperative ileus. In these situations, its antiarrhythmic effects may provide some additional preventive or therapeutic benefits.

## VENTRICULAR ARRHYTHMIAS

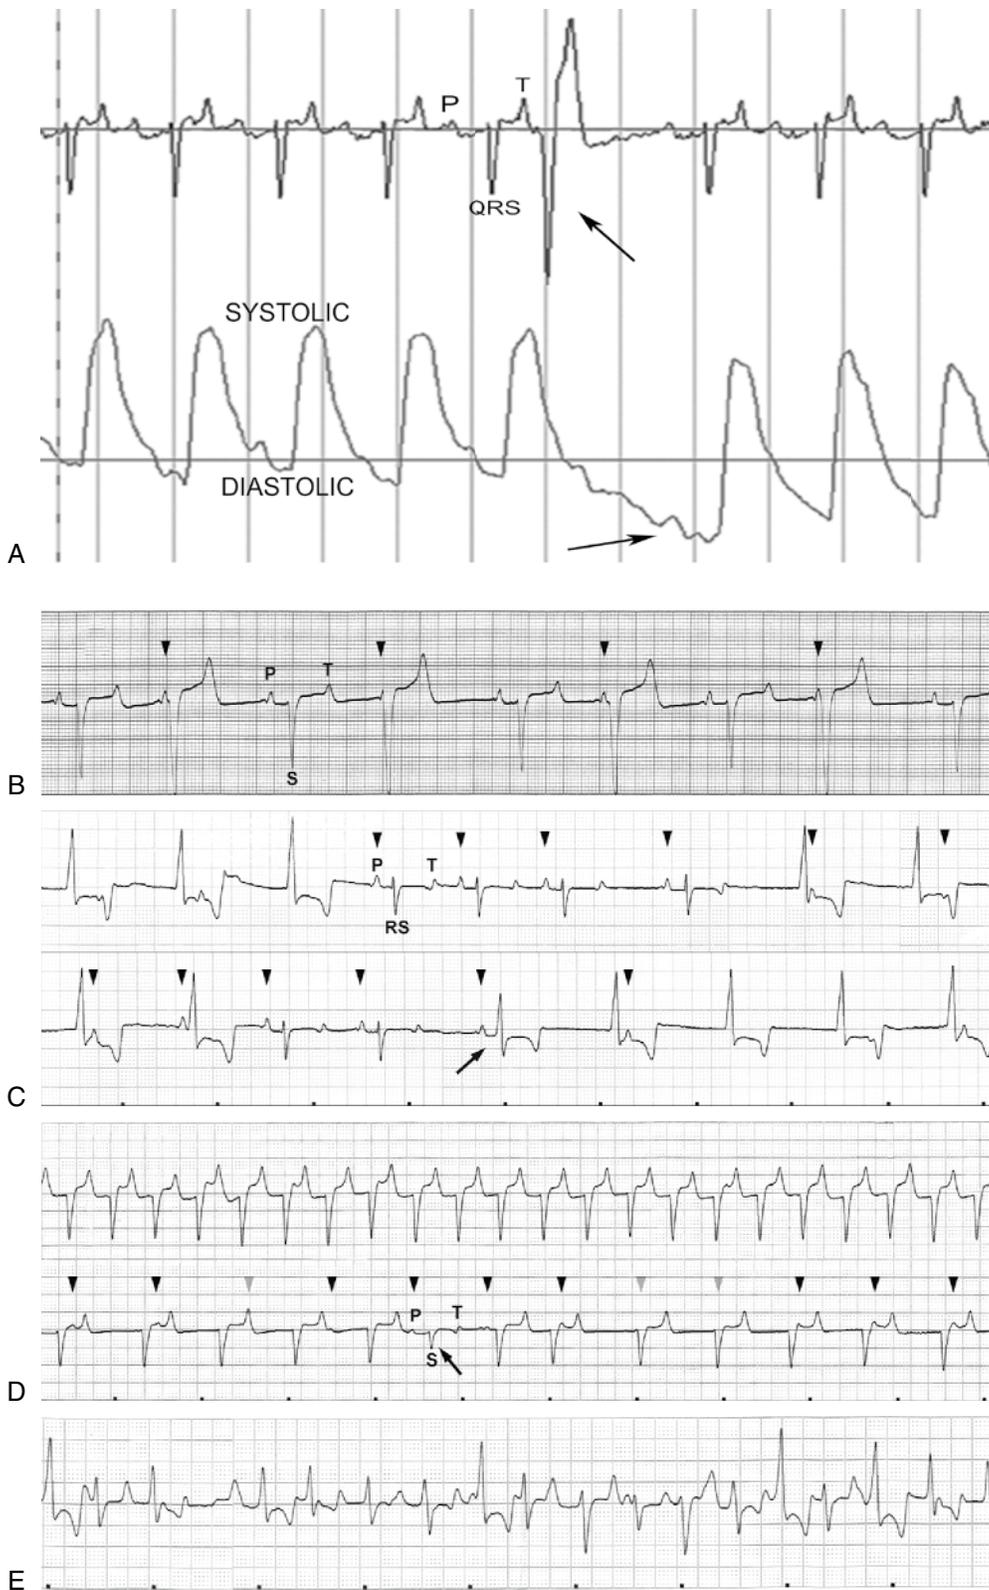

Ventricular arrhythmias are less common than atrial arrhythmias but are more likely to be associated with underlying structural cardiac disease, lesions of the myocardium, or a multisystemic disorder, including infections.<sup>\*</sup> Ventricular arrhythmias may be observed with severe toxemia or sepsis or primary gastrointestinal disorders including proximal enteritis and large bowel disorders. Potassium, magnesium, and calcium activities can affect myocardial electrophysiology,<sup>771</sup> and electrolyte disorders can induce ventricular ectopy. Other potential causes of ventricular arrhythmias include metabolic disorders, ischemia, hypoxia, drugs, ionophores, and systemic inflammation. Primary heart diseases including severe valvular regurgitation, cardiomyopathy, myocarditis, endocarditis, and pericarditis can induce ventricular arrhythmias. Thus the approach to the horse with ventricular arrhythmias should emphasize ruling out the noncardiac causes, correcting them (if possible), and then following if necessary with a complete CV examination, including electrocardiography and echocardiography. Serum troponin should be measured to identify cardiac injury, although it may be problematic to separate primary from secondary causes of cardiac troponin elevations. Ventricular ectopic rhythms are classified as indicated in Box 10-9.

## VENTRICULAR PREMATURE COMPLEXES

Ventricular premature complexes are characterized by premature, widened complexes, often followed by compensatory pauses. The pause occurs because the next sinus impulse is blocked by the refractory AV conduction system. If the sinus rate is slow or the ventricular premature complex is closely coupled to the preceding normal sinus beat, then it may be interpolated between two normal beats. Ventricular ectopic impulses are characterized by QRS and T waves that are wide and often bizarre in appearance (see Figures 10-58 and 10-59). The premature QRS bears no relationship to any preceding P waves, although the induction of ventricular ectopics may be dependent on underlying cardiac cycle length or heart rate. The morphology of the ventricular premature complexes may be uniform (monomorphic) or multifiform (polymorphic) as shown in Figure 10-58, E. The relationship of a ventricular extrasystole to the preceding sinus QRS-T is expressed by the “coupling interval” between them. Often the coupling interval is fixed, although it may vary minimally<sup>769</sup> or markedly in horses. A very short coupling interval may place the ectopic QRS on the preceding T wave, a phenomenon called *R on T* and related experimentally to increased ventricular vulnerability for fibrillation.

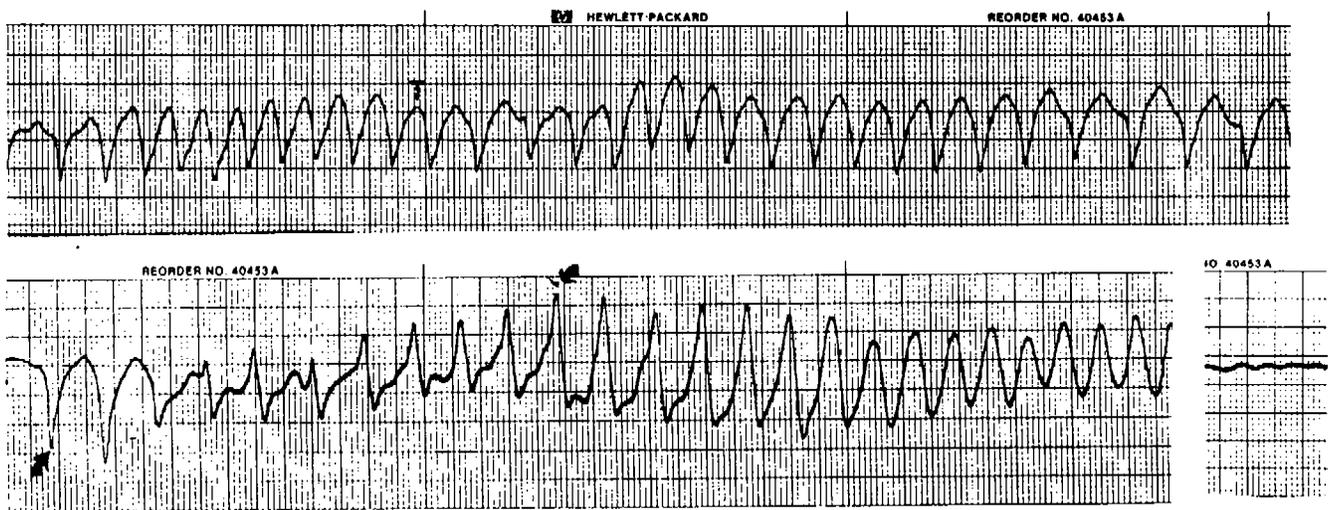

Ventricular premature complexes are generally considered abnormal, except for possibly those occurring immediately after exercise.<sup>337</sup> However, ventricular ectopy was identified in

\*References 110, 199, 359, 432, 447, 469, 489, 668, 672, 763-770.

**FIGURE 10-58** Ventricular arrhythmias. **A**, The ectopic complex (*arrow*) is premature and abnormal in morphology. A compensatory pause follows the extrasystole because the next sinus P wave is blocked in the atrioventricular node. The effect of the premature complex on arterial blood pressure (ABP) in the lower tracing (*arrow*) is noticeable. **B**, Base-apex lead electrocardiogram (ECG) recorded from a 15-year-old Arab male with ventricular bigeminy. Normal sinus beats alternate with slightly larger and wider ventricular ectopic beats. SA node discharge is not affected by the ectopic beats, as indicated by the presence of nonconducted P waves immediately before the ectopic beats (*arrowheads*) (paper speed 25 mm/sec).

**Figure 10-58, cont'd C**, Base-apex lead ECG recorded from an 18-year-old Arab mare recovering from acute diarrhea and endotoxemia. The ECG shows an intermittent accelerated idioventricular rhythm at a rate of 50 beats/min. P wave intervals are indicated (*arrowheads*). The recording demonstrates that the ectopic focus is suppressed at higher rates of SA node discharge. The ventricular rhythm only becomes manifest when the sinoatrial (SA) rate drops below the rate of the ventricular pacemaker. SA node discharge is not affected by the ectopic rhythm, resulting in AV dissociation. A fusion beat is present (*arrow*), resulting from summation of a conducted sinus impulse with an ectopic ventricular beat (paper speed 25 mm/sec, voltage calibration 0.5 cm/mV). **D**, Base-apex lead ECG recorded from a 3-year-old Clydesdale gelding. The top recording shows a regular tachycardia at a rate of 120 beats/min. The appearance of the QRS-T complexes does not allow conclusive distinction between a supraventricular rhythm with rapid ventricular response and a ventricular rhythm. However, as the rate slows down (*bottom strip*), AV dissociation because of a ventricular tachycardia (VT) becomes apparent. P waves (*arrowheads*) and a capture beat (*arrow*) are indicated (paper speed 25 mm/sec, voltage calibration 0.25 cm/mV). **E**, Base-apex ECG recorded from a 5-year-old Clydesdale stallion with acute myocardial necrosis of unknown cause. The serum cardiac troponin I concentrations were severely elevated (404 ng/ml; normal <0.15 ng/ml). The ECG shows multiform VT at a rate of 120 beats/min (paper speed 25 mm/sec, voltage calibration 0.5 cm/mV). (B to E from Schwarzwald CC, Bonagura JD, Muir WW: The cardiovascular system. In Muir WW, Hubbell JAE, editors: Equine anesthesia: monitoring and emergency therapy, ed 2, St Louis, 2009, WB Saunders.)

**FIGURE 10-59** Sustained, rapid ventricular tachycardia (VT) (*top*) of varying rate that develops into a polymorphic ventricular rhythm with varying morphology complexes (*torsades de pointes*). The horse died of cardiac arrest (*lower right panel*). The arrows indicate QRS complexes of varying polarity (25 mm/sec).

14% of clinically normal horses during routine 24-hour continuous electrocardiographic monitoring.<sup>359</sup> The distributional pattern of ventricular ectopics may include haphazard distribution of single complexes, bigeminy (sinus beats followed, at a fixed coupling interval, by premature ventricular beats; Figure 10-58, *B*), couplets (pairs of ventricular premature complexes), triplets, or runs (four or more) of ventricular ectopics. Runs of accelerated ventricular rhythm, usually developing at relatively slow heart rates, are not uncommon. Runs of ventricular ectopics at a rapid rate—VT—are more likely to be hemodynamically and electrically unstable, particularly when they develop at rates higher than 100 per minute (see Ventricular Tachycardia below).

When premature ventricular beats are identified by auscultation, an ECG should be obtained, and a workup similar to that outlined in Box 10-4 should be undertaken. Occasional premature ventricular complexes, as with occasional supraventricular premature complexes, may be clinically insignificant and not require treatment. Rest is highly recommended for horses with frequent ventricular premature complexes. In the majority of horses with premature ventricular complexes

occurring in the absence of significant structural heart disease, the arrhythmia seems to resolve spontaneously after 4 to 8 weeks of rest. The horse may then be able to return successfully to its prior performance level. Antiarrhythmic therapy is usually successful in abolishing ventricular premature complexes, but most return when the antiarrhythmic agent is discontinued, unless the underlying problem has been resolved and chronic administration is not practical. Dexamethasone and other anti-inflammatory drugs have been used to treat ventricular arrhythmias, but their use is controversial and they should certainly not be administered to horses with a recent or current infection.

### VENTRICULAR TACHYCARDIA

Ventricular tachycardia is an ectopic ventricular rhythm characterized by either a regular or irregular ventricular rate (see Figures 10-58 and 10-59). *Torsades de pointes* represent a specific form of polymorphic VT, characterized by progressive changes in QRS direction leading to a steady undulation in the QRS axis (see Figure 10-59). VT is recognized clinically by an increased heart rate, often exceeding 100 beats/min. Arterial

pulses are typically weak or variable in intensity. Multiform VT is characterized by an irregular rhythm (see [Figure 10-58, E](#)). With multiform VT, heart sounds are more likely to vary in intensity and arterial pulses are likely to be abnormal. Jugular pulsations may be detected because of AV dissociation. Syncope is associated with higher rates of VT (180 beats/min or higher). Respiratory distress and pulmonary edema may develop from impaired ventricular function. Protracted junctional tachycardias or VTs (>120 beats/min) may lead to CHF because of reversible myocardial failure (tachycardia-induced cardiomyopathy).<sup>110</sup> VTs can also progress to *ventricular flutter* and *ventricular fibrillation*, characterized by chaotic ventricular activation patterns leading to uncoordinated undulations of the electrical baseline. These rhythms often represent terminal rhythms and usually result in cardiac arrest (see [Figure 10-59](#)).

VT may be life threatening if R on T complexes are detected, if the arrhythmia is rapid (>180-200 beats/min), if multiform VT is detected, or if polymorphic tachycardia (torsades de pointes) is evident. Immediate treatment of CV collapse may be required.<sup>717</sup> IV therapies for VT include lidocaine, procainamide, quinidine magnesium salts, amiodarone, and propafenone (for refractory VT). Administration of antiarrhythmic drugs (see [Table 10-6](#)) can be associated with side effects, including proarrhythmia, seizures, and sudden death. Lidocaine causes central nervous system (CNS) excitation; however, boluses and infusions can be well tolerated in horses, and the drug causes minimal hemodynamic or electrophysiologic alterations at nontoxic doses.<sup>623,624,772</sup> Quinidine may be used for treatment of ventricular arrhythmias but is a myocardial depressant and vagolytic drug. Procainamide<sup>773</sup> has been studied to a limited degree, but it is generally well tolerated when given in graded doses. It has similar electrophysiologic effects to quinidine, but seems less vagolytic and possibly has less gastrointestinal side effects. Cumulative doses of up to 10 mg/kg are generally well tolerated; additional dosing should be guided by ECG, QRS duration, and ABP. Magnesium sulfate is an alternative antiarrhythmic that can be effective in both normomagnesemic and hypomagnesemic horses and is generally well tolerated at therapeutic doses. Amiodarone has been evaluated in a small number of horses<sup>756,757</sup> and can be considered as a second-line drug for serious, drug-resistant VT. Other antiarrhythmics, including IV propafenone<sup>761</sup> or phenytoin, may be tried in refractory ventricular arrhythmias.

A period of rest (4 to 8 weeks) followed by electrocardiographic and echocardiographic re-evaluation (including an exercising ECG) is indicated for follow-up of horses that have developed sustained VT. A substantial number of these horses can be successfully returned to performance after treatment with antiarrhythmics and rest, so long as significant and untreatable structural heart disease is not evident. The use of anti-inflammatory drugs in horses with VT is empiric.

## CONDUCTION DISTURBANCES

Once a cardiac electrical impulse is formed, it is conducted rapidly throughout the heart. The sequence of cardiac electric activation is usually dictated by the specialized conducting tissues in the atria, the AV node, the bundle of His, the bundle branches, and the Purkinje fiber system. This conduction system permits orderly activation of atrial and ventricular muscle and facilitates effective mechanical activity of the heart. A variety of conduction disorders are recognized, including SA nodal exit block, atrial standstill (usually because of

hyperkalemia), AV block, bundle branch block, and ill-defined ventricular conduction disturbances ([Figures 10-60 and 10-61](#)).\*

Rarely, accelerated conduction occurs in the heart, which involves a pathway around the normally slow-conducting AV node and results in early excitation of the ventricles.<sup>775</sup> These syndromes are termed *pre-excitation* and have various associated labels related to similar human disorders (e.g., Wolff-Parkinson-White syndrome). A shortened P-R interval is typically found.

## ATRIOVENTRICULAR CONDUCTION BLOCK

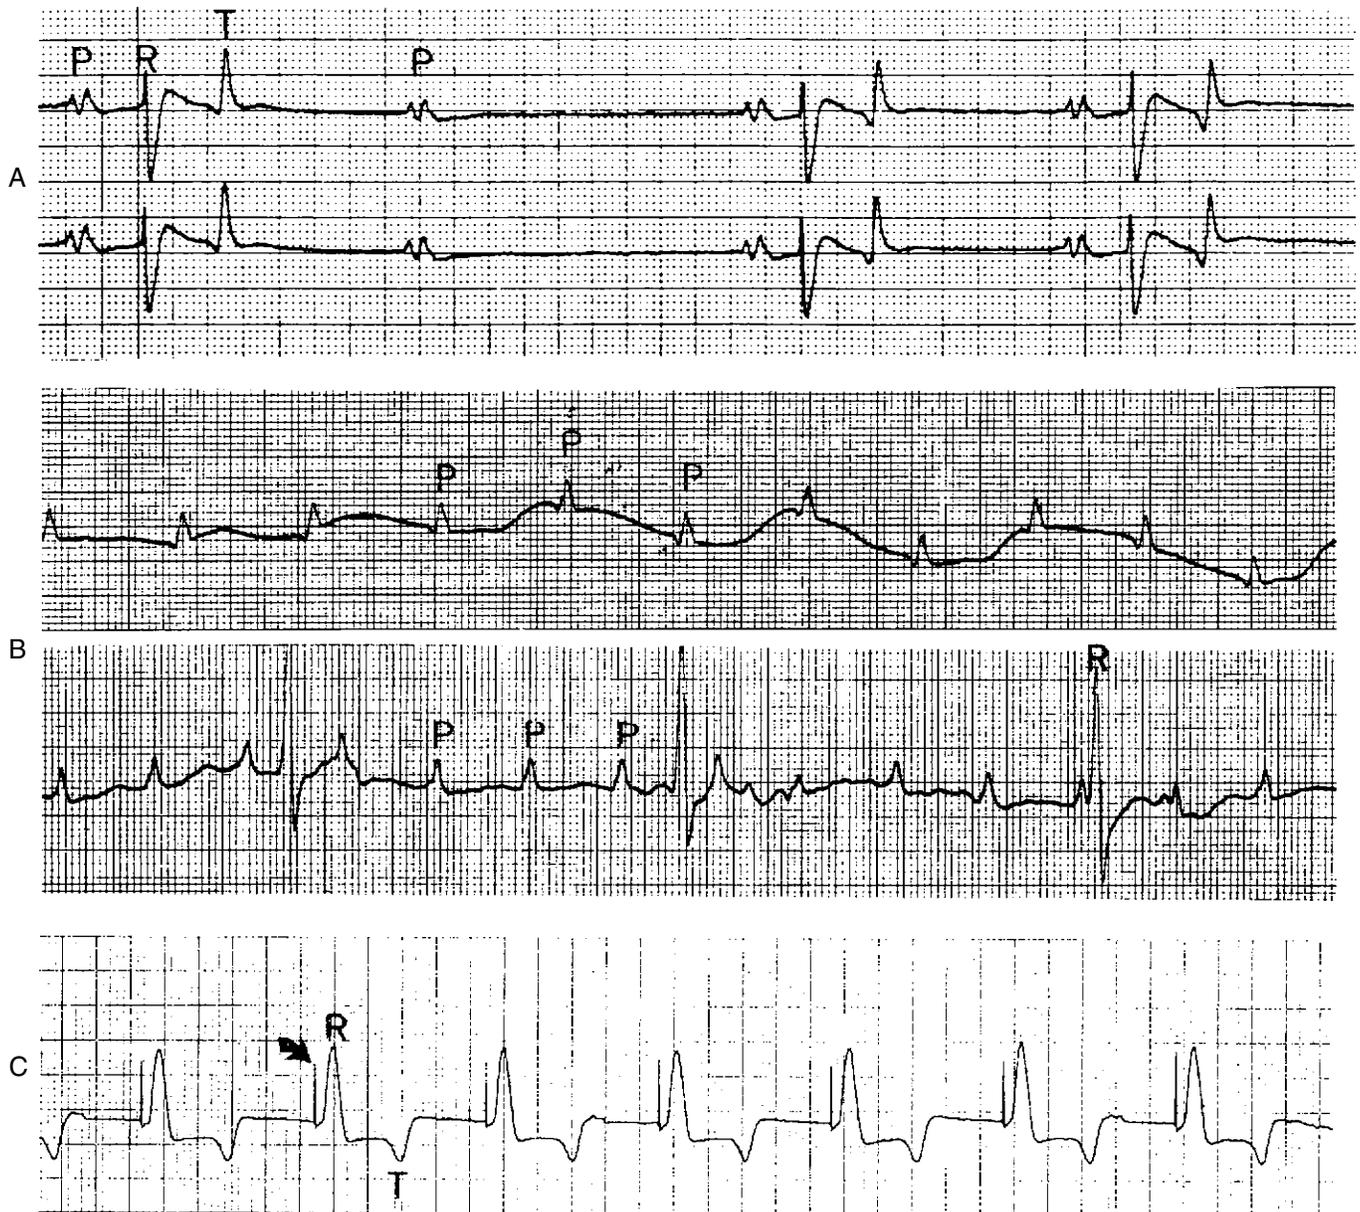

Delays in AV conduction are the most common conduction blocks. These delays are classified as *first-*, *second-*, and *third-degree* (or *complete*). *First-degree AV block* occurs when the PR (or PQ) interval exceeds a certain value (approximately 500 ms in large-breed horses and 320 ms in small breeds and ponies) while the atrial impulse still transmits through the AV conduction system and activates the ventricle, causing a QRS complex. Some P waves are not conducted to the ventricles during *second-degree AV block*, which results in occasional P waves not followed by a QRS-T complex (see [Figure 10-60, A](#)). Second-degree AV block after progressive prolongation of the PQ interval is classified as *Mobitz type I (Wenckebach) block*. Conversely, the AV block is termed *Mobitz type II* if the PQ interval is constant. Occurrence of two or more consecutive second-degree AV blocks in presence of a normal or slow sinoatrial rate is called *high-grade (advanced) AV block*, although this can be a normal (vagally induced) finding in approximately 1% of healthy horses, based on 24-hour ECG findings of one of the authors (VBR). *Third-degree or complete AV block* is characterized by an absence of atrial to ventricular conduction. P waves are not followed by or related to QRS complexes, and to prevent ventricular asystole, a junctional or ventricular escape rhythm must develop below the level of the AV block (see [Figure 10-60, B](#)).

First- and second-degree AV block are considered normal variations.<sup>764</sup> These rhythms are most often associated with high vagal tone and may be seen with sinus bradycardia or sinus arrhythmia. Second-degree AV block can usually be abolished with exercise, stress, or vagolytic drugs such as atropine or glycopyrrolate (although drugs are rarely needed). Complete AV block is indicative of organic heart disease, severe drug toxicity, or abnormally high vagal activity. Generally speaking, third-degree AV block caused by vagal-efferent traffic is short-lived. Sudden development of high-grade or complete AV block may require the administration of atropine or a catecholamine, or it may require rapid transvenous insertion of a pacing wire into the RV. Chronic third-degree AV block requires treatment with a pacemaker;<sup>507,776-779</sup> and pacemakers have been successfully placed epicardially and transvenously in several horses and in a number of Miniature Donkeys with possible congenital complete AV block (see [Figures 10-60, C, and 10-62](#)).

## INTRAVENTRICULAR CONDUCTION BLOCKS

Intraventricular conduction blocks, such as bundle branch block, are less common and more difficult to diagnose. Widening of the QRS complex and axis deviation are typical features. These abnormalities may also be found after APCs, from overdose with quinidine sulfate, from severe hyperkalemia, or secondary to supraventricular tachycardias with rapid ventricular response.

\*References 173, 192, 198, 344, 470, 764, 774.

**FIGURE 10-60** Conduction disturbances. **A**, Second-degree atrioventricular block. Nonconducted P waves and varying P-R intervals are evident (base-apex lead recorded at 25 mm/sec). **B**, The tracings are from a horse with third-degree atrioventricular block. The upper strip demonstrates multiple blocked P waves. The lower tracing shows nonconducted P waves and ventricular escape complexes (base-apex lead recorded at 25 mm/sec). **C**, Permanent transvenous ventricular pacing in a Miniature Donkey with a complete atrioventricular block. A pacemaker spike (*arrow*) precedes each paced ventricular complex.

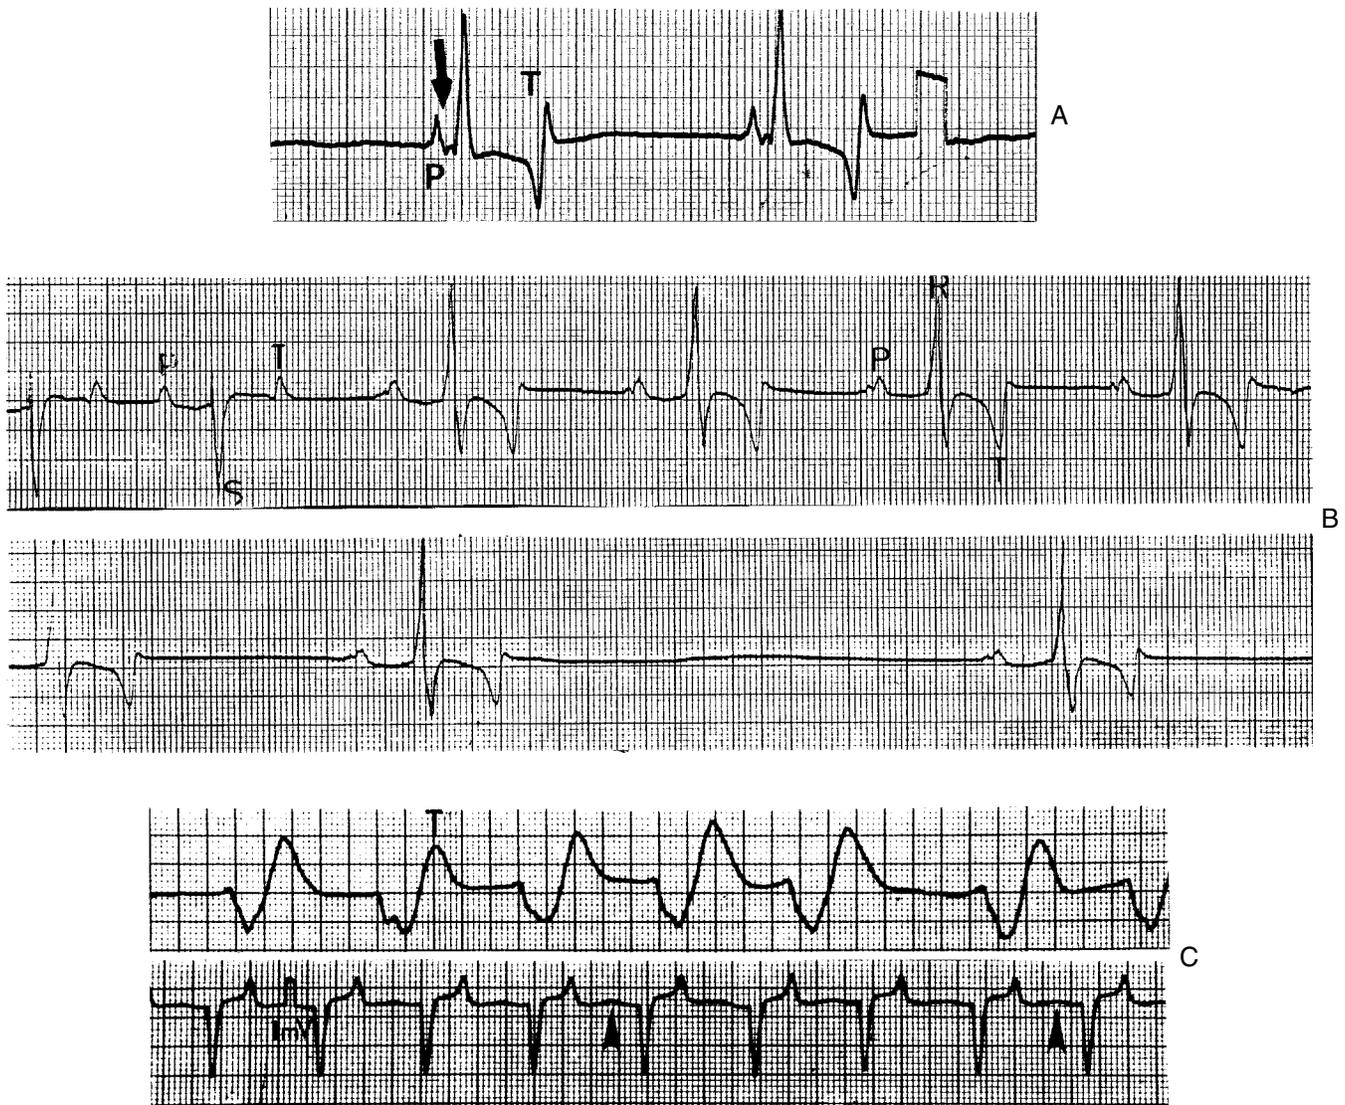

### PRE-EXCITATION

Pre-excitation, or accelerated AV conduction, has been reported sporadically,<sup>775</sup> but the clinical significance of this electrocardiographic abnormality has yet to be determined in this species. Ventricular pre-excitation in humans and in dogs is often due to an anomalous conducting pathway around the AV node, which serves as a path for re-entrant supraventricular tachycardias. These rhythm disturbances may cause hypotension and syncope. Whether pre-excitation syndromes are important has yet to be determined. Nevertheless, ECG traces occasionally show evidence of ventricular pre-excitation and are characterized by a P-QRS-T relationship but with an extremely short

PR interval, early excitation of the ventricle characterized by a slurring of the initial QRS complex (a delta wave), and an overall widening of the QRS complex (see Figure 10-61, A).

### HYPERKALEMIA

Hyperkalemia can cause significant depression of atrial, AV, and ventricular conduction and can shorten ventricular repolarization. Serum potassium is most likely to be markedly elevated after renal failure and oliguria, during shock, with severe metabolic acidosis, in foals with ruptured bladder or ureter and uoperitoneum, or after excessive IV potassium replacement. Hyperkalemia also occurs in Quarter Horses with hyperkalemic periodic paralysis.

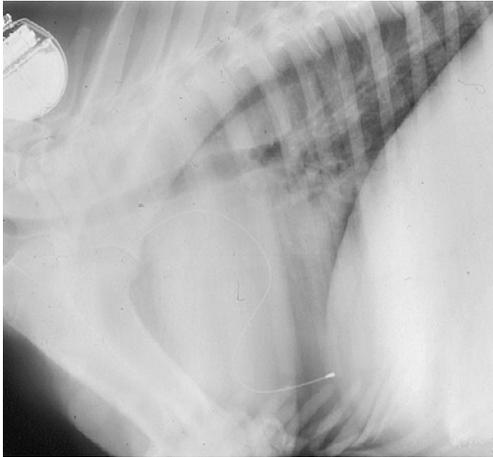

**FIGURE 10-61** Conduction disturbances. **A**, Ventricular pre-excitation. The short P-R interval (*arrow*) and small deflection in the P-R segment (delta wave) indicate an accessory pathway around the atrioventricular node with premature activation of a portion of the ventricle (delta wave and initial portion of the QRS). The large QRS and secondary T wave changes can be explained by the loss of normal cancellation of ventricular electrical forces. **B**, A sinus arrhythmia and intraventricular conduction disturbance. The sudden change and widening of the ventricular conduction pattern are notable, despite the consistent P-R interval and probably represent a bundle branch block, although this diagnosis is difficult to make in horses (base-apex lead recorded at 25 mm/sec). **C**, Hyperkalemia in a foal with a ruptured bladder. The top strip demonstrates atrial standstill (no P waves), significant widening of the QRS complexes, and large T waves with a shortened ST segment. The lower tracing shows the effects after initial medical therapy for hyperkalemia, which included treatment with saline and sodium bicarbonate. The normalization of the QRS complexes and the appearance of low-amplitude P waves (*arrows*) are notable. (Tracing courtesy of Ron Hilwig, DVM, PhD.)

Changes in the ECG are usually evident at potassium serum concentrations greater than 6 mEq/L, with severe changes evident when serum concentrations are between 8 and 10 mEq/L.<sup>198,780-782</sup> Broadening and flattening of the P wave are the most consistently observed change. Prolongation of the PQ interval and bradycardia develop, excitability decreases, and atrial standstill (sinoventricular rhythm)—characterized by complete absence of P waves—may be observed. Either inversion or enlargement (tenting) of the T waves is also likely. Marked widening of the QRS complex may be noted as near-lethal

concentrations of potassium are approached. Ventricular asystole or fibrillation can develop. The QT interval is not a reliable indicator of induced hyperkalemia, and other electrolyte and acid-base alterations, including serum calcium and sodium, influence the effect of hyperkalemia on the heart.

Therapy for hyperkalemia includes correction of the underlying problem, infusion of isotonic crystalloid solutions and dextrose, and administration of calcium salts and sodium bicarbonate. Lactated Ringer's solution (LRS) can be used in patients with hyperkalemia; the small amount

**FIGURE 10-62** A lateral radiograph of a permanent transvenous pacing system in a Miniature Donkey. The pacemaker is evident at the upper left of the radiograph. The thin transvenous pacing wire extends from the device through the jugular vein and vena cava and into the right ventricular (RV) apex.

of potassium contained in LRS is generally not considered problematic, because the beneficial effects of volume replacement and treatment of metabolic acidosis largely outweigh the potential negative effects of additional potassium supply. Alternatively, sodium chloride (NaCl) or NaCl/dextrose solutions may be used, but maintenance solutions should not be used because of their relatively high potassium content. Dextrose (or glucose) can be administered as a bolus of 0.25 to 0.5 g/kg, IV over 15 minutes. The administration of regular insulin (0.1 IU/kg) in conjunction with dextrose infusion (0.5 to 1.0 g/kg, IV over 15 minutes) may be considered in cases of life-threatening hyperkalemia. Sodium bicarbonate may be used in cases of severe metabolic acidosis (provided that ventilation is adequate) at a dose of 1 to 2 mEq/kg, IV over 15 minutes (or depending on the base excess obtained by blood gas analyses [mEq sodium bicarbonate = 0.3 (–0.5) × BE × kg BWT]). In cases of severe arrhythmias, 1 ml/kg calcium gluconate 23% can be administered over a 10-minute period to effect.

# DISORDERS OF THE MUSCULOSKELETAL SYSTEM

## CHAPTER 11

Jennifer M. MacLeay

### FUNDAMENTALS OF THE MUSCULOSKELETAL SYSTEM, DIAGNOSTIC TECHNIQUES, AND CLASSIFICATION OF MYOPATHIES

Jennifer M. MacLeay

The innate ability of the horse to learn and trust is a special attribute that allows human beings to take advantage of their extraordinary strength and agility. Horses have contributed to human life by assisting in agriculture, business, travel, and recreation. Although effective locomotion depends on the coordination of many body systems, movement ultimately depends on skeletal muscle. This chapter endeavors to review the many disorders that affect the muscular system of the horse.

### STRUCTURE

Mammalian skeletal muscle consists of approximately 75% water, 18% to 22% protein, 1% carbohydrate, and 1% mineral, with variable lipid content. Depending on the breed and type of horse, between 44% and 53% of the live weight of a mature 500-kg horse has been estimated to be muscle.<sup>1</sup> The myofiber, or individual muscle cell, is the fundamental building block of muscle, and each is a fusiform, multinucleated cell. Combined, myofibers constitute 75% to 90% of the volume of muscle. The myofibers are arranged in parallel along the length of the muscle such that the force of contraction is additive. The rest of the muscle tissue is made up of fibroblasts, capillaries, adipose cells, nerves, and connective tissue fibers. The composition of any muscle varies depending on the muscle surveyed and the overall fitness level, age, and breed of the horse. Muscles begin and end with tendons of various sizes, which attach the muscle to bone. Golgi tendon organs act as end organs of muscle sense and are found in the major tendinous origins and insertions. The nerve and blood vessels that supply an individual muscle typically enter near the midpoint of the muscle belly at a region called the neurovascular hilum. The nerve bundle splits off into individual nerves once it enters the muscle. A single nerve contacts several myofibers

such that they contract in unison when stimulated (motor unit). A single nerve innervates each myofiber at a single point known as the motor end plate.

Each myofiber is bounded by a complex membrane called the sarcolemma, which invaginates into the muscle fiber at numerous points to form the T, or transverse, tubules. The T tubules terminate within each muscle cell in proximity to the sarcoplasmic reticulum of the cell, contacting the myofibrils between the A and I band twice within each sarcomere. The T tubule lies between two terminal cisterns of the sarcoplasmic reticulum. Together these three structures form the triad.

A basement membrane surrounds the sarcolemma and attaches closely to a layer of connective tissue called the *endomysium*. The endomysium is continuous with the perimysium, which surrounds groups or bundles of muscle fibers. The perimysium, in turn, is continuous with the epimysium, which surrounds the entire muscle. Satellite cells, which consist of a simple cell membrane around a nucleus with a minimal amount of cytoplasm and few mitochondria, lie in shallow indentations on the myofiber surface between the sarcolemma and the basement membrane. Satellite cells give rise to new myofibers after rhabdomyolysis (dissolution of muscle fibers). The nuclei of the satellite cells and mature myofibers are oriented to the long axis of the muscle fiber. The muscle fiber nuclei lie at the periphery of the cells just within the sarcolemma.

Within each myofiber are parallel arrays of myofibrils, the basic contractile units of muscle. Myofibrils are composed of end-to-end stacks of rodlike structures or contractile units called *sarcomeres*. Each stack of sarcomeres forms a long filament, and arrays of filaments form the myofibrils. Sarcomeres are composed of the contractile proteins actin, myosin, tropomyosin, and troponin. Troponin is a complex of troponin T, troponin I, and troponin C, whereas myosin is made of heavy and light chains and a globular head that contains the myosin adenosine triphosphatase (ATPase). [Figure 11-1](#) shows an electron micrograph of several myofibrils. The alternating bands of light and dark are notable. The dark A band is composed of the thick myosin filaments and is transected by a darker line called the M line. Each myosin filament is surrounded by, and interdigitates with, six thin filaments composed of actin, tropomyosin, and troponin. Areas where the thin filaments are

**FIGURE 11-1** Electron micrograph of several muscle myofibrils ( $\times 45,000$ .)

not overlapping with myosin form the lighter I band. The dark line running across the I band is called the *Z line*. A sarcomere is defined as the region between each Z line. At the Z lines the protein  $\alpha$ -actinin anchors actin. Because of the differing way these structures absorb light, the regular alternation of A bands and I bands in adjacent myofibrils produces the striated appearance characteristic of skeletal muscle fibers as viewed with light microscopy. Mitochondria fit into the small spaces around the myofibrils and produce the adenosine triphosphate (ATP) necessary for the contraction-relaxation cycle. The number, size, and shape of mitochondria vary depending on the fitness of the individual and the muscle fiber type predominant within the muscle sampled.<sup>1-3</sup>

## ☞ MUSCLE CONTRACTION

To understand the pathophysiologic features of many muscle disorders, defining the sequential steps that lead to contraction is valuable. This process is known as *excitation-contraction coupling*.

### EXCITATION

Excitation begins with the origination of a nerve impulse within the central nervous system. The impulse exits the spinal cord, travels along a motor neuron, and arrives at the motor end plate of an individual myofiber. Motor end plates are located in deep primary clefts or folds of the sarcolemma. The nerve impulse arrives at the motor end plate, releasing acetylcholine, which traverses the synaptic cleft and binds to nicotinic receptors. The binding of acetylcholine produces a conformational change in the nicotinic receptor, which results in the opening of ion channels, producing increased sodium and potassium conductance in the end plate membrane and causing depolarization and generation of an end plate action potential. The T tubule system propagates the action potential across the sarcolemma in all directions and carries it deep into the muscle fiber. Diffusion of acetylcholine from the receptors or hydrolysis by acetylcholine esterase causes depolarization to cease.

### EXCITATION-CONTRACTION COUPLING

Coupling of excitation with contraction begins with the arrival of the action potential at the triad region, which causes opening of sodium channels embedded in the T tubule membrane and rapid influx of sodium into the cell. The rapid influx through the sodium channel results in a change of polarity across the membrane that we associate with depolarization. As a result the inside of the sarcolemma becomes more positive relative to the outside of the membrane. Depolarization of the T tubule membrane triggers a voltage-gated calcium channel known as the dihydropyridine receptor, which is also located within the T tubule membrane. Activation of the dihydropyridine receptor triggers the closely related ryanodine receptor in the terminal cisternae of the sarcoplasmic reticulum, causing it to release calcium into the sarcoplasm.

### CONTRACTION

Calcium released into the sarcoplasm binds to troponin C, resulting in a conformational change of the tropomyosin molecule and unmasking part of the actin filament responsible for binding to myosin: the G-actin monomer. With binding of myosin to the G-actin monomers, a 90-degree cross-bridge forms. As soon as the cross-bridge forms, myosin ATPase cleaves ATP to form adenosine diphosphate (ADP) and adenosine monophosphate (AMP), resulting in another conformational change converting the 90-degree angle to a 45-degree angle. The contractural force is generated by the movement of the cross-bridge myosin head from a 90-degree to a 45-degree angle with a coincident sliding of the myofilaments relative to one another toward the center of the sarcomere. The hydrolytic products of ATP then detach from the myosin head enabling the cycle to recommence. The addition of new ATP to the myosin molecule results in the rapid dissociation of the actin and myosin filaments.<sup>4,5</sup> Sustained contraction occurs with the rapid repetition of this mechanochemical cycle.<sup>5</sup>

Each sarcomere shortens in unison in successive ratchetlike movements composed of multiple acts of relaxation and reengagement depending on the degree of shortening demanded by the nervous system. With input from the central nervous system to relax opposing muscles, the process of excitation-contraction coupling produces smooth coordinated movement.

### RELAXATION

For the cell to relax and return to baseline polarity, the sarcoplasmic reticulum and the plasmalemma must reaccumulate calcium, thereby lowering the concentration of calcium in the sarcoplasm and the T tubule while sarcolemmal membranes begin to repolarize. Sarcoplasmic calcium concentrations decrease when calcium-magnesium ATPase pumps return calcium to the sarcoplasmic reticulum and sodium-potassium ATPase pumps move sodium extracellularly and potassium intracellularly. Energy-dependent reaccumulation of calcium by the sarcoplasmic reticulum results in the release of calcium from troponin C, restoration of the resting configuration of the troponin-tropomyosin complexes, and ultimately disruption of the linkage between the myosin and actin filaments. Further details on muscle structure and contraction are available.<sup>4-7</sup>

TABLE 11-1

Energy Sources in Muscle*				
	Creatine Phosphatase	Anaerobic Glycolysis	Aerobic Glycolysis	Fatty Acid Oxidation
Rate of ATP synthesis	73 mmol/s	40 mmol/s	17 mmol/s	7 mmol/s
Relative rate	100	55	23	10
Duration	4 s	2-3 min	1-2 h	Many hours

\*Exact measurements vary somewhat by species; numbers are approximate.  
ATP, Adenosine triphosphate.

An important note is that all of the processes necessary for relaxation are active, meaning they require energy in the form of ATP for them to occur. In the absence of ATP, actin and myosin remain engaged, and the muscle remains in the shortened or contracted position known as rigor.

Several terms are frequently used when referring to the shortening of muscle in veterinary medicine. *Contraction* implies a shortening or tightening of the muscle that is initiated by the central nervous system. This electrical activity is recorded readily using electromyography. A *contracture* is considered to be the shortening of a muscle because of abnormal activity within the muscle cell or cells. A contracture originates within the muscle fiber itself and is therefore electrically silent on electromyography. Contractures occur in disorders characterized by muscle cramping such as polysaccharide storage myopathy or recurrent exertional rhabdomyolysis in which muscle shortening is typically electrically silent. The term *spasm* is more generic and may refer to a transient or sustained contraction or contracture. If a spasm is painful, the term *cramp* is often used. Fibrous tissue within a muscle may prevent complete stretching and shortening of a muscle, thereby limiting the range of motion of a limb or joint. This process occurs in fibrotic myopathy as described in a subsequent section.

### SOURCE OF ENERGY FOR CONTRACTION

Understanding the sources of energy for contraction is important because most metabolic myopathies arise from derangements in these processes. ATP stores in muscle are very minimal and are quickly exhausted. Thereafter, ATP must be generated to sustain muscle function. In short, ATP is generated by either aerobic (oxidative) or anaerobic mechanisms. The primary substrates for aerobic metabolism include circulating nonesterified fatty acids and glucose or intramuscular stores (or both) of glycogen and triglycerides.

When the phosphate bond of ATP is cleaved, the resulting by-products include ADP, inorganic phosphate, and energy. At the onset of muscle activity, cleavage of the phosphate bonds of creatine phosphate (or phosphorylcreatine) in the presence of ADP by the enzyme creatine kinase produces creatine and ATP. This anaerobic pathway is quickly supplanted by other pathways to produce energy (Table 11-1).

Numerous different processes within the muscle fiber generate ATP after creatine phosphate and include glycogenolysis, glycolysis, Krebs cycle,  $\beta$ -oxidation of free fatty acids, and purine nucleotide deamination. Which pathways are most active depends on factors that include the underlying muscle

fiber composition, the number of motor units recruited, capillarization of the muscle, the underlying oxidative and glycolytic capacities of the muscle fibers, and the delivery of oxygen and other energy substrates to the muscle. In turn, the breed and age of the horse, the length or stage of exercise, the intensity of exercise, and the fitness level of the horse influence these factors.

For specifics on glycolysis and generation of ATP via the Embden-Meyerhof pathway or the hexose monophosphate shunt, the reader is directed to a physiology text. Glycolysis or the breakdown of glucose (a 6-carbon molecule) to carbon dioxide and water in the presence of oxygen liberates 38 moles of ATP per mole of glucose. Whereas the fatty acid oxidation of a similar 6 carbon fatty acid yields 44 moles of ATP.

The primary sources of glucose include circulating glucose in the blood, small quantities of free glucose within the sarcoplasm, and stored glycogen within the muscle cell. Glycogen is a branched polymer of individual glucose molecules consisting of 1:4 $\alpha$  and 1:6 $\alpha$  linkages. Breakdown of glycogen, or glycogenolysis, results in the liberation of 37 moles of ATP per mole of glycogen. A large, extramuscular storage site of glycogen is the liver. With exercise, the liver begins to liberate free glucose into the blood. Muscle cells take up glucose by glucose transporters located in the cell membrane. Athletes who have exercised frequently over time develop a denser network of capillaries about each muscle cell to facilitate the delivery of oxygen, free fatty acids, and glucose to the cell and the removal of by-products.

Glycogen is made through the action of glycogen synthase and glycogen branching enzyme. The breakdown of glycogen's 1:4 $\alpha$  linkages is mediated by phosphorylase, whereas the breakdown at the 1:6 $\alpha$  linkages is mediated by glycogen debranching enzyme. To prevent a futile cycle of formation and degradation, these sets of enzymes are reciprocally regulated. Glycogen synthase is stimulated when glucose-6-phosphate is plentiful, whereas the presence of glucose-6-phosphate and ATP inhibit phosphorylase. Phosphorylase is activated when levels of AMP are elevated. Hormones may also activate phosphorylase. Epinephrine stimulates phosphorylase in both the liver and skeletal muscle, leading to elevations in blood lactate and glucose. Glucagon acts only on liver phosphorylase, resulting in elevations in blood glucose and not lactate.

Glycolysis and glycogenolysis are rapid processes and produce adequate energy for aerobic exercise. When exercise intensity increases and oxygen demand cannot be met, glucose is metabolized anaerobically. Anaerobic glycolysis of glycogen yields 3 moles of ATP and lactic acid as a by-product. The accumulation of lactic acid within the cell lowers the pH

of the sarcoplasm, inhibits the function of many intracellular enzymes, and contributes to fatigue.

After a period of light aerobic exercise (this varies between individuals but in many is after approximately 15 to 20 minutes), the muscle begins to rely more on the  $\beta$ -oxidation of free fatty acids than on glycolysis for the production of ATP. Small stores of fat are located within the muscle. However, most of the free fatty acids are liberated from body fat stores or the liver and are taken up by the muscle cell during exercise. The longer the aerobic exercise, the more energy is derived from metabolism of free fatty acids. More intensive aerobic exercise uses a combination of carbohydrate and fatty acids as energy sources. The amount of energy derived from fatty acid metabolism appears also to be partially influenced by diet. The higher the intake of fat, the more muscle appears to rely on free fatty acids for energy. The optimal ratio of fat in the diet of the horse has yet to be determined.

The onset of fatigue during aerobic exercise is different from that during anaerobic exercise. During aerobic exercise, glycogen depletion, hyperthermia, and electrolyte depletion appear to be major factors, whereas during anaerobic exercise, lactic acidosis and depletion of creatine phosphate and ATP appear to be important factors initiating fatigue. Accumulation of lactic acid within the muscle cell leads to decreased intracellular pH and inhibition of the enzymes important in glycolysis. A low intracellular pH also inhibits excitation-contraction coupling. In aerobic and anaerobic forms of exercise, eventual onset of myalgia and decreased motivation appear to be additional factors in fatigue.

When most forms of energy within the muscle are exhausted the last source of energy within the cell is the formation of ATP from two molecules of ADP in a process known as the myokinase reaction. A by-product of this reaction is ammonia. Increasing ammonia concentrations in the circulation are well correlated with depletion of ATP. Depleted fibers may develop a painful, electrically silent contracture that is similar to rigor, and severely affected fibers may die.

The death of muscle cells related to exercise is known as exertional rhabdomyolysis. Rhabdomyolysis is often assessed by the measurement of enzymes such as creatine kinase or lactate dehydrogenase that are released into the blood when muscle cells are severely stressed (the cell membranes become permeable) or the cells lyse.

## ☞ FIBER TYPE

### DIFFERENTIATION

Under light microscopy using simple staining techniques, skeletal muscle appears to be a homogeneous tissue. However, muscle is composed of many fibers with differing characteristics. Myofibers may be grouped into two categories: type 1 and type 2. Table 11-2 gives a summary of the characteristics of different fiber types. The type 1 and 2 classification is broad, and a spectrum of fibers has characteristics of both categories. The differences between fibers arise from variability in the proteins that comprise the contractile elements. Several different isoforms have been identified for the myosin heavy and light chains, tropomyosin, troponin I, troponin T, and troponin C. The greatest variability is in the isoform of the myosin heavy chain. In addition, the calcium pumping capacity of the sarcoplasmic reticulum may vary from cell to cell.

All types of fibers are found in most skeletal muscles. Type 1 fibers are high in oxidative capacity and therefore rely on glucose, free fatty acids, and a high amount of oxygen to supply energy for contraction. Their sarcoplasmic reticula have a moderately slow reuptake of calcium capacity. Therefore type 1 fibers are best suited to moderate contraction speeds and sustained contractions over long periods. As expected, these fibers predominate in muscles involved in posture. Type 2 fibers have a fast myosin ATPase rate and a rapid capacity to reuptake calcium into the sarcoplasmic reticulum. They are large-diameter fibers compared with type 1 fibers and have a higher glycolytic capacity, making them suited to powerful

TABLE 11-2

Fiber Type Characteristics			
	TYPE 1	TYPE 2*	
		A	B
<b>PHYSIOLOGIC CHARACTERISTICS</b>			
Speed of contraction/twitch	Slow	Fast	Fast
Fatigability	Low	Intermediate	Rapid
Maximal tension developed	Low	High	High
<b>HISTOCHEMICAL PROPERTIES</b>			
Myofibrillar ATPase stain pH 9.4	Light	Dark	Dark
Preincubation at a pH of:			
≈4.5	Dark	Light	Medium
≈4.3	Dark	Light	Light
Oxidative capacity	High	Intermediate high	Low
Enzymes for glucose breakdown	Intermediate	High	High
Enzymes for free fatty acid breakdown	High	Intermediate	Low
No. of capillaries	High	Intermediate	Low
Glycogen content	Low	High	High

*ATPase*, Adenosine triphosphatase.  
\*Type 2C fibers have been described after acid preincubation with staining intensities between the light type 2A and medium type 2B fibers.

fast contractions. These fibers predominate in the skeletal muscles involved in locomotion and rapid fine-motor movements such as around the eye. Type 2 fibers that have activities closer to type 1 fibers are called type 2A, whereas those that exhibit high anaerobic capacity are characterized as type 2B. Because of the high oxidative capacity of type 1 fibers, these muscles often appear to have a deeper red color than fibers high in type 2A and 2B fibers.

Histologically, differentiation of muscle fiber types relies on the measurement of myofibrillar ATPase activity (the enzyme responsible for the breakdown of ATP at the actin-myosin cross-bridges). Staining for this enzyme distinguishes two distinct fiber types at pH 9.4. The slow-twitch type 1 fibers have a low activity at this pH and so appear lighter in color than the fast-twitch type 2 fibers. The type 2 fibers can be divided further by preincubation at a more acidic pH into types 2A, 2B, and even 2C (the pH values required for this differentiation vary with the laboratory but are around 4.5 and 4.3).

The varying capacities of muscle fiber types is largely the result of variations in myosin heavy-chain isoforms. These isoforms are identified through antibody and electrophoresis techniques. In mammals, at least nine have been identified. Two are developmental (embryonic and neonatal), two are found in cardiac muscle (alpha and beta), three are common in skeletal muscle (2a, 2b, and 2x), and two are rare with greatest expression in jaw, extraocular, and laryngeal muscles. Beta is also found in skeletal muscle and is an isoform with properties of slow twitch, high oxidative capacity, low glycolytic capacity, and low ATPase activity similar to the histologically identified type 1 myofibers. Type 2a myosin heavy-chain isoforms are typically found in fibers exhibiting fast twitch, high glycolytic, high ATPase activity, and high oxidative capacity and as such resist fatigue. Type 2b and 2x isoforms are found in muscles that are fast twitch, produce strong contractions, have high glycolytic and ATPase activity but have low oxidative capacity and, as such, fatigue faster than type 2a rich myofibers.<sup>8-11</sup>

## INNERVATION

A neuron and all of its innervated myofibers constitute a motor unit. Each motor neuron may innervate a few or several hundred myofibers, and all of those myofibers exhibit similar contraction characteristics. Each myofiber, however, is innervated only by a branch of one motor neuron. Two types of motor nerve fiber are found, slow and fast. The type and pattern of electrical activity on a muscle cell is related to the type of myosin isoforms expressed: The large phasic motor nerve fibers innervate the type 2 myofibers, whereas the small tonic fibers innervate the type 1 fibers.<sup>11</sup>

Muscle spindles are a bundle of specialized muscle fibers that run parallel to nonsensory muscle fibers and which contact sensory axon endings. Muscle spindle cells are important in telling the nervous system about the tone and length of the muscle. They are also important in maintaining posture. Discharges are relayed directly to the ipsilateral spinal motor neurons that innervate the muscle in which the spindle is located, resulting in a reflex arc. Two types of sensory neurons innervate each spindle: the primary endings are from the large-diameter group 1A afferent axons, whereas the less elaborate secondary endings are from the smaller group 2 afferent axons. The spindle cell fibers also receive motor

neuron innervation from small  $\gamma$ -motor neurons, which helps keep the spindle taut when the muscle contracts, which, in turn, enables the sensory endings to respond to a wide range of muscle lengths.

Muscle spindle cells are different from the muscle Golgi tendon organ. Golgi tendon organs are found at the ends of the muscle fibers at the musculotendinous junction and are formed from a common tendon to which several muscle fibers are attached. A sensory nerve ending wraps around each Golgi tendon organ. The sensory nerve innervating the Golgi tendon organ responds to tension generated by the contraction of any of these muscle fibers, and the discharge is relayed to the ipsilateral  $\alpha$ -motor neurons, where it is inhibitory. This action forms another reflex arc responding to muscle tension and helps ensure that muscles of flexion and extension do not contract simultaneously.

## FIBER RECRUITMENT

Under neural control, an orderly selection of fibers occurs with increasing demands. When just maintaining posture or walking the horse uses only the nerves supplying the slow-twitch type 1 and possibly a few of the intermediate type fast-twitch high-oxidative type 2A fibers. As the speed or intensity of work increases, more and more fibers are recruited. Thus, at a medium trot, approximately 50% of the muscle cells within a muscle belly are contracting, whereas at a gallop, most or all fibers are involved. The fibers are recruited in a set order: type 1, type 2A, and then type 2B. The gradation in response of a muscle is known as the recruitment of motor units. A motor unit consists of a motor nerve and the cells it innervates. The smoothness of a muscular contraction occurs because of the asynchronous contraction of the various motor units.

## DISTRIBUTION

The proportions of fiber types present within a muscle vary according to individual traits of the horse, the muscle location, the breed, and the age of the horse.<sup>1,8,10,12-15</sup> In some muscles (in particular the middle gluteal muscle, which is sampled most commonly) the distribution also depends on the sampling site or depth because the distribution of fiber types is nonhomogeneous.<sup>1,10,15,16</sup> The suggestion has been made, however, that within a specific muscle of an individual, the variation in fiber types is small if samples are taken from the same site or an identical contralateral site under controlled conditions.<sup>15,17</sup> This arrangement is why it is generally recommended to biopsy specific muscles to diagnose certain disorders. It provides a relatively homogeneous baseline from which to evaluate a muscle. The exception is when a specific muscle is affected (e.g., exhibits atrophy) wherein it should be biopsied.

## ☞ GROWTH, TRAINING, AND PERFORMANCE

Fiber type predominance does affect performance. However, with growth and training muscle cells adapt and may change fiber type over time.<sup>1,7,18-22</sup> Training results in (1) an increase in the ability of a fiber to use oxygen by increasing the number of mitochondria within the sarcoplasm, (2) a decrease in the use of muscle glycogen and blood glucose with a greater

reliance on fat oxidation to supply ATP, and (3) a decrease in the amount of lactate produced per given intensity of exercise. Variable results have been reported on the effects of exercise on fiber size and capillarization. The extent and nature of the changes appear to depend on the duration, intensity, and type of exercise involved, as well as the age of the animal. Over the last decades, much information has been gained in the field of equine exercise physiology, and multiple texts are available on the subject both in print and online that extend beyond the scope of this chapter.<sup>23-26</sup>

## ☞ PATHOLOGIC CHANGES

### GENERAL RESPONSE OF MUSCLE TO INJURY

Muscle responds to injury or damage in a limited number of ways. A growing body of evidence indicates that myopathic conditions share a similar final pathway of muscle fiber degeneration, although the number and type of fibers affected and the degree of damage varies.<sup>27</sup> The final common pathway involves failure to sequester calcium ions from the sarcoplasm. Prolonged calcium accumulation within the sarcoplasm leads to activation of cellular enzymes and prolonged activation of myofilaments. This process is visible histologically as hypercontraction. Consequently, mitochondria take up excess calcium in an attempt to prevent cellular damage. Accumulation of calcium within the mitochondria leads to failure of energy production (i.e., ATP) within the cell and eventually failure of all intracellular energy-dependent mechanisms, which leads to failure of membrane pumps and ultimately cell swelling and lysis.<sup>27,28</sup>

The exact nature of these calcium-activated degenerative pathways is still unknown. A key step may be calcium-induced membrane phospholipid hydrolysis via the activation of phospholipase enzymes, resulting in the production of tissue-damaging metabolites. Other processes, however, involving nonenzymatic lipid peroxidation also may be activated. During exercise the flow of oxygen increases. At the same time an overall depletion of ATP sources occurs. The resultant metabolic stress leads to a greatly increased rate of oxygen free radical production that may exceed the scavenger and antioxidant defense systems of the cell, leading to a loss of cell viability and damage. The increase in free radical activity can lead to a failure of calcium homeostasis and consequent muscle damage, or, alternatively, calcium overloading may lead to an activation of free radical-mediated processes.<sup>29</sup> Multiple initiators likely lead to this final common pathway, depending on the type of exercise, fitness level, presence or absence of underlying genetic defects in muscle metabolism, and nutritional status of the horse. Free radical-induced skeletal muscle damage may be especially important if reperfusion follows a period of ischemia.<sup>30</sup>

### ATROPHY AND HYPERTROPHY

Atrophy may be defined as a decrease in muscle fiber diameter or cross-sectional area. Atrophy can occur in a variety of circumstances, including denervation, disuse, and cachexia, in many muscle diseases, after circulatory disturbances, and after extensive myolysis. Within 2 or 3 weeks after peripheral denervation, up to two thirds of the original muscle mass may be lost, although this may not always be obvious clinically because of the presence of superficial and intramuscular fat

deposits. Histologic changes reflect the affected nerve and the muscle fiber supplied. In disuse (e.g., atrophy resulting from a tenotomy) a preferential atrophy of type 1 fibers is apparent, often with hypertrophy of type 2 fibers. In contrast, with cachexia and malnutrition, type 2 fibers are preferentially affected, especially in the postural muscles. Not all muscles show the same degree of atrophy, even within one disease process. In cachexia, the back and thigh muscles tend to be the first affected, and the loss of muscle is usually symmetric, with a concurrent loss of fat deposits. A localized asymmetric atrophy is associated with paralysis, immobilization, and denervation.<sup>31</sup>

As indicated previously, hypertrophy may occur through training. A compensatory hypertrophy may also occur in the fibers surrounding an area where fibers have been lost or have decreased greatly in size. Often, large fibers are visible histologically in such conditions, with evidence of incomplete longitudinal division.<sup>31</sup>

### REPAIR AFTER DENERVATION

Denervation results in atrophy, as remarked previously, but also leads to abnormal muscle excitability. Muscle becomes more sensitive to circulating acetylcholine. The result is the presence of fine, irregular contractions or fibrillations detectable using electromyography. Fibrillations are not visible clinically and should not be confused with fasciculations that appear grossly as jerky muscle contractions in response to pathologic spinal motor neuron discharges.<sup>11</sup> With reinnervation the fibrillations cease. Reinnervation can occur in two ways. Damage without severing the nerve is called axonotmesis. The axon is damaged but the Schwann cell and endoneurial fibrous sheaths remain. Axons from the proximal part of the damaged nerve may reestablish connections within the empty residual Schwann cell sheath to the distal portion of the original nerve. Initially, atrophy of scattered muscle fibers is visible, but after reinnervation a proportion of the muscle fibers are restored to their normal size and function. Even if the affected muscle is not fully restored, other surrounding unaffected muscles may be able to compensate so that overall function is maintained, although slight gait abnormalities may remain.

The second type of reinnervation occurs when some nerve fascicles are severed completely or when the nerve lesion is located a great distance from the muscle, for example, when lesions involve the motor neuron cell bodies or nerve roots or both. In this case, collateral reinnervation from adjacent, unaffected axons can occur. Given that the nerve type characterizes the muscle type, this action results in regrouping of muscle fibers so that clusters of fibers of the same histochemical type are found rather than the normal checkerboard pattern. This phenomenon is known as fiber type grouping.

### REPAIR AFTER INJURY

Regeneration where a break in the continuity of the muscle fiber has occurred differs considerably from neurologic damage. In such cases, repair involves multiplication of nuclei and formation of new internal structures and organelles followed by fusion and alignment into a new multinuclear myofiber. Regeneration can be swift when parts of the affected fiber remain intact. In this case, regeneration occurs at the healthy end of the severed fiber (continuous or budding regeneration). When damage is more severe, regeneration occurs by

fusion of mononuclear myoblasts to form a myotube, which develops in a similar way to fetal fibers (discontinuous or embryonic regeneration). The origin of myoblasts is primarily satellite cells, and their origins and function have been well reviewed.<sup>32,33</sup> If the scaffolding, basement membrane, and supporting tissues remain intact, and if the initiating disease process subsides, new fibers tend to orient in a way similar to the original fibers. This type of regeneration usually occurs with segmental necrosis in which necrosis of the whole diameter of the fiber has occurred involving several sarcomeres. Fibroblastic and vascular reactions are minimal in this type of regeneration. Therefore full function of the muscle is restored without residual dysfunction.

Massive trauma, hemorrhage, infection, or infarction can result in damage to the basement membrane and other supporting structures resulting in complete disorientation of the regenerating fibers with significant proliferation of fibroblasts and vessels. In such cases, regeneration may result in significant deformation of the muscle with disruption of its normal function. Regenerated cells often have centrally located nuclei and larger diameters than older myofibers.

## ☞ DIAGNOSIS OF SKELETAL MUSCLE DISORDERS

Because damage to muscle tissue often occurs along similar pathways, recognizing that muscle disorders can only rarely be diagnosed based on muscle histopathology alone is important. A thorough history that includes genetic background, exercise, nutrition, patient signalment, and clinical description of the muscular disorder is mandatory.

Skeletal muscle disorders broadly fall into two categories: acquired or inborn. Acquired myopathies include those of traumatic or infectious origin and ones arising secondarily from endocrine or nutritional disease or electrolyte imbalances (acquired metabolic myopathies).<sup>34</sup> Inborn errors of metabolism that manifest as metabolic myopathies originate primarily from defects in muscle energy metabolism. As such, they can be grouped as errors in carbohydrate, lipid, or purine metabolism; as mitochondrial defects; or as primary disorders of ion channels (channelopathies).

Acute trauma typically produces obvious clinical signs such as an open wound, severe lameness, heat, pain, swelling, or any combination. Healed traumatic injuries may be evident by abnormal gait or scar tissue, or both, within the muscle as primary complaints. Infectious myositis may also cause heat, pain, swelling, or crepitus, in addition to systemic signs of colic, endotoxemia, and shock if the infection is severe and widespread. In general the metabolic myopathies reveal a more chronic history involving some of the following client complaints: episodic weakness or muscle cramping, progressive weakness, atrophy, muscle wasting, reluctance to move, rapid muscle fatigue with exercise, intermittent or consistent gait abnormalities, muscle fasciculations, or discolored urine.

Modalities used to diagnose equine myopathies may include a thorough history (including use, diet, genetic background, signalment, and client complaint), physical examination, serum chemistry profile, complete blood count, urinalysis (including analysis for myoglobin and fractional excretions of sodium, potassium, phosphorus, and chloride), muscle biopsy (histology, histochemistry, electron microscopy), electromyography (EMG), thermography, genetic testing, nuclear

scintigraphy, or any combination. In horses with suspected metabolic myopathies, diagnostics may be strategically put together as part of an exercise challenge test that includes the history, observation of the horse at work, pre- and postexercise measurement of serum muscle enzyme activity and lactate, urinalysis with fractional excretions of electrolytes, genetic testing, and muscle biopsy.

## PLASMA AND SERUM ENZYME ACTIVITIES

The enzymes that are most useful in evaluating the equine muscular system are creatine kinase (CK), aspartate transferase (AST), and lactate dehydrogenase (LDH). A change in the plasma activity of any enzyme can occur for a variety of reasons, including alteration in the permeability of the enclosing cell membrane, cell necrosis, impaired removal or clearance of the enzyme, and increased or impaired synthesis. Decreases in plasma enzyme activities are not usually clinically significant. Often, no one specific organ of elimination is responsible, although most elimination occurs via the liver, kidneys, and lungs. Therefore, under most circumstances, the elimination rate of an enzyme from the plasma remains fairly constant, and the rate of influx to the plasma is the crucial factor.

Increases most commonly occur because of a defect in the integrity of the membrane containing the enzyme-rich sarcoplasm.<sup>6,35</sup> The defect results from complete disruption of the cell or a transient change in the permeability of the membrane without cell death. A complete explanation for the pattern of release of intracellular constituents from diseased muscles cannot be given here. Most of the enzymes that are detectable in increased concentrations in the blood with the various muscle disorders are the major soluble (sarcoplasmic) enzymes, although one can also detect the mitochondrial form of AST with severe injury.

The degree of muscle damage does not correlate with the magnitude of increase in serum muscle enzyme activity; a small amount of severely damaged muscle may release a similar amount of enzyme as a larger quantity of mildly damaged muscle. Under general circumstances, the rate of efflux of an enzyme most likely depends not only on its molecular weight and intracellular localization but also on its binding to various intracellular structures and relative intracellular and extracellular concentration. No explanation for the significant differences in half-lives of the various plasma muscle enzymes reported for human beings and horses has been given.

## CREATINE KINASE

Creatine kinase is the enzyme responsible for breaking down creatine phosphate to creatine and phosphate, releasing energy for muscular contraction. This reaction is the sole source of energy in muscle at the initiation of exercise. Thereafter, energy is supplied by oxidation of glucose and free fatty acids as described previously. Because this enzyme is responsible for the breakdown of creatine phosphate, it is often called creatine phosphokinase. This term, however, is inappropriate, and one should use creatine kinase. In the horse, CK is found mainly in skeletal muscle, the myocardium, and the brain.<sup>36</sup> Little or no exchange of CK between the cerebrospinal fluid and plasma appears to occur. A significant increase in total plasma CK activity therefore is caused by cardiac or skeletal muscle damage. CK (molecular weight, 80,000 daltons [Da]) does not enter the bloodstream directly after its release from

the muscle cell but transits through the lymph via the interstitial fluid. The total quantity of circulating CK in the horse under normal conditions is estimated to be equivalent to the quantity of CK in approximately 1 g of muscle; a threefold to fivefold increase in plasma CK activity corresponds to the apparent myolysis of approximately 20 g of muscle.<sup>37</sup> However, as described previously, making assumptions as to the amount of muscle damaged based on serum CK activity is difficult because muscle cells appear to be able to release significant quantities of CK without necessarily being lysed.

In human beings, two monomers of CK are known and are designated M and B. The enzyme is dimeric, and three possible primary forms exist: MM, MB, and BB. In simplified terms, MM is found mainly in skeletal muscle, BB in the brain and epithelial tissues, and MB in the myocardium. In the horse, some confusion over CK isoenzymes exists, with workers reporting different electrophoretic bands and tissue activities, perhaps because of the different techniques used.<sup>38-41</sup> In one study the heart and skeletal muscle were found to contain predominantly the MM dimer; the brain, pancreas, and kidney, mainly the BB dimer; and the intestine, the MB and BB dimers.<sup>39</sup> This work suggests that in the horse, CK isoenzymes on their own could not be used to differentiate between skeletal and cardiac muscle damage. This problem is alleviated largely by the current availability of tests for cardiac troponin I. Unfortunately, commercial tests for skeletal troponin I are not available. In the absence of clinical cardiac disease, elevations in CK primarily can be attributed to skeletal muscle. The plasma half-life of CK in the horse is short (108 minutes,  $123 \pm 28$  min with a plasma clearance of  $0.36 \pm 0.1$  ml/kg/min)<sup>37,42</sup> in contrast to reports of 12 hours in human beings.<sup>43</sup>

### ASPARTATE AMINOTRANSFERASE

AST is found mainly in skeletal muscle, liver, and heart, although lower activities are present in several other tissues. Therefore AST is not tissue specific.<sup>36,44,45</sup> Two isoenzymes have been identified by electrophoresis: MAST (found exclusively in the mitochondria) and CAST (originating from the cytoplasm or sarcoplasm). The ratio of cytosolic to mitochondrial enzyme in horse serum is significantly greater than that found in human beings and many other mammals.<sup>46</sup> In the horse, the ratio of these two forms varies between tissues, and no tissue specificity is apparent for either isoenzyme. The plasma half-life of AST in the horse is 7 to 10 days,<sup>42</sup> far longer than the 11.8 hours in human beings.<sup>43</sup>

### LACTATE DEHYDROGENASE

Lactate dehydrogenase is a tetrapeptide that occurs in five different isozymic forms produced by combinations of two kinds of subunits (H [heart] and M [muscle]) in groups of four to produce the functional tetrameric molecule. The five isoenzymes are labeled as LDH<sub>1</sub> to LDH<sub>5</sub>, or H<sub>4</sub>, MH<sub>3</sub>, M<sub>2</sub>H<sub>2</sub>, M<sub>3</sub>H, and M<sub>4</sub>, respectively. Similar to AST, LDH is found in most tissues and is therefore not organ specific. However, tissues contain various amounts of the LDH isoenzymes, and the isoenzyme profile obtained by electrophoretic separation has been used to identify specific tissue damage.<sup>47</sup> For the most part, LDH<sub>5</sub> (plus some LDH<sub>4</sub>) is found in the locomotor muscles, the liver contains mainly LDH<sub>3</sub> (with some LDH<sub>4</sub> and LDH<sub>5</sub>), the heart contains mainly LDH<sub>1</sub> (with LDH<sub>2</sub> and LDH<sub>3</sub>), and all types have been found in certain nonlocomotor muscles.<sup>38,41</sup>

Training has been shown to increase the percentage of LDH<sub>1</sub> to LDH<sub>4</sub> and decrease that of LDH<sub>5</sub> in skeletal muscle.<sup>48</sup> The practitioner should use nonhemolyzed samples for LDH determinations because red blood cells contain large amounts of LDH. In general, though, assays for CK and AST are most commonly used to evaluate skeletal muscle.

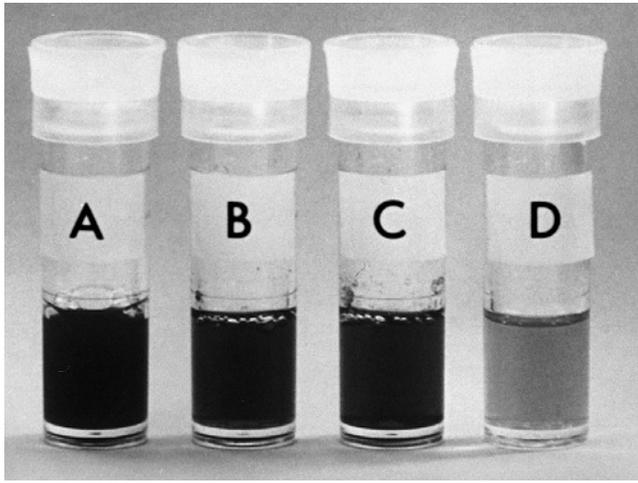

### URINALYSIS: MYOGLOBINURIA

Myoglobin (molecular weight 16,500 Da) is essential for the transport of oxygen into and within muscle cells. Most mammalian muscles contain approximately 1 mg myoglobin per gram of fresh tissue, and the suggestion has been made that acute destruction of at least 200 g of muscle must occur before serum myoglobin levels rise sufficiently for detection in the urine.<sup>49</sup> Serum myoglobin has a short half-life, and therefore measuring serum myoglobin is of limited diagnostic value. In human beings, myoglobinuria occurs in a variety of conditions, including myocardial infarction, crush and burn injuries, malignant hyperthermia, idiopathic and exertional rhabdomyolysis, and certain genetic metabolic abnormalities.<sup>6,49-52</sup> In the horse, myoglobinuria has been seen in equine exercise or trauma-induced rhabdomyolysis,<sup>53,54</sup> white muscle disease in foals,<sup>55</sup> and postanesthetic myositis.<sup>56</sup>

Pigmenturia or dark urine may be caused by increased myoglobin, hemoglobin, or whole blood in the urine. Low levels of myoglobin, hemoglobin, or whole blood may occur in the urine and can be detected by urine dipstick or laboratory test before visible changes in the color of urine. Therefore considerable amounts of myoglobin, hemoglobin, or whole blood must be present for visible pigmenturia to occur. Many causes of hemolysis in the horse can result in hemoglobinuria, including oxidative damage to erythrocytes,<sup>57</sup> neonatal isoerythrolysis, hepatic disease, and renal disease.<sup>59</sup>

Unfortunately, stored urine, concentrated urine, and urine containing myoglobin, hemoglobin, or other porphyrins can appear similar in color<sup>57,59,60</sup> (Figure 11-2). Therefore myoglobinuria cannot be distinguished by color alone. The orthotoluidine-impregnated strips commonly used by veterinary clinicians (urine dipstick tests such as BM-Test-8, Boehringer Ingelheim Pharmaceuticals, Ridgefield, Conn.) are insensitive to the presence of myoglobin and hemoglobin.<sup>54,61</sup> The differential salting out of hemoglobin with ammonium sulfate gives false results in human beings<sup>49,50,59,62</sup> and the horse but is used commonly in many laboratories.<sup>49,50,59,61,62</sup> Visual inspection of the serum or plasma may indicate the cause of the pigmenturia. The low affinity of myoglobin for haptoglobin means that myoglobin is excreted at plasma concentrations around 0.2 g/L, whereas hemoglobin only appears in the urine at plasma concentrations greater than 1.0 g/L. At this concentration a pink discoloration of the plasma occurs, indicating that hemoglobin is present.<sup>9,49,50,63</sup>

On electrophoretic separation on cellulose acetate, myoglobin migrates as a  $\beta_2$ -globulin and hemoglobin as an  $\alpha_2$ -globulin. This method can distinguish the two proteins in urine containing high concentrations (>125  $\mu$ g/ml) of either protein, provided no other proteins, apart from albumin, are present. Immunoassays are the most sensitive and specific tests and can be used for detecting small amounts of myoglobin in blood and urine.<sup>61,64,65</sup> Sequelae of acute tubular necrosis and acute renal failure are associated with myoglobinuria in human beings<sup>66</sup> and horses.<sup>44,63</sup> Renal disease associated with myoglobinemia in the horse seems to be associated most with

**FIGURE 11-2** Four urine samples. **A**, With 3 mg/ml hemoglobin. **B**, With 3 mg/ml myoglobin. **C**, Normal stored for 1 month at 18° C. **D**, Control (fresh urine).

horses that are highly stressed (causing decreased renal blood flow), dehydrated, or have lactic acidosis associated with rhabdomyolysis. Therefore horses suffering from “capture” myopathy (e.g., cast in a stall or trailer accident and struggling for a prolonged period) and endurance horses are most at risk.

## MUSCLE BIOPSY

The practitioner can obtain muscle biopsy samples by surgical excision under general or local anesthesia<sup>63</sup> or by percutaneous needle biopsy from the standing horse.<sup>9,14,67</sup> Because of the variation in fiber composition in muscles, which muscle is chosen, as well as the position and depth of sampling, is important. Good specimen preparation for frozen sections is vital to prevent artifacts such as ice crystals.<sup>6,9,68</sup> For laboratories that prefer examination of frozen sections, specimens are typically shipped chilled overnight so that the laboratory may freeze the sample to minimize artifacts. Other laboratories prefer formalin-fixed specimens. The practitioner should discuss sample procurement, preparation, and shipment procedures with the laboratory before biopsy.

Muscle biopsy allows the morphologic, biochemical, and physiologic properties of the myofibers to be examined with the animal still alive and causes little morbidity. Typical sites used for percutaneous biopsy with a 6-mm modified Bergstrom needle in cases of generalized muscle disease or for research purposes include the semimembranosus, the biceps femoris, and most commonly the middle gluteal muscle. Although convenient, the necessity to have a modified Bergstrom needle means that most practitioners opt for open biopsy of the semimembranosus muscle over percutaneous middle gluteal muscle biopsy. Instructions on how to obtain a muscle biopsy are available online.<sup>69</sup>

To biopsy the semimembranosus a 6- to 10-cm<sup>2</sup> area is clipped and surgically prepared slightly lateral to and below the anus. At this location, if a scar occurs after the procedure the tail will hide it. An inverted L lidocaine block of the skin and subcutaneous tissues is performed. Local anesthetic is not injected into the muscle itself, which may induce artifact into the biopsy. The muscle belly is innervated poorly for pain, and

reaction to transection of a small piece of muscle is minimal. A piece of muscle measuring approximately 1 × 1 × 2 cm is dissected free, and sutures are used to close the subcutaneous layer and skin. Buried skin sutures that do not need to be removed or skin staples appear to be preferable because they are less likely to cause skin irritation and therefore are less likely to be rubbed out by the patient. Should the horse open the biopsy site, the wound typically heals well by second intention with general wound care. This procedure rarely has complications; however, the horse should be current on tetanus prophylaxis as a general precaution. The biopsy is wrapped loosely in saline-dampened gauze and placed in a sealed container for shipment on ice-packs to a laboratory skilled in muscle biopsy assessment.

Histochemical staining of frozen muscle sections aids in the detection of glycolytic enzyme deficiencies and storage of various atypical metabolic compounds.<sup>6,70-72</sup> Pathologic changes that can be found in muscle include presence of degenerate or regenerate myofibers, abnormal cytoplasmic inclusions, accumulations of polysaccharide, changes in fiber volume, number, shape, malformation, degeneration or proliferation of organelles, and disruption of the basic architecture of the fiber. Aggregates of inflammatory cells, reactive changes in vessel walls, occlusion of blood vessels, and increased amounts of fibrous tissue are other possible pathologic findings. In some conditions, such as tetanus or botulism, no significant changes may be seen. Further information on the types of changes that occur is available.<sup>6,31</sup>

Various histologic stains have been developed to highlight the different morphologic changes and inclusions that occur. The most important of these is the periodic acid-Schiff stain that highlights glycogen stores within a cell and membrane structures containing mucopolysaccharide, glycoproteins, mucoproteins, glycolipids, or phospholipids. Large aggregates of abnormal polysaccharide occur in Quarter Horses and Draft-breed horses with polysaccharide storage myopathy. Histochemical staining for fiber type enables the pathologic changes to be recognized as affecting all fibers or those of one type only. In cases of reinnervation, large groups of a single fiber type are visible as opposed to the more interspersed pattern typically observed.

Immunocytochemical studies have been used to investigate neuromuscular disorders in human beings and to diagnose autoimmune streptococcal-associated myositis in the horse.<sup>73,74</sup> Specialized staining techniques help to localize specific enzymes and intracellular and extracellular muscle components such as the various collagen and myosin types, complement, and fibronectin. Electron microscopic studies enable investigation into the ultrastructure of muscle fibers.

## ELECTROMYOGRAPHY

Needle EMG is the study of the electrical activity of muscles. EMG may be useful in horses with unusual gait or muscle changes and can be used to discriminate between neurogenic and myogenic causes and more specifically to identify areas or regions of an abnormality.<sup>75</sup> A recording needle electrode is placed into the muscle, and the electrical activity is amplified, recorded on an oscilloscope, and projected audibly into a loudspeaker. The electrical status of muscle membranes depends on the integrity of the whole motor unit. Thus an EMG evaluates the function of the ventral motor horn cell, its axon, axon terminals, and neuromuscular junctions, as well as the muscle fibers it innervates.

Investigations are usually carried out in two phases. First the practitioner assesses the electrical potentials associated with the physical disruption of the sarcolemma resulting from insertion of the needle. These insertional potentials, if relayed through a loudspeaker, tend to emit a sound similar to short bursts of loud static. They vary among muscles, probably because of differences in the size and number of motor units present.

The second phase involves assessment of electrical potentials when the needle electrode is at rest in the muscle. Normally, electrical silence occurs with cessation of needle movement, unless the needle is located in proximity to a nerve branch or the end plate zone when miniature end plate potentials are recorded continuously; these sound similar to low-intensity static.

In relaxed, diseased muscles, different types of abnormal electrical activity have been recognized. In cases of denervation, insertional activity may persist after needle movement has stopped because of increased excitability of the muscle fiber membranes. Positive, sharp waves are slow monophasic waves, rapid in onset, with a slow decay to the baseline, which occur repeatedly with variable amplitude (100  $\mu\text{V}$  to 20 mV). Their cause is uncertain, they often occur with denervation, and they may represent a nonpropagated depolarization region in the muscle fibers near to the tip of the electrode. When occurring in trains, these positive sharp waves sound similar to a waning brrrr. Fibrillation potentials are electric signals generated by a single muscle fiber. Long, random volleys of mono- or biphasic (occasionally triphasic) potentials of short duration (0.5 to 5.0 ms), with amplitudes of usually less than 200  $\mu\text{V}$ , commonly occur in denervation (depending on the stage). Constant and repetitive fibrillation potentials, which sound similar to rain on a tin roof or the sizzling of frying eggs, can be found especially in the early stages of denervation. Fibrillation potentials can also be seen in myopathic disorders in which segmental muscle necrosis may have caused, for example, the separation of a muscle fiber and its nerve supply.

Myotonic discharges—high-frequency (up to 1000 Hz) repetitive discharges with waxing and waning of potentials is seen and heard with a characteristic, musical, dive-bomber, or more precisely, revving motorcycle-like sound—are found in the myotonias (myotonia congenita, myotonia dystrophica, and hyperkalemic periodic paralysis) if the practitioner moves the exploring EMG electrode or percusses the muscle externally. Bizarre, high-frequency discharges (often called *pseudomyotonia*) may produce a dive bomber-like sound. No true waxing and waning occurs, although the amplitude and frequency of the potentials may change abruptly to mimic a revving motorcycle-like sound. The discharges are often in couplets or triplets and are likely to terminate abruptly. These, or similar discharges, occur in long-standing denervations, ventral horn cell disease, polymyositis, and certain myopathies. Unlike the myotonic discharges, pseudomyotonic discharges may be abolished by curare and therefore are believed to originate presynaptically.

Fasciculations, visible muscle twitching, are caused by the spontaneous contraction of some or all of the constituent fibers of a motor unit. They can be local or generalized and occur primarily with any cause of muscular weakness (myasthenia), especially in neurogenic disorders such as tetanus and certain debilitating and metabolic disorders. In addition, one can assess the electric activity induced by electric stimulation

of nerves or associated with voluntary or induced muscle contraction. Further information on EMG is available.<sup>76</sup>

## THERMOGRAPHY

An infrared thermographic scanner converts the radiated thermal energy of the skin to electric signals that can be amplified and displayed on a video screen. By using isotherm colors of known temperature, the examiner can obtain two-dimensional, graphic, and quantitative information regarding the precise temperature of the skin surface. The practitioner can use this technique noninvasively as a means of detecting changes in skin temperature resulting primarily from changes in peripheral blood flow. Inflammation, atrophy, neoplasia, and neurologic lesions, particularly of the autonomic supply to the skin, can alter local blood flow.

Abnormalities have been found in exercise-exacerbated focal thoracolumbar gait abnormalities, as well as disuse atrophy.<sup>77</sup> The technique has been useful in documenting hindlimb muscle strain as a cause of lameness in horses.

## SCINTIGRAPHY

Bone-seeking radiopharmaceuticals have been used to detect and localize skeletal muscle involvement, especially in poor performance cases, but are of limited routine value in the field. Accumulation in damaged muscle may be related to the deposition of calcium in damaged fibers, binding by tissue hormones or enzyme receptors, tagging to denatured proteins, or altered capillary permeability. Uptake of labeled phosphates appears to occur only when muscle damage is ongoing and does not occur in areas of repair. Three main types of muscle uptake were identified in one study of horses with skeletal muscle damage: a diffuse, severe, and generalized uptake; bilateral symmetric uptake involving muscle groups that perform synergistic functions; and asymmetric radioisotope uptake in one or more muscle groups on one side of the animal.<sup>78</sup> The reasons for the various patterns have not been elucidated fully. Scintigraphy can be used as part of a series of tests to identify atypical or difficult-to-pinpoint lamenesses in horses that may have primary muscle lesions among other problems.<sup>79,80</sup>

## EXERCISE TESTS

Certain physiologic changes can result in a transient alteration in cell membrane permeability. Hypoxia, catecholamines, hypoglycemia, changes in pH, and altered ionic concentrations have been reported as causing such a change in membrane permeability.<sup>45,81,82</sup> Many of these changes are believed to act by decreasing the amount of ATP available for the maintenance of cell integrity, which becomes especially important during exercise.<sup>83</sup>

Measuring the CK and AST activities before and after a controlled period of exercise has been suggested as an aid to diagnosing certain muscle disorders. A major difficulty has been to establish exactly the normal enzyme response to exercise. Much confusion exists in the literature regarding this parameter, partly because of the differences in the intensity and duration of the exercise undertaken, the varying sampling intervals used in the reports, and the possible inclusion of individuals with muscular problems. The majority of workers have suggested that an increase in CK activities occurs with hard exercise,<sup>83-85</sup> whereas with slower work, others have

shown no significant increase. This difference suggests that intensity could be an important factor.<sup>86,87</sup> Such a conclusion is supported by work in dogs, which shows that CK activities correlate with the intensity of muscular activity.<sup>85</sup> Another study in the horse,<sup>88</sup> however, suggested that CK elevations did not vary according to the intensity of the work, and one researcher<sup>89</sup> proposed that the duration of exercise was the more important factor. Another study suggested that when the duration of exercise was kept constant, the intensity of the exercise in fact did have an effect on the extent of CK activity increase.<sup>90</sup>

Although no significant increase in CK activity was found after trotting exercise in conditioned animals by one worker, others recorded significant increases when horses performed the same exercise after 1 or more days of rest.<sup>87</sup> Increases in AST activities of 35% have been reported after a 1500-m canter<sup>91</sup> and of 50% after strenuous exercise in previously rested animals.<sup>84</sup> Most other workers have found little increase in AST after different types of exercise.<sup>42,46,89,92</sup>

Therefore the effects of exercise on plasma muscle enzyme activities may depend on the fitness of the animal and the intensity and duration of the exercise, as well as on the environment.<sup>38,63,89</sup> However, concurrent lameness does not appear to alter postexercise CK activity significantly in healthy horses without myopathy.<sup>93</sup> In horses, as in human beings, large intersubject variability may occur in the postexercise rise in CK activities that must be taken into account.<sup>37</sup> Plasma volume changes may affect the activities recorded, especially if measured immediately after exercise.

As discussed previously, the physiologic increase in CK activity after exercise is believed to be caused by a change in cell membrane permeability, possibly caused by hypoxia, although other factors are likely involved. Hypoxia may occur at lower workloads in unconditioned horses, and these horses may be expected to show higher postexercise activities than a fit horse given the same work. The suggestion has been made that the magnitude of the exercise-induced increase in enzymes lessens with training.<sup>42,88,89</sup> Some workers have found no significant changes in the AST and CK responses to exercise during a training program,<sup>92</sup> whereas others have found that after an endurance ride the fittest animals (indicated by the speed of heart rate recovery after an endurance ride) had lower increases in CK activities.<sup>86</sup> The magnitude of exercise-induced changes in CK activities increases with detraining. This study concluded that increases of more than 100% in AST activity after exercise likely are abnormal, regardless of the intensity of the exercise or the fitness of the animal. Also, if a short, submaximal exercise test is carried out the serum CK and AST activities at 2 hours after exercise should not rise to more than 250% and 50% of the pre-exercise values, respectively, regardless of fitness.<sup>90</sup>

The point has been stressed that, although exercise might result in statistically significant changes in CK and AST activity, these may not always be of biologic or clinical significance.<sup>94,95</sup> The practitioner must always take into consideration the clinical history and clinical presentation when interpreting enzyme values. For example, a young racehorse given its first gallop often has activity changes greater than those described (e.g., from a pre-exercise level of 40 U/L to a 2-hour postexercise level of 350 U/L), although this is unlikely to be clinically significant. However, in cases of recurrent exertional rhabdomyolysis (RER) or polysaccharide storage myopathy (PSSM), similar changes may indicate ongoing subclinical muscular dysfunction. For example, in the author's experience, horses

#### BOX 11-1

### WORKUP FOR A HORSE WITH CHRONIC EXERTIONAL RHABDOMYOLYSIS

1. History: genetic background, diet, use, description of previous episodes, housing conditions
2. Physical examination
3. Collection of urine for fractional excretions (Na<sup>+</sup>, K<sup>+</sup>, Cl<sup>-</sup>, and PO<sub>4</sub>, if desired)
4. Collection of blood for baseline CK, AST, electrolytes, and lactate (if desired)
  - a. A full profile is recommended in horses without a recent one performed.
  - b. A complete blood count may be performed if inflammatory disease is suspected.
5. Exercise at a trot for 30 minutes either under saddle or on a lunge line; after 15 minutes, stop every 5 minutes for 1 minute to observe if stiffness or gait abnormalities are developing. If so, stop exercising the horse.
6. Postexercise CK analysis 4 to 6 hours after exercise. A 24-hour postexercise AST may be examined if desired.
7. Muscle biopsy. Middle gluteal, semimembranosus or other muscle if indicated.

AST, Aspartate transferase; CK, creatine kinase; Cl, chloride; K<sup>+</sup>, potassium; Na<sup>+</sup>, sodium; P, phosphorus.

with RER or PSSM may have 4-hour postexercise serum CK activities of 10,000 to 15,000 U/L without outward clinical signs of rhabdomyolysis.

Currently the author recommends a standardized submaximal exercise test wherein the practitioner can interpret the results in the light of the horse's history and presentation. [Box 11-1](#) shows the work up for a horse with chronic exertional rhabdomyolysis, and [Box 11-2](#) illustrates a normal response to a standardized submaximal exercise test. Horses that have recently ridden in a trailer a long distance for evaluation may require 24 hours of hospitalization to ensure a normal CK value before the examination.

### OTHER FACTORS AFFECTING ACTIVITIES OF ASPARTATE AMINOTRANSFERASE AND CREATINE KINASE

#### GENDER AND AGE

A group of Thoroughbreds was sampled over a 9-month period, and the 2-year-old fillies showed more significant fluctuations in AST and CK activities than the 3-year-old fillies and colts. Unfortunately, no 2-year-old colts were studied.<sup>96</sup> In a later study of 66 2- and 3-year-old Thoroughbred racehorses in training the fillies were more likely to have high CK and AST activities than colts, and 2-year-olds were more likely to have increased AST activity than 3-year-olds. The effect of age on the incidence of increased muscle enzyme activities

## BOX 11-2

**CRITERIA FOR A NORMAL RESPONSE TO A  
SUBMAXIMAL EXERCISE TEST  
DESIGNED FOR A GIVEN HORSE**

1. Pre-exercise:  
CK activity <470 IU/L (laboratory resting reference range, 100 to 470 IU/L)  
AST activity <375 IU/L (laboratory resting reference range, 185 to 375 IU/L)
2. Not more than a doubling of the resting CK activity at 2 to 4 hours after exercise
3. Return to baseline CK activities at 24 hours after exercise
4. Not more than a 50% increase in AST activity
5. No clinical signs of stiffness

AST, Aspartate aminotransferase; CK, creatine kinase.

was thought not to have been caused by the natural loss of 2-year-olds from training with high enzyme activities, especially because several of these raced and won.<sup>97</sup> Certain animals may have physiologically higher plasma activities, or their muscle enzymes may be removed more slowly from the circulation. Alternatively, they may be more sensitive to the various insults that cause permeability changes in muscle fiber membranes. Age or training or both could have a dampening effect on muscle membrane changes. In dogs a significant decrease in CK activities has been reported with age, but no difference was found between males and females.<sup>98</sup> In one study, no correlation was found between plasma progesterone concentrations and the fluctuations in CK and AST activities.<sup>99</sup> However, a later study showed that when fillies with high median AST activities were removed from the study group, a highly significant relationship was found between progesterone and AST but not CK activities, and estradiol showed a significant effect on CK but not on AST activities. In rats, CK release after exercise or *in vitro* electric stimulation is greater in males than in females. Estradiol has been suggested to have a protective effect and to attenuate CK influx.<sup>99,100</sup> However, further work on the role of such hormones in CK and AST activities in the horse is necessary before conclusions can be drawn. In addition, all studies in large groups of horses must be examined with some scrutiny when one considers that the incidence of some underlying myopathies can be high within a population. Considering that AST and CK tend to rise exponentially with muscle damage, a few outliers in a study may skew results significantly. The incidence of RER in Thoroughbred horses may be as high as 5% of the population,<sup>101</sup> which may account for some of the increases in CK and AST activities observed in the studies cited.

#### TIME OF YEAR AND TRAINING

Several workers have suggested that AST plasma activities increase in the early stages of training and then decrease as training progresses.<sup>102,103</sup> Time of year does not have a significant effect on the number of animals with normal or with high AST and CK activities.<sup>97</sup> However, researchers observed an increase in mean activities peaking in April and May followed

by a decrease to a low in September in a group of Thoroughbred racehorses in the Northern Hemisphere.<sup>97</sup> The high mean activities in April, May, and June were accompanied by high standard deviations, which made definitive conclusions difficult. Researchers also found large standard deviations in another study of Thoroughbreds in training.<sup>9</sup> On an individual basis a change in AST activities does not always seem to occur with training.<sup>104</sup> Therefore decreases or increases in the serum levels of AST activity are probably not good indicators of peak fitness or overtraining.<sup>105</sup>

In a study of AST activities in a small number of barren and pregnant Standardbred mares, researchers apparently found evidence for a diurnal rhythm, with the lowest activities occurring in the early morning (4 to 6 AM) and the highest activities at night (10 to 12 PM). The mean activities increased from September to November until March. Circannual cyclicity was found, but the pattern differed between the two groups. In barren mares the arcophase appeared to occur in the second half of January, whereas for pregnant animals it occurred in September (approximately month 5 of pregnancy). The standard error, however, was broad.<sup>106</sup>

#### RELATIONSHIP TO PERFORMANCE

Elevated CK and AST activities have been suggested to decrease the chance of a horse winning.<sup>107</sup> However, a group of 500 Standardbred trotters with a recent history of equine rhabdomyolysis and increased plasma muscle enzyme activities had a significantly better racing record compared with a large group of apparently unaffected horses.<sup>1</sup> Another study found that 50% of the horses with high median AST activities raced and won at least once.<sup>97</sup> However, determining whether these horses would have given better performances or won in better classes if they had not had such increased muscle enzyme activities obviously is not possible.

### ☞ CLASSIFICATION OF MYOPATHIES

As the body of knowledge concerning equine myopathies grows the ability to classify them becomes more similar to that used in humans.<sup>34</sup> Broadly, equine myopathies may be inborn or acquired. Inborn errors of metabolism or primary myopathies may include disorders of carbohydrate, lipid or purine metabolism, mitochondrial myopathies, or disorders of ion movement across the cellular membranes (channelopathies). Secondary or acquired myopathies occur as a result of endocrine disorders (equine Cushing's syndrome), nutritional deficiencies (vitamin E, selenium), trauma (cast in a stall or other similar accident, overexertion under saddle, etc.), infection, and electrolyte imbalances. Manifestation of the aforementioned disorders may occur with or without recent exercise and may be obvious at birth or not until adulthood.

Practitioners may find approaching horses with muscle disorders from a problem-based approach most helpful. In this approach, horses are categorized into five categories: (1) those having muscle cramping with exercise, (2) those with permanent gait alterations, (3) those with muscle weakness, (4) those with muscle wasting, and (5) those with acute, severe rhabdomyolysis with or without recumbency or death. These clinically based classifications are not mutually exclusive, and some disorders fall into more than one category. However, the author believes that this approach is the most comprehensive, considering the current volume of knowledge relating to muscle disorders in the horse.

Box 11-3 shows how the various equine skeletal disorders might be classified under the pathophysiologic system using current information. Box 11-4 demonstrates a problem-based classification of the most common muscular disorders in the horse. The practitioner should note how many equine myopathies share common clinical presentations. Therefore a thorough history including genetic background, environment, and athletic history in conjunction with physical examination and laboratory workup are necessary to determine the most probable underlying cause in each case. Before discussing the

specific muscle diseases the next section covers some general concepts and traditional thoughts concerning exertional rhabdomyolysis.

### EXERTIONAL RHABDOMYOLYSIS

Exertional rhabdomyolysis refers to the syndrome of muscle cramping that occurs during physical exertion or exercise. Differential diagnoses for exertional rhabdomyolysis are extensive (Box 11-5). Terms used to describe the disorder include

#### CLASSIFICATION OF EQUINE MYOPATHIES ACCORDING TO CAUSE

- |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |

### PROBLEM-BASED APPROACH TO HORSES WITH MUSCLE DISEASE

Disorders are grouped according to similar clinical appearance. (No category is mutually exclusive. Disorders are grouped by most common clinical presentation. The reader is directed to the text for more extensive discussion for each disorder or disease.)

- I. Profound muscle cramping with exercise, tying-up syndrome, increased plasma/serum creatine kinase (CK) activity after exercise
  - A. Horses with inborn myopathy (inborn error of metabolism)
    1. Recurrent exertional rhabdomyolysis in Thoroughbreds
    2. Polysaccharide storage myopathy in Quarter Horses and Draft Horses
    3. Idiopathic chronic exertional rhabdomyolysis
    5. Mitochondrial myopathy (also has lactic acidosis)
  - B. Horses without inborn myopathy
    1. Overexertion
    2. Vitamin E or selenium deficiency
    3. Electrolyte depletion
- II. Horses with altered gait but without inborn myopathy and without muscle cramping; with or without elevated CK
  - A. Acute: muscle strain, sprain, tear
  - B. Chronic: fibrotic myopathy
- III. Muscle weakness
  - A. Hyperkalemic periodic paralysis (intermittent)
  - B. Myotonia congenita and myotonia dystrophica (worsens with exercise)
  - C. Equine motor neuron disease (worsens when standing still)
  - D. Equine polysaccharide storage myopathy in Draft Horses (can be progressive over time; rule out shivers as a differential diagnosis)
- IV. Muscle wasting
  - A. Generalized, may be accompanied by mild elevations in CK activity
    1. Equine motor neuron disease
  2. Streptococcal immune-mediated myositis: mediated by IgG
  3. Cachectic atrophy
  4. Disuse atrophy
  5. Endocrine; equine Cushing's syndrome
- B. Segmental
  1. Neurogenic
  2. Disuse atrophy
  3. Fibrotic myopathy
  4. Posthealing of severe trauma
- V. Acute rhabdomyolysis, swollen painful musculature, with or without recumbency, with or without death
  - A. Severe, acute exercise-related rhabdomyolysis as from I.A. and I.B. above
  - B. Malignant hyperthermia/postanesthetic myopathy
  - C. Clostridial myonecrosis
  - D. *Sarcocystis* spp.
  - E. Streptococcal immune-mediated myositis; Henoch-Schönlein purpura
  - F. Aortic-iliac thrombosis
  - G. Toxic plants
    1. *Cassia occidentalis*
    2. White snakeroot
  - H. Ionophore toxicity (may also present as chronic heart failure without a history of acute rhabdomyolysis)
- VI. Disorders of the neonate
  - A. White muscle disease/nutritional myodegeneration
  - B. Foal rhabdomyolysis
  - C. Glycogen branching enzyme deficiency
  - D. Arthrogyrosis
- VII. Miscellaneous disorders
  - A. Atypical myoglobinuria
  - B. Postanesthetic myasthenia
  - C. Polymyopathy
  - D. Abscesses
  - E. Tumors

Ig, Immunoglobulin.

chronic exertional rhabdomyolysis, equine rhabdomyolysis syndrome, azoturia, Monday morning disease, tying-up, myositis, setfast, and chronic intermittent rhabdomyolysis.<sup>53,105,108-110</sup> Broadly, horses experience exertional rhabdomyolysis for two main reasons: the horse has an underlying myopathy (chronic exertional rhabdomyolysis), or the horse has been overexerted physically (sporadic exertional rhabdomyolysis). Horses with underlying myopathies generally experience repeated episodes of rhabdomyolysis after short bouts of exercise; therefore the condition may be characterized as chronic. However, horses that are overexerted may experience only a single episode in their lifetime because the bout of rhabdomyolysis is caused by physical and environmental circumstances as opposed to an underlying pathologic condition of the muscle.

Identifying horses with underlying myopathies that are characterized by chronic exertional rhabdomyolysis is a rapidly developing field of veterinary medicine. To date, two major syndromes have been described: RER in Thoroughbred horses and PSSM in Quarter Horses and Draft-breed horses. Several less-common inborn errors of metabolism have also been described. Horses that have chronic exertional rhabdomyolysis but that cannot be diagnosed with any of the aforementioned disorders may be assumed to have a new or previously undescribed equine myopathy, provided no physical or environmental cause can be determined. Until more is known, horses with multiple bouts of rhabdomyolysis associated with minimal exercise that do not appear to fit into the categories of RER or PSSM are grouped and classified as having idiopathic chronic exertional rhabdomyolysis. One

should not assume that all Thoroughbreds, Quarter Horses, and Draft-breed horses demonstrating chronic or sporadic exertional rhabdomyolysis have RER or PSSM, respectively, simply because of their breed.

In the past, exertional rhabdomyolysis in the horse was described in the literature under diseases of the liver, kidney, blood, or muscle. Exertional rhabdomyolysis has also been attributed to infection, cold weather, intoxication, nervous irritation, calcium deficiency, excess of glycogen, lactic acid poisoning, an increase in red blood cells, and an unbalanced alkali reserve.<sup>111</sup> Most theories have not undergone thorough scientific scrutiny to rule them in or out as an inciting cause, contributing factor, or primary cause.

Exercise is the common triggering factor in horses with exertional rhabdomyolysis. However, in horses with underlying myopathies the amount of exercise necessary to trigger muscle cramping is often minimal in contrast to healthy horses exhibiting a sporadic episode of rhabdomyolysis because of overexertion. Similarly, horses with underlying myopathies suffer from repeated episodes, whereas overexerted but otherwise healthy horses do not, provided they are not pushed repeatedly beyond their level of fitness.

### CLASSIC THEORIES FOR EXERTIONAL RHABDOMYOLYSIS

For centuries, horses were believed to tie up for a single as yet undetermined reason. The most popular reason was inactivity (i.e., stall rest) accompanied by a full ration of grain. This scenario was most likely to occur in Draft Horses rested on Sunday and worked on Monday, hence the name Monday morning disease. Currently the influence of diet, specifically carbohydrates, on exertional rhabdomyolysis is an area of active research. Diet plays a role in horses that are predisposed to exertional rhabdomyolysis from several different underlying myopathies (see specific disorders

in the following sections), but how diet may influence muscle function in normal, healthy horses is still largely unknown.<sup>112-114</sup>

**Lactic Acidosis** From 1914 to 1915, history records that when oats were scarce and raw sugar was fed to horses as a substitute the incidence of metabolic diseases, especially azoturia, increased.<sup>115</sup> In two papers that are much quoted in the literature, excessive glycogen buildup was postulated to result in an overproduction of lactic acid during exercise.<sup>116,117</sup> These studies reproduced the condition by feeding horses 3 kg of molasses daily and then exercising the horses after a rest period. However, in these studies the levels of lactate measured in horses experiencing rhabdomyolysis were similar or lower than the values concurrently measured in normal, healthy horses exercising anaerobically. Therefore lactate alone is unlikely to trigger exertional rhabdomyolysis in healthy horses.<sup>118</sup> The role of lactic acid in horses with underlying myopathy has been investigated only in Thoroughbred horses with RER. That study found no correlation between lactate levels and CK activity measured 4 hours after exercise.<sup>112</sup> In investigations of other breeds of horses with chronic exertional rhabdomyolysis the relationships between rhabdomyolysis and lactate are less clear.<sup>27,110,119,120</sup>

**Hypothyroidism** Muscular problems are a common symptom of hypothyroidism in human beings.<sup>121,122</sup> In mild human cases, fatigue may be the only presenting symptom, although more severe cases may be accompanied by overt muscle cell damage, increased resting plasma CK activities, and sometimes increased myoglobin levels.<sup>123</sup> Poor racing performance and certain myopathies have been related to mild secondary hypothyroidism,<sup>124</sup> although this conclusion has been challenged.<sup>125</sup> Oral thyroxine supplementation may improve performance or decrease the incidence of myopathies in documented cases of hypothyroidism.<sup>63,124</sup> However, considerable debate still exists as to whether hypothyroidism is important in the pathogenesis of exertional myopathies in the horse.<sup>53</sup>

Resting thyroxine concentrations did not differ significantly between animals believed to be suffering from chronic rhabdomyolysis and those suffering from a variety of other conditions. However, some rhabdomyolysis sufferers may have a lowered response to thyrotropin-releasing hormone,<sup>90</sup> which may reflect a decreased thyroid reserve, but too few cases have been investigated to date. A study examined exercise in thyroidectomized horses and documented exercise intolerance but not increases in CK activity.<sup>126</sup> Conversely, in the author's experience, oversupplementation with thyroxine may lead to iatrogenic hyperthyroidism and symptoms of mildly increased CK activity and muscle wasting.

### VIRAL CAUSES

Muscle pain or myalgia is a common symptom in the acute phase of influenza and other viral illnesses in human beings, although few reports of severe muscular problems are available.<sup>51,127,128</sup> Myalgia and myoglobinuria have been observed with herpesvirus infections.<sup>51</sup> Some horses are stiff and unwilling to work during or after an attack of the virus.<sup>129</sup> Viral infection has been reported as being one of the predisposing factors to equine rhabdomyolysis.<sup>130</sup>

A clinical investigation of an outbreak of muscle stiffness and poor performance in a flat-racing stable of Thoroughbreds

revealed that more than one third of the horses demonstrated signs of muscular stiffness over 2 months, and 64% at one or more of the sampling times had increased CK and AST activities.<sup>131</sup> Serologic tests were highly suggestive of an equine herpesvirus type 1 infection. The possibility of a viral cause, at least in outbreaks of stiffness in racing yards, needs more in-depth evaluation. The virus could affect muscle directly, resulting in an increased susceptibility to exercise-induced damage. Alternatively, the increase in blood viscosity observed after infection could result in an impaired blood flow and decreased oxygen delivery to the peripheral tissues.<sup>1</sup> A study of horses exercised after experimental infection with equine influenza virus failed to demonstrate significant effects on muscle function or CK activity or evidence of muscle stiffness.<sup>132</sup>

### TREATMENT OF RHABDOMYOLYSIS

Treatment of rhabdomyolysis depends on the underlying cause. For example, horses experiencing muscle damage because of sepsis or trauma require different approaches than horses experiencing rhabdomyolysis caused by underlying, heritable myopathies. Horses with rhabdomyolysis are often treated for colic or nonspecific signs of pain. Other differential diagnoses include disorders that are frequently associated with depression or a reluctance to move and include but are not limited to anthrax infection, postcastration abscesses, colic, cystitis, neurologic disorders, lymphadenitis, laminitis, nephritis, peritonitis, pleuritis, tetanus, and skeletal injury or infection.

The practitioner should perform a thorough physical examination and obtain a detailed history. The initial workup of a horse suspected of having rhabdomyolysis should include a complete blood count, chemistry profile, and urine collection. Treatment should follow the observations made on physical examination and changes observed in the blood count and chemistry profile. The practitioner should rehydrate horses with significant dehydration with fluids that reflect electrolyte deficiencies identified on a chemistry profile and should treat horses in significant discomfort with nonsteroidal antiinflammatory drugs (NSAIDs), provided renal perfusion and function are supported. The practitioner should not treat horses experiencing rhabdomyolysis in the face of extreme exhaustion and dehydration with nephrotoxic medications (aminoglycosides or NSAIDs) until ascertaining renal function. Horses that typically fall into this category include those with capture myopathies (e.g., horses that are trapped and struggle in trailer accidents, get wrapped up in ropes or fences, are being taught to tie to a fixed object, or get cast in a stall) and endurance horses. Treatment for horses with mild cases of rhabdomyolysis includes keeping them warm, minimizing movement, and providing stall rest and NSAIDs as appropriate. Muscle enzyme activity and the physical response of the horse to being asked to move and exercise can guide the practitioner as to when returning the horse to normal physical activity is appropriate. Therapies specific to each type of rhabdomyolysis are discussed in their respective sections.

### NEUROGENIC MYOPATHY

Neurologic diseases are discussed in detail in Chapter 12, Disorders of the Neurologic System.

## INBORN ERRORS OF METABOLISM

*Jennifer M. MacLeay*

### DISORDERS OF CARBOHYDRATE METABOLISM

#### POLYSACCHARIDE STORAGE MYOPATHY

Polysaccharide storage myopathy is a disease characterized by repeated episodes of exertional rhabdomyolysis that may be induced with little exercise. Increased CK activity in the plasma or serum accompanies episodes of rhabdomyolysis. The most distinctive characteristic of the disease is a mild to severe accumulation of abnormal polysaccharide within the sarcoplasm. Based on a histologic diagnosis of abnormal polysaccharide, PSSM has been described in Quarter Horses, Warmbloods, Draft breeds (Belgians, Percherons, Clydesdales, Shires, Haflinger, Norwegian Fjord, Suffolk, Irish Draft, Draft crosses, and a Draft mule), and rarely in Thoroughbreds and Arabians. A mutation in the glycogen synthase enzyme gene (GYS1) is highly associated with the presence of abnormal polysaccharide in muscle biopsies.<sup>1</sup> The metabolic defect resulting from this mutation leads to the classic or type 1 form of PSSM that accounts for more than 90% of PSSM in some breeds of horses. A modifying genetic mutation in the RYR1 gene is associated with a more severe clinical phenotype of PSSM in Quarter Horses and related breeds than that observed in horses with the GYS1 mutation alone.<sup>2</sup> This RYR1 mutation is associated with malignant hyperthermia. Genetic tests for the PSSM and MH mutations are now commercially available through the University of Minnesota Veterinary Diagnostic Laboratory.

Based on the glycogen synthase mutation, PSSM has been diagnosed in Quarter Horses, Belgians, Percherons and their crosses, Paints, Appaloosas, Morgans, Mustangs, Tennessee Walkers, Rocky Mountain Spotted Horses, and some Warmbloods among others.<sup>1</sup> Among biopsies submitted to the University of Minnesota Neuromuscular Diagnostic Laboratory for horses with a suspicion of muscle disease, the overall prevalence of a diagnosis of PSSM was 22%. Quarter Horses were most likely to be diagnosed, followed by Draft and Warmblood horses. In a broader survey of Quarter Horses the overall prevalence of PSSM in American Quarter Horses at large was estimated to be between 6% and 12%.<sup>3</sup> Draft and Warmblood horses are more likely to have a client complaint of gait abnormality than Quarter Horses with PSSM. Among horses at necropsy, 86% of Draft horses had evidence of abnormal polysaccharide.<sup>4</sup> In a survey of 103 Belgian horses the incidence of PSSM was 36%, and the incidence of shivers, which can be mistaken for PSSM, was 18%, and 6% of horses had both.<sup>5</sup> This survey indicates that both diseases are common among Belgian horses but are not likely associated with one another. Of horses suspected of having a muscular problem and having muscle biopsies submitted for analysis, the incidence of PSSM among Draft horses was 54%.<sup>6</sup> In an epidemiologic study of Warmblood horses that had muscle biopsies submitted for analysis, 55% had a diagnosis of PSSM.<sup>7</sup> A general study concerning the overall incidence of PSSM among Warmblood horses has not been performed.

**FIGURE 11-3** Draft Horse with equine polysaccharide storage myopathy standing with a base-narrow, weak stance.

### CLINICAL SIGNS AND LABORATORY FINDINGS

Horses with PSSM have frequent episodes of muscle cramping and rhabdomyolysis that typically occur within the first 30 minutes of exercise. Clinical signs and laboratory changes (increased muscle enzymes, myoglobinuria) associated with an episode of PSSM rhabdomyolysis appear similar to other causes of rhabdomyolysis. Mild episodes are characterized by a stiff gait, anxiety, and a stretched-out stance. More severe episodes are characterized by anxiety, painful behavior, sweating, and reluctance to move or recumbency. Horses appear to vary in the severity or expression of the disorder. Some horses also appear to tolerate exercise better than others despite similar changes in CK activity after exercise. This finding may reflect a tolerance of the individual horse to muscular discomfort associated with exercise. Episodes are especially prevalent when exercise intensity increases. A complaint of a consistently abnormal gait or weakness is more common in Draft and Warmblood-bred horses than Quarter Horses. Some Draft horses may exhibit progressive poor performance, shivers or a shiverslike gait, progressive muscle wasting, muscle weakness, recumbency, and death (Figure 11-3).

Horses that experience frequent episodes of rhabdomyolysis and have considerable accumulations of abnormal polysaccharide within the muscle fibers may have persistent elevations in serum or plasma CK activity even when stall confined. Whether this accumulation represents ongoing subclinical rhabdomyolysis or an alteration in the permeability of the muscle cell membrane is unknown. Muscle biopsy or genetic testing of horses with a history of chronic exertional rhabdomyolysis is indicated. Horses with PSSM have subsarcolemmal accumulations of an abnormal polysaccharide that is visible with a periodic acid-Schiff stain and is characteristically amylase resistant.

### CAUSES AND PATHOPHYSIOLOGY

A glycogen synthase enzyme deficiency inherited as an autosomal recessive trait has been identified.<sup>1</sup> In addition the accumulations of abnormal polysaccharide observed in periodic acid Schiff-stained muscle sections appears to increase with age and therefore may be a secondary feature of the

disease. Significant accumulations of abnormal polysaccharide may not be visible until 3 years of age in some horses, despite documented intermittent exercise-associated increases in serum and plasma CK activities at a younger age. Affected horses show great variability in expression of the disorder, as reflected in the amount of abnormal polysaccharide observed in muscle sections, desire and ability to exercise, frequency and severity of episodes of rhabdomyolysis, and degree of elevations in CK activity.

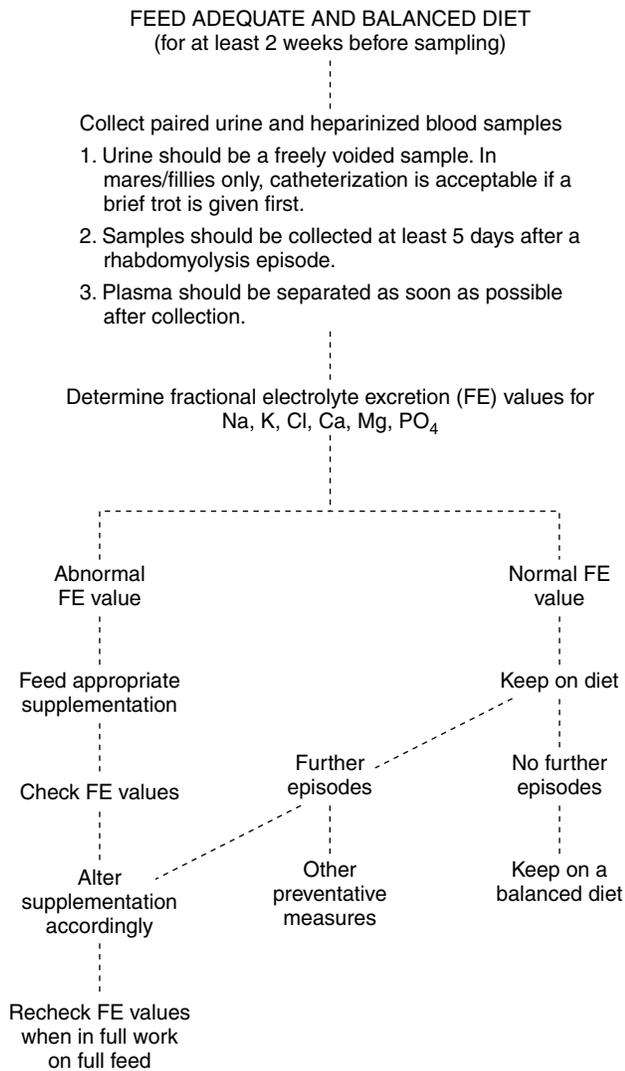

Studies have shown PSSM to be a disorder in which enhanced insulin sensitivity and elevated glucose excursion leads to increased synthesis of muscle glycogen, which appears to be independent of augmented glucose transport protein (GLUT4) or insulin receptor quantity.<sup>8</sup> Overall, affected horses demonstrate greater total muscle glycogen content compared with control horses. In addition, when fasted, horses with PSSM have consistently lower blood glucose concentrations than healthy controls. When given intravenous or oral glucose, horses with PSSM clear glucose from the blood stream at a faster rate than healthy controls. When administered insulin, horses with PSSM became severely hypoglycemic and remained so longer than healthy control horses. Why horses with PSSM have an increased sensitivity to insulin is unknown. However, this increased sensitivity results in increased uptake of glucose into the muscle cell. When the muscle cell takes up glucose from the blood, glycogen synthase is typically stimulated. However, the mutation affects the function of this enzyme. Horses with PSSM can break down the abnormal glycogen for energy albeit inefficiently. Horses with PSSM have glycogen branching enzyme with apparently normal activity.

Exercise influences glucose uptake into muscle cells. The physiologic changes associated with exercise result in changes in the number and activity of glucose transporters within the muscle cell membrane. Horses with PSSM have glucose tolerance curves more similar to healthy controls when they are exercised regularly,<sup>9,10</sup> which may explain why regular exercise and maintaining a certain level of fitness appears to help affected horses. Diets high in fat also appear to help these horses and may be related to a less severe postprandial glycemic response and decreased uptake of glucose by muscle cells.

### DIAGNOSIS

A genetic test is now available and may be augmented by documenting the presence of abnormal polysaccharide on a periodic acid Schiff-stained muscle biopsy. Because the accumulation of abnormal polysaccharide appears to be a secondary feature of the disease, accurately diagnosing affected horses until 3 years of age or more may not be possible without genetic testing. Some anecdotal evidence supports the theory that mildly affected horses fed diets low in carbohydrates may accumulate polysaccharide in smaller amounts or more slowly than other affected horses.

An exercise tolerance test can be a useful diagnostic tool in horses with PSSM. Affected horses commonly experience a doubling or more of baseline CK activity after 15 to 30 minutes of trotting. The practitioner draws blood before and 4 to 6 hours after the exercise. The practitioner also should have fractional excretions of electrolytes (Figure 11-4), measurements of serum selenium (or GSHPx activity), and vitamin E concentration determined on horses with PSSM. The practitioner should supplement dietary electrolytes and selenium and vitamin E intake if these are abnormal.

**FIGURE 11-4** Protocol for using the fractional electrolyte excretion test in clinical cases of the equine rhabdomyolysis syndrome. The electrolyte status should not be evaluated without also evaluating vitamin E and selenium status.

## TREATMENT

Horses with PSSM have a heritable myopathy that, in many horses, can be managed readily. Because of the nature of the disorder the practitioner should counsel owners, trainers, and riders of affected horses that the horse may not be able to perform at elite levels of competition if the condition is severe. However, many horses do perform well and have only occasional episodes of rhabdomyolysis. Horses should be exercised regularly because a good level of basal fitness appears to protect against episodes; however, increases in exercise intensity should be made gradually. Horses may live in stalls, but living outside where the horse may move around readily appears to lessen the frequency of episodes of rhabdomyolysis. A diet with less than 5% digestible energy as starch and more than 12% digestible energy as fat can reduce signs of exertional rhabdomyolysis potentially by increasing availability of free fatty acids for muscle metabolism.<sup>11</sup> Many horses can do well consuming only a grass or alfalfa hay and a simple vitamin and mineral supplement. If additional calories are necessary, they

can be supplied as fats. Many different fat sources are available and include corn or vegetable oils, linseed oil, or rice bran. Commercial grain mixes that are high-fat, low-carbohydrate feeds are available and may be a good source of fat for the horse without the concern associated with other sources of fat. Oils can spoil, and larger quantities of oils or rice bran may not be palatable for some horses. Routine daily exercise helps with the metabolism of glucose in affected horses. Overall, owners that implement dietary changes with regular exercise have the greatest success in limiting the incidence of future episodes of rhabdomyolysis.<sup>7,12</sup>

## GLYCOGEN BRANCHING ENZYME DEFICIENCY

Glycogen branching enzyme deficiency was likely first identified in 1999 as amylopectinosis by Render et al.<sup>13</sup> It is a heritable disorder in human beings and cats.<sup>14-16</sup> Affected foals may be aborted, still born, or born weak, similar in appearance to foals with hypoxic ischemic encephalopathy or sepsis. Live foals have been presented to referral hospitals for sepsis, prematurity, and failure of passive transfer.<sup>17</sup> At presentation, foals often have concurrent sepsis, which necessitates treatment. These foals typically have elevated liver enzymes and persistent problems with hypoglycemia during hospitalization. Increases in serum CK activity may be present. Foals may die acutely during hospitalization or respond well to therapy and be discharged. Shortly after discharge the foal is discovered dead.

Muscle biopsy from affected horses shows a complete lack of normal glycogen staining. Normal glycogen is lacking in skeletal muscle, heart muscle, and liver. The disorder has been diagnosed only in Quarter Horses and Paint Horses and is inherited as a recessive trait. To date, all affected animals identified have been homozygous for a mutation (tyrosine to a stop codon) in the glycogen branching enzyme gene, and, where investigated, both parents have been heterozygous for this missense mutation.<sup>18-20</sup> A genetic test is available to identify affected offspring or carrier animals through the University of California Veterinary Genetics Laboratory, Davis, Calif.

## DISORDERS OF LIPID METABOLISM

Multiple acyl-CoA dehydrogenase (MADD) deficiency was recently diagnosed in two Warmblood bred horses in Europe.<sup>21</sup> They exhibited clinical signs of a stiff gait and myoglobinuria progressing to recumbency. Both had elevations in AST, LDH, and CK; hyperglycemia and lactic acidemia; and impaired renal function. Urine and plasma had increased organic acids and acylcarnitines and free carnitine. Muscle biochemical analysis revealed deficiencies of short- and medium-chain acyl-CoA dehydrogenase and isovaleryl-CoA dehydrogenase. The disorder may be acquired as opposed to inherited. Further work is necessary to determine if MADD is more widespread and to determine the origin of the disorder.

## MITOCHONDRIAL ENZYME DEFICIENCIES

A small family of horses has been described with a syndrome of severe exercise intolerance. In this family, one mare was found to have a deficiency of complex I respiratory chain enzyme. She had severe exercise intolerance and muscle stiffness with extreme lactic acidosis in relationship to the degree of exercise but without rhabdomyolysis. Muscle biopsy demonstrated large accumulations of mitochondria with bizarre

cristae formations. Biochemical analysis revealed low activity of nicotinamide adenine dinucleotide coenzyme Q reductase, the first enzyme complex of the mitochondrial respiratory chain, which resulted in impaired oxidative capacity for exercise and heavy reliance on anaerobic metabolism for muscular energy.<sup>22</sup> Examination of related horses provided evidence that the condition was likely familial.

## ☞ CHANNELOPATHIES: ABERRATIONS OF ION AND ELECTROLYTE FLUX

Disorders discussed in this section have in common a defect in ion or electrolyte flow either across the sarcolemma or involving the sarcoplasmic reticulum. Hyperkalemic periodic paralysis, myotonia congenita, and myotonia dystrophica are characterized by an alteration in electric conduction across the outer muscle cell membrane. Equine motor neuron disease results from chronic vitamin E deficiency and consequential long-term oxidative stress, and although it results in altered membrane function, it is discussed under the acquired muscle disease section. The exact abnormality resulting in RER in Thoroughbreds is unknown. However, alteration in calcium homeostasis within the cell is the most likely candidate. Therefore it is included under this heading.

### HYPERKALEMIC PERIODIC PARALYSIS

In human beings, three types of periodic paralysis are described: hypokalemic, hyperkalemic, and normokalemic. These disorders are caused by abnormalities in membrane permeability or a defective cation pump, resulting in an altered electrochemical gradient across the sarcolemma. The alteration, in turn, results in a change in resting membrane potential and threshold potential, resulting in a muscle fiber that is more or less excitable.<sup>23</sup> Together these disorders are classified as paramyotonias.

### CLINICAL SIGNS AND LABORATORY FINDINGS

In horses, hyperkalemic periodic paralysis (HYPP) occurs in Quarter Horses, Paint Horses, Appaloosas, and other horses carrying bloodlines that trace back to the sire Impressive. Affected horses tend to be well muscled. Because of this phenotype the defect has been postulated to confer or be linked closely with other genes that are associated with a heavily muscled phenotype. Between episodes, horses appear to be clinically normal and can be highly successful show horses.<sup>24</sup> In fact, many breeders believe that being a heterozygote greatly enhances the physique of horses and is therefore necessary to compete in the show ring. Scientific research confirming or refuting this has not been performed.

Prolapse of the membrana nictitans may be the initial sign at the onset of an episode of HYPP with or without facial muscle spasm and generalized muscle tension. One may observe sustained contraction of the muscles of the muzzle and drooling. Heart rate and respiratory rate are often normal or only slightly increased. Whole-body sweating has been reported. Muscle fasciculations are common, especially in the shoulders, flanks, and neck area. One may observe myotonia (sustained muscle contraction in response to percussion).<sup>24-26</sup> Although the horse may remain standing, it may not be able to lift its head and may show intermittent buckling at the knees and hocks. In mild cases, however, the only signs observed may be mild muscle fasciculations or twitching similar to signs

of shivering. Recumbency may occur in some horses with diminished tendon reflexes, although affected animals tend to remain conscious and alert and may eat if offered food. Duration of episodes is usually short (20 minutes to 4 hours, typically 30 minutes to 1 hour). Death can occur during an episode, usually from cardiac arrest, respiratory failure, or asphyxiation caused by upper airway obstruction (secondary to muscle flaccidity at the pharynx).

Some horses demonstrate altered vocalization and audible respiratory stridor, which may indicate laryngeal spasm or paralysis.<sup>27</sup> In a survey of 69 homozygous horses, more than 90% were reported to suffer some degree of abnormal airway noise, often between episodes, which tended to be an inspiratory stridor and was continuous in 21% of those evaluated. Exercise, excitement, and stress were possible triggering factors. Upper airway endoscopy of 24 horses revealed 9 with pharyngeal collapse, 10 with laryngeal spasm, 9 with pharyngeal edema, and 6 with a displaced soft palate. Clinically, homozygous affected animals tend to show exercise intolerance, whereas heterozygous animals may tolerate exercise well.<sup>28</sup>

In affected horses, one usually observes clinical episodes before 3 years of age.<sup>29</sup> However, a wide variation in clinical expression of the condition occurs (incomplete penetrance of the gene), with some affected animals showing minimal clinical signs. The variability in clinical signs may result from higher expression of mutant channels in the muscle of horses with symptoms than in those that are asymptomatic. Although variability in the severity of disease occurs between horses, in general, homozygous animals tend to have more severe clinical signs compared with heterozygotes. Muscle fiber diameter or fiber type is related to clinical expression. Management factors such as diet (high versus low potassium intake) and environmental stress may be more influential in the expression of the disorder.<sup>28</sup>

Between episodes, serum potassium concentration is usually within normal limits but may be increased slightly. During an episode, serum potassium concentration usually is increased (5.0 to 11.7 mmol/L),<sup>28</sup> although episodes without associated hyperkalemia have been reported.<sup>30,31</sup> Therefore the absence of hyperkalemia during an episode does not preclude a diagnosis of HYPP. Sodium and calcium concentrations may be decreased and hemoconcentration also may be observed during an episode. Serum CK and AST activities may be normal or mildly increased.<sup>24,26,32</sup> Recovery from an episode is associated with a decrease in serum potassium concentration.

Acute death from hyperkalemia-induced cardiac standstill may occur and is more likely in horses that are homozygous or poorly managed. Poor management may include feeding of diets high in potassium and irregular feeding, traveling, or strenuous exercise schedules.

### CAUSES AND PATHOPHYSIOLOGY

Hyperkalemic periodic paralysis in human beings is inherited as an autosomal dominant trait and has been studied extensively, as has paramyotonia congenita. To date, only HYPP has been diagnosed in horses, and the disorder also appears to be inherited as an autosomal dominant trait.<sup>28,33,34</sup> In human beings and horses, HYPP is characterized by intermittent attacks of weakness or paralysis, which are precipitated by several factors, including potassium intake, fasting, cold, heavy sedation, anesthesia, and rest after exercise. Paramyotonia congenita is typically associated with a cold-induced myotonia. Both conditions have been linked to the human

adult skeletal muscle sodium gene on chromosome 17q. The genetic mutation responsible for HYPP in human beings affects a gene at the *SCN4A* locus that encodes the  $\alpha$ -subunit of the adult human skeletal muscle voltage-dependent sodium channel.<sup>35</sup> In the horse the mutation is a phenylalanine to leucine mutation in the transmembrane domain IVS3 of the  $\alpha$ -subunit of the sodium channel.<sup>36,37</sup> In affected individuals an increase in membrane sodium conductance occurs because of the defective subpopulation of the voltage-dependent sodium channels failing to inactivate and remaining open or repeatedly opening. A small rise in the serum potassium concentration because of clinical variation, ingestion of potassium, or muscular activity may trigger a further increase in membrane sodium conductance, depolarization of the muscle membrane, and movement of potassium out of the muscle cells. As the membrane depolarization develops, the membrane initially becomes hyperexcitable and shows myotonic behavior. With further depolarization of the muscle the muscle cell membrane becomes unexcitable and paralysis occurs.<sup>35,38</sup> In Quarter Horses, all affected horses can trace their lineage to a stallion named Impressive.<sup>36,37</sup> For this reason the disorder is occasionally called Impressive disease. Whether the mutation in Impressive was a spontaneous mutation or was inherited is unknown. The mutation has become common in the Quarter Horse population because of the success of Impressive and his offspring in the show arena and the consequential extensive and long breeding career of Impressive. Of the more than 20,000 samples collected between 1992 and 1995, approximately 63% were homozygous normal (N/N), 36% were heterozygous affected (N/H), and 1% were homozygous affected (H/H).<sup>28</sup> These data translate to a gene-positive frequency of 4.4% of the Quarter Horse population. Because of the prevalence of the mutation the American Quarter Horse Association made genetic testing mandatory in 1998 and has not allowed homozygous affected horses to be registered since 2007.<sup>33</sup>

Plasma potassium concentrations of normal horses undergoing intensive exercise may reach the levels recorded during an episode of HYPP without any associated clinical signs,<sup>39</sup> which suggests that increased plasma potassium concentration alone is not responsible for all the clinical signs typically observed.<sup>40</sup>

### HISTOLOGIC AND MUSCULAR CHARACTERISTICS

In human beings, periodic paralysis conditions are sometimes called vacuolar myopathies. The vacuoles, visible on light microscopy, arise from coalescence of dilated components of sarcoplasmic reticulum, fusion of T-system networks, or focal fiber destruction.<sup>41</sup> In the horse, no abnormalities are found on light microscopy.<sup>26,34</sup>

Affected animals have a lower intracellular potassium concentration and a higher intracellular water volume than normal horses. Using whole-fiber intercostal muscle biopsies, the mean resting membrane potential of five affected horses was significantly closer to the threshold potential compared with unaffected horses.<sup>34</sup> This finding may indicate a defect in membrane transport.

No difference is apparent between muscle fiber type distribution and fiber diameter between horses with HYPP and those without. However, the genetic defect may alter other less-measurable muscle traits such as tone, which is why it appears that breeders and judges prefer affected horses to unaffected ones.

### ELECTROMYOGRAPHY

Numerous EMG abnormalities are apparent in HYPP horses at rest and during an episode.<sup>30,31,34</sup> Complex repetitive discharges are the most consistent abnormal finding, although one may observe myotonic potentials, fibrillation potentials, and positive sharp waves as well. The amount of abnormal spontaneous EMG activity can fluctuate substantially on repeated examinations.

### DIAGNOSIS

The most accurate way to confirm a diagnosis of HYPP is a genetic test using DNA extracted from equine hair or whole blood samples. The American Quarter Horse Association recognizes results of HYPP genetic tests that are performed through a licensed laboratory. Tests are reported as homozygous normal (N/N), heterozygous (N/H), and homozygous affected (H/H). Before the development of the genetic test, a potassium challenge test was recommended to identify affected horses. This test has potential adverse effects and is no longer recommended. If a Quarter Horse dies acutely and HYPP is suspected, one may collect hair samples at postmortem for DNA testing. Increased potassium concentrations in aqueous humor samples support a diagnosis of hyperkalemia at the time of death.

Differential diagnoses for HYPP include other causes of collapse such as syncope, narcolepsy or cataplexy, and seizures, as well as other electrolyte disorders, neurologic dysfunction, and vitamin E-responsive and selenium-responsive myopathy.<sup>32</sup>

### TREATMENT

Recommended treatment for horses with acute episodes of HYPP varies depending on the severity of clinical signs. Mildly affected horses (i.e., nonrecumbent but with muscle fasciculations) may be exercised lightly. Caution is advised because collapse is a potential risk in these horses. One may feed the horse a readily absorbable source of carbohydrate (oats or light Karo syrup) to promote insulin-induced cellular reuptake of potassium. Acetazolamide at 3 mg/kg orally also may be beneficial. Such procedures are often undertaken routinely by responsible and experienced owners of affected animals.

During more severe episodes, especially when recumbency occurs, one may administer 5% dextrose with sodium bicarbonate (with or without insulin) to decrease serum potassium concentration. Slow intravenous administration of 23% calcium gluconate at 0.2 to 0.4 ml/kg diluted in 1 to 2 L of 5% dextrose (5% dextrose at 4.4 to 6.6 ml/kg) or bicarbonate at 1 to 2 mEq/kg have been recommended for treatment of acute, severe episodes of HYPP.<sup>24,26,34,41</sup> Administration of calcium lowers the depolarization threshold and should make muscle cell membranes less likely to depolarize. If required, one may administer potassium-free isotonic fluids. Glucocorticoids may be contraindicated in susceptible horses because they induce episodes in human beings with similar disorders.<sup>24</sup> Inhalation of  $\beta$ -adrenergic agents has aborted acute attacks in human beings, but the use of such drugs has not been reported in HYPP-affected horses.<sup>41,42</sup>

### PROGNOSIS

In humans with HYPP, the prognosis for normal activity is considered good, although a permanent myopathy and weakness may occur, which also seems to be the case in the horse. In at least one horse the condition progressed, necessitating euthanasia.<sup>24</sup> A recent report suggested that "the chances of

a paralytic episode occurring while the horse is being ridden appear unlikely. However, because episodes of paralysis are unpredictable, we recommend that only persons experienced with the symptomatology handle and ride affected horses and to use caution if any abnormal clinical signs are observed."<sup>28</sup> Thousands of carrier horses are handled, ridden, and shown daily throughout the United States and elsewhere with little to no apparent danger to human beings.

### PREVENTION

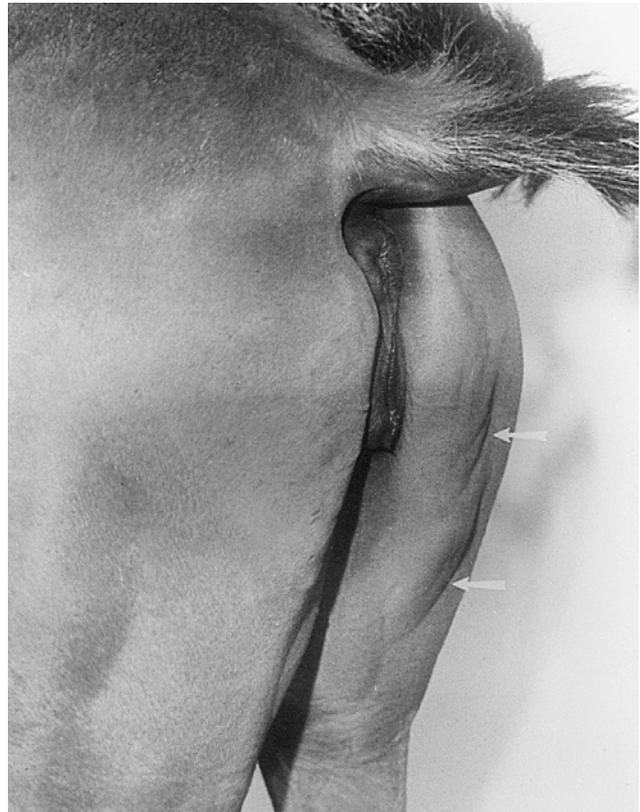

In horses, acetazolamide has been recommended as a daily medication to decrease the frequency and severity of HYPP episodes. The recommended dose is 2 to 3 mg/kg orally every 8 to 12 hours for maintenance.<sup>24,28,33</sup> Hydrochlorothiazide also has been used.<sup>26</sup> One should feed affected horses oats or timothy hay rather than alfalfa to decrease total potassium intake to less than 1.1% of the total ration as potassium. Feedstuffs generally low in potassium include fescue, Bermuda, Kentucky blue grass, oat or timothy hay, rice bran, fats and oils, beet pulp, corn, oats or barley, pasture grass, wheat, wheat bran, or soy hulls. Hays should be tested for potassium concentration because the amount of potassium varies with soil conditions and time of year harvested. Feeding grain two or more times a day, providing access to white salt (without potassium chloride added), and regular mild exercise also may be beneficial. One should establish a regular feeding and exercise schedule and should avoid rapid changes in diet, fasting, and water deprivation. Turnout to pasture or paddock may be beneficial.

In human beings, preventive therapy consists of frequent meals with high carbohydrate content, avoidance of fasting or of exposure to cold or overexertion, and the use of diuretics such as acetazolamide or chlorothiazide, which promote potassium wasting in the urine. Small doses of albuterol, a  $\beta$ -adrenergic agent, also have been recommended in human beings.<sup>42</sup> Albuterol is believed to work by stimulating sodium and potassium ion pumps, enhancing potassium transport across the muscle cell membrane. Tocainide, a frequency-dependent antiarrhythmic drug, may prevent the weakness caused by the myotonia.<sup>41</sup>

### MYOTONIA CONGENITA AND DYSTROPHICA

Similar to HYPP, myotonia congenita and myotonia dystrophica are characterized by abnormal electric conduction across the muscle cell membrane.<sup>41,43</sup> Myotonia is defined as the "delayed relaxation of skeletal muscle after a voluntary contraction or a contraction induced by an electric or mechanical stimulus."<sup>41</sup> Two forms of myotonia congenita are described in human beings, Thomsen's disease and Becker myotonia. Both forms result from chloride channel mutations. Thomsen's disease is inherited as an autosomal dominant trait; Becker myotonia is inherited as a recessive trait.<sup>41</sup>

In the horse, no membrane chloride defect has been identified. As in human beings, at least one form of the condition in horses persists in the face of neuromuscular blockade.<sup>41,44</sup> Only a few horses with myotonia have been described. Affected foals have a severely abnormal gait at birth and are usually euthanized. Because of the small number of affected horses described, whether myotonia in this species is heritable or results from spontaneous point mutations is unknown. To date a complete description of clinical, histopathologic, and electrophysiologic findings in horses with myotonia congenita or myotonia dystrophica is not available.

**FIGURE 11-5** Prominent muscle groups of the hindquarters and a knot of sustained muscular contraction after mechanical stimulation in a foal suffering from clinical myotonia.

### CLINICAL SIGNS AND LABORATORY FINDINGS

Stiffness of gait and prolonged contraction of affected muscle after local mechanical stimulation (finger flick) are the hallmarks of clinical myotonia (Figures 11-5 to 11-7). Clinical presentation of horses with myotonia varies.<sup>32,45-50</sup> One horse exhibited the presence of myotonic discharges on EMG with no overt primary muscular problems.

A second myotonic syndrome in horses is characterized by early onset of progressive deterioration in muscle function. Signs are usually apparent within the first 6 months of life. Initially, lameness associated with stiffness and hypertrophy of the affected muscles may occur. The lack of fluid, smooth movement is most pronounced after rest and diminishes with exercise. In most affected horses the abnormality is confined to the hindquarters, although all four limbs may be involved.<sup>48,51</sup> No other body systems are affected. In many cases the horses become progressively weaker, although the clinical course may vary. Based on clinical, electrophysiologic, and pathologic findings<sup>46</sup> this form of myotonia in horses has been suggested most to resemble human myotonia congenita or an undefined myotonia.<sup>52</sup>

A third, severe, and progressive form of myotonia reported in young horses is characterized by onset of clinical signs as early as 1 month of age.<sup>48</sup> Initially, horses exhibit generalized myotonia with hypertonicity of the larger proximal limb muscles, progressing rapidly to muscle stiffness, atrophy, and weakness. In one report the authors also observed testicular hypoplasia, early cataract formation, and mild glucose

**FIGURE 11-6** A young horse with myotonia. The heavy muscling of the hindquarters with atrophy of the distal limb and neck musculature are notable.

intolerance, suggesting multisystemic involvement. This myotonic dystrophy–like disorder is associated with specific histologic changes.<sup>48,52</sup>

Serum CK and AST activities may be elevated in horses with myotonia, but these increases are often not sustained throughout the course of the disease and tend to be unpredictable.

Not all muscles that exhibit classic myotonic discharges (see the diagnosis section) show histologic changes. Fiber size variation, changes in number and size of the individual fiber types, increased numbers of central nuclei, and clustering together of fiber types with signs of necrosis and degeneration have been reported.<sup>23,46,53</sup> Differences in the histologic findings may reflect different forms of the condition.<sup>46</sup> Dystrophic changes and a normal distribution of fibers would be more likely in a diagnosis of myotonia dystrophica. In a muscle biopsy from a yearling horse with a likely diagnosis of myotonia congenita, histopathologic examination of the muscle revealed small anguloid atrophy of type 2A and 2B fibers. In addition, the muscle fibers in the biopsy were almost exclusively type 2B with fewer type 1 and 2A fibers. No evidence of central nuclei, muscle necrosis, or macrophage infiltration was apparent.

### DIAGNOSIS

The diagnosis of myotonia congenita or myotonia dystrophica is based on clinical signs, appropriate histopathologic changes in muscle, and the classic waning (dive bomber) or waxing and waning (revving motorcycle) sounds of the EMG trains of high-frequency discharges (see Figure 11-7). These waveforms are visible on insertion of the EMG electrode and on voluntary, mechanical, or chemical stimulation of the affected muscle. After percussion or stimulation, positive sharp waves and fibrillation potentials may be visible. These abnormal discharges ultimately subside when the muscle has been at complete rest for some time, although they can be initiated readily after the patient is given neuromuscular blockade (e.g., curarization).

**FIGURE 11-7** Prolonged myotonic discharges present on needle electromyographic examination. These high-frequency discharges emit a sound similar to a revving motorcycle but with no true waxing and waning. Instead the amplitude and frequency of the discharges change suddenly (as shown), altering the tone heard. Under general anesthesia, suxamethonium or tubocurarine does not abolish these discharges.

### TREATMENT

In human beings, quinine, procainamide, taurine, and phenytoin (diphenylhydantoin) have been recommended for treatment of myotonia. Most of these drugs decrease muscle excitability by blocking sodium movement.<sup>38</sup> The duration of EMG relaxation time after maximal voluntary effort is the only reliable indicator of muscle excitation and response to therapy in human beings<sup>41</sup> and is impractical in the horse.

Acepromazine, xylazine, thiopentone, pancuronium bromide, quinidine, and phenytoin have been used to treat horses with myotonia; however, significant improvement in clinical signs has not been observed.<sup>54,55</sup> Prolonged times to 90% muscle relaxation *in vitro* were observed in two horses with myotonia; these relaxation times were normalized by the administration of phenytoin to the affected horses. However, no obvious clinical improvement or significant effect on EMG was observed with the short duration of therapy.<sup>45</sup> The long-term effects of phenytoin on the clinical signs or progression of myotonia is unknown. The prognosis for horses with any type of myotonia is poor; most affected horses are euthanized because of their inability to function as athletes.

### RECURRENT EXERTIONAL RHABDOMYOLYSIS

Racing Thoroughbreds share a high degree of relatedness. As much as 80% of the genome of the modern Thoroughbred directly traces to 31 animals.<sup>56</sup> This extensive amount of linebreeding makes associating diseases with a particular ancestor difficult because so many horses, healthy or not, may be related to a particular individual. The suggestion has been made that many Thoroughbred horses share a similar genetic trait that leads to RER.<sup>57,58</sup> Epidemiologic surveys of racing Thoroughbreds support that exertional rhabdomyolysis is common. A U.S. survey found approximately 5% of racing Thoroughbreds were affected, and a study in the United Kingdom found 6.7%.<sup>59</sup>

### CLINICAL SIGNS AND LABORATORY FINDINGS

Thoroughbred horses with RER may have mild to moderate signs of muscle cramping. Clinical signs of RER are similar to those of other horses exhibiting exertional rhabdomyolysis.

The predominant clinical signs are mild to severe muscle cramping of the major muscle groups of the hindquarters, including the gluteal, semimembranosus, semitendinosus, biceps femoris, and quadriceps femoris muscles. Involvement of these muscle groups is not exclusive, and muscle cramping of the forelimb musculature may occur. Cramping is associated with mild to severe pain demonstrated by anxiety, profuse sweating, refusal to move, and increased heart and respiratory rates. Affected muscles are firm and painful on palpation. The practitioner can palpate generalized or focal areas of flocculation that may be associated with focal areas of muscle tearing or edema. In mild to moderate cases, muscle contractures abate within minutes to several hours, and the horse moves about more comfortably. In severe cases, rhabdomyolysis may lead to recumbency, necessitating a prolonged convalescence, which, in turn, may lead to further complications. Recovery is related to the severity of muscle fiber necrosis and may take days to weeks in mild and moderate cases and months in horses with severe rhabdomyolysis. In most cases, horses readily return to athletic function.

Damaged muscle fibers release myoglobin and the intracellular enzymes LDH, AST, and CK into the circulation. Myoglobin is filtered by the kidneys and is excreted in the urine. With moderate to severe muscle necrosis, myoglobin causes the urine to be orange to brown. In horses with systemic acidosis and dehydration that suffer significant muscle damage, myoglobin may cause tubular nephrosis with acute or delayed renal damage or failure.<sup>60</sup> In Thoroughbreds with RER, onset of rhabdomyolysis most commonly occurs soon after the onset of aerobic exercise, and for this reason accompanying systemic acidosis or dehydration does not occur and renal damage is rare.

After an episode of rhabdomyolysis, CK levels increase exponentially from the reference range to levels at or above 100,000 U/L. CK is a sensitive indicator of muscle damage, with activity peaking 4 to 6 hours after insult. If muscle necrosis is not ongoing, CK levels decrease rapidly over the next 24 to 48 hours because of the relatively short half-life (108 minutes). Serum AST activity takes 12 to 24 hours to peak, and activity may remain elevated for 7 to 14 days after insult.<sup>61</sup>

In Thoroughbred horses with RER, CK activity appears to peak 4 to 6 hours after activity, and affected horses have intermittent elevations in CK activity that are not associated with clinical signs of muscle cramping (subclinical exertional rhabdomyolysis).<sup>62</sup> Subclinical exertional rhabdomyolysis is common in Thoroughbred horses with RER, and CK activity may be at or above 10,000 U/L. Normal healthy horses participating in race training also may have occasional increases in CK activity but do not appear to have them as frequently as horses with RER.

## ETIOLOGY

A group of Thoroughbreds with a history of chronic exertional rhabdomyolysis were studied and found to have similar abnormalities.<sup>58,63-65</sup> Muscle biopsies of the middle gluteal muscle did not identify any abnormal accumulations of polysaccharide, but an increased number of centrally located nuclei were found in mature muscle fibers. In vitro contracture studies demonstrated increased sensitivity to caffeine and halothane and faster times to peak contraction and 50% and 90% relaxation compared with healthy Thoroughbred horses or Quarter Horses with PSSM.<sup>64</sup> The in vitro contracture study is considered the gold standard for diagnosing RER in the Thoroughbred horse but requires a specialized laboratory. Therefore

diagnosis is generally based on history, breed, and muscle biopsy results.

The muscle contracture results are similar to pigs with malignant hyperthermia.<sup>66</sup> However, further testing has demonstrated that the cellular defect in Thoroughbreds with RER and pigs with malignant hyperthermia is different. Therefore RER represents a disorder similar but not identical to malignant hyperthermia in swine.<sup>67,68</sup> Of interest is that occasional incidences of malignant hyperthermia in Thoroughbred horses with chronic exertional rhabdomyolysis have been reported.<sup>25,69-73</sup> This scenario may indicate that Thoroughbred horses with RER may be more susceptible to episodes of malignant hyperthermia while under general anesthesia, but the incidence is far less common than in swine. The exact cellular mechanism that leads to RER in Thoroughbred horses has yet to be elucidated, and genetic studies are currently under way.

## PATHOPHYSIOLOGY

Recurrent exertional rhabdomyolysis affects as much as 5% of the racing Thoroughbred population and likely is inherited as an autosomal dominant trait.<sup>57,74,75</sup> However, expression of the disorder is multifactorial and depends on the fitness level and exercise schedule of the horse, diet, age, gender, temperament, and the presence of any skeletal lameness.<sup>57</sup> Expression of RER in Thoroughbred horses has been postulated to be related to the physicochemical changes experienced by the body during a high level of stress or anxiety. Such a trigger would be similar to that seen in swine with malignant hyperthermia. One study has ruled out the sarcoplasmic reticulum calcium release channel (RYR1) gene, the sarcoplasmic reticulum calcium ATPase (ATP2A1) gene, and the transverse tubule dihydropyridine receptor-voltage sensor (CACNA1S) gene.<sup>67</sup> Therefore the exact mechanism of how anxiety may trigger exertional rhabdomyolysis in susceptible horses remains unknown.

Many of the factors listed previously may influence the mental and physical state of the horse. For example, the typical Thoroughbred horse with RER has long been described as a 2- or 3-year-old filly with a nervous temperament.<sup>57,59,76-78</sup> A recent epidemiologic survey carried out in the United Kingdom showed that females are more likely than males to suffer from this condition, particularly in the birth to 2-year-old and 5- to 6-year-old age groups.<sup>40,79</sup> However, an equal sex ratio was reported in another study.<sup>80</sup> Genetic studies support that RER likely is inherited as an autosomal dominant trait.<sup>74</sup> The increased expression of RER in female Thoroughbreds and in younger horses might be because of temperament. Fillies are more likely to be described as having a nervous temperament by their trainers, and young horses may find the racetrack environment stressful.<sup>57</sup>

Diet also influences expression of RER, and affected horses often consume quantities of grain in excess of 10 lb (4.5 kg) per day. Higher CK activity has been documented in horses with RER compared with control horses when both groups were fed diets high in carbohydrates. In addition, dietary studies have shown that feeding horses diets high in carbohydrates at levels at which the caloric intake exceeds body demands may accentuate nervousness. This effect has been observed in Thoroughbreds with RER and in normal healthy horses.<sup>62</sup> Conversely, horses with RER that are fed diets higher in fat demonstrated a decrease in CK activity, and horses with RER and healthy horses consuming diets high in fat are often regarded as being more calm and less fearful.<sup>81</sup> Several high-fat, low-carbohydrate commercial grain mixes are now available for

the horse owner, and anecdotal reports support laboratory findings that the number of incidences of rhabdomyolysis in horses with RER consuming these diets are reduced. Whether the influence of diet on the expression of RER is caused by temperament alone, another factor, or a combination of factors has yet to be determined.

Racehorses with RER are more likely to have an episode of rhabdomyolysis when exercised at a medium gallop as opposed to walking, trotting, breezing, or racing. Horses with RER that are exercised at the trot were more likely to have increased CK activity than when galloping at high intensity. The influence of temperament also may be a factor. Thoroughbreds at the race track are often trotted against traffic as a warm-up and then are turned around to gallop back home at a controlled rate of speed. This training scenario was the most frequent form of exercise associated with episodes of rhabdomyolysis and may result from excitement or anxiety that triggers the episode of rhabdomyolysis in susceptible horses. Horses that are fit for racing may find this training scenario especially exciting because they often pull and try to run faster. When racehorses were allowed to gallop full out, as in breezing or racing, episodes of rhabdomyolysis were infrequent.<sup>57</sup>

Horses with an underlying lameness are predisposed to episodes of exertional rhabdomyolysis. Whether changes in gait may be related to muscle pain or soreness or whether underlying skeletal disorders may alter a horse's way of going, precipitating an episode of rhabdomyolysis, or whether running in pain from a skeletal disorder may trigger an episode of rhabdomyolysis is unclear. Inclement weather has often been cited as causing an increase in the incidence of RER, as has the time of year.<sup>82,83</sup> In a 2-year survey in the United Kingdom, significantly more episodes of rhabdomyolysis were reported from November to February than during other times of the year.<sup>40,79</sup>

At the race track, large groups of horses are fed, exercised, and housed under similar conditions. Yet some horses are particularly predisposed to chronic exertional rhabdomyolysis, which underscores the likelihood of a genetic basis for the disorder. One is tempted to assume that all affected Thoroughbreds at the racetrack have RER. However, the practitioner must be wary about diagnosing all Thoroughbreds with chronic exertional rhabdomyolysis as having RER until the genetic fault is identified and a genetic test is available.

## DIAGNOSIS

Currently the gold standard for diagnosing RER is the caffeine or halothane muscle contracture test.<sup>65</sup> However, this test requires a biopsy sample from intercostal muscle and is not readily available. Therefore diagnosis of RER is based on history, laboratory documentation of rhabdomyolysis, and histopathologic examination of muscle. Horses with RER should be Thoroughbreds or Thoroughbred crosses because of the likelihood that the disorder is inherited as an autosomal dominant trait. The horse should have experienced multiple bouts of muscle cramping after nonintensive exercise accompanied by documented elevations in CK activity. Muscle biopsy reveals recent rhabdomyolysis, regeneration, an increased number of central nuclei, and absence of abnormal polysaccharide.

## TREATMENT

Treatment of horses with RER aims at managing the frequency of the clinical episodes of rhabdomyolysis, considering that the disorder is likely a primary myopathy. Environmental and dietary factors appear to influence the expression of RER. Such

factors include dietary fat and carbohydrate content, dietary electrolytes, exercise regimens, housing and turnout conditions, and underlying skeletal lameness. The practitioner must pay particular attention to the temperament of the individual horse. The most successful trainers modify the affected workout schedule of the horse to minimize stress. For example, horses that prefer to work alone or with company should do so. If a horse is calmer to work when the track is empty, the trainer should exercise it early in the day; others may benefit from a long, slow warm-up to minimize stress. One should make similar stress-reducing modifications for affected horses used in other disciplines.

The diet should be modified to provide adequate but not excessive amounts of calories for the level of work being performed such that a greater proportion is supplied from fats as opposed to carbohydrates. High-calorie diets composed primarily of fat are effective in decreasing postexercise CK activities in affected horses.<sup>84</sup> The optimal fat source and percentage of fat in the diet have yet to be determined, but several commercially available feeds on the market have been found to be useful. The exact mechanism by which increased dietary fats lower CK activity in horses with RER has yet to be determined.

Dantrolene has been used in human medicine to treat and help prevent malignant hyperthermia. In this condition an abnormal release of calcium from the sarcoplasmic reticulum appears to occur, resulting in prolonged contracture, hyperthermia, metabolic and respiratory acidosis, and muscle damage. Dantrolene is thought to decrease the rate of calcium release from the sarcoplasmic reticulum and to affect charge movement in the T tubule system. Dantrolene has been used in human beings to treat chronic exertional rhabdomyolysis.<sup>85</sup> In one study, dantrolene (800 mg) given orally 1 hour before exercise in Thoroughbreds that had experienced a day of rest before exercise has been shown to be effective.<sup>86</sup>

Although dantrolene sodium has been suggested for treating equine rhabdomyolysis, the drug is used more commonly in prevention. Giving 2 mg/kg/day diluted in normal saline by a stomach tube for 3 to 5 days and then every third day for a month has been recommended.<sup>76,87</sup> A lower daily dose (300 mg) may be equally beneficial<sup>87</sup> and perhaps preferable because the drug is hepatotoxic.<sup>76</sup> Another recommendation is 500 mg orally for 3 to 5 days and then 300 mg every third day for a time. The time period depends on the circumstances and the effect on the liver, but prolonged treatment is not recommended. Monitoring of hepatic status and function is recommended because the effects on the liver seem to be individually variable. Up to 1 g of dantrolene, given with a small feed 1.5 to 2 hours before exercise for 3 to 5 days has been used with apparent success in racehorses, but in some cases the horses may have been suffering from overexertion rather than RER. Researchers have suggested that lower doses are unlikely to reach therapeutic levels. The drug appears not to be as bioavailable in the horse as in human beings and is cleared more quickly.<sup>69</sup>

## IDIOPATHIC CHRONIC EXERTIONAL RHBADOMYOLYSIS

Horses of many breeds and types other than Thoroughbreds, Draft Horses, and Quarter Horses may experience recurrent episodes of exertional rhabdomyolysis. Of special note are

Standardbred and Arabian horses. These breeds share some common genetic heritage with Thoroughbred horses, and individuals with chronic exertional rhabdomyolysis may have muscle biopsy findings consistent with RER. These individual horses may respond favorably to management changes (high-fat diet and regular exercise) recommended for Thoroughbreds with RER. However, muscle contracture testing of affected Standardbred and Arabian horses has not been performed to confirm similar muscle pathophysiology.

Some horses with idiopathic exertional rhabdomyolysis do not respond to management and dietary recommendations described previously. Practitioners should counsel owners of horses that suffer from repeated episodes of rhabdomyolysis despite multiple management changes to decrease the exercise intensity the horse is performing or retire the horse from regular work.

## ACQUIRED MYOPATHIES

Jennifer M. MacLeay

### ☞ TRAUMATIC MUSCLE INJURY CHRONIC MUSCLE INJURY: FIBROTIC MYOPATHY

Fibrotic myopathy tends to be a chronic, progressive disorder and may occur after excessive exercise over a long period that has resulted in the repeated tearing and stretching of muscle fibers.<sup>1</sup> Fibrotic myopathy has also been observed in Quarter Horses and stock horses after maneuvers such as sliding stops, in which the large thigh muscles are contracting while the stifle and hock are extending,<sup>2,3</sup> and in horses tied by a halter and shank that pull back and fight strongly. Fibrotic myopathy has also been described as congenital, perhaps caused by periparturient trauma,<sup>4</sup> and after intramuscular injection.<sup>5</sup> The semitendinosus muscle is most frequently affected, but adhesions to the semimembranosus and biceps femoris are common. Myopathy also may involve the gracilis or biceps brachii muscles.

The altered gait seen in horses with fibrotic myopathy of the hamstring muscles is characteristic. The horse walks with a shortened anterior phase of stride and then snaps the foot to the ground with a slap. The pathophysiologic process appears to involve trauma (external or work related) followed by inflammation, muscle fiber atrophy, and replacement by fibrous tissue. Occasionally, mineral deposits form in the affected tissues, in which case the condition has been labeled as an ossifying myopathy.<sup>5</sup> The characteristic gait likely results from a combination of scar tissue preventing normal extension and contraction of the muscle belly and possibly an altered  $\gamma$ -efferent loop with an abnormal setting of the muscle spindle trigger, which may allow the early unchecked contraction of caudal thigh muscles during the late swing phase of the stride.<sup>6</sup>

#### CLINICAL SIGNS

Fibrotic myopathy has been described as a nonpainful mechanical lameness associated with a distinct gait abnormality (Figure 11-8). The condition can be unilateral or bilateral,

**FIGURE 11-8** A horse with abnormal muscle contour secondary to fibrotic myopathy. (Courtesy Dr. Gary Baxter.)

and the horse pulls the affected limb or limbs back and down before the end of the protraction phase so that the foot slams down, resulting in a louder sound on impact than that of an unaffected limb and in a shortened cranial or swing phase and a lengthened weight-bearing phase,<sup>4</sup> which has been called a *goose-stepping gait*. The condition tends to be most obvious at the walk. If the condition involves the biceps brachii muscle the horse shows a shortened cranial phase of the thoracic limb with a tendency for the foot to land at the toe in a way similar to those animals affected by navicular syndrome. Occasionally, one can identify the area of muscle damage because of a dimpling or depression in the skin overlying the muscle. In cases in which significant fibrous tissue or calcification of the muscle occurs, the site is readily palpable. The lameness tends to be unresponsive to routine anti-inflammatory therapy.

#### DIAGNOSIS

The diagnosis of fibrotic myopathy is based on clinical signs and history. In one report, two horses with congenital fibrotic myopathy did not have palpable thickening of the muscle or tendon and had no evidence of scar formation.<sup>7</sup> Histologically, one may observe a band of dense collagenous connective tissue or irregular, jagged pieces of mineral. Diagnostic ultrasound has been useful in some cases to confirm the diagnosis and to determine whether mineralization is present in addition to the fibrosis.

Fibrotic myopathy may be distinguished from stringhalt by closely observing the gait. In horses with stringhalt the rear limb hyperflexes during the cranial or swing phase, and a step-wise caudal jerking movement does not occur just before the foot hits the ground.<sup>3</sup>

#### TREATMENT AND PROGNOSIS

Surgical treatments described for fibrotic myopathy include resection of the fibrotic band, semitendinosus myotectomy, and simplified semitendinosus tenotomy.<sup>5,7,8</sup> Some

improvement in gait may occur in some horses after surgery, but complete resolution of lameness is an unlikely result. Long-term prognosis is poor because the condition tends to recur after surgery. Postoperative problems with wound healing are common.<sup>5</sup> Transection of the semitendinosus tendon insertion on the tibia distal to the myotendinous junction has been said to result in much less postoperative trauma, which may help to decrease the potential for recurrence,<sup>7</sup> and full recovery has been reported anecdotally in a few cases. Performing a less-radical excision and combining this with passive postoperative flexion-and-extension physiotherapy therefore may be preferable. Surgery is unlikely to be of value if the biceps brachii is involved.<sup>5</sup>

### **GASTROCNEMIUS MUSCLE RUPTURE**

Rupture of the gastrocnemius muscle occurs in horses attempting to get up after a long period of recumbency (e.g., after anesthesia or postpartum paralysis). Rupture also occurs in animals that rear and fall over backward and occurs occasionally after overextension. In foals, ruptures have been reported after the first attempt of the foal to rise, especially if the foal has poor muscle tone or coordination. The condition also occurs in foals after an assisted delivery (dystocia) and in foals after manual attempts to straighten a fixed tibiotarsal joint. A rupture occurring in the tendon of insertion may result in avulsion of a portion of the tuber calcanei. If rupture occurs in the muscle belly, a hematoma may form and may calcify. The condition can occur unilaterally or bilaterally; however, the animal will be unable to stand if rupture is bilateral or if complete Achilles tendon rupture occurs. The affected hock or hocks may be flexed excessively because of the loss of the extensor influence of the gastrocnemius, giving the horse a squatting appearance. Heat, swelling, and pain are normally evident in the initial stages. The plasma muscle enzyme activities also tend to be elevated, at least initially.<sup>9,10</sup> Treatment involving support in a sling with the affected limb immobilized in an extended position has been recommended,<sup>10</sup> but the prognosis is guarded for a return to normal function.

### **SERRATUS VENTRALIS RUPTURE**

Rupture of the serratus ventralis is rare and occurs as a consequence of dorsal impact trauma over the withers and neck region or after jumping a high fence or jumping off a raised platform. Animals are usually affected bilaterally. The thorax drops between the paired scapulae so that the dorsal borders are above the thoracic spinous processes. The croup is often higher than the withers. The condition is painful, and radiographs are needed to eliminate the possibility of dorsal spinous process fracture. The prognosis is poor. Recommended treatment is a prolonged period in a sling if the horse is suited temperamentally to such a restriction.<sup>2</sup>

### **SORE AND PULLED MUSCLES**

Pulled muscles (i.e., muscle tears or strains resulting in some disruption of muscle architecture and occasionally the formation of a hematoma) are often exhibited immediately after exercise. Depending on the extent of the trauma and the muscle groups involved, obvious swelling and apparent pain on palpation may or may not be present. Plasma CK and AST activities may or may not be elevated significantly. Definitive

diagnosis may be difficult, especially in chronic cases. Faradic stimulation, scintigraphy, thermography, and diagnostic ultrasound are some of the more common techniques used to diagnose a pulled muscle. Treatment tends to be a combination of rest and physiotherapy (e.g., manipulation, faradism, ultrasound). Perhaps one should differentiate pulled muscles from the overexerted or sore muscle in which the associated damage tends to be at the cellular level involving structural damage of the contractile elements. Delayed-onset muscular soreness (DOMS) is a commonly recognized condition in human beings. The soreness tends to increase in intensity over the initial 24 hours after exercise and peaks around 24 to 72 hours, hence its name. Whether DOMS occurs in the horse is not certain, although the diagnosis has been suggested when a stiff gait, palpable soreness, and a reluctance to move, as well as increased hydroxyproline concentrations, are observed 24 hours after exercise. Free radicals may be involved in the pathophysiologic features of acute and delayed-onset postexercise muscular soreness. Treatment of DOMS in human beings varies from rest to light exercise with or without analgesia and the external application of heat. In the horse, continued exercise may be contraindicated if the horse has experienced significant exertional rhabdomyolysis as diagnosed by moderate to high CK activity and in horses with an obvious muscle tear as indicated by the presence of heat, pain, swelling, and abnormal gait. In human beings the best prevention for DOMS is moderate daily increases in the degree of training.

### **INFECTIOUS MYOSITIS**

Infectious agents (bacteria, viruses, and parasites) can affect skeletal muscles. Some agents produce inflammatory reactions (myositis), whereas others give rise to mild degenerative changes (i.e., myopathy). The differentiation can be difficult, especially in subacute and chronic cases, because an inflammatory reaction often induces secondary degenerative changes and vice versa.

### **CLOSTRIDIAL MYONECROSIS**

Gas gangrene, malignant edema, and clostridial myonecrosis are terms used to describe infection of skeletal muscles with any of several *Clostridium* organisms (*C. septicum*, *C. perfringens*, *C. novyi*, *C. sordelli*, and *C. chauvoei*). Germination of spores and vegetative growth occur when suitable local anaerobic conditions (e.g., alkaline pH, low oxidative reduction potential) exist after castration, parturition injuries, puncture wounds, and, in particular, intramuscular injections.<sup>11</sup> Toxin production results in the destruction of the cellular defense mechanisms and significant tissue necrosis.

Affected animals may be found recumbent or dead. In less acute cases, mild to severe lameness, colic, or obtunded mentation may be the presenting complaint. Painful muscular swellings may be present, and one may feel flocculation or gas crepitation. The overlying skin may initially feel hot and then progressively becomes cool, tough, firm, and insensitive. Affected animals are often extremely obtunded with systemic signs of profound toxemia. The prognosis is poor without treatment because the condition often progresses rapidly with ataxia, recumbency, coma, and death.

Diagnosis usually is made from the clinical signs and history. The finding of a nonclotting, malodorous fluid on needle aspiration (with or without gas) can be indicative of clostridial infection. Anaerobic culture, cytologic examination, and

fluorescent antibody identification of the organism in tissue specimens has been recommended for definitive diagnosis.<sup>12</sup>

Clinicopathologic changes tend to be nonspecific and similar to those seen in other septic-toxic conditions. Although increased serum muscle enzyme activities may be observed, they often do not appear to be in proportion to the degree of muscle damage.<sup>13</sup> In gas gangrene, extensive disintegration of muscle tissue occurs, with serosanguineous exudate and bubbles of gas. Malignant edema is characterized by a cellulitis with sparing of muscle fibers, although this may progress to gangrene.<sup>12,14</sup>

Treatment must be aggressive and typically includes initial administration of high doses of potassium penicillin G (44,000 IU/kg intravenously every 6 to 8 hours) and surgical débridement. One may administer penicillin with metronidazole (20 to 25 mg/kg orally every 8 hours or 20 mg/kg intravenously every 8 to 12 hours). Surgical débridement, fenestration, or both are essential to remove necrotic tissue and disrupt the anaerobic environment.<sup>12</sup> Long-term antibiotic and nursing care of the resulting wound usually is required. Antibiotic therapy should be continued until infection has resolved and for a minimum of 7 days thereafter. In many instances, diffuse cellulitis extending down fascial planes occurs, necessitating therapy for at least several weeks. Supportive fluid therapy and analgesics are often necessary in the initial stages while signs of systemic toxemia are evident. Corticosteroids should be used with caution, although initial short-term therapy may be beneficial in horses with evidence of shock. Prognosis in most horses is guarded.<sup>11</sup> Survival appears to be most frequent with *C. perfringens* infections, although extensive skin and muscle sloughing may occur, which, in turn, may necessitate euthanasia.

Immune-mediated hemolysis has been described in several horses with *C. perfringens* myositis.<sup>15,16</sup> The anemia may be characterized by regeneration, autoagglutination, and a positive Coombs' test. Type 3 echinocytes, spherocytocytes, and reticulocytes may be observed. In such cases, immunosuppressive therapy must be judiciously implemented to treat the anemia without allowing the infection to go unchecked. Treatment of horses with penicillin has also resulted in immune-mediated hemolytic anemia.<sup>17,18</sup> In such cases, use of oxytetracycline and metronidazole should be considered.

## STREPTOCOCCAL IMMUNE-MEDIATED MYOSITIS

Purpura hemorrhagica is an immune-mediated vasculitis associated with sensitization and cross-reactivity to proteins in the cell wall of *Streptococcus equi* subsp. *equi*. Purpura hemorrhagica in its most common form may be associated with mild muscular lesions secondary to vasculitis.<sup>19</sup> Skeletal muscle necrosis with fragmentation and swelling of muscle fibers and a cellular infiltration may be visible histologically. Classically, the lesions are believed to be caused by a type III hypersensitivity vasculitis.

Some bacteria may share similar immunodeterminants with muscle so that antibodies produced against the bacteria also affect the muscle directly, causing necrosis.<sup>20</sup> This type of purpura has myositis as its primary clinical sign rather than vasculitis. Two forms of immune-mediated myositis have been described in horses in association with *S. equi* subsp. *equi*: immunoglobulin (Ig) G and IgA mediated. Both are less

common complications of *S. equi* subsp. *equi* infection than purpura hemorrhagica.<sup>21,22</sup>

IgG-mediated myositis in horses is characterized by rapid onset of muscle wasting (2 to 14 days; Figure 11-9). The amount of muscle mass lost is often astounding considering the time frame. Horses typically have a history of clinical *S. equi* subsp. *equi* infection or live on farms where infection is endemic. Muscle biopsy reveals inflammatory cell infiltration of the muscle and muscle cell atrophy. Horses are otherwise bright and alert and have a normal appetite. Blood and serum profiles are within normal limits with the exception of increased CK and AST activity. Globulin fractions may increase slightly. Horses respond favorably to a 4- to 8-week course of corticosteroid therapy (dexamethasone or prednisolone, or both). In horses in which the practitioner suspects an internal nidus of infection (abscess) as the cause of long-term exposure to the antigen, concurrent antibiotic therapy should be instituted.

The IgA-mediated form of poststreptococcal myositis of horses is similar to Henoch-Schönlein purpura of humans and is a significantly more malignant form of myositis. Horses do not exhibit loss of muscle mass but may have residual loss of muscle mass should they survive. Affected horses have severe obtundation, muscle pain, stiff gait, thrombosis, and colic and may have areas of flocculent serosanguineous fluid several centimeters in diameter over the major muscle groups. Signs are progressive over the first 24 hours. In the first hours, blood analysis may show only a stress or endotoxic leukogram and high CK and AST activities. Physical examination and blood analysis progresses to support early disseminated intravascular coagulopathy and CK activities of greater than 100,000 U/L. Postmortem examination of these horses shows large areas of hemorrhagic necrosis within the large muscle groups (Figure 11-10). Histologic examination demonstrates myositis. Early, aggressive cardiovascular support combined with large doses of dexamethasone is essential in an attempt to treat these horses because mortality rates are high. If major vital organs are infarcted the horse will not likely survive. However, with aggressive support and long-term steroid therapy (1 to 2 weeks

**FIGURE 11-9** A horse with immunoglobulin G-mediated *Streptococcus equi* subsp. *equi* myositis. The profound atrophy of the lumbar muscles is notable. The horse responded well to a course of prednisolone therapy.

**FIGURE 11-10** Muscle taken postmortem from a horse with immunoglobulin A–mediated *Streptococcus equi* subsp *equi* myositis. The sharp demarcation between normal and infarcted muscle is notable.

at high doses, followed by a longer-term, declining dose regimen) the horse may survive. These horses often have pockets of *S. equi* subsp. *equi* infection internally that may have been the nidus initiating the immune mediated reaction. Areas to be examined include the guttural pouches and thoracic and abdominal cavities. Because these horses may have a nidus of infection, treatment also should include aggressive antibiotic therapy.

### **SUPPURATIVE MYOSITIS: ABSCESSATION**

Suppurative myositis may be hematogenous in origin or result from penetrating wounds, intramuscular injections, or an extension of an infective focus in an adjacent or distant structure. Almost any bacteria may be isolated from such abscesses, but two are particularly common in horses: *S. equi* subsp. *equi* and *Corynebacterium pseudotuberculosis*. *S. equi* subsp. *equi* may occur secondary to (1) hematogenous spread, (2) misinjection of intranasal vaccines intramuscularly, or (3) skin contamination from aerosolized *S. equi* subsp. *equi* and subsequent intramuscular injection after administration of intranasal or intramucosal strangles vaccines.<sup>23</sup> Injections of a variety of intramuscular vaccinations can also lead to abscessation. Affected horses initially have an ill-defined cellulitis, which may heal, progress to a classic organized abscess, or in the case of certain staphylococci, may extend, resulting in extensive muscle damage. Abscesses may heal slowly, expand, or fistulate to the surface. Once fistulated, abscesses may collapse and heal, usually with scar tissue, or persist as chronic granulomata (especially *Staphylococcus aureus* in the neck and pectoral region).<sup>14</sup>

### **CORYNEBACTERIUM PSEUDOTUBERCULOSIS**

*Corynebacterium pseudotuberculosis* is a gram-positive, pleomorphic, rod-shaped, intracellular, facultative anaerobe with worldwide distribution that may be isolated from large abscesses in various muscles, in particular, the pectorals. A significant geographic variation appears in the clinical presentation of *C. pseudotuberculosis* infection. Worldwide, ulcerative lymphangitis—usually with sores, abscesses, fever, lameness, anorexia, and lethargy, which may progress

to chronic lameness and weight loss—is the most common condition associated with this infection. However, in the United States, especially in more arid regions, the organism tends to be associated with ventral midline, inguinal, and pectoral abscesses, although internal abscesses may occur. The condition has been called *pigeon fever* (after the swollen pectorals giving the appearance of a pigeon breast), dry land distemper, or Colorado strangles (after its geographic distribution).

Suppurative myositis can occur at any time of the year but is more common in late summer, fall, and early winter. One or more horses within a group may be affected. Outbreaks in a significant number of horses at a single establishment have been reported. *C. pseudotuberculosis* can survive in the soil and enter the body via lesions in the skin or mucous membranes and spread via the lymphatics. Insect vectors may be involved. Clinical signs vary with the stage of the condition and the site of the abscess or abscesses.<sup>24,25</sup> The affected horse may be pyrexia and anorectic during the maturation phase of the abscess. Ventral pitting edema, lameness, weight loss, and depression may also occur. If the abscesses are located in the axillary or inguinal regions the affected animal can be very lame and is more likely to be intermittently febrile. Such cases can be difficult to diagnose because the abscesses may take weeks or even months to develop fully. Increased white blood cell counts and plasma fibrinogen concentration may be observed, although, in the more chronic stages, few clinicopathologic changes are seen. Abscesses typically form deep in muscles and can be large with thick capsular walls filled with a nondorous, light tan pus. The differential diagnosis includes seromata, tumors, and other bacterial abscesses. One can confirm the diagnosis by ultrasound or culture of any aspirated fluid. Abscesses in the axillary region in particular can be difficult to locate, even with ultrasound. A synergistic hemolysis inhibition test detects antibodies to the organism, but the intensity of the antibody response depends on several factors, including thickness of the capsule surrounding the abscess and chronicity of the infection. For example, horses with chronic thick-walled abscesses that have been lanced recently may have low or undetectable circulating antibody concentrations, perhaps because antibodies have been consumed during the massive toxin release. The test can be helpful in determining whether one should include internal *C. pseudotuberculosis* abscessation in the differential diagnosis.

Recommended treatments include encouraging the maturation process via hot poultices, lancing, flushing, and draining. In some cases, surgical intervention may be required to expose the abscess adequately. Some controversy exists over the use of antibiotics, especially respecting the timing of administration, which may depend on the stage of abscessation. Antibiotics commonly recommended include procaine penicillin G at 20,000 U/kg intramuscularly every 12 hours or potassium penicillin G at 40,000 U/kg intravenously every 6 hours, sulfadiazine (or sulfamethoxazole)-trimethoprim, or erythromycin. Rifampin (2.5 to 5.0 mg/kg) given orally every 12 hours is often recommended in combination with penicillin or sulfas. Antibiotic therapy should ideally continue for several weeks.

The prognosis is guarded; some abscesses do not resolve completely with treatment. Some recur when antibiotic therapy is discontinued; others may recur months later. In a few horses, internal abscesses may develop, resulting in

chronic weight loss and sometimes ventral edema, ascites, dyspnea, recurrent colic, exercise intolerance, and recurrent pyrexia, among other conditions. Abortion can also be a sequela.<sup>25</sup> Avoiding contamination of paddocks from a draining lesion and dealing with contaminated bedding appropriately have been recommended. Good fly control can also be beneficial.

## PARASITIC MYOSITIS

### SARCOCYSTIS

*Sarcocystis* spp. are protozoal parasites that have an obligatory two-host life cycle. *Sarcocystis* spp. are found in horse muscle as part of the intermediate host infection. The horse consumes sporocysts with herbage that has been contaminated by carnivore feces. Sporozoites are released and migrate to various sites. Second- or third-generation schizonts develop within muscle fibers as thin-walled cysts. Entry into muscle fibers can result in extensive fiber degeneration and significant enzyme release if a heavy infestation occurs. Enlargement of the cysts over the next 100 days or so can result in further muscle damage and lameness. Four *Sarcocystis* species (*S. bertrami*, *S. equicanis*, *S. neurona*, and *S. fayeri*) have been recognized in horses, although some controversy exists as to whether they are all distinct species.<sup>14,26</sup> A high postmortem prevalence of sarcocysts in muscle sections (especially the tongue), occasional presence of sarcocysts in other skeletal muscle biopsies, and evidence of transplacental infection have been reported,<sup>27,28</sup> suggesting that inapparent infection is probably common. A light and electron microscope study of sarcocysts in the horse has been described.<sup>29</sup>

Some dispute exists as to how heavy an infestation is necessary to cause clinical muscle disease in the horse. Twelve of 91 horses with a history of chronic muscle problems were positive for sarcocysts on muscle biopsy.<sup>28</sup> Separating the group of animals with sarcocysts from others based on laboratory findings, history, or clinical signs was not possible. Weight loss, lethargy, difficulty in chewing and swallowing, generalized muscle weakness, and fasciculations have been reported in one horse with widely distributed sarcocysts, and clinical signs were attributed to the sarcocyst infestation.<sup>30</sup> Chronic illness in an experimentally infected pony also has been reported.<sup>31</sup> A heavy infestation is likely necessary to cause clinical disease.<sup>32</sup>

### TRICHINELLA SPIRALIS

The nematode *Trichinella spiralis* can be found as an encysted larva in a bulging glassy segment of a muscle fiber in horses given feed containing contaminated porcine muscle tissue. Trichinosis is therefore rare. Interestingly, a survey in Serbia found that feeding meat to horses as food refuse was relatively common and may be practiced elsewhere in Europe as well. This observation led the investigators to conclude that surveillance for *Trichinella*, a meat-born parasite, should continue in Europe.<sup>33</sup> Usually, one cyst per fiber is present, and the larva may be up to 100  $\mu$ m long. Degeneration (plus regeneration) may occur in neighboring muscle fibers. The larva can live for many years, but if the parasitized segment degenerates, the larva is exposed and soon dies; this in turn results in an acute, predominantly eosinophilic inflammation.<sup>14,34</sup> The parasitic infection appears to be asymptomatic but may present a human health hazard in countries where consumption of horse meat is common.

**FIGURE 11-11** A horse with postanesthetic myositis of the right gluteal muscles. The severe swelling is notable. The horse recovered fully with supportive care.

## CIRCULATORY PROBLEMS RESULTING IN MYOSITIS

### POSTANESTHETIC MYOSITIS

Postanesthetic muscle damage may occur in 6% of anesthetized horses.<sup>35</sup> Postanesthetic myopathy may be divided into two forms: localized (the more common form) and generalized.

#### PATHOPHYSIOLOGIC CHARACTERISTICS OF LOCALIZED POSTANESTHETIC MYOSITIS

The localized form of postanesthetic myositis is likely a consequence of undergoing anesthesia combined with positioning of the horse during anesthesia with minimal padding (Figure 11-11). Recumbency results in direct pressure damage to the nerves or muscles (or both) or perfusion disturbances resulting in increased pressure within the osteofascial compartments, and local ischemia. In this context, compartment is defined as a muscle or group of muscles enclosed within a low-compliance envelope of fascia and sometimes periosteum.<sup>36</sup> This definition is comparable to compartmental syndrome described in human beings and down cattle. Venous occlusion tends to result in a greater inflammatory response and more extensive fibrous tissue repair than arterial occlusion. Sufficiently high intramuscular pressures have been reported during anesthesia of horses to compromise capillary blood flow and possibly affect neural transmission.<sup>36-40</sup> Postanesthetic compartmental syndrome per se has been reported only rarely in the horse, perhaps because compartmental pressures decrease rapidly when a horse stands.<sup>41</sup>

An increase in the lactate concentration of blood draining from dependent muscle, a significant postischemic hyperemia in dependent muscles, and increases in the plasma concentrations of thromboxane and prostaglandin E<sub>2</sub> have been reported in anesthetized horses. Damage may result from reperfusion of ischemic muscles rather than the ischemia itself. Reperfusion generates strong oxidants, possibly initiating membrane lipid peroxidation and muscle damage.<sup>38</sup>

Risk factors associated with postanesthetic myositis include the weight and fitness of the horse, positioning, padding, duration of anesthesia, hypoxemia, blood pressure, and the type of drugs or anesthetic used.

Postanesthetic myositis has been reported in the upper limb, as well as the dependent limb. Therefore support for the upper limb should be provided in addition to adequate padding. However, even when protective padding is used, hypotension and hypoxemia resulting may predispose horses to postanesthetic myositis.<sup>36,38,42-44</sup> No increase in the incidence of problems is apparent when repeated episodes of normotensive anesthesia are undertaken, even with halothane use.<sup>42</sup> Usually, the practitioner observes clinical signs in the limb that is down (compressed) when in lateral recumbency. In the forelimbs, the triceps, deltoids, and occasionally the brachiocephalic and cranial pectoral muscles tend to be affected. In the hind limbs the biceps and vastus lateralis are usually affected. The flank muscles and masseter muscles may also be involved. Occasionally the upper limb may be affected if its circulation is compromised. The position that appears to provide adequate surgical access to the lower limb with low compartmental and venous pressures in the upper limb is the flexed horizontal forward position (i.e., leg parallel to the floor, fully flexed at the carpus, and pushed gently forward).

When a horse is anesthetized in dorsal recumbency, the gluteal and occasionally the longissimus dorsi muscles tend to be affected. In one study, the adductor, pectineus, and gracilis muscles were involved, a finding attributed to arterial hypotension coupled with partial occlusion of the artery supplying these muscles (the medial circumflex femoral artery), perhaps because of the hind limbs being flexed passively.<sup>45</sup>

### CLINICAL SIGNS

Clinical signs of postanesthetic myositis are normally seen during the initial recovery period but may occasionally be delayed for 1 hour or more. One may first suspect the condition if recovery is prolonged or the horse has repeated unsuccessful attempts to stand. Signs attributable to damage to one muscle group, one peripheral nerve, or mixtures of muscle groups and peripheral nerve or nerves may be visible. Affected muscle groups tend to be hot and swollen. The horse resents palpation and is usually reluctant to bear weight on the affected limb. One may observe signs of severe pain with sweating. Classically, with forelimb muscle involvement, the affected animal stands as if the radial nerve has been paralyzed but can use the extensor muscles. If hind limbs are involved, knuckling of the fetlock may occur; if the quadriceps femoris is involved, the stifle and hock may buckle, and the animal may not be able to rise, especially if both hind limbs are affected. Signs may persist for several days, even in uncomplicated cases.

Raised painful plaques of edematous muscle with or without fore or hind limb dysfunction may be seen. These swellings usually occur over the table contact areas (hip, rib, or facial area) and may be caused by inadequate padding, trauma from positioning devices, or the weight of the patient.<sup>44</sup> Serum CK and AST activities increase in affected individuals, and one may observe myoglobinuria with significant muscle damage.

On occasion, after recovery from general anesthesia, a horse demonstrates considerable discomfort with continued treading of the feet, sweating, holding its limbs (usually the hind limbs) in abnormal positions, and kicking out. The syndromes appear nonresponsive even to large doses of opiate or other analgesics, serum CK activities are not increased

within the subsequent 48 to 96 hours, and no myoglobinuria is observable. These syndromes are assumed to be a form of paresthesia (pins and needles) caused by sensory neuropraxis, and a strong clinical similarity to the condition of postanesthetic neuromyopathy is suggested.

### PATHOPHYSIOLOGIC CHARACTERISTICS OF GENERALIZED POSTANESTHETIC MYOSITIS

The generalized form of postanesthetic myositis may be caused by a condition similar to malignant hyperthermia in human beings and swine. Signs may appear during recovery, with many muscle groups affected independent of positioning. The cause of generalized postanesthetic myositis in horses is uncertain but has been suggested to result from local ischemia that becomes more generalized because of hypotension, sensitivity of muscle cells to anesthetic drugs, depolarizing muscle relaxants (suxamethonium), or a combination of these factors. In two studies that looked at the effect of hypotensive anesthesia, cases of generalized myositis occurred during recovery.<sup>42,44</sup> In vitro examination of muscle using an adapted human contracture test (used for the identification of malignant hyperthermia susceptibility) has shown increased sensitivity to caffeine and halothane in samples taken from certain susceptible Equidae.<sup>46</sup> Given that some of these studies are older, horses with inherited myopathies may have unwittingly been included.

Whether horses with inherited myopathies are more or less prone to malignant hyperthermic events or postanesthetic rhabdomyolysis compared with the general horse population is unknown. Certainly, given the common nature of these disorders, one can be confident in saying that not every horse anesthetized that has an underlying myopathy has a malignant hyperthermic or postanesthetic rhabdomyolytic event. However, in human beings, many different muscle disorders have been associated with an increased chance of malignant hyperthermic event when under general anesthesia. Therefore the potential exists, and inquiring whether a horse has a history of exertional rhabdomyolysis before performing general anesthesia is prudent. If a horse is believed to be at risk, premedicating that horse with dantrolene may be of benefit.

Generalized myositis may occur at any time during anesthesia. The temperature, heart rate, and respiratory rate increase, and muscles may fasciculate and contract. The horse may resist assisted ventilation and appear rigid. Death can occur. Postoperative cases also tend to occur regardless of the length of the anesthesia and positioning. Signs of extreme pain are apparent, and the affected animal is unable to rise. The muscles may be rigid, and excessive sweating usually occurs. Signs of colic with myoglobinuria may be present, as well as fluid disturbances.

One may need to differentiate the condition from postanesthetic myelopathy, in which signs can range from difficulty in standing to paraplegia with flaccid paralysis and analgesia involving the pelvic limbs. In addition, loss of sensation and spinal reflexes over several contiguous segments may occur.

### LABORATORY FINDINGS

Plasma and serum CK, AST, and LDH activities usually increase in both forms of postanesthetic myositis of horses. Increased plasma muscle enzyme activities may help differentiate those animals with overt muscle damage from those with conditions similar to paresthesia (possibly caused by a reduced blood supply to sensory nerve endings). Fluid and electrolyte disturbances may also be present. Hypocalcemia, hypomagnesemia,

hyperphosphatemia, metabolic acidosis, hyperkalemia, and hyperglycemia have been reported and should be treated if present. Myoglobinuria may occur, and renal function may be compromised, necessitating treatment with intravenous fluids, furosemide, and dopamine. Muscle biopsy histologic examination is consistent with rhabdomyolysis.

### TREATMENT

The aims of treatment are to relieve pain, prevent further damage, correct fluid and electrolyte disturbances, and maintain renal function. The added clinical manifestation in some cases is malignant hyperthermia in which muscle contractures cause a rapid increase in body temperature. The treatment usually recommended is similar to that for exertional rhabdomyolysis. If a metabolic acidosis is present, the horse may require intravenous sodium bicarbonate. If the signs are recognized while the horse is anesthetized, one should stop using the anesthetic, whenever possible, and use alternative intravenous agents. If hyperthermia is present the horse should be cooled rapidly, and one should consider administration of fluids and dantrolene intravenously. Initial fluid infusion rates of up to 10 to 20 ml/kg/hour have been recommended, slowing to 4 to 5 ml/kg/hour. Analgesics that have been used include the NSAIDs and opioids. The effect of intravenously administered lidocaine in this scenario has not been evaluated. Diazepam and glyceryl guaiacolate to reduce muscle spasm may be of value, but one should use them with caution because of possible ataxia and therefore increased problems with standing. The horse may require sedation if it is awake and anxious because of the pain. The  $\alpha_2$ -agonists (xylazine, detomidine, romifidine) may provide good sedation and analgesia, but may exacerbate ataxia; promote sweating, hypoinsulinemia, and hyperglycemia; and increase urine output, which may further exacerbate fluid loss. The vasoconstrictive effect of these agents together with their effect on cardiac output may compromise tissue blood flow further. Their use in the more violent cases may be warranted however. Acetylpromazine in combination with opioids may provide good sedation with minimal ataxia, and the vasodilatory effect may help improve tissue flow, provided circulatory volume is maintained and hypovolemia does not occur.

Intravenously and then orally administered dantrolene sodium has been suggested to be beneficial.<sup>47</sup> Dantrolene at 1 mg/kg body mass orally has been used successfully to treat postoperative cases. However, recent work on the pharmacokinetics of dantrolene<sup>46</sup> has suggested that higher doses are likely to be needed to establish and maintain effective blood levels. An intragastric dose of 2.5 mg/kg every hour after a loading dose of 10 mg/kg has been recommended.<sup>48</sup> Alternatively, an intravenous loading dose of 1.9 mg/kg has been suggested to achieve a more immediate therapeutic effect.<sup>46</sup> Dantrolene is not licensed for use in horses, is expensive, and is potentially hepatotoxic. Transient weakness and ataxia have been associated with intravenous administration.

### PREVENTION

Correct positioning to prevent restriction of venous drainage or arterial input and the use of appropriate padding are recommended. Foam padding, for example, has been reported to be inferior to air mattresses or waterbeds.<sup>43</sup> Positioning is important, and various recommendations have been made. For example, the practitioner should elevate the upper limb and reduce pressure on the lower triceps by pulling the leg

forward in a bent position.<sup>40</sup> In lateral recumbency the hind legs should be kept parallel or above parallel to the table and sufficiently separated to promote venous drainage. In dorsally recumbent horses, rather than letting the hind limbs position themselves passively, one should provide support for them in slight extension by a hoist. Problems with hind limb adductor myopathies do not always develop with passive positioning. The practitioner should avoid pulling back the hind limbs. If the hind limbs must be drawn back in full extension, for example, for certain arthroscopic examinations, one should keep the surgical time to a minimum to reduce the risk of quadriceps myopathy. The flexed horizontal forward position, with the uppermost (noncompressed) forelimb parallel to the floor, fully flexed at the carpus, and pushed gently forward, is preferable when the surgeon needs access to the medial aspect of the lower carpus and distal radius.<sup>49</sup>

Withholding grain feed for 48 to 72 hours before general anesthesia may be beneficial. Heavily muscled, Draft-breed, and more athletically fit horses may be at an increased risk for postanesthetic myositis, in particular those with athletic-induced sports injuries. The practitioner should maintain blood pressure at more than 80 mm Hg (mean arterial blood pressure) to maintain muscle perfusion, should minimize halothane use, and may find intraoperative fluids and inotropes valuable.

Prophylactically administered dantrolene has been recommended, especially if the horse has a history of exercise-induced rhabdomyolysis or muscle problems after previous episodes of general anesthesia or in Draft breeds. Various doses have been used. In the United Kingdom, intragastric administration at 2 to 4 mg/kg has been recommended, whereas higher doses (10 mg/kg) have been used in the United States.<sup>50</sup> However, no objective data exist to confirm the efficacy of prophylactic dantrolene administration for prevention of postanesthetic myositis in horses.

### PROGNOSIS

Prognosis depends partially on the extent of the muscle damage, the treatment instituted, and the temperament of the individual. Affected horses often recover completely, especially if the condition is localized to one muscle group. Occasionally the horse may be left with residual muscle atrophy, fibrosis, and scarring. Death can occur with massive areas of ischemic myonecrosis and intrafascicular nerve fiber degeneration post-mortem. Euthanasia may be required on humane grounds in horses that remain recumbent, have severe rhabdomyolysis, or that have uncontrollable pain.

## AORTIC-ILIAC THROMBOSIS

### PATHOPHYSIOLOGY

Predisposing factors and causes of aortic-iliac thrombosis remain unclear but can occur in adult athletes as well as foals.<sup>51-53</sup> Thrombi may result from damage to the vessel intima by migrating *Strongylus vulgaris* larvae or in hypercoagulable states associated with septicemia. Hormonal, nutritional, and mechanical factors, as well as prior infection with *S. equi* subsp. *equi* or equine influenza virus, have also been proposed as predisposing factors to thrombus formation.<sup>52,54-56</sup> The internal iliac arteries are bound more closely to fascia than many other arteries. This, coupled with the large forces generated during movement, could increase the risk of injury to these vessels.

## CLINICAL SIGNS AND LABORATORY FINDINGS

Weakness of the hind limbs at rest or after exercise, lameness, ataxia, collapse and in one case failure to ejaculate have been reported.<sup>52</sup> After exercise in affected animals, ischemia of the muscle usually occurs because of circulatory interference. The ischemia is usually reversible because the blood flow may be adequate when at rest or at light work. The clinical signs vary in severity according to the degree of vascular occlusion, the vessels affected, and the extent of collateral circulation. The lameness tends to become more severe as exercise continues. Mild cases may be missed, however, because the horse appears normal when pulled up after a disappointing performance. Clinical signs may include poor performance, intermittent hind limb lameness, transient lameness or weakness with exercise, a tendency to drag the toe and occasionally knuckling over, and gradual shortening of the stride leading to a transient inability to move. A peracute condition with paraplegia, shock, and death also has been recognized.

Hind limbs may be affected, although usually one more than the other. After exercise the superficial veins on the more affected limb may appear collapsed (because of delayed filling) compared with the distended vessels on the more normal limb. The superficial veins of the affected limb or limbs may take up to 90 seconds to fill after intense exercise compared with approximately 10 seconds in normal horses. The affected limb often feels cooler than expected, especially around the gaskin, and may not sweat. One may feel a reduced digital pulse. The animal may sweat profusely on the body, head, and neck and sometimes cow-kicks or shakes the affected limb (perhaps because of paraesthesias following reduced blood supply to sensory nerve endings). Full recovery tends to occur within 20 to 30 minutes. On palpation of the peripheral pulses at rest, one may detect abnormalities, including a flattened, weak, and prolonged contour to the pulse distal to the site of obstruction, whereas proximally the pulse may be normal or increased in strength. Alternatively, certain pulses may be absent.

Aortic-iliac thrombosis has been reported in males and females, although a greater incidence of clinical problems has been reported in males. One of the reasons for this difference in incidence may be a more efficient collateral circulation in females. The mean age of affected animals was 5.2 years in one study. Plasma and serum muscle enzyme activities are usually within normal limits before and after exercise. In severe cases with significant muscle damage, however, increases in CK have been reported.<sup>52</sup>

On postmortem examination, affected vessels tend to be enlarged, and a large thrombotic mass is usually present at the aortic quadrifurcation (Figure 11-12) that may be attached to, and therefore possibly originate from, organized masses in the internal and external iliac arteries. These may extend to the bifurcation of the popliteal artery, but rarely do they extend far into the tibial arteries or the muscular branches of the femoral artery. Histologically, affected muscles show signs of ischemia. Damaged fibers and supporting structures tend to be remodeled with little sign of inflammation or fibrosis.<sup>51</sup>

## DIAGNOSIS

Diagnosis of aortic-iliac thrombosis is based on clinical signs and palpation of the thrombus per rectum or ultrasonic demonstration of the thrombus. Nuclear scintigraphy may also be used.<sup>53</sup> Abnormalities such as decreased arterial pulse or an unusual firmness of a vessel may easily be missed during rectal

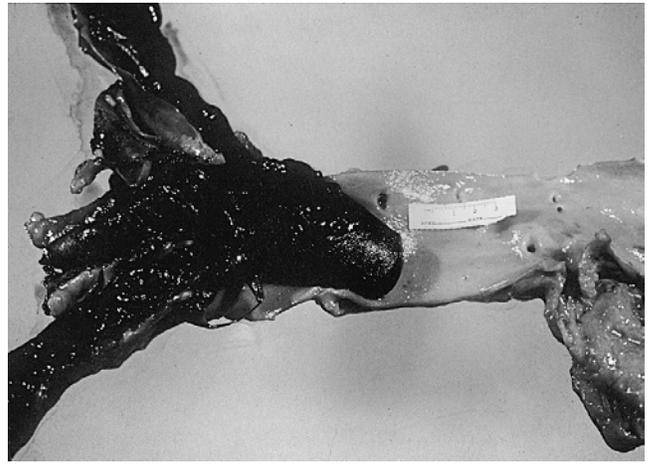

FIGURE 11-12 Aortic-iliac thrombosis.

examination. The obstruction may be peripheral resulting in an increase in pulse quality proximally. Ultrasonography is therefore the definitive method for diagnosis. A linear array ultrasound probe with a frequency of 5.0 or 7.5 MHz has been recommended.<sup>56,57</sup> Differential diagnoses include exertional rhabdomyolysis, cervical vertebral malformation, and degenerative joint disease of the sacroiliac, lumbosacral, or coxofemoral or distal limb joints.

## TREATMENT

Diagnosis of aortic-iliac thrombosis rarely occurs before more than 75% of arterial flow has been compromised. As a result, therapy is difficult and often aimed at salvage rather than return to athletic function. Thrombolytics including sodium gluconate and recombinant tissue plasminogen activator have been used. Sodium gluconate at 450 mg/kg body mass by slow intravenous infusion has been recommended to treat horses with aortic-iliac thrombosis,<sup>58</sup> but no evidence exists that the drug has any effect on a mature thrombus.<sup>52</sup> Prednisolone sodium succinate (100 mg 30 minutes before administration of sodium gluconate) may help eliminate the systemic reactions frequently associated with this drug.<sup>51,52</sup> Aspirin (60 grains orally daily or every other day) is often recommended because of its antiplatelet actions that may prevent thrombus propagation. Heparin and low-molecular-weight dextran have been recommended for similar reasons. Other suggested protocols include monthly administration of ivermectin (Eqvalan, MSD-AGVET) and twice-daily oral doses of phenylbutazone at 2.2 mg/kg body mass for 3 months.<sup>56</sup> Improvement observed in some treated horses may be the result of the development of effective collateral circulation over time. Prognosis for severely affected horses is poor, and a hereditary predisposition has been suggested,<sup>51</sup> although little supporting evidence exists.

In humans, direct infusion of fibrinolytic agents into the body of the thrombus via an indwelling arterial catheter has been efficacious. The relative maturity and chronicity of thrombi frequently identified in affected horses suggests that mechanical clot removal may be more likely to be successful than this type of antifibrinolytic therapy. One horse was successfully treated with balloon catheter thrombectomy. The combination of surgical and medical therapy in this horse resulted in significant improvement, although a thrombus obstructing approximately 20% of the diameter of the arterial

lumen remained present in the left external iliac artery when the horse was reexamined 8 weeks after surgery.<sup>59</sup>

## ☞ NUTRITIONAL PROBLEMS ASSOCIATED WITH MUSCULOSKELETAL DISORDERS

### VITAMIN E, SELENIUM, AND EXERTIONAL RHABDOMYOLYSIS

Vitamin E and selenium are powerful antioxidants that are essential for normal muscle function and deficiencies associated with neuropathy and myopathy. Historical studies examining vitamin E or selenium (or both) may be confounded by inclusion of animals with inherited myopathies. Although deficiencies in vitamin E have been described and will be summarized here, notably the optimal level of vitamin E for horses has not been determined, and toxicity has not been described, which may explain why some studies have found a benefit to supplementation while others have not.<sup>60-69</sup> A complex interaction likely exists between low or marginal vitamin E, selenium, electrolyte balance, and optimal muscle function (affected by glycogen concentration and fitness). Further, horses with heritable errors in muscle function may have altered basal needs for vitamin E, selenium, or electrolytes.

Disorders that have been attributed to dietary deficiencies of vitamin E and selenium include equine motor neuron disease, equine degenerative myelopathy, nutritional myodegeneration (white muscle disease), neonatal rhabdomyolysis, a predisposition to postanesthetic myopathy, and adult cases of exertional rhabdomyolysis. Severe masseter myonecrosis and tongue myopathy have also been attributed to selenium and vitamin E deficiency.<sup>68</sup>

Supplemental vitamin E may be beneficial in horses with underlying myopathies or healthy horses as an additional source of antioxidants in the diet. In fact, horses in heavy work do appear to need more vitamin E in their diet than many commercial feeds provide.<sup>69</sup> However, how chronic low vitamin E or selenium intake may affect performance in horses predisposed to rhabdomyolysis or in healthy horses is unknown. In horses with measured low levels of vitamin E or selenium, supplementation should always occur, and other causes for myopathy should be ruled in or out. In addition, it can be argued to increase vitamin E intake in horses with chronic exertional rhabdomyolysis and healthy horses performing hard work, even though the scientific work to uphold this recommendation has not been performed. Supplementation with selenium without serum measurements is not recommended because of the risk of toxicity.

### ROLE OF VITAMIN E AND SELENIUM IN MUSCLE FUNCTION

GSHPx, a selenium-containing enzyme, and vitamin E help protect cells against free radicals,<sup>70</sup> which are formed by the reduction of molecular oxygen during normal oxidative processes. A free radical (or reactive oxygen species) is any chemical substance that has an unpaired electron in its outer orbit. The presence of this electron makes the free radical inherently unstable. Superoxide radicals, for example, in solution form hydrogen peroxide by dismutation. The superoxide radical can also react with hydrogen peroxide and hydrogen ions to

produce the potent hydroxyl radical (HO<sup>•</sup>). The hydroxyl radicals can, in turn, react with almost any organic molecule to produce other organic radicals via chain reactions.

Free radical reactions are responsible for a significant number of key biochemical events, including mitochondrial electron transport, prostaglandin synthesis, phagocytosis, and degradation of catecholamines. Under controlled circumstances, free radicals are therefore necessary for life, but when uncontrolled, they may result in several degenerative disease processes. For example, free radicals can cause irreversible denaturation of essential cellular proteins and lipid peroxidation of exposed polyunsaturated fatty acids within the phospholipid structure of cellular membranes, resulting in structural damage and the formation of further hydroperoxides. The cellular membrane damage may, in turn, result in the release of liposomal enzymes and further damage. The free radicals can also cause damage to hyaluronic acid and collagen, resulting in enhanced prostaglandin production, and can uncouple oxidative phosphorylation and inactivate certain enzymes.

A system of natural antioxidant defenses is present within the body to counteract such free radical induced damage, including GSHPx and vitamin E. GSHPx acts to reduce the production of hydroxyl radicals by reducing hydroperoxides to alcohols as part of a cyclic system re-forming glutathione. Within red blood cells the enzyme acts as an integral part of the system, protecting against the conversion of hemoglobin to methemoglobin by hydroperoxides. Vitamin E acts as a scavenger of free radicals, and vitamin C may assist by reducing the tocopheroxyl radicals formed by this scavenging. In addition, vitamin E helps block lipid peroxidation and may also form an important part of the membrane structure because of its interaction with membrane phospholipids. Other naturally occurring antioxidant defenses include chelators that bind to and decrease the concentrations of transition metals (e.g., iron).

Vitamin E and selenium deficiencies have been implicated in muscular problems in several species, especially sheep, cattle and pigs.<sup>34,71,72</sup> In the horse, myopathy or white muscle disease attributed to vitamin E and selenium deficiency has been reported in foals from birth to 9 months of age.<sup>73</sup> In older animals, maxillary myositis, polymyositis, and dystrophic myodegeneration have also been attributed to such deficiencies.<sup>74</sup> In foals the syndrome apparently has been well documented in geographic areas of known selenium deficiency and inadequate vitamin E intake,<sup>75</sup> although many foals raised in such areas may have decreased GSHPx activities and low blood selenium concentrations without being affected.<sup>76</sup>

Two common sources of free radicals during exercise are increased activity of xanthine oxidase during anaerobic degradation of purine nucleotides and the partial reduction of oxygen during oxidative phosphorylation within mitochondria. The precise mechanisms leading to muscle damage and fatigue during exercise are uncertain, although free radicals or reactive oxygen species possibly play an important role. After strenuous exercise, especially under conditions of high heat and humidity, free radical production may exceed the capacity of the natural defense mechanisms of the cells, leading to muscle cell damage.<sup>77</sup>

Vitamin E has an apparent protective effect on experimental damage to rat skeletal muscle and may act via a non-antioxidant mechanism, with the hydrocarbon chain being an important mediator of the effects seen.<sup>78</sup> An apparent protective

effect occurs from supranormal extracellular vitamin E concentrations on normal rat muscle, and exacerbation of exercise-induced damage to skeletal muscle by vitamin E deficiency has been reported. Nutritional modification of skeletal muscle, perhaps by reduction of the unsaturation of skeletal muscle membranes or enhancement of the antioxidant status of muscles, or a combination of both, may help prevent or reduce calcium-induced skeletal muscle damage.<sup>79</sup> Artificial methods to reduce oxidant damage during exercise include the administration of exogenous sources of naturally occurring antioxidant defenses (e.g., vitamin E) and limiting the formation of free radicals by minimizing the formation of inosine monophosphate from purine degradation during exercise.

Type 1 and type 2A fibers are most likely to participate in excess free radical formation because they are the most oxidative fibers and contain the most intracellular lipid stores. Selective type 1 fiber degeneration is found in nutritional myopathies of horses, sheep, and pigs that are responsive to vitamin E and selenium.<sup>80</sup>

Some differences in the pathologic processes exist between the equine conditions associated with vitamin E and selenium deficiencies and those in other species. Vitamin E deficiencies in calves and chicks show mitochondrial alterations early in the condition. In vitamin E-deficient and selenium-deficient lambs and chickens, early changes occur in small vessels, connective tissue, and neuromuscular elements. In the horse the changes appear to affect the myofibrils first. Morphologic changes in mitochondria and the sarcoplasmic reticulum seem to occur only in fibers with advanced lesions.<sup>67,81</sup>

Factors that may predispose horses to vitamin E and selenium deficiency include rancid feed, the addition of fish or plant oil to feed, prolonged storage of grain (e.g., dry grain loses tocopherol activities far more slowly than moist grain), poor-quality hay or hay stored for prolonged periods, and lush pastures.<sup>2</sup> Pastures associated with acid, poorly aerated soils, soils with a high sulfur content, or volcanic rock are more likely to be selenium deficient. Cases of deficiency are more likely to occur in areas with low (<0.05 ppm) plant selenium content. Dietary levels of selenium may be misleading, however, not only because other factors are likely to be involved in the pathogenesis of the condition but also because the biologic availability of the various types of selenium have not been determined. In addition, high but nontoxic levels of copper, silver, tellurium, and zinc can interfere with selenium availability and therefore induce typical lesions in animals on diets containing amounts of selenium usually considered to be adequate.

Other factors such as stress (including management and environment) and increased physical activity may be important for expression of clinical signs in the face of a deficiency or near deficiency and may explain why two similar groups of animals receiving the same dietary intake can show different clinical responses to similar dietary amounts of vitamin E or selenium or both. Acute selenium toxicity in the adult horse may also be associated with myodegeneration plus pulmonary edema, gastroenteritis, hepatic degeneration, and necrosis.<sup>2,67</sup>

## EQUINE MOTOR NEURON DISEASE

Equine motor neuron disease is a disorder in horses characterized by neurologic and muscular dysfunction and muscle wasting. Initially the disorder was thought to have an inherited component or a specific geographic distribution.<sup>82,83</sup> Equine motor neuron disease is now accepted as being caused by chronic

(6 to 24 months or more) vitamin E deficiency and has been reproduced experimentally.<sup>84,85</sup> Chronic vitamin E deficiency leads to chronic oxidative stress and resulting death of motor neurons and myopathy. Some horses exhibit equine motor neuron disease as a primarily neurogenic disorder, and others have pathologic conditions of the muscles and nerves. The disorder is also discussed in the chapter on neurologic diseases.

Clinically, affected horses exhibit various signs depending on the stage of the disease. Early complaints include weight loss and muscle atrophy (Figure 11-13). As the disease progresses, gait abnormalities become evident. The muscles of posture are primarily affected. The horse stands with a base-narrow stance, frequently shifts weight between legs, and may stand with the tail elevated, which progresses to tremors when the horse stands still. At the walk or trot, the gait initially appears normal despite the return of tremors when the horse stands still. Some horses stand with the head low, apparently too weak to hold it in an elevated position. The penis may be partially prolapsed. Affected horses may progress to recumbency or may stabilize without further progression. Ocular manifestations include a characteristic fundic abnormality with a mosaic pattern of dark brown to yellow brown pigment deposited in the tapetal zone and a horizontal band of pigment at the junction of the tapetum and nontapetum. This abnormal pigmentation is associated with chronic oxidative injury resulting in lipid peroxidation of the retina.<sup>82</sup>

Horses with equine motor neuron disease may have mild elevations in CK and AST activity. Complete blood counts are usually normal. Cerebrospinal fluid may have mild increases in protein and CK activity. Muscle biopsy may reveal neurogenic and myogenic atrophy.<sup>86</sup> Biopsy of the ventral branch of the accessory nerve reveals degeneration of the myelinated axon of the nerve and is present in acute and arrested cases. Muscle and nerve biopsies may yield important information. Vitamin E levels in affected horses are significantly decreased (too low to read to 100 µg/dl; normal 400 µg/dl). Often, multiple animals housed under identical conditions have similarly low vitamin E levels, but only one or a small number of horses may be demonstrating clinical signs. All horses should receive oral supplementation of vitamin E at 2000 to 5000+ IU/day. Horses eating a vitamin E-deficient diet for many months have consistently low serum vitamin E concentrations that

**FIGURE 11-13** A horse with equine motor neuron disease. The generalized loss of muscle mass, the base-narrow stance, and raised tail head are notable.

may take weeks to months to return to the normal range even with supplementation of the grass hay diet with commercial grains. Horses displaying clinical signs at the time of diagnosis are unlikely to regain normal function. Once serum vitamin E levels are normal, aggressive vitamin E supplementation is no longer necessary. However, one should optimize daily intake to prevent future deficiency.

Low vitamin E intake is most common in horses eating hay and living without access to green pasture. Hay stored for long periods has less vitamin E than freshly cut hay. Many grain supplements have minimal quantities of vitamin E. Horses fed a grass hay diet without fresh pasture should have their vitamin E levels monitored and supplementation altered appropriately.

### NUTRITIONAL MYODEGENERATION/WHITE MUSCLE DISEASE

Vitamin E or selenium deficiency and the resulting muscle disorder are often described in the literature as a muscular dystrophy. The term is inappropriate considering that muscular dystrophy is defined in human medicine as a group of progressive genetically determined primary myopathies. They are usually not present at birth, and neural and vascular components are not involved initially. Regeneration of muscle cells is absent or inadequate, and replacement of muscle cells with fat and fibrous tissue occurs, which differs from the nutritionally associated disease in horses, and the term nutritional myodegeneration should be used.

#### CLINICAL SIGNS AND LABORATORY FINDINGS

Clinical signs and laboratory findings in horses with nutritional myodegeneration (NMD) vary depending on distribution of the muscular lesions and the extent of damage. Signs are seen most commonly in animals less than 2 months of age but may occur in any age horse. Differentials for NMD include atypical myoglobinuria, botulism, cerebellar disease, rhabdomyolysis, muscular dystrophy, spinal cord disease, meningitis, tetanus, dysphagia caused by cleft palate, HYPP, and cardiac defects leading to respiratory failure (Box 11-6). In severe cases, death may occur peracutely from a fatal arrhythmia, diaphragmatic failure, or after a few hours from exhaustion and circulatory collapse. The myocardium, diaphragm, and respiratory muscles are usually involved, leading to heart failure, dyspnea, and pulmonary edema.<sup>87</sup>

In less severe cases, clinical signs can include dysphagia, weakness, stiffness, and lethargy. Body temperature can vary from subnormal to supernormal. Affected horses may become recumbent and unable to rise and hind limb muscles may be sore upon palpation. Dysphagia may be the first sign noted because of involvement of the tongue and pharyngeal and sometimes masticatory muscles, and development of aspiration pneumonia may occur. Regurgitation, starvation, and ptyalism are other possible complications. If the heart is involved, tachycardia, arrhythmias, systolic murmurs, and respiratory distress are noted. Myoglobinuria has been reported in several cases. A swollen tongue and tachypnea are unusual presenting signs. A 10-month-old aborted fetus with histologic lesions typical of this condition has been reported.<sup>76</sup> No gender or breed predilection has been found. Recovery can occur within days or weeks of the presenting signs.<sup>76</sup> Signs may occur in an individual animal or several animals within a group.

#### BOX 11-6

### DIFFERENTIAL DIAGNOSIS OF NUTRITIONALLY RELATED MYODEGENERATION

- Atypical myoglobinuria
- Botulism
- Cerebellar diseases
- Colic
- Equine motor neuron disease
- Equine rhabdomyolysis syndrome
- Medullary diseases, such as herpesvirus type 1 and myelitis
- Muscular dystrophy
- Purpura hemorrhagica
- Rabies
- Septic polyarthritis
- Spinal cord diseases
- Suppurative meningitis
- Tetanus
- Tick paralysis
- Trauma
- Various causes of dysphagia (e.g., cleft palate, ulcers, and peripheral damage to certain cranial nerves)
- Various causes of dyspnea (e.g., pneumonia and cardiac disease)

In the acute form, AST and CK activities are elevated. In the recovery stages the values may be increased only slightly or may be within the normal range. Increased CK and AST activities have also been found in approximately 25% of the mares of affected foals and in 20% of clinically normal foals in the same stable suggesting the existence of subclinical lesions.<sup>88</sup> Because selenium is incorporated into erythrocytes during erythropoiesis, the GSHPx activity of red blood cells may be a better indicator of long-term selenium status than serum selenium values. Low GSHPx, selenium, or vitamin E values have been reported in affected animals. In the author's laboratory, for example, GSHPx values of greater than 30 IU/ml of red blood cells would be expected in stabled animals fed a balanced diet. Values greater than 25 IU/ml may be expected in grazing animals with adequate intake and values less than 20 IU/ml are associated with deficient intake. Serum vitamin E concentrations of at least 400 µg/dl are considered normal. Concentrations between 200 and 400 µg/dl are considered marginal, and below 200 µg/dl suggests deficiency. Reference values vary according to the laboratory. One should take care with collection of samples, especially for vitamin E determination, because contact with rubber may interfere with analysis and heat may decrease values. Daily recommendations for vitamin E in foals are at minimum 2 to 6 IU/kg body weight and may be increased in a foal that appears to have NMD. Single-serum sample assays cannot be used as an indicator of vitamin E status in individual horses because of the high variability in values between animals and within the same animal.<sup>89</sup> Normal vitamin E concentrations have been reported in some affected foals, possibly reflecting recent ingestion of colostrum. Many of the dams of these foals had low serum vitamin E concentrations (<200 µg/dl), and possibly the selenium levels of affected foals were low before suckling. Mares

should be supplemented with 1 mg of selenium orally per day in deficient areas.<sup>66</sup>

In foals with evidence of nutritional myodegeneration a full hematologic and clinical chemistry profile with a urinalysis is advisable. Laboratory analyses may reflect concurrent diseases such as failure of passive transfer, sepsis, pneumonia, or rhabdomyolysis. Electrolyte disturbances associated with rhabdomyolysis can include hyperkalemia, hyponatremia, hypocalcemia, and hypochloremia. Such findings may be associated with a poorer prognosis.

Some horses with NMD exhibit acute or chronic masseter myonecrosis or myodegeneration.<sup>90</sup> Acutely, horses show severely swollen and painful masseter muscles and difficulty eating or opening their mouths. Chronic cases are identified most often in young horses that exhibit rapid weight loss after weaning. On physical examination the masseter muscles are atrophied bilaterally, and it is impossible to open the mouth because of chronic fibrosis of the muscles. Serum activity of muscle enzymes is usually increased in affected horses. Whole blood selenium and glutathione peroxidase activity are usually below normal limits.

### POSTMORTEM FINDINGS

Postmortem examination of neonatal foals with peracute white muscle disease reveals few macroscopic lesions. In acute cases, muscle may appear pale and streaks may be present, representing areas of coagulative necrosis next to less affected tissue. All muscle groups of the pelvic and thoracic limbs are commonly affected. The muscles of mastication, diaphragm, tongue, pharynx, and cervical musculature are commonly involved. Distribution of lesions is usually bilateral and symmetric. In subacute cases, one may observe yellow-white streaks in the heart and muscle, representing calcification.<sup>13</sup> Steatitis, yellow fat deposits, and fat necrosis have also been described in some but not all cases.<sup>76</sup> Typical histologic findings observed at various stages of NMD have been described. During the first few days, extensive floccular, granular, and severe hyaline degeneration of myofibers occurs. After approximately 1 week, phagocytosis of necrotic tissue occurs with endomysial thickening caused by edema, mononuclear infiltration, and proliferation of fibroblasts. By 2 weeks, epimyseal connective tissue has proliferated. Early regenerating fibers may coexist with signs of myodegeneration. Histologic lesions in horses with masseter myodegeneration may range from acute to subacute degeneration, with regenerative changes accompanying ongoing degeneration, to chronic degeneration with fibrotic replacement of muscle tissues. Affected horses may have lesions in skeletal and cardiac muscle as well.<sup>90</sup>

### DIAGNOSIS AND TREATMENT

Diagnosis is made based on clinical signs, AST and CK activities, decreased blood selenium, GSHPx or vitamin E values (or both), or response to treatment. Reduction of physical activity and prompt administration of vitamin E and selenium usually are recommended. Ideally, mares are tested for vitamin E and selenium, and only supplemented as necessary to avoid toxicity. If needed, 1 mg of selenium per day or 600 to 2000 IU of vitamin E (or both) for a 500 kg horse is recommended for mares during gestation. In affected foals, selenium can be given by deep intramuscular injection at a dose of 0.06 mg/kg body weight (2 to 3 mg/45 kg of body weight).<sup>91</sup> The pectoral muscles are recommended to avoid making the neck sore, which would discourage the foal from

nursing. Vitamin E concentration in many commercial, injectable preparations is too low to be used therapeutically. Therefore higher-concentration (300 IU/ml) preparations or oral therapy is recommended at 2 to 10 IU/kg daily. Aggressive daily oral supplementation of vitamin E coupled with a single intramuscular injection of selenium may be the best route of therapy when it is unknown whether low vitamin E or selenium is the cause of NMD in a particular case. Nasogastric feeding or feeding from a low bowl is preferable in dysphagic, anorectic, or recumbent foals. Other concurrent disorders such as pneumonia and sepsis should be treated appropriately. Prognosis for foals with NMD is guarded, especially if treatment has been delayed, signs are severe, or if complications are present. Prognosis also seems to be less favorable in animals with acid-base and electrolyte disturbances.

### PREVENTION

Fresh pasture is typically associated with adequate vitamin E intake, although low vitamin E has been documented in horses on pasture in Europe.<sup>92</sup> Selenium status appears to be more dependent on access to pasture and geographic locale. Only limited amounts of selenium cross the placenta, which may explain why clinical cases may occur in offspring of supplemented mares.<sup>13,93</sup> The milk from mares that have been supplemented appears to contain more selenium than milk from unsupplemented animals, but the amount present is small because selenium is not concentrated in milk. Organic selenium supplementation appears to be more beneficial than inorganic. Therefore, although many authorities recommend, especially in deficient areas, that mares be supplemented from late gestation through lactation, others prefer to supplement the foals at birth, 2 weeks, and 6 weeks later.<sup>76,93</sup> This supplement action may not prevent the cases seen at birth or in the first few days of life. Other researchers recommend that, in problem areas, a selenium injection be given at birth and then every 2 to 3 months during the first 6 months of life.<sup>2</sup> In pigs, selenium may be teratogenic. Teratogenesis has not been observed in mares, but one recommendation is that selenium injections not be given early in a pregnancy. One must take special care with selenium administration because toxicity can occur. The single minimal lethal dose of oral sodium selenite is 3.3 mg/kg in the adult horse and results in a variety of clinical signs, including severe dyspnea, incoordination, diarrhea, recumbency, and death within a few hours. One should not expect increases in GSHPx activity in the blood until 2 to 3 weeks after selenium supplementation. GSHPx values tend to plateau before toxic levels of selenium are reached, and several months may pass before levels decrease after cessation of supplementation.

### ELECTROLYTE DEPLETION

Alterations in the intracellular or extracellular concentrations of electrolytes can occur in response to dietary deficiency and sweat losses or as a normal response to high-intensity exercise. The best way to assess the total-body level of electrolytes is to use fractional urinary excretions.<sup>61,94,95</sup> Table 11-3 lists recommendations for correcting abnormal dietary electrolytes. A table of fractional excretions for potassium, chloride, phosphorus, and calcium is provided in the chapter on Disorders of the Urinary System. For example, in endurance exercise, horses may lose significant amounts of sodium, potassium, and chloride in sweat, which may contribute to fatigue,

TABLE 11-3

**Examples of Supplementation Given to 400- to 500-kg Horses Based on Fractional Electrolyte Excretion Test Results**

FE Values	Supplementation
Low Na <sup>+</sup>	2 oz (56 g)/day NaCl
Low Na <sup>+</sup> and K <sup>+</sup>	2 oz (56 g) NaCl plus 10 oz (28 g) KCl/day for 2 weeks, then 2 oz (56 g) NaCl/day
High PO <sub>4</sub>	Decrease bran intake if horse is fed, plus 2 oz (56 g) CaCO <sub>3</sub> /day or alternative source(s) of calcium
High Na <sup>+</sup>	Lower Na <sup>+</sup> intake (e.g., change source of hay if grown near the coast)

Data from Harris P, Colles C: The use of creatine clearance ratios in the prevention of equine rhabdomyolysis: a report of four cases, *Equine Vet J* 20:459, 1988.

FE, Fractional electrolyte; CaCO<sub>3</sub>, Calcium carbonate; K<sup>+</sup>, potassium; KCl, potassium chloride; Na<sup>+</sup>, sodium; NaCl, sodium chloride; PO<sub>4</sub>, phosphate.

Normal values: FE<sub>Na<sup>+</sup></sub> = 0.04-0.8; FE<sub>K<sup>+</sup></sub> = 35-80; FE<sub>PO<sub>4</sub></sub> = 0-0.2

exertional rhabdomyolysis, and synchronous diaphragmatic flutter. During anaerobic exercise, cellular acidosis occurs because of incomplete oxidation of pyruvate and the resulting accumulation of lactate. Volume depletion and poor circulation to muscle exacerbate acidosis. Systemic acidosis increases the serum fraction of ionized calcium and induces extrusion of potassium from muscle cells,<sup>96</sup> which may lead to changes in the action potential across the sarcolemma.

Aside from its role intracellularly in calcium-magnesium ATPase, extracellular magnesium influences muscle cell function. Extracellular magnesium concentration is inversely proportional to acetylcholine concentration at the neuromuscular junction; therefore small changes in the serum concentration of magnesium reflect proportionately large shifts in whole-body magnesium levels. Low blood levels of magnesium lead to increased membrane irritability and dysfunction of many enzymes necessary for protein, carbohydrate, and lipid metabolism. The most dramatic example of hypomagnesemia is grass tetany, which occurs in cattle grazing magnesium-deficient pasture.<sup>97</sup> Whole-body calcium balance is also important in muscular function, and hypocalcemia can be life threatening in most species. In horses, hypocalcemic tetany may be associated with blister beetle toxicosis, heavy lactation, intestinal disorders, endurance exercise, and malnutrition.<sup>96</sup>

Sodium, chloride, potassium, calcium, and magnesium play key roles in muscle fiber contractility and irritability. Therefore small imbalances may lead to muscle dysfunction and possibly exertional rhabdomyolysis. Diagnosis of whole-body electrolyte deficits can be difficult to confirm because of the rigorous homeostatic mechanisms in place that serve to maintain serum concentrations. Therefore a lack of correlation exists between intracellular ion concentrations and serum ion concentrations. In addition, electrolyte balance may shift in the body as a direct response to disease processes. For example, a whole-body deficit of potassium may exist, but

plasma potassium may be normal because of efflux of potassium from damaged or acidotic muscle.<sup>98</sup>

Kinslow, Harris, Gray, et al.<sup>99</sup> performed one study examining the role of total body electrolyte balance and its effect on exertional rhabdomyolysis in 1995. The authors followed four mature Thoroughbred mares through their estrous cycles. Group mean percentage fractional excretion of electrolytes in urine showed cyclical trends that appeared to fluctuate in relation to the stage of the estrous cycle. They saw large increases in the urinary excretion of sodium, calcium, and magnesium in samples collected during the period from 2 days before to 4 days after estrus. The authors found significant correlations in individual animals between low progesterone concentrations and 24-hour fractional excretions of sodium, potassium, chloride, calcium, and phosphorus and between serum estradiol 17 $\beta$  and calcium, magnesium, and chloride. These results suggest that ovarian steroid hormones may exert an influence on urinary excretion of electrolytes in mares. Therefore estrous cycle-induced losses of sodium, calcium, and magnesium in mares consuming a diet marginal or deficient in electrolytes could predispose them to exertional rhabdomyolysis.

To examine the effect of total-body potassium on exertional rhabdomyolysis, Bain and Merritt<sup>100</sup> measured potassium concentrations within red blood cells and plasma in Thoroughbred horses with and without exertional rhabdomyolysis. The authors found that in fillies with exertional rhabdomyolysis, potassium concentration within red blood cells was lower than that of controls within 48 hours after an episode of exertional rhabdomyolysis. Whether decreased red blood cell potassium is an inciting cause of exertional rhabdomyolysis or results from exertional rhabdomyolysis is unknown. Beech and Lindborg<sup>101</sup> did not repeat these findings; they found no difference in red blood cell potassium concentration in horses with and without exertional rhabdomyolysis. However, the authors did find a significantly lower concentration of muscle potassium on a dry weight basis in horses with exertional rhabdomyolysis. Unfortunately, lower concentrations of muscle potassium did not correlate with the histologic appearance of the muscle. The authors concluded that low red blood cell potassium concentration may not be a valid indicator of reduced muscle potassium, and they did not associate potassium concentration with a predisposition for exertional rhabdomyolysis.

A study using potassium-depleted horses further clouds the role of potassium in exertional rhabdomyolysis.<sup>102</sup> In this study the authors depleted healthy horses of potassium by withdrawing feed and by administering sodium bicarbonate and furosemide. The result was decreased plasma potassium (2.9  $\pm$  0.3 mEq/L, treatment group; 3.3  $\pm$  0.5 mEq/L, control), chloride, calcium, and magnesium compared with control horses. Red blood cell potassium concentration remained unchanged. A significant increase in CK activity occurred in the potassium-depleted horses compared with controls 240 minutes after exercise (296  $\pm$  211 U/L, potassium depleted; 86  $\pm$  20 U/L, control). After exercise, three of the six horses developed diaphragmatic flutter, and two horses had CK activity beyond the normal range (685 U/L and 1374 U/L), and one horse was reported to walk with a stilted gait after exercise. The authors postulated that potassium depletion may play a role in exercise-induced muscle damage but could not conclude that it was the sole cause of increased serum CK activity. Unfortunately a similar study has not been performed in horses with underlying myopathies such as RER or PSSM to

determine if potassium depletion influences rhabdomyolysis in a susceptible population.

Harris and Snow<sup>64</sup> also investigated the role of electrolyte imbalance in the pathophysiologic features of exertional rhabdomyolysis in 1991. The authors found that 100 of 144 Thoroughbred horses with exertional rhabdomyolysis had fractional excretions of electrolytes outside the normal range. Of those horses with abnormal fractional excretions, 72 of 100 responded favorably to additional electrolytes in their diet. However, the normal ranges for fractional excretions used in this study were narrower than other published normal ranges, and other investigators have not duplicated the authors' results.<sup>97</sup> The intermittent nature of exertional rhabdomyolysis in racehorses also makes the verification of a real response to therapy difficult to confirm.

One must consider the relative concentration of electrolytes in the diet when examining their influence on exertional rhabdomyolysis. Poorly balanced electrolyte supplements may exacerbate dietary deficiencies of other ions. For example, high concentrations of serum potassium may aggravate the effects of low serum calcium, resulting in muscular hyperactivity.<sup>103</sup> Such increased levels of serum potassium are found during normal exercise. In 1998, Harris and Colles<sup>104</sup> described a case study that may support this theory. In this study, low dietary calcium and increased phosphate excretion were found in two of four horses experiencing exertional rhabdomyolysis. Urinary clearance ratios were low for potassium in one case and low for sodium in another. All horses were reported to improve with dietary changes, according to the investigators.

Electrolyte balance within the body and interactions between the major electrolytes play important roles in normal muscular function. In healthy horses, imbalances and deficiencies may occasionally cause muscular dysfunction. The fractional electrolyte test is the best test available to assess electrolyte state but must be applied and interpreted with care,<sup>105</sup> and the different feeding practices among countries may mean that electrolyte supplementation based on the fractional electrolyte test may have more or less relevance. In horses predisposed to exertional rhabdomyolysis, identical imbalances or deficiencies may lead to more severe rhabdomyolysis because of preexisting abnormalities in muscular function.

## **MUSCLE WASTING WITH MALIGNANT DISEASE/CACHECTIC ATROPHY**

Because of a combination of cachexia, malnutrition, disuse, infection, and old age, muscle weakness and occasionally muscle necrosis may develop with malignancies involving other body systems.

## **OVEREXERTION**

Overexertion may be defined as physical exertion to a state of abnormal exhaustion. Many horses willingly work to a point at which they are too exhausted to go on. If a horse is worked to a point of exhaustion, especially in an environment of heat and high humidity, multiple organ failure may result. Rhabdomyolysis is a frequent component of overexertion. Rhabdomyolysis may be precipitated from glycogen depletion and electrolyte depletion. Because horse sweat is hypertonic, profound and prolonged exercise leads to significant

electrolyte depletion. Lactic acidosis induced by dehydration and anaerobic glycolysis further complicates electrolyte depletion. Laboratory tests typically reveal muscle enzymes 10 to 1000 times greater than normal; depletion of sodium, potassium, and chloride; dehydration; and azotemia. Muscle biopsy demonstrates acute rhabdomyolysis without evidence of previous rhabdomyolysis. Horses require emergency resuscitative therapy, including intravenous fluids and restoration of electrolytes. Horses in anuric or oliguric renal failure may respond favorably to furosemide or dopamine therapy.

The exhausted horse syndrome tends to occur when horses have been pushed past their performance limits. The syndrome is believed to have a complex cause involving a combination of fluid and electrolyte losses, depletion of energy stores, and extremes of environmental conditions. The syndrome therefore usually occurs in association with Three-Day Events, endurance contests, and long-distance rides.<sup>3,106</sup> A brief summary of some of the possible contributing factors follows. More detailed information is available.<sup>60,96,107,108</sup> The amount of sweat produced by an exercising horse depends on the environmental conditions, the nature of the work, and the fitness of the animal. Under favorable climatic conditions, sweat loss can be on the order of 5 to 8 L/hr on long-distance rides. In hot, humid conditions, where sweating is partially ineffective, sweat production can be as high as 10 to 15 L/hr. An endurance horse can lose at least 25 to 30 L or more if conditions are unfavorable, which far exceeds the 1 to 5 L lost by a racehorse performing a sprint at top speed. Early on in exercise and when the sweat losses are low, much of the water loss can be made up by absorption of water from the large intestine. However, if water losses via sweat are between 5% and 10% of body weight a decrease in circulatory volume occurs. The decrease tends to occur after approximately 3 hours of exercise with moderate sweating but occurs much sooner during exercise in high heat and humidity.

Sweat contains low concentrations of calcium and phosphate but is hypertonic to plasma with respect to sodium, potassium, and chloride. During exercise, the horse appears to be able to maintain, initially at least, its plasma electrolyte concentrations at the expense of other body compartments. This is especially true for sodium, for which the contents of the gastrointestinal tract are believed to provide an important reservoir. Decreases in plasma sodium of up to 6 mmol/L occur during endurance rides in hot weather. The decreases are likely to result from significant sodium and water losses followed by partial replacement of the water deficit by drinking. Sodium concentrations may in fact increase in those animals that are not allowed to drink or that refuse to drink.

Potassium losses in sweat are also significant during prolonged exercise. Potassium is lost in sweat and is exchanged for sodium and lost into the gastrointestinal tract. During heavy exercise and sweating, muscle tissue is the major source of potassium replacement. Hypochloremia is observed commonly after endurance rides, reflecting chloride losses in sweat. Chloride is the major anion absorbed in the kidney, and in its absence, bicarbonate is resorbed.

The most consistent acid-base alteration associated with endurance in hot environments is metabolic alkalosis, probably related to hypochloremia and hypokalemia caused by heavy sweating, and therefore may not be seen in cooler conditions. Hypocalcemia has sometimes been observed in endurance horses and might result from calcium losses

in sweat or from disturbances of calcium homeostasis. These disturbances have been suggested to include energy deficiency, alkalosis, or competition with sodium and potassium exchange in the skeleton.

Even with frequent access to water, many endurance horses may develop clinical signs of slight to moderate dehydration during the course of a ride, as well as signs caused by some disturbance in electrolyte status. The combination of dehydration and sodium depletion results in a decreased plasma volume as determined by raised packed cell volume, total protein, and blood viscosity and may, in turn, result in inadequate tissue perfusion and inefficient oxygen and substrate transport, which can result in impaired renal function. Alterations in acid-base balance plus calcium, magnesium, and potassium depletion may contribute to the development of gastrointestinal tract stasis or ileus, as well as muscle cramps, synchronous diaphragmatic flutter, and rhabdomyolysis. If severe losses of water and electrolytes occur, then sweat production may decrease, resulting in even less effective thermoregulation.

Severe cases of dehydration coupled with electrolyte depletion may result in decreased renal perfusion and oliguria or anuria. Rhabdomyolysis may result from a combination of electrolyte depletion, poor perfusion, and resulting membrane instability. Myoglobinemia in human beings with decreased renal perfusion leads to kidney failure. Myoglobinemia leading to renal failure is less common in the horse, possibly because metabolic alkalosis occurs more commonly than metabolic acidosis in heavily exercised horses. If volume depletion is severe enough, metabolic acidosis may occur in the horse because of anaerobic glycolysis and may contribute to kidney failure in some cases.

### CLINICAL SIGNS AND LABORATORY FINDINGS

Box 11-7 shows some of the signs seen in exhausted horses and the associated laboratory findings. Signs may last for several days. Various guidelines have been given in the literature to help distinguish the exhausted horse from the nonexhausted, tired horse. The heart and respiratory rates may be similar in both cases at the end of an endurance ride, but in the nonexhausted horse the rates tend to return to normal far quicker, for example, to a heart rate of less than 60 to 70 beats per minute with a respiratory rate of less than 40 per minute within 25 to 30 minutes, unless the ambient temperature is high. In the exhausted horse the heart rate tends to remain greater than the respiratory rate, for example, greater than 70 beats per minute 30 minutes after exercise, with a persistently elevated rectal temperature.<sup>2,3,96</sup>

### TREATMENT

Horses that appear depressed with persistently elevated heart and respiratory rates may respond to rest, cooling out, and access to salt, feed, and water. If no improvement is seen within 30 minutes the horse often needs fluid therapy. In the more severe case of a horse that refuses to eat or drink the horse needs prompt and vigorous fluid therapy. Fluids restore circulating blood volume, correct electrolyte deficits, and provide a source of readily metabolizable energy. Fluids may be administered orally or intravenously. The practitioner can give 5 to 8 L orally every 30 minutes to 1 hour, if required, but this should be stopped if any discomfort or gastric reflux becomes apparent. Oral hypertonic solutions should be avoided. In severely affected animals, up to 10 to

#### BOX 11-7

### CLINICAL SIGNS AND LABORATORY FINDINGS IN THE EXHAUSTED HORSE

#### Clinical signs (not all are present in all cases):

- Depression
- Dehydration, anorexia, decreased thirst
- Elevated respiratory rate
- Elevated heart rate
- Hypo or hyperthermia
- Decreased pulse pressure
- Decreased intestinal sounds
- Laminitis
- Muscle cramping
- Poor sweating response
- Poor jugular distention, increased capillary refill
- Recumbency
- Refusal to move
- Synchronous diaphragmatic flutter

#### Laboratory findings:

- Metabolic alkalosis
- Paradoxical aciduria
- Hypokalemia, hyponatremia, hypochloremia
- Increased CK, AST, LDH activities
- Proteinuria
- Azotemia
- Lipidosis
- Signs of hepatic failure

AST, Aspartate aminotransferase; CK, creatine kinase; LDH, lactate dehydrogenase.

20 L/hr of fluids can be given intravenously; in addition, inserting a stomach tube may be necessary. One can use saline or lactated Ringer's solution with potassium chloride added to provide approximately 10 mEq/L. After the horse starts eating hay, potassium supplementation may be discontinued. The practitioner can administer glucose as 5% dextrose in saline or add 50% dextrose to Ringer's solution to deliver between 50 and 100 g/hr (concurrent insulin administration has been recommended). Slow administration of calcium also may be of value. Sodium bicarbonate administration is not indicated, because acidosis, if present, resolves with fluid volume expansion and is contraindicated if the horse is in a state of metabolic alkalosis. The horse may require other therapeutic agents to control pain and anxiety, although one should use the NSAIDs and phenothiazine derivatives with extreme caution in the face of dehydration (low blood pressure) and possible renal dysfunction. Avoiding corticosteroid administration has been recommended unless absolutely necessary.

The practitioner can use cold water body sprays and alcohol baths, particularly over the head and neck region, to cool the patient. A common myth is that ice water bathing may lead to muscle cramping. However, whole-body ice water bathing and cold water spray fans have been used successfully in major international events under hot and humid conditions without adverse effects. In recumbent, hyperthermic patients, one should give cold water enemas delivered via a handheld gravity-feed rectal tube. Further information concerning exercise

physiology under environmental conditions of high heat and humidity is available.<sup>60,96,106-108</sup>

## PREVENTION

Many endurance competitors train their endurance horses to drink electrolyte-rich water, which may help to restore electrolyte concentrations in addition to water during a race. However, plain water should always be available as an alternative. The proper amount of water intake during competition is unknown because the maximal absorption of water from the gastrointestinal tract is unknown, considering that exercise draws circulation away from the intestine. The amount of water contained in the intestinal tract depends on the amount of fiber contained therein. Research is ongoing to determine the optimal combination and time of feeding of grains, forage, electrolyte supplements, and water before and during long-distance competition. These findings also vary depending on the type of competition (endurance versus Three-Day Event) and length of course (10, 50, or 100 miles).

Various suggestions have been made as to the optimal nature of any electrolyte supplement. Supplements containing from one to four times more sodium than potassium have been recommended. Sodium bicarbonate has often been suggested as part of an electrolyte mix, but because most endurance horses tend to become alkalotic, this suggestion may in fact be counterproductive and is not recommended. Additional sodium and potassium chloride supplementation for a few days after competition may also be helpful in replenishing body stores but is often unnecessary if the basic diet is acceptable.<sup>60,96,108</sup>

Many workers have reported beneficial effects from oral or parenteral administration of vitamin E and selenium.<sup>62,109</sup> The beneficial effects of these compounds have been noted as being difficult to assess because they are often given in addition to changes in diet and exercise.<sup>96</sup> Benefit would presumably be the result of limiting or preventing free radical-induced muscle damage. Oral administration is preferable to intermittent injection.

## ☪ TOXICOSES

Only a few available and palatable toxic compounds cause muscle fiber degeneration in the horse. White snakeroot (*Eupatorium rugosum*) and coffeeweed (*Cassia occidentalis*) are the most common plants that may cause rhabdomyolysis. Ionophore contamination of feed may also lead to life-threatening rhabdomyolysis. For additional information, see Chapter 22, Toxicologic Problems.

### WHITE SNAKEROOT

White snakeroot is a common plant in the central midwestern and northeastern United States. White snakeroot is a shade-loving plant growing well in damp, wooded areas, shaded river banks, and in steep canyons.<sup>110</sup> The toxic principle is tremetol, a fat-soluble high-molecular-weight alcohol, and plants may be toxic in fresh and dried forms. Clinical signs of white snakeroot ingestion include progressive muscle tremors, weakness, choke, constipation, recumbency, arrhythmias, and death. Serum muscle enzyme activities increase significantly. At postmortem, one observes skeletal muscle necrosis and subepicardial and myocardial hemorrhages with grayish streaks in the myocardium.<sup>111</sup>

### CASSIA OCCIDENTALIS

*Cassia occidentalis* (coffeeweed, senna) is toxic to horses and may cause ataxia, incoordination, recumbency, and death with liver and muscle damage. However, natural ingestion of this plant is uncommon.<sup>112</sup>

### MISCELLANEOUS TOXICOSES

Selenium, iron, thallium, and perhaps sulfur and cobalt may cause muscle disease when fed at toxic levels. Metals such as iron may act by affecting vitamin E and selenium status or lipid peroxidation.<sup>14</sup> If ingested, bracken (*Pteridium aquilinum*), horsetail (*Equisetum arvense*), and rock fern (*Cheilanthes sieberi*) may induce thiamine deficiency with signs of anorexia, gait disturbances, staggering, lack of coordination, lethargy, a weak and irregular pulse, and muscular tremors.<sup>113</sup>

### IONOPHORE TOXICITY

#### PATHOPHYSIOLOGY

Monensin, rumensin, lasalocid, and salinomycin are ionophores commonly fed as coccidiostats in food animals. Monensin is a carboxylic ionophorous antibiotic fermentation product derived from *Streptomyces cinnamonensis* and is used as a coccidiostat for poultry and as a feed additive for cattle because it increases feed utilization by altering rumen fermentation. Access to ruminant feed or accidental contamination of horse feed in a mill producing poultry, cattle, and horse feed are the most common causes for intoxication. Much is known about monensin toxicosis, and as such it will be used as the model for this discussion.

The lipid-soluble monensin-sodium complex releases sodium in exchange for a proton after it crosses the cell membrane. The protonated monensin leaves the cell to pick up more sodium, and the cycle repeats. The increase in intracellular sodium concentration stimulates the sodium-potassium ATPase pump and indirectly results in an increase in calcium. This increase in intracellular calcium may then result in the release of certain factors such as catecholamines, which, in turn, may be responsible for some of the clinical signs seen, especially in relation to the heart. When mitochondria become saturated with calcium, the process of oxidative phosphorylation is disturbed and supplies of ATP decrease. Swelling and disruption of mitochondria follows, resulting in release of stored calcium, which may potentiate or precipitate catecholamine-induced cardiac arrhythmias. Increased intracellular calcium concentrations may also result in a brief period of extreme contraction of muscle (because of effects on actin-myosin binding), as well as release of various cellular lytic enzymes. The rapid onset of cardiac or skeletal muscle necrosis may result from energy deficiency resulting from these lytic processes. Small concentrations of monensin also may result in an increase in intracellular potassium concentration; large concentrations of monensin tend to decrease intracellular potassium concentration. Other tissues less dependent on ATP may not show such severe signs.<sup>34,114,115</sup> In muscle, swelling and disintegration of mitochondria are the first visible lesions, although monensin does not cause mitochondrial structural defects in cultured muscle cells.<sup>116</sup> Further work is needed to determine if other substances or metabolites of monensin are involved in pathophysiologic features of toxicity in vivo.<sup>114</sup>

## CLINICAL SIGNS

Horses are sensitive to monensin. Signs of toxicity may be apparent after ingestion of 2 to 3 mg/kg body mass of crystalline monensin (compared with 20 to 34 mg/kg for cattle). (The median lethal dose for mycelial monensin is estimated to be  $1.38 \pm 0.19$  mg/kg body mass.) The increased susceptibility of horses to monensin toxicity may be because horses do not clear monensin from the bloodstream as rapidly as cattle. In addition, equine heart muscle is sensitive to the effects of catecholamines.<sup>114</sup> After ingestion of a single toxic dose, signs of lethargy, muscular weakness, and stiffness, often with recumbency, occur within 24 hours. In the early stages, progressive hypokalemia resulting in cardiac conduction disturbances occurs.<sup>115</sup> Cardiovascular signs may include tachycardia with possible arrhythmias, prominent jugular pulse, congested or pale mucous membranes, cold extremities, weak pulse, and profuse sweating. Tachypnea, hyperpnea, or dyspnea may be apparent. Early on, affected animals may show signs of colic, including sweating, increased heart rate, and increased or absent borborygmus. Amounts of feces may be reduced, or no feces may be passed. Animals may be anorectic. Myoglobinuria and muscle tremor also may be apparent, together with progressive ataxia and signs of central nervous system malfunction. Depending on the dose ingested (and the individual), death may occur within 24 hours. Hind limb muscles tend to be involved most severely.<sup>14,34,114</sup> Progressive cardiac insufficiency, weight loss, and sometimes renal failure are more common with chronic toxicity in the weeks after a single, lower dose exposure. In such cases, clinical signs related to skeletal muscle involvement may disappear, although poor performance and muscular weakness may be apparent if the horse is asked to perform. Signs of chronic toxicity may not be noticed for weeks after ingestion of the compound has stopped.<sup>117</sup> Monensin-containing feeds are often unpalatable, and owners may recollect a "bad" bag or shipment of feed that some horses refused to eat in the recent past.

## LABORATORY FINDINGS

In peracute cases, in which the horse dies within 24 hours, a progressive hemoconcentration associated with increased urine output and decreased urine specific gravity, together with increased blood urea nitrogen and creatinine concentrations is typically observed.<sup>115</sup>

Serum CK and AST activities may be elevated moderately to significantly, primarily because of skeletal muscle damage. The increase in total LDH activity appears (at least initially) to be caused by LDH<sub>1</sub> and LDH<sub>2</sub> isoenzymes and may be related to increased erythrocyte fragility and hemolysis. Increases in alkaline phosphatase activity have also been observed, apparently from an increase in the bone isoenzyme.<sup>115</sup> Hemoglobinuria, myoglobinuria, or both may occur.

Sodium concentrations do not change greatly. Serum calcium concentration tends to decrease initially, within the first 12 to 24 hours, by approximately 10% to 15% and then recovers. Hypokalemia tends to occur in the first 24 hours with a decrease of 1 to 2 mmol/L followed by a return to normal by 36 hours. In chronic toxicity, clinical findings are often non-specific and reflect the various organs involved. In one study of 32 horses with a history of unthriftiness and poor performance after prior ingestion of monensin-contaminated feed the authors observed decreased serum bilirubin concentration

and increased alkaline phosphatase activity. In four horses, they also observed increased LDH<sub>5</sub> activity.<sup>117</sup>

In horses that die peracutely, one may not observe gross lesions and may rely on feed analysis for diagnosis. In less acute cases the gross changes are not pathognomonic for monensin toxicosis and can include edema, hydropericardium, hydrothorax, ascites, hemorrhages, and pale areas in the heart or diaphragm.<sup>114,116,117</sup>

## DIAGNOSIS

Differentiating this condition histologically from vitamin E and selenium deficiency, atypical myoglobinuria (pasture myopathy), or exertional rhabdomyolysis may be difficult.<sup>14</sup> However, history of feed problems, signs in multiple horses, and evidence of heart failure in chronic cases aid in the diagnosis. The finding of high monensin concentrations in feed and stomach contents may confirm the diagnosis. The ingestion of blister beetles (*Epicauta* spp.) can cause cardiomyopathy, and one should exclude this from the differential diagnosis along with white snakeroot toxicosis.

## TREATMENT AND PROGNOSIS

In acute monensin toxicosis, intensive isotonic polyionic fluid therapy with additional potassium has been recommended for treatment. Although this therapy may support the horse during the initial crisis, the prognosis is guarded because longer-term actions of monensin, particularly on the heart, still may cause death.<sup>115,117</sup> Activated charcoal or mineral oil administered orally may help to decrease further monensin absorption. The practitioner should avoid purgatives that act by stimulating the vagal system because of the risk of causing arrhythmias in an already damaged heart. Similarly, intravenously administered calcium may not be advisable. One should avoid cardiac glycosides because they may work synergistically with monensin, resulting in extensive cardiac muscle damage. Horses that have clinical signs of heart failure after previous exposure have a poor prognosis for long-term survival.

## MUSCLE TUMORS

Primary tumors of skeletal muscle are rare, malignant tumors being twice as frequent as benign ones. Rhabdomyosarcomata of the limbs, head, or neck appear as hard, spherical masses deep in the muscle. A significant proportion appears to occur in sites of earlier muscle fiber destruction and repair. Frequently, animals younger than 2 years are affected. Other benign and malignant primary tumors, including lipomata, liposarcomata, fibromata, fibrosarcomata, myxomata, and heman-giosarcomata, can occur in muscles. Metastatic spread to the muscles, especially of malignant melanomas, angiosarcomata, and tumors of the lymphoreticular system, also may occur.<sup>14</sup>

## ATYPICAL MYOGLOBINURIA

Sudden death from exertional rhabdomyolysis is rare and usually occurs in an animal that has undergone some degree of exertion before the attack. Severe and often fatal attacks of a condition with similarities to exertional rhabdomyolysis have been reported in the United Kingdom and elsewhere in Europe in groups of animals out at pasture with no history of sudden exertion.<sup>118-120</sup> The condition has been called *atypical myoglobinuria* or *pasture myopathy*. A similar syndrome has been reported in the United States.<sup>121</sup> Clinical signs are

consistent with rhabdomyolysis, and prolonged recumbency may be seen with weakness and tremors. Muscle enzymes are significantly elevated. Some horses may have signs consistent with cardiomyopathy as well.

### PATHOPHYSIOLOGY

Factors common to many atypical myoglobinuria cases include adverse climatic conditions before the outbreak and the availability of tree bark, often on dead wood. This atypical syndrome characteristically affects a group of horses over a short period, and therefore the possible predisposing trigger or etiologic factor is thought to be environmental or toxic. No consistent abnormality in selenium or GSHPx values has been seen. Low vitamin E concentrations are inconsistently seen and have not been implicated.<sup>119-121</sup> In some but not all cases, *Trichoderma* spp. fungi were isolated from grass and wood taken from the fields grazed by the affected horses. Mycotoxins have therefore been suggested as being of possible significance.

No access to toxins such as monensin or salinomycin was demonstrated in any case. Oak trees with acorns were not always present, and gastrointestinal signs associated with acorn poisoning were not observed.<sup>122</sup> Spraying with an atrazine herbicide occurred before one outbreak.<sup>123</sup> Simazine residues were not thought to be at toxic levels and clinical signs were not those seen with triazene herbicide toxicity (i.e., severe colic, cessation of eating and drinking, and a dog-sitting posture).<sup>120</sup>

The cause of atypical myoglobinuria therefore has not been identified. In some cases the death may be inappropriately attributed to white snakeroot toxicity. In a case series in which white snakeroot was thought probable, retrospective analysis failed to identify tremetone.<sup>121</sup> In horses that died the precise cause of death was uncertain, but damage to the heart and diaphragm in association with biochemical alterations such as hypocalcemia may have been important. Renal failure may be a contributory cause but is unlikely to be the primary cause of death.

### CLINICAL SIGNS

Atypical myoglobinuria occurs most frequently in horses and ponies grazing pasture of low quality. One or more animals in a group may be affected. A sudden onset of stiffness unrelated to exertion occurs, soon followed by severe myoglobinuria. Temperature, heart rate, and respiratory rate are generally within the normal range. No age, sex, or breed predilection has been observed, but few cases have been investigated. Of cases that have been well documented, progression of clinical signs is rapid and mortality is high. Serum CK activities are greatly increased, and advanced myodegeneration of all muscles, including the heart, may be present.<sup>119-121</sup>

Myodegeneration affecting mostly type 1 fibers with Zenker degeneration and necrosis has been described.<sup>118</sup> Large hyperchromatic hepatocyte nuclei were observed in some liver sections together with patchy vacuolation and infiltration of neutrophils into the portal areas. Pink proteinaceous granular material tended to be present in the kidney tubules and within Bowman's capsule.<sup>120</sup> Skeletal abnormalities may not be obvious on gross postmortem examination.

High CK activity (as much as 900,000 U/l) caused by myodegeneration is observable. AST activity also tends to be increased greatly. High sorbitol dehydrogenase values (up to 28.8 IU/dl; laboratory reference range, 4 to 15 IU/dl) were found in several cases in one investigation. Hypocalcemia may

occur, especially in the terminal stages. Myoglobin is usually present in a sufficiently high concentration in the urine to be detectable by electrophoresis on cellulose acetate.

### TREATMENT

Because the cause of the condition is unknown, symptomatic treatment is recommended, including intensive fluid therapy, which should be based on biochemical monitoring. The calcium status in particular should be monitored because horses may become hypocalcemic. Feeding a readily available source of calcium may be of benefit in some cases. In one study, horses were treated with supportive care and antioxidants, including polyionic fluids, vitamin E and selenium, vitamin C, dimethyl sulfoxide (DMSO), and flunixin meglumine.<sup>121</sup>

### POSTANESTHETIC MYASTHENIA

Postanesthetic myasthenia has been reported in three horses.<sup>8</sup> The condition could be a form of botulism or a drug-induced myasthenia. The characteristic signs were a difficult recovery from anesthesia, lack of any facial expression, flaccid tongue, mydriasis, an inability to raise the head, and dysphagia. All three patients recovered totally with supportive care.

## PATHOPHYSIOLOGY AND TREATMENT OF ACUTE LAMINITIS

Ashley M. Stokes, Susan C. Eades, Rustin M. Moore

Acute laminitis (founder) is a severely debilitating, excruciatingly painful, and potentially career-ending and life-threatening disease of the soft tissues (sensitive and insensitive laminae) of the equine digit, affecting adult horses and ponies of any breed or use. Laminitis is frustrating for veterinarians because current knowledge and understanding of the pathophysiologic nature of the disease is incomplete, limiting efforts at prevention and treatment. Laminitis causes profound emotional stress and economic loss to horse owners and trainers because of the agonizing pain experienced by affected horses. Laminitis often leads to poor body condition and prolonged periods of recumbency with secondary pressure sores. Many affected horses rise only for short periods and demonstrate a characteristic stance of rocking or shifting their weight onto their rear feet, which is accompanied by anxiety, muscle fasciculations, and sweating.

### ☞ PREDISPOSING CONDITIONS

Fifteen percent of horses in the United States are estimated to be afflicted with laminitis over the course of their lifetime. From an economic perspective the diagnosis and treatment of laminitis costs horse owners millions of dollars annually. Numerous primary diseases are known to be associated with the development of laminitis, such as colic, diarrhea, pneumonia, metritis, endocrine and metabolic disorders, and musculoskeletal injuries resulting in altered loading of a supporting limb.<sup>1-3</sup> A recent study examined records for horses that developed laminitis during hospitalization for illness or injury and found that endotoxemia was the

condition with the greatest significant correlation to laminitis development. The diseases found most associated with endotoxemia in this study were acute diarrhea, surgically managed colic, interstitial pneumonia and bronchopneumonia, and retained placenta and metritis in postpartum mares.<sup>2</sup> Another study found that gastrointestinal disease occurred in 53% of horses that developed laminitis.<sup>4</sup> Of horses admitted for duodenitis or proximal jejunitis, the prevalence of laminitis was 28%, and a study of horses with acute diarrhea admitted to a referral hospital over a 7-year period found that 11.5% of those cases developed laminitis.<sup>5,6</sup>

A considerable amount of recent focus in laminitis research is in regard to the link between metabolic and endocrine abnormalities of horses and laminitis pathogenesis. Feeding of starch-rich (a diet with a high glycemic index) and fat-supplemented rations, combined with relative inactivity, can lead to metabolic syndrome and obesity in adult horses.<sup>1</sup> A review of equine insulin resistance found a significant relationship between this condition and laminitis.<sup>7</sup> In support of these concepts a recent study found that a definite interrelationship exists among obesity, inflammatory cytokines, and insulin sensitivity in the horse,<sup>8</sup> and other researchers have linked these metabolic abnormalities with laminitis.<sup>9</sup> Another study confirmed the prevalence and clinical features of horses with laminitis and the relationship with the endocrine disease pituitary pars intermedia dysfunction.<sup>10</sup> All of these studies point to the importance of the predisposition of laminitis development or progression in association with metabolic and endocrine abnormalities. More information is needed to understand fully the effects of these metabolic and endocrine conditions on laminitis in this particular group of horses.

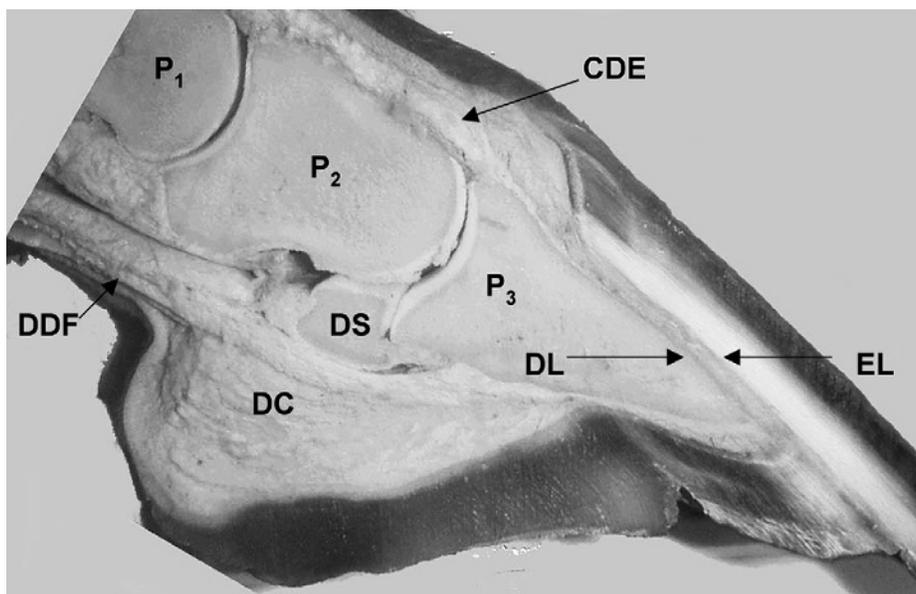

Scientific investigations have identified some important pathophysiologic events involved with laminitis and have determined some pathways common to all initiating diseases. However, additional studies are needed to unravel the remaining mysteries regarding the initiation and propagation of laminitis. Currently, numerous and varied therapies

are used to prevent and treat laminitis; however, clinicians' preferences and impressions regarding the most effective treatments are based on an incomplete understanding of the initiating events in this disease. Because of the gaps in knowledge of the pathophysiologic features of laminitis, the effectiveness of the currently used treatments is inconsistent at best. Therefore developing a more thorough understanding of the cascade of events involved with the onset and propagation of acute laminitis should help veterinarians develop more effective and cost-efficient therapies to prevent and treat a disease with profound humane, emotional, and economic effects on horses, horse owners, trainers, and veterinarians. This section provides a comprehensive review of the current knowledge of the pathophysiologic features of acute laminitis and presents experimental findings that should contribute to a better understanding of this pathogenic cascade and may ultimately help improve the prevention and treatment of laminitis in horses.

## ANATOMY AND PHYSIOLOGY OF THE DIGIT

The normal laminar tissue and its vasculature are unique in numerous aspects. The ability of the horse to walk depends on the integrity of the interdigitating primary and secondary laminae, which structurally unite the hoof wall, distal phalanx, and the sole of the foot into a single unit.<sup>11</sup> The bulk of the hoof is composed of the stratum medium, which is composed of avascular, highly keratinized stratified squamous epithelium. This layer blends with the stratum internum, which comprises the primary and secondary epidermal laminae. Approximately 600 primary laminae form longitudinal grooves for interdigitation with the vascular laminae of the laminar dermis (corium). The laminar corium unites with the subcutis and periosteum of the distal phalanx.<sup>12</sup>

The bones of the digit are the proximal, middle, and distal phalanx and the distal sesamoid bone (navicular bone; Figure 11-14). The primary joint of the digit is the distal

**FIGURE 11-14** Cross-section of the equine digit. *CDE*, Common digital extensor tendon; *DC*, digital cushion; *DDF*, deep digital flexor tendon; *DL*, dermal laminae; *DS*, distal sesamoid bone; *EL*, epidermal laminae; *P*<sub>1</sub>, proximal phalanx; *P*<sub>2</sub>, middle phalanx; *P*<sub>3</sub>, distal phalanx.

interphalangeal joint composed of the middle and distal phalanx and the distal sesamoid bone. The short collateral ligaments join the distal end of the middle phalanx and the proximal edges of the distal phalanx. The collateral sesamoid ligaments extend from the distal aspect of the proximal phalanx and insert on the edges of the distal sesamoid bone. A branch of this ligament also inserts on the palmar process of the distal phalanx. The distal sesamoid impar ligament arises from the distal aspect of the distal sesamoid bone and extends to the palmar surface of the distal phalanx. A fibrous connection between the palmar surface of the middle phalanx and the deep digital flexor tendon forms a T-ligament. The deep digital flexor tendon inserts on the palmar aspect of the distal phalanx, and the common digital extensor tendon inserts on the extensor process of the distal phalanx.<sup>12,13</sup>

The distal interphalangeal joint capsule joins with the common digital extensor tendon, the collateral ligaments of the distal interphalangeal joint, the distal sesamoid impar ligament, and the T-ligament. The joint capsule has two main pouches, the dorsal pouch and the palmar pouch, and the palmar pouch is divided further into proximal and distal pouches. The digital cushion is a large soft-tissue structure located between the base of the cartilages, structures located palmar to the collateral ligaments composed of hyaline cartilage that progress to become predominantly fibrocartilage. The digital cushion is composed of fibroelastic tissue, adipose tissue, and a small percentage of fibrocartilage. A venous plexus is also located within the digital cushion.<sup>12</sup>

The nutrients to maintain the integrity of the corium come from the laminar arteries branching from the circumflex artery as it curves around the toe. These laminar arteries course in a distal to proximal direction. The laminar veins that course distally into the circumflex vein remove metabolic wastes and drain into the bulbar vein and digital veins. Arteriovenous shunts between the circumflex artery and vein have been demonstrated in acute laminitis.<sup>12</sup> These shunts provide a path of rapid flow from the laminar arteries to the veins, thus bypassing the laminar capillaries, and have the potential to rob the laminae of nutrient flow via its capillary bed. An example of the potential significance of this is that recent work using 15 micrometer microspheres injected into the arterial circulation of the digit has demonstrated that increased weight-bearing on a forelimb results in decreased laminar perfusion in that foot. Blood flow at the level of the fetlock was unaltered during this study, pointing to involvement of arteriovenous shunts in redirecting blood flow away from the laminae in the face of altered weight bearing.<sup>14</sup> There may be significant involvement of arteriovenous shunts in other aspects of laminitis pathogenesis that is currently unknown.

The conduction vasculature (digital arteries and veins) supplying the hoof has unique characteristics unlike other vascular beds. The digital veins are highly muscular compared with veins in other tissues and other species.<sup>15</sup> This muscular wall is probably needed to withstand the high vascular pressures exerted in these dependent tissues. The highly muscular wall is likely responsible for the low compliance of the veins.<sup>16</sup> In exercising horses the pressure in the venous circulation may reach 200 mm Hg.<sup>17</sup> The equine digital arteries and veins are highly sensitive to vasoconstrictive substances, most notably norepinephrine and endothelin.<sup>18</sup> Furthermore, the digital veins are most sensitive *in vitro* to vasoconstrictive substances.<sup>19</sup> For example, contraction induced by angiotensin, thromboxane, norepinephrine, serotonin, and endothelin

is twice as strong in veins as arteries.<sup>18-20</sup> Recent studies have examined the nutrient vasculature (laminar arteries and veins) and have found similar patterns in their vascular reactivity.<sup>21</sup>

The culminating effects of low compliance and high sensitivity to vasoconstrictive substances predispose the equine digit to high venous pressures, thereby increasing hydrostatic pressure and thus the likelihood of edema formation. The microcirculation of the equine foot is adapted poorly to handling edema. In normal tissues, three safety factors counteract edema formation, including capillary permeability, pre- to postcapillary resistance, and lymphatic drainage. An impermeability of the capillary endothelium serves as a barrier to fluid and protein transudation, which results in a higher gradient between the capillary and tissue oncotic pressure, favoring movement of fluid into the capillary lumen. Paradoxically, the equine digital capillary bed is highly permeable to fluid and macromolecules and is more permeable than the vasculature of the dog and rat paw.<sup>16</sup> This permeability results in a higher concentration of interstitial protein, favoring edema formation. A high precapillary (arteriolar) resistance and low postcapillary (venous) resistance reduce the capillary pressure, thereby reducing the hydrostatic pressure for transcapillary fluid filtration. The precapillary-to-postcapillary resistance ratio in healthy horses is comparable to that in other musculoskeletal beds in other species. However, during the prodromal stages of experimentally induced laminitis (either the black walnut extract [BWE] or the carbohydrate overload [CHO] models) the contribution by the postcapillary portion increases, thus favoring edema formation. Lymphatic drainage provides the third edema safety factor. The small diameter and number of metacarpal lymphatics and the hydrostatic gradient to lymph flow reduce the likelihood that lymphatic circulation can effectively protect the foot against edema when the hydrostatic forces in the capillary favor edema formation.<sup>22</sup>

## CLINICAL SIGNS AND DIAGNOSIS

Laminitis is a disease that can affect all four feet; however, laminitis most commonly affects the forelimbs because they bear approximately 60% of the mass of the horse.<sup>11</sup> The increased load of the forelimbs compared with the hind limbs is thought to account for the increased occurrence of laminitis in the forelimbs. To define better the severity of clinical signs exhibited by horses, Obel established a grading system in 1948. Grade 1 is the least severe and states that the horse alternately and incessantly lifts the feet and that lameness is not evident at a walk but is evident at a trot as a short, stilted gait. Horses that walk with a stilted gait but are still willing to have a foot lifted are classified as grade 2. Horses with grade 3 laminitis move reluctantly and vigorously resist lifting of a foot. The most severe classification is grade 4, noted by the horse refusing to move unless forced.<sup>23</sup> Other clinical signs characteristic of laminitis are heat present over the dorsal surface of the hoof wall, bounding of the digital pulse (increase in the difference between the systolic and diastolic digital arterial pressure), sensitivity to hoof testers, swelling of the coronary band, and alteration of stance to redistribute weight to the hind limbs (sawhorse stance or rocking of weight to the hind limbs) if laminitis is principally affecting the front limbs (Figure 11-15). More severe signs are a dropped sole or palpation of a depression located at the level of the coronary band, both indications of rotation or distal displacement (sinking) of the

distal phalanx within the hoof wall.<sup>13,24</sup> Lateral radiographs of the digit are indicated for detection of rotation and distal displacement of the distal phalanx within the hoof capsule (Figures 11-16, A and B). The placement of a radiopaque marker 1 cm below the coronary band is helpful when determining the presence of distal displacement of the distal phalanx.

**FIGURE 11-15** A few of the clinical signs commonly associated with laminitis include weight redistribution, pressure sores, and poor body condition, as demonstrated in this horse with forelimb laminitis.

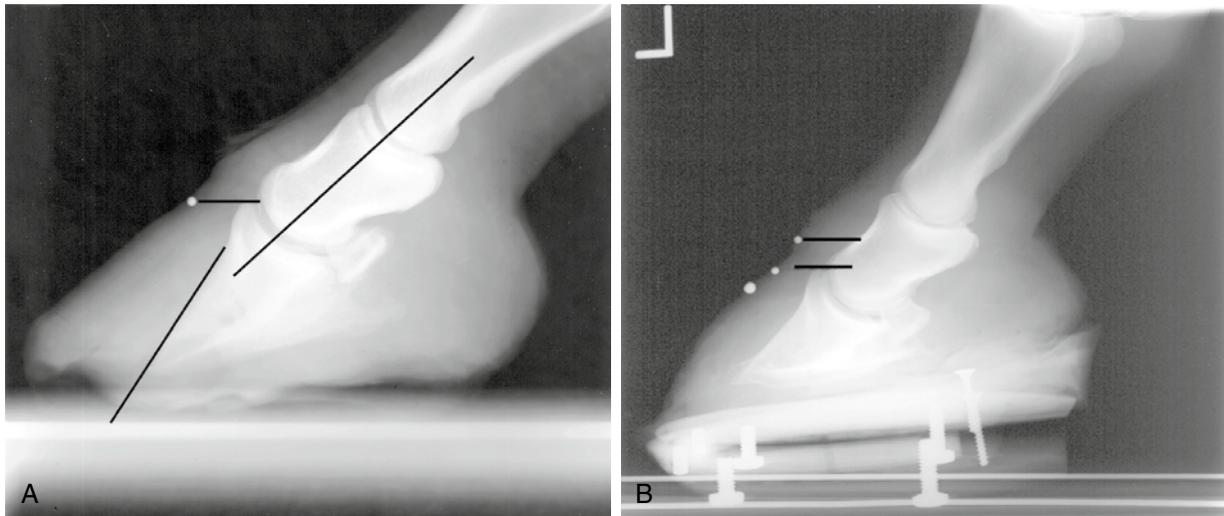

The presence of a linear radiopaque marker in the block on which the horse stands is helpful to assess the angle and degree of rotation.

### HISTOPATHOLOGIC FINDINGS

Histologic study of laminar changes during laminitis has been performed 48 to 96 hours after induction of laminitis with cornstarch or wheat flour gruel. Lameness begins approximately 30 hours after administration of the induction ration.<sup>22</sup> Evaluation of a progression of lesions by these studies is difficult because the onset and severity of lameness varies substantially from horse to horse. Studies using these models are confounded further by the fact that approximately 10% of horses appear to be resistant to the ration.

After the onset of lameness, the initial histologic alteration occurs in the digital vasculature, including swelling of the endothelial cells and mild edema formation.<sup>25</sup> Laminar capillaries become obstructed with erythrocytes within 8 hours. Within 6 to 12 hours, a perivascular leukocyte infiltration occurs that then dissipates as the inflammatory cells migrate into the epidermal layer. Arteriolar endothelial cells become deformed because of cytoplasmic processes that extend into the lumen. Microvascular thrombi and accompanying severe edema formation occur within 24 hours, and hemorrhage occurs within the primary dermal laminae by 72 hours.

Primary histologic alterations of the laminae occur within 8 hours after lameness develops.<sup>25</sup> Initially, thinning and lengthening of the lamellar structures is accompanied by reduction, flattening, and displacement of epithelial cells.

**FIGURE 11-16** **A**, Lateral radiograph of the equine digit demonstrating rotation of the distal phalanx within the hoof capsule. Note the black line drawn parallel to the dorsal surface of the phalanx and the angle this forms with the radiopaque marker in the block, which is used to aid in the assessment of the magnitude of rotation. The line drawn axially through the proximal and distal interphalangeal joints should be approximately parallel to the dorsal surface of the distal phalanx in the normal horse, and deviation from this angle represents distal phalanx rotation. Also, note the placement of the round radiopaque marker in the dorsal hoof wall 1-cm distal to the coronary band, which is used to evaluate distal displacement of the phalanx. This marker should be approximately at the level of the extensor process in normal horses. The vertical distance between this line and the line drawn at the level of the extensor process represents the degree of displacement. **B**, Lateral radiograph of the digit demonstrating marked distal displacement of the phalanx. Note the three radiopaque markers that were used for serial radiographic evaluation. These can also be helpful in assessing dorsal hoof wall growth. (Courtesy Dr. Ralph E. Beadle.)

The secondary laminae become redirected such that laminae nearer the base of the dermal lamina are directed toward the coffin bone and those nearer the laminar tips are directed toward the hoof wall. Morphologic alterations after epithelial cell damage include swelling, vacuolization, nuclear swelling and pyknosis, and leukocytic infiltration of the secondary epidermal lamina, which is observable as early as 24 hours after the onset of lameness.

## PATHOGENESIS

The mechanisms involved in the pathogenesis of laminitis are most likely numerous and interrelated. Inflammation (systemic inflammatory response syndrome [SIRS]), insulin resistance and endothelial dysfunction, enzyme activation, and excessive weight bearing and trauma are factors at the forefront of current investigations.

Systemic sequelae to inflammation (SIRS) commonly precede laminitis in horses with gastrointestinal disease, including pleuropneumonia, colitis, enteritis, peritonitis, and endometritis. Although researchers once questioned whether the disease should be called *laminar degeneration* because of the minimal neutrophilic infiltration present histologically, application of more sensitive research tools has produced abundant evidence of inflammatory changes during laminitis. In carbohydrate overload laminitis, neutrophils become aggregated to platelets in the early prodromal stage and at the onset of lameness.<sup>26,27</sup> During BWE laminitis, significant emigration of neutrophils and monocytes from the dermal capillaries<sup>28</sup> occurs along with emigration of activated leukocytes from the systemic circulation, which produce reactive oxygen species<sup>29</sup>; furthermore, expression of interleukin (IL)-1 and IL-10 in dermal tissues is increased.<sup>30</sup> Horses treated with BWE have increased concentrations of measured osmolality in plasma, laminar tissue, and skin, providing convincing evidence for systemic activation of neutrophils, neutrophil emigration into the integument and laminae, and neutrophil degranulation.<sup>31,32</sup> Calprotectin, a leucocyte marker and amplifier of the inflammatory state, was identified in myeloid cells and keratinocytes of horses with BWE-induced laminitis.<sup>33</sup> Significantly increased lamellar mRNA expression of cytokines important in the innate immune response are present at the developmental stage of the BWE model, and at the onset of acute lameness in both the BWE model and oligofructose model.<sup>30,34</sup> Cyclooxygenase (COX)-2 expression is also substantially increased in the early stages of laminitis.

Evidence also suggests endothelial cell dysfunction during equine laminitis. Substantial increases in digital venous resistance follow intense venous vasoconstriction and facilitate laminar edema formation in the early stages of carbohydrate overload and BWE-induced laminitis as also demonstrated by decreased endothelial-dependant vasodilator responses in vitro, suggesting decreased endothelial production of nitric oxide during these two diseases.<sup>19,22,35-37</sup> Although measurement of digital venous blood nitric oxide concentrations failed to confirm reduced nitric oxide synthase activity, researchers have found increased endothelial synthesis of endothelin (ET)-1 and restoration of digital hemodynamic changes after administration of ET-1 antagonists.<sup>18,38,39</sup> Concurrent with increased ET-1 concentrations are increased digital blood glucose, insulin, and platelet–neutrophil aggregates suggesting that endothelial dysfunction occurs during equine carbohydrate overload laminitis.<sup>39</sup> Laminar concentrations of IL-1beta,

IL-6, IL-8, COX-2, intercellular adhesion molecule (ICAM)-1, and E-selectin mRNA increase in the first few hours after laminitis induction before the onset of lameness, suggesting early endothelial changes.<sup>40</sup>

Endothelial dysfunction can be caused by hyperglycemia, hyperinsulinemia, or insulin resistance. Insulin resistance and elevated plasma insulin concentrations often occur in obese horses with laminitis and in horses with pars intermedia dysfunction. Ponies predisposed to laminitis had higher plasma insulin concentrations than ponies not developing laminitis. Increased insulin concentrations in response to feeding insulin and fructan were greatest in horses predisposed to laminitis.<sup>41</sup> In addition, horses with carbohydrate overload laminitis develop elevations of plasma insulin concentration. Insulin resistance may be associated with development of laminitis by three mechanisms: (1) glucose uptake impairment, (2) insulin causes endothelial dysfunction, and (3) insulin has proinflammatory effects.

Insulin stimulates glucose uptake into tissues via GLUT4 proteins, particularly in muscle and adipose tissue. Insulin resistance impairs GLUT4 function, potentially leading to glucose deprivation of tissues, starving them and causing cell death or damage. In support of this finding is the research that has shown that healthy hoof tissue has an absolute requirement for glucose such that when hoof explants are incubated in the absence of glucose, or in the presence of a glucose uptake inhibitor, the secondary epidermal laminae separate rapidly from their basement membrane, as they do when laminitis occurs.<sup>42</sup>

Insulin signal transduction pathways during insulin resistance in human patients and laboratory models have been recently reviewed.<sup>43</sup> Of interest to the pathogenesis of laminitis is the insulin pathway–specific impairment of the phosphatidylinositol (PI)-3-kinase–dependent signaling pathway that interferes with GLUT4-mediated glucose uptake in skeletal muscle reduces nitric oxide production in vascular endothelium. In contrast, insulin-stimulated secretion of ET-1 is mediated by mitogen-activated protein (MAP)-kinase signaling that is unimpeded during insulin resistance. That is, a key feature of insulin resistance is that it is characterized by specific impairment of PI-3-kinase–dependent signaling pathways, but the rennin-angiotensin system and MAP-kinase–dependent pathways are unaffected. Therefore hyperinsulinemia will promote secretion of ET-1 despite decreased production of nitric oxide. In addition, hyperinsulinemia activates the rennin-angiotensin system, thereby increasing generation of reactive oxygen species and adhesion molecules that accelerate cellular activation.<sup>43</sup> Evidence of oxidant stress during equine laminitis has been documented.<sup>44</sup> The end result of insulin resistance and hyperinsulinemia in people is endothelial dysfunction and an inflammatory state. Similar mechanisms in horses could contribute to epithelial damage and laminar separation. The importance of hyperinsulinemia in the pathogenesis of laminitis has been highlighted by a study inducing laminitis by infusing insulin intravenously causing hyperinsulinemia for 72 hours.<sup>45</sup>

Laminin and type IV and type VII collagen are components of the laminar basement membrane. The enzymes metalloproteinase-2 and metalloproteinase-9 are believed to dissolve these substances, and under normal physiologic states, controlled dissolution allows the movement of epidermal laminae past the dermal laminae as growth occurs.<sup>46-48</sup> Excessive activation of these enzymes leads to uncontrolled

dissolution of the basement membrane components, resulting in separation of the epidermal laminae from the dermal laminae. Lamina samples from horses 48 hours after induction of laminitis using the CHO model demonstrated loss of basement membrane attachments.<sup>49,50</sup> In horses with naturally acquired acute and chronic laminitis, zymography of laminar connective tissues found increased activation of extracellular metalloproteinases compared with nonlaminitic horses.<sup>51</sup> Activation of the metalloproteinases is hypothesized to be induced by one or more exotoxins from *Streptococcus* species, especially *S. bovis*, a gram-positive bacteria found in the normal cecal flora.<sup>46,52,53</sup> Using the CHO model, researchers have identified changes in the bacterial population of the cecum with fermentation of the CHO, resulting in excessive lactate production, rapid decline in intracecal pH, and death of cecal bacteria including *Streptococcus* species.<sup>52,54</sup> In addition, activated neutrophils generate matrix metalloproteinase-9 capable of degrading the laminar basement membrane leading to laminar separation.<sup>55</sup> Thus evidence for the neutrophil's role in generating devastating tissue damage during equine inflammatory disease states is mounting.

The mechanical or traumatic theory is based on causes of laminitis resulting from direct trauma to the digit and not a primary systemic disease leading to the development of laminitis.<sup>24</sup> Common examples of traumatically linked laminitis are road founder, laminitis after unilateral lameness of the opposite foot (support limb laminitis), and development of laminitis after long trailer rides.<sup>3,24</sup> The exact mechanisms that lead to structural failure of the laminae are unknown, but several hypotheses have been suggested. Excessive force applied to the dermal and epidermal laminar interdigitations may initiate an inflammatory response with vasospasm, thereby increasing capillary hydrostatic pressure, leading to edema formation and ultimately resulting in a compartment-like syndrome similar to that of the ischemic-vascular theory. Another hypothesis is that application of excessive force results in tearing of the dermal and epidermal laminar interdigitations; the inflammatory response or vasospasm or both then ensue, leading to ischemic damage of the laminar interdigitations.<sup>24</sup>

Obviously, numerous mediators are present in acutely laminitic horses; therefore the authors believe that a single unifying mechanism is unlikely to cause the laminar damage. Most likely, vascular derangement and direct mediator damage coincide.

## ☞ CURRENT TREATMENT

Treatment of laminitis remains empiric and is often based on the experience and preference of the clinician. Effective treatment of laminitis requires aggressive and appropriate treatment of the primary disease process. Additionally, the cornerstones of treatment of horses with acute laminitis are directed at different components of the pathophysiologic process. The practitioner should consider acute laminitis a medical emergency and should institute treatment immediately after clinical signs develop or, preferably, before the onset of clinical signs. The authors believe the goals of treatment are to eliminate or minimize any predisposing factors, reduce pain, reduce or prevent the magnitude of permanent laminar damage, and prevent further movement of the distal phalanx within the hoof capsule. Considerable controversy exists regarding the treatment of laminitis because of the lack of understanding of the pathophysiologic nature of this disease.

To institute preventive treatment for laminitis, one must identify those horses at risk. Many of the primary diseases thought to predispose horses to develop laminitis are associated with circulating endotoxin. One of the most important preventive measures is combating the effects of endotoxemia and sepsis effectively by decreasing the severity of the primary illness. Recommended treatments include administration of mineral oil (if the horse engorged on grain), intravenous fluids, parenteral antibiotics, NSAIDs, and hyperimmune serum or plasma. Corrective hoof trimming, placement of the horse in a deeply bedded stall, and frog support are vitally important preventative measures.

Because of the anatomy of the normal lamina and hoof and the microvascular alterations that develop with the onset of laminitis, horses are predisposed to developing significant laminar edema, which leads to compression of the nutrient capillaries, resulting in laminar ischemia, reduction of metabolic waste removal, and ultimately laminar necrosis and degeneration. Therefore steps should be taken to minimize laminar edema formation. The best approach is to ensure that the plasma oncotic pressure is sufficient by supplementation with plasma or another colloidal solution such as hydroxyethyl starch or plasma. Additionally, one should take care when administering intravenous fluid therapy to horses with acute laminitis or those predisposed to develop it because excessive intravascular volume caused by overzealous fluid administration could perpetuate development of laminar edema in horses with abnormal digital hemodynamics (i.e., increased capillary hydrostatic pressure). Therefore the authors suggest that fluid therapy be monitored carefully so as to avoid administering fluids in excess of the volume needed to maintain normal hydration. Although venous vasoconstriction is one of the events involved in the pathogenesis of laminitis, drugs currently available do not appear to be effective at blocking this vaso-constrictive response. Acepromazine (0.03 to 0.06 mg/kg intramuscularly or intravenously every 6 to 8 hours) must be administered at low doses to prevent hypotension and sedation. Glyceryl trinitrate applied topically (2 or 4 mg/hr patches) does not increase digital blood flow. Isoxsuprine hydrochloride (1.2 mg/kg orally every 12 hours) appears safe, but no evidence of efficacy has been found.

Continuous cooling of the limbs (up to the carpus and tarsus) reduces the severity of laminitis in experimental models. Expression of mRNA for matrix metalloproteinase (MMP)-2 and histologic lesions were reduced by continuous bathing of the limbs in water kept at 0° C.<sup>56</sup> Reduced blood flow, inflammation, and enzymatic activation are all possible sequelae to this intense cooling. The clinical efficacy of this practice is less than that reported experimentally. Maintaining constant immersion of limbs of compromised patients in these cold baths and initiating cryotherapy in the earliest stages of naturally occurring disease are very difficult.

Antiinflammatory medications are indicated to decrease inflammation, edema, and pain associated with laminitis. Phenylbutazone appears to have the best anti-inflammatory and analgesic effect of any of the NSAIDs commonly used in horses. The practitioner can administer a dose of 2.2 to 4.4 mg/kg of phenylbutazone intravenously or orally every 12 hours. Alternatively, flunixin meglumine can be administered at 0.5 to 1.1 mg/kg intravenously or orally every 8 to 12 hours. A dose of 0.25 mg/kg flunixin meglumine administered intravenously every 8 hours interrupts eicosanoid production associated with endotoxemia but provides little analgesic effect at that dose. Ketoprofen and firocoxib are also available for

use in horses. DMSO is an antiinflammatory drug that scavenges hydroxyl radicals, decreases edema, and therefore is used to counteract the effects of ischemia-reperfusion injury. Although the involvement of oxygen free radicals generated by ischemia-reperfusion is questionable, oxygen free radical generation caused by insulin resistance is potentially an important event in the pathogenesis in some horses. DMSO can be administered at 0.1 to 1.0 g/kg intravenously diluted in a polyionic fluid with dextrose to a concentration of 10% to 20% every 8 to 12 hours. Some clinicians prefer to place DMSO topically on the coronary bands.

Pentoxifylline is a phosphodiesterase inhibitor that improves blood flow in people through actions on the red cell membrane. Pentoxifylline does improve red blood cell deformability in horses but does not increase digital blood flow in healthy horses when administered orally at relatively low doses.<sup>57,58</sup> Although pentoxifylline has not been evaluated in the treatment of equine laminitis, numerous *in vivo* and *in vitro* studies performed in horses document anti-inflammatory activities.<sup>59-63</sup> Recent data suggest intravenous (8.5 mg/kg) and oral (10 mg/kg) delivery yields plasma drug concentrations similar to those used for the treatment of intermittent claudication in people. The efficacy of these plasma concentrations in equine disease is not known.<sup>64</sup>

Doxycycline has recently been approved for use as an MMP inhibitor in human patients. Extrapolation has led to use of doxycycline in equine laminitis to inhibit MMP-mediated destruction of laminar connections. In contrast, results of recent studies in horses with endotoxemia reveal that doxycycline is a very weak inhibitor of MMPs in horses.<sup>65</sup> The alteration of microbial flora that may occur with oral administration of doxycycline may be contraindicated in horses with alimentary-associated laminitis.

Because microthrombi and platelet-platelet or platelet-neutrophil aggregates have been shown to form during laminitis, some clinicians prefer to administer heparin or aspirin to horses as a preventive or therapeutic agent. One can administer heparin using several regimens, but administration is often subcutaneous at a dose of approximately 20,000 to 40,000 units for a 450-kg horse. Heparin leads to microagglutination and a subsequent decrease in packed cell volume. No evidence indicates that administration of heparin prevents the onset of laminitis. Aspirin is often administered at a dose of 10 to 20 mg/kg orally once every 48 hours. Aspirin irreversibly inhibits platelet cyclooxygenase and therefore production of thromboxane, which should decrease platelet aggregation and vasoconstriction.

Efforts to reduce mechanical forces and stabilize the distal phalanx are imperative to effective treatment of acute laminitis. Horses should not be exercised during the acute stages because it can lead to increased mechanical forces that could lead to shearing of laminae. Owners should bed the stall deeply with sand or other material that provides support to the frog and provides some cushion if the horse spends long periods recumbent. Providing early and effective mechanical support of the distal phalanx can spare weakened, separating lamellae and improve the outcome. Ideally, mechanical support should be instituted before or at the onset of foot pain. Frog support is one of the more effective methods of providing support to the distal phalanx and can be achieved by using roll gauze taped to the frog in the shape of a triangle. One also can use a commercially available triangular, rubber frog pad. Using a moldable material such as dental putty or a thermoplastic material,

a frog support can be conformed to the shape and sulci of the frog and sole, allowing for a more effective distribution of the mechanical support to the frog and subsequently the distal phalanx. The practitioner must take care to support the frog fully but not allow excessive pressure on the sole because this added pressure may increase pain.

Another method to decrease mechanical forces on the distal phalanx is to transect the deep digital flexor tendon to reduce caudal pull on the coffin bone. A deep digital flexor tenotomy has been performed in several horses in acute and chronic stages of laminitis to prevent or reduce coffin bone rotation. Although the short-term outcome was promising, the long-term survival and soundness proved to be less successful. The most appropriate use of a deep digital flexor tenotomy may be to perform it in association with corrective trimming and shoeing during the chronic stages of laminitis to help reverse the amount of rotation.

Each clinician will undoubtedly develop a therapeutic plan based on current literature and on past experiences with the effectiveness of these treatments. The information presented here simply represents some of the currently used methods. Obviously, other methods have not been discussed that may also have merit. The effectiveness of preventive and therapeutic measures needs to improve significantly to help manage this devastating disease. Improvement will become a reality only as researchers collectively work to unravel the remaining mysteries of the pathophysiologic events leading to acute laminitis.

## PROGNOSIS

Many horses that demonstrate clinical signs of acute laminitis that receive prompt, appropriate medical treatment and mechanical foot support may recover completely. However, horses, even with mild laminitis, should be withheld from exercise until all signs have subsided and only cautiously returned to athletic function. The primary disease that initiates the onset of laminitis also plays an important role in the prognosis and outcome. Management of the primary disease (i.e., strict dietary management and structured exercise in the case of obesity) is critical to slowing or stopping the progression of laminitis. If radiographs demonstrate signs of coffin bone rotation the prognosis for soundness and even survival must be more guarded. In general the greater the degree of coffin bone rotation, the worse the prognosis. Horses with greater than 15 degrees of rotation accompanied by distal displacement into the hoof capsule within 4 to 6 weeks of the onset of laminitis have a poor prognosis. Prolapse of the distal phalanx through the sole is often accompanied by subsolar abscessation. These horses often require extensive, long-term treatment, and the prognosis is grave because of the recurrent, crippling pain and recumbency, and they often require euthanasia for humane reasons. In one study of horses with acute laminitis admitted to a university veterinary hospital, 75% did not return to athletic function, and most were destroyed humanely within 1 year because of a lack of response to therapy or development of severe complications.<sup>4</sup>

## SUMMARY

Laminitis is very complex in its pathogenesis, and researchers and clinicians will need to dedicate substantial resources to continue studies of the various predisposing conditions,

converging pathways, and effective treatments to decrease ultimately the numbers of horses with and the severity of laminitis.

# DISORDERS OF THE NEUROLOGIC SYSTEM

## CHAPTER 12

*Stephen M. Reed, Frank M. Andrews*

### NEUROLOGIC EXAMINATION

*Stephen M. Reed*

Assessment of the central nervous system (CNS) in horses may seem a difficult task; however, with careful examination using a craniocaudal approach, assessment is not difficult. A craniocaudal approach is the most logical and efficient. The examination focuses on the neuroanatomic localization of the lesion or lesions and should be completed as part of the physical examination. Subtle neurologic deficits may be hidden by musculoskeletal disease or missed because of lack of knowledge or understanding of these disorders. To accomplish a complete and accurate neurologic examination, the veterinarian must feel comfortable with the format chosen for evaluating the nervous system and must have knowledge of which musculoskeletal disorders commonly are associated with neurologic disease. Problems such as osteochondrosis of the stifle, hock, and shoulder joints often occur concurrently in horses with cervical vertebral stenotic myelopathy.

Examples of typical histories in horses presented for neurologic examination, especially for signs of spinal ataxia, include previous medial patellar desmotomy, bilateral bog spavin in early life, osteochondrosis of the distal tibia or femur, and contracted tendons. All of these problems associated with developmental orthopedic diseases are examples of conditions that may occur simultaneously. Bilateral bog spavin often is associated with osteochondrosis of the distal tibia or other sites in the tibiotarsal joint. Patellar desmotomy to correct upward fixation of the patella may be necessary because of a conformational problem of the stifle joint or as a result of abnormal joint proprioception or quadriceps weakness after neurologic disease. The foregoing problem is more commonly associated with neurologic disease than many veterinarians realize, and the gait deficits caused by these lamenesses often mimic neurologic disease. Horses with bilateral osteochondritis dissecans (OCD) lesions of the stifle joints will often “bunny-hop” while running, which may be interpreted as a sign of neurologic disease rather than as a result of an underlying musculoskeletal disease.

The goals of a neurologic examination are to establish whether a neurologic problem is present and to determine the

anatomic localization of the problem. Being able to account for all clinical signs with a single lesion is ideal; however, if this is not possible, then one should consider the possibility of multifocal disease or multiple diseases. In addition to anatomic localization of a lesion, it is important to record the findings of the examination as a baseline for comparison of future evaluations. After anatomic localization, one must decide what additional testing is necessary to determine the underlying cause of the clinical signs. Cervical radiography, cerebrospinal fluid (CSF) analysis, and electrodiagnostic testing may be useful in locating and determining the cause of the lesions.

The neurologic examination should be considered part of the physical examination. The author prefers to begin the examination at the head and proceed caudally to the tail. The examiner should proceed in a consistent fashion and should record findings in an orderly manner to avoid any part of the examination being omitted. [Figure 12-1](#) shows a sample format. One may use the craniocaudal approach for all animals, whether ambulatory or recumbent.

The equine neurologic examination procedure has been described in detail elsewhere.<sup>1-13</sup> The author follows the format developed by Mayhew,<sup>1</sup> which divides the examination into five categories: (1) the head and mental status, (2) gait and posture, (3) neck and forelimbs, (4) trunk and hindlimbs, and (5) tail and anus. The functional divisions of the nervous system include the sensory, integration, and motor systems.

Before starting the examination, one should know the age, gender, breed, and use of the horse, although these are not essential. This information is useful because horses of various breeds behave differently. One should ask the owner about any unusual behavior the horse has exhibited and the date of onset of the behavior. Age is helpful because problems such as cervical vertebral stenotic myelopathy and cerebellar abiotrophy begin at a young age, usually less than 1 year. These problems occur more often in certain breeds. For example, cervical vertebral stenotic myelopathy is most common in Thoroughbreds, and cerebellar abiotrophy most often is observed in Arabians.

### ☞ EXAMINATION

The evaluation of the head should include observation of the horse at rest and during motion; palpation, postural reactions, cranial nerve function, and cervicofacial reflexes; and evaluation

of sensation. At the start of the examination the horse should be observed for alertness, mentation, attitude, and behavior (remembering that the animal's environment may influence its degree of excitement). Evaluation of the head includes observation of the behavior and mental status of the horse. One can complete this portion of the examination by careful observation even before handling the horse. A close and careful examination is necessary to evaluate the head and neck posture

and coordination and to identify abnormalities of the cranial nerves. Initial consideration includes the environmental awareness of the horse. A normal horse appears bright and alert and responds appropriately to external stimuli. While the horse is being caught, the examiner can look for unusual behaviors such as yawning, abnormal or aimless wandering, seizures, or circling or head tilt and can begin to assess the vision and hearing of the horse. This is also a good time to observe how the horse is

FIGURE 12-1, cont'd.

standing and whether it has the limbs positioned appropriately under its body. The veterinarian should note any behavioral abnormalities, such as head pressing (a clear sign of cerebral disease) and aggressiveness (noted in animals that are not feeling well, as well as animals with CNS disease). If the examiner suspects rabies, then the examiner should take precautions to avoid unnecessary and potentially dangerous exposure.

Lesions of the reticular activating system or the cerebral hemispheres could result in coma or obtundation of consciousness. Horses demonstrating compulsive walking

may have a diffuse cerebral disease, whereas a horse walking in large circles may have an asymmetrical forebrain lesion. Horses that have a serious systemic illness also may appear depressed or stuporous. One records the level of consciousness as *alert*, *depressed*, *stuporous*, *semicomatose*, or *comatose*. An animal that is depressed may react to its environment in an inappropriate or unresponsive fashion. Stuporous horses may appear to be asleep unless stimulated with pain, light, or noise and often demonstrate impaired reactivity.

Head posture and coordination are controlled by the cerebellar and vestibular regions of the brain and brainstem in response to sensory input from receptors in the head, limbs, and body. Examining the head and neck posture with the horse at rest, while eating, and while moving is helpful. In horses with normal head carriage, the head should be held straight and upright when viewed from the front. Head posture and coordination are controlled by the vestibular and cerebellar systems in response to sensory input from the head, neck, limbs, and trunk. Careful examination of the vestibular region is important because many horses develop a head tilt resulting from head trauma, temporohyoid osteoarthropathy (THO), or a guttural pouch infection. A head tilt is characterized by the poll deviated about the muzzle and must be distinguished from abnormal or unusual turning of the head or lateral deviation of the head as may occur with damage to the forebrain or injury to the cervical vertebrae. Additional signs that may accompany vestibular disease or injury include nystagmus, ipsilateral weakness, and facial nerve paralysis.

Postural abnormalities of the head and neck sometimes can be difficult to distinguish from head tilt. Horses with torticollis of the head and neck may have a congenital abnormality of the vertebrae or may have injured the muscles of the neck region. Damage to the dorsal gray columns can result in abnormal head and neck posture (acquired scoliosis) that has been described as a result of parasitic migration such as *Parelaphostrongylus tenuis*.<sup>4</sup> Careful examination, including palpation, should help identify fractures of the cervical vertebrae or painful muscles caused by trauma or an injection reaction. Neck pain may manifest as a reluctance to move the head and neck through a full range of motion. In the absence of pain or mechanical limitations to movement, normal horses should be able to turn their head to retrieve feed offered at the lateral thorax on each side, elevated to a level above the withers, or lowered to a point between the front legs just beneath the pectoral muscles. In some horses, radiographs of the cervical vertebrae may be useful to confirm a fracture or osteomyelitis. Blindness sometimes can lead to an abnormal head or neck posture.

The cerebellum helps regulate rate and range of motion. With damage to this area a horse often shows fine resting tremors of the head that worsen with intentional movements.<sup>3</sup> One may normally observe this tremorous movement of the head and neck in the newborn or young foal, but it is not normal in older foals and adult horses. In young Arabians and a few other breeds, a condition of cerebellar abiotrophy has been reported.<sup>1-3</sup> Horses with this condition show a hypermetric gait, failure to blink when exposed to bright light, and absence of a menace response.

After evaluating the alertness, mental attitude, head and neck posture, and coordination of the horse, the examiner should examine the cranial nerves closely. Systematic examination of the first to twelfth cranial nerves helps to ensure that a subtle lesion along the brainstem is less likely to be missed, although in fact the examiner assesses many of the cranial nerves simultaneously on approach to the horse. The examiner evaluates facial symmetry, facial sensation (including sensation inside the nares), head posture, eyes, nose, mouth, jaw tone, pharynx, and larynx. To determine if an animal can detect scent is usually not as important, but determining if it can see, hear, breathe, and swallow is critical.

Examination of the eyes should include evaluation of the blink or menace response, the ability of the horse to negotiate in a strange environment, pupillary light response, and in

some cases a funduscopic examination. If a horse has a lesion of the eye or optic nerve, then the lesion will result in complete or partial ipsilateral blindness. To develop contralateral blindness, the horse would have to have a lesion in the optic tract or the lateral geniculate nucleus.<sup>1</sup>

Examination of the face should include evaluation of pupil size and symmetry, which are under control of the autonomic nervous system and are affected by environmental light and level of fear or excitement. To test the pupillary response, one should direct a light in each eye and note the constriction of the pupil. Identifying a consensual response in the horse is often difficult when one works alone. A swinging light test has been described.<sup>1</sup> In the performance of this test, the light is shone alternately into each eye and the more powerful direct pupillary light response is observed. A unilateral lesion affecting the afferent tracts in the eye, optic nerve, optic chiasm, or optic tract to the level of the midbrain will result in ipsilateral dilation when the light reaches the affected eye. Moving the light from side to side takes advantage of the ipsilateral light response being stronger than the consensual response. The examiner can perform this procedure alone. These reflexes are in the brainstem and are not affected by lesions in the visual cortex.

One possible cause of asymmetrical pupils in a horse is Horner's syndrome. Horner's syndrome is the collection of clinical signs associated with dysfunction of the sympathetic nerve supply to the head and neck. The sympathetic nerve supply to the head includes upper motor neurons in the caudal hypothalamus, parts of the midbrain and pons, as well as parts of the medulla oblongata. Axons from these centers descend in the cervical spinal cord to the preganglionic neurons in the cranial thoracic spinal cord. From here, preganglionic axons leave the cord and join the paravertebral sympathetic trunk, where they ascend up the neck to synapse in the cranial cervical ganglion in the guttural pouch.<sup>4</sup> This syndrome includes ptosis of the upper eyelid, miosis of the pupil, and protrusion of the third eyelid (nictitating membrane). In addition, the horse has unilateral facial sweating, increased facial temperature, and hyperemia of the nasal and conjunctival membranes. These signs should alert the examiner to the possibility of a previous perivascular injection, a guttural pouch infection, or damage to the sympathetic nerves in the vagosympathetic trunk, which courses from the cranial thoracic spinal cord through the thoracic inlet and upward to the orbit.<sup>5</sup> Loss of sympathetic innervation to the head results in the triad of clinical signs described, with the most prominent initial sign being increased sweating, which is not what one would expect and the exact cause of which is not well understood.<sup>6,7</sup>

Loss of symmetrical positioning of the eyes or the presence of abnormal deviation (i.e., strabismus) occurs when a horse has injured the third (oculomotor), fourth (trochlear), or sixth (abducens) cranial nerve or the connections between the eighth (vestibulocochlear) cranial nerve and these nuclei in the brainstem along the medial longitudinal fasciculus. Deviations of the eyes may occur with head trauma or midbrain lesions or can be normal variations in newborn foals. When the head is elevated dorsally, the eyes should move ventrally to maintain a normal horizontal gaze. When the head is moved from side to side, the eyes should move slowly opposite to the direction of the head movement, then move quickly in the direction of the head movement; this is referred to as *normal vestibular nystagmus*. Spontaneous or positional nystagmus is always abnormal.

The nuclei along the fifth (trigeminal) cranial nerve are among the largest nuclei along the brainstem of the horse. The fifth cranial nerve contains motor and sensory branches that supply innervation to the muscles of mastication and sensation to the skin and mucous membranes of the head. Injury to this nerve leads to dropped jaw and ipsilateral loss of, or decreased sensation to, the side of the face and the inside of the nares.

Damage to the seventh (facial) and eighth cranial nerves is common in horses. Injury to the seventh cranial nerve results in unilateral facial paralysis. This nerve contains branches that supply the ears, eyelids, and nares, and so injury to this nerve may affect all or only part of these structures. The most easily recognized sign is deviation of the nares toward the unaffected side coupled with drooping of the eyelid and ear on the affected side. Because this nerve also innervates the salivary and lacrimal glands, loss of or damage to this nerve may cause dry eye and decreased salivation.

Eighth cranial nerve deficits are easy to recognize, because unilateral injury to this nerve results in a head tilt toward the affected side. The eighth cranial nerve is important to hearing and control of balance. Projections from this nerve pass to the medulla and cerebellum. A horse that has damage to this nerve often appears disoriented and has a head tilt toward the side of the lesion along with abnormal position of the limbs and body and horizontal nystagmus. If the lesion involves the peripheral portion of the vestibular system, then the fast phase of the nystagmus is directed away from the side of the lesion. If the lesion involves the central portion of the vestibular system, then the nystagmus may appear vertical, rotary, or horizontal and may not always appear the same, depending on head position.

Horses that have peripheral damage to the vestibular system usually compensate for the deficits in a short time by use of visual and proprioceptive input. Therefore avoiding the use of a blindfold in cases of suspected vestibular disease is judicious. Using a blindfold hampers the ability of the horse to compensate, and the horse may become dangerous. However, blindfolding a horse with a suspected vestibular disease, but no longer showing an obvious head tilt, may be helpful to localize the lesion.

Within the medial compartment of the guttural pouch, along the caudodorsal and lateral walls, are the ninth (glossopharyngeal) cranial nerve and a branch of the vagus nerve. When a horse develops a guttural pouch infection, these nerves may be damaged, resulting in loss of innervation to the pharyngeal muscles. The clinical signs include dysphagia on the same side as the damaged nerve. If the infection is severe enough to involve the internal carotid nerve, which contains postganglionic sympathetic fibers to the structures of the head and eye, then Horner's syndrome results. As mentioned previously, the signs include ptosis of the upper eyelid, enophthalmos resulting in prolapse of the third eyelid, miosis of the pupil, and sweating along the side of the face.

Other diseases one should consider when Horner's syndrome is evident during a neurologic examination include injury or infarction to the cranial thoracic spinal cord, avulsion of the brachial plexus, a hematoma, or tumor invading the sympathetic trunk in the region of the caudal, cervical, or cranial thoracic sympathetic trunk. Mycosis of the guttural pouch can cause damage to the internal carotid nerve or the cranial cervical ganglion along the caudodorsal wall of the guttural pouch. Finally, an injury to or neoplasia of the structures within or just behind the orbit also may cause Horner's syndrome.

Focal sweating in a horse indicates involvement of the peripheral pre- or postganglionic sympathetic neurons. Identification of this problem also can aid in the anatomic localization of a neurologic lesion.<sup>1</sup>

Intact innervation to the larynx and pharynx is important, especially if the horse is to be used as an athlete. The easiest means to evaluate this region is by endoscopic examination of the pharyngeal and laryngeal regions. One can perform throat latch palpation and a laryngeal adductory slap test. Endoscopic examination is helpful and important to a complete evaluation. The innervation of the pharynx and larynx is via the ninth, tenth (vagus), and eleventh (accessory) cranial nerves and the connections of these nerves in the caudal medulla oblongata.

The twelfth cranial nerve, the hypoglossal nerve, has cell bodies in the hypoglossal nucleus of the caudal medulla oblongata and provides motor innervations to the muscle of the tongue. Normal horses provide a strong resistance to withdrawing the tongue from the mouth; horses with unilateral cranial nerve XII dysfunction have unilateral atrophy with weak retraction. Bilateral dysfunction interferes with prehension and swallowing, the tongue often protrudes from the mouth, and the horse has difficulty or is unable to withdraw the tongue. Severe cerebral lesions may also interfere with tongue retraction because of interference with voluntary control pathways.

After careful examination of the mental status and behavior of the horse and of the head, neck, and cranial nerves, the examiner should look for asymmetry of the muscles of the trunk, pelvic region, tail, and anus. Identification of focal sweating, focal muscle atrophy, or increased or decreased pain responses is helpful in localizing signs. In addition, the horse has two cervical reflexes. The cervicofacial reflexes result in a local twitch and drawing back of the lips (smile reflex) when one pricks the skin along the side of the neck down to the region of the second cervical vertebra. Below the region of the second cervical vertebra one should observe a local response.<sup>14</sup>

To evaluate the tail and anus, one should begin by observing the tail carriage at rest and with the horse in motion. The normal tail carriage is straight down but with free movement in all directions. Some normal horses allow the tail to be lifted, giving little resistance, whereas other horses strongly resist and clamp the tail. The usual response to anal stimulation is to clamp the tail and squat down, although with prolonged stimulation the horse may relax and eventually raise its tail.

## EVALUATION OF GAIT

Evaluation of the gait of the horse should include examination of postural reactions and may include evaluation of spinal reflexes in young or small horses. Although they may appear weak and ataxic, foals are ambulatory within hours after birth, making it possible to evaluate gait. Because postural reactions are sometimes difficult to interpret in horses, using gait abnormalities to help localize a lesion is essential. The author nearly always places the feet and limbs in an unusual position to observe the response of the horse. Gait abnormalities that are observed commonly in horses with neurologic disease include ataxia, spasticity, and weakness or paresis.<sup>1-3,4,15,16</sup>

Evaluation of gait is critical because subtle neurologic gait deficits often go unrecognized or sometimes, incorrectly, may be considered insignificant. One should conduct the examination to observe the horse at a walk and trot in a straight line and while turning. In some horses, observing the

horse negotiate over small obstacles such as a curb is helpful. When possible, the examiner should observe the horse turned free and walking up and down an incline. Elevation of the head and walking on a slope may exaggerate a subtle deficit and make it more noticeable.

One should include in the examination observation of the horse at rest to observe its posture while standing, walking, trotting when possible, and sometimes while the horse is being ridden. The examiner should pay attention to which limbs show abnormal posture or abnormal movements and must be able to determine whether the horse has a painful or mechanical musculoskeletal problem or a neurologic gait deficit. The examiner must identify the presence of weakness, ataxia, and spasticity in each limb.

The important centers for posture and coordination in the brainstem and spinal cord are located in the regions of the sixth cervical to second thoracic (T2) and fourth lumbar to second sacral (S2) vertebrae in the spinal cord, along with coordination centers in the brainstem. Horses that demonstrate a wide base stance at rest often have a lesion of the cerebellum or vestibular system or may have conscious proprioceptive abnormalities.

To evaluate the gait of an animal, one begins by observing the horse at a walk and trot. At a walk the examiner can walk alongside, in step with first the pelvic limbs and then the thoracic limbs. This allows the examiner to more easily determine the stride length and foot placement. A weak limb often has a low arc and longer stride length.

One also should observe the horse walking in a circle, on a slope, and with its head elevated. These procedures provide a degree of "challenge" to the horse and may help to demonstrate if the horse is showing persistent irregular movements with its limbs. Horses with a musculoskeletal problem have been described as being a regularly irregular gait, whereas a horse with neurologic gait deficits shows less consistency placing its limbs (an irregularly irregular gait). Although observing the horse running free in a paddock or round pen and while being ridden can sometimes be helpful, this is not always possible. One must consider safety for the horse and rider, as well as certain legal ramifications before asking a person to ride a horse during the examination.

Additional tests that may be helpful during a neurologic examination include blindfolding the horse, walking it over a curb or other obstacle, and walking it with its head and neck extended. One can evaluate the strength and ability of the horse to correct body positions by performing a sway test by applying lateral pressure at the shoulder, hip, and tail while the horse is standing and walking. One should apply pressure several times while the horse is walking to catch the limb in various stages of weight bearing. Observing a horse during the backing process is important. When a normal horse is backing, it should lift each leg and place it in a coordinated and appropriate location. Horses with neurologic abnormalities often place the limbs in wide-based positions or lean back and are reluctant or refuse to move. The horse also may step on the feet of a pelvic limb with the front feet.

The horse should be observed closely while being turned in a tight circle to identify abnormal wide outward excursions of the pelvic limb (circumduction). Additional tests to assess proprioceptive function include a standing sway test in which one applies pressure to the shoulder. The horse initially should press into the examiner and then lean away, and finally it should step away with the offside limb. The author also crosses the limbs over the opposite thoracic or pelvic

limb to determine if the horse recognizes and tolerates these unusual limb positions. After this, the examiner might lift one thoracic limb and force the horse to hop on the opposite limb in a modified postural reaction.

The examiner should observe the movements of each limb carefully to determine if a deficit is present and should assign a grade to the deficit. The author uses a system modified from the grades described by deLahunta<sup>3</sup> and Mayhew.<sup>1</sup> The severity is graded between 0 and 5. Grade 0 means no gait deficits. A grade 1 deficit requires careful observation to be certain the gait abnormality is caused by a neurologic dysfunction. Grade 2 deficits are mild to moderate but obvious to most observers as soon as the horse begins to move. Grade 3 deficits are obvious and are exaggerated during the negotiation of a slope or with head elevation. Grade 4 gait deficits may cause a horse to fall or nearly fall. When attempting to walk, an animal with these severe deficits often displays abnormal positioning while standing in its stall. Grade 5 horses are recumbent.

Weakness or paresis is a deficiency of voluntary movement as a result of loss of muscle power because of either damage to upper motor neurons, lower motor neurons, or the muscle. It can be described as knuckling, stumbling, or buckling and sometimes can be characterized by toe-dragging while walking. Weakness may be associated with an upper motor neuron or lower motor neuron lesion. In the case of a lower motor neuron or peripheral nerve injury or illness, the horse shows muscle atrophy and sensory loss. A spastic movement of the limbs often accompanies the weakness that results from loss of upper motor neurons. Ataxia is typified by abnormal foot placement and wide swaying of the foot and limb, especially while turning. Ataxia appears as a lack of coordination of motor movements. It can arise from damage to the vestibular, cerebellar, or sensory portions of the nervous system. Ataxia in horses is most often a result of loss of sensory input through injury, damage, or disease in the spinal cord blocking normal input to the cerebellum. Cerebellar ataxia is seen most often in young horses, typically Arabians with a condition known as *cerebellar abiotrophy*. Vestibular ataxia is often accompanied by a head tilt and other cranial nerve deficits.

Horses may also demonstrate dysmetria, which is characterized as exaggerated hypermetric or hypometric movements of the limbs. Horses with hypometric gaits often appear to have a straight leg or "tin soldier" way of moving (sometimes referred to as *spasticity*). A spastic gait is the result of increased muscle tone and is generally associated with upper motor neuron disease resulting from reduced inhibition of extensor motor neurons.

The gait abnormalities, along with the findings from other parts of the neurologic examination, allow the examiner to determine the neuroanatomic site of the problem. The severity of the clinical signs also helps one evaluate the extent or severity of the problem.

One should reexamine horses with an obscure or unusual gait that might be the result of lameness after the use of local anesthetics (to block selected peripheral nerves) or intra-articular medications. The use of nonsteroidal anti-inflammatory drugs (NSAIDs) for a period of 1 to 2 days also may alleviate pain and help one distinguish between lameness and a neurologic gait deficit.

One must realize that many horses that have minimal (grade 1 or mild grade 2) deficits often can race or perform other athletic activities.<sup>13</sup> The examining veterinarian has the responsibility of separating a neurologic from a musculoskeletal

gait deficit and helping the owner determine the usefulness of the horse. For example, a horse with gait deficits up to grade 3 may be useful as a broodmare or breeding stallion (if the horse is handled by careful, knowledgeable persons who understand the risks and have the facilities to accommodate a horse in need of special management). Stallions with this degree of impairment may require assistance when mounting and dismounting mares. If the breed association allows artificial insemination, then the stallion may be easier to manage.

## LOCALIZATION OF THE LESION

At the conclusion of the examination, the veterinarian needs to determine if a neurologic abnormality exists and where it is located. If the horse showed no evidence of abnormal behavior, seizures, or abnormal mental status and showed no cranial nerve deficits, then the lesion is most likely caudal to the foramen magnum.

The most difficult lesions to localize are in the brainstem, unless the signs include cranial nerve deficits or depression. Horses with brainstem lesions often show signs of weakness and ataxia similar to horses with a lesion in the cervical spinal cord. Two of the most common brainstem lesions in horses involve the seventh and eighth cranial nerves. Vestibular disease or injury may be a sequela of head trauma or an inner ear infection. Facial nerve paralysis may result from trauma to the nerve root origin in the brainstem or where the nerves course along the neck and face to the ears, eyelids, and nares.

Specific cranial nerve involvement, such as head tilt, facial nerve paralysis, or loss of facial sensation, can result from trauma, guttural pouch infection, THO, or equine protozoal encephalomyelitis. In addition, cranial nerve deficits may occur with polyneuritis equi and equine motor neuron disease (EMND).

Cerebellar lesions are characterized by a failure to blink to bright light, lack of a menace response, and a head tremor that worsens with intentional movements. The most common form of cerebellar disease in horses is abiotrophy, which occurs most frequently in Arabian horses.

Cervical spinal cord disease includes gait and proprioceptive deficits in all four limbs with no signs of brain, brainstem, or cranial nerve deficits. One should note that horses with cervical vertebral stenotic myelopathy might have mild pelvic limb deficits with minimal or barely detectable signs in the thoracic limbs.<sup>16</sup>

Horses with signs of neurologic gait deficits confined to the pelvic limbs have a neuroanatomic localization caudal to T2. When examining a horse with a lesion caudal to T2, carefully checking the tail and anus for involvement of the peripheral nerves or spinal cord segments in this region is important.

Horses that have peripheral nerve injury (Table 12-1), EMND, or polyneuritis equi show evidence of weakness, muscle atrophy, and in some cases selected areas of sensory loss. Primary muscle diseases such as exertional rhabdomyolysis, myotonia (congenita or dystrophica), and hyperkalemic periodic paralysis are covered elsewhere in this book (see Chapter 11). These conditions sometimes can mimic a neurologic problem.

## DESCRIPTION OF NORMAL GAITS

A walk is a natural four-beat gait in the horse. At this gait the normal horse has three feet on the ground at all times. Therefore the walk is a stable gait. Overtracking and interference

may occur if the conformation of the horse is abnormal (e.g., with long limbs and a short body) and not as a result of neurologic disease.<sup>11</sup> The trot is a two-beat symmetrical gait in which the diagonal limbs are in contact with the ground at the same time. If one examines the horse on hard pavement, then the trot is the most helpful gait to distinguish lameness from a neurologic gait deficit. The pace is a two-beat symmetrical gait in which the legs on the same side of the body strike the ground simultaneously, resulting in significant truncal sway. In horses that have neurologic disease, identifying ataxia with truncal sway, which is often accompanied by pacing, is common. In horses with subtle ataxia, one observes pacing when horses walk with the head held in an extended position. Whenever one observes a horse pacing, the pacing may indicate an underlying neurologic disorder.

The gallop is a high-speed four-beat gait that often seems to be easier to perform than walking in a tight circle or moving at a slow trot. Therefore some horses with a neurologic gait deficit may perform better at high speed. As the horse accelerates or slows down, one may detect abnormalities, and one must observe the horse carefully at this time when an ataxic horse is most unsafe.

Abnormal gaits associated with stringhalt, upward fixation of the patella, and fibrotic myopathy deserve careful attention. Horses that show these gait abnormalities have a mechanical lameness, although the exact cause is unknown and may sometimes be associated with underlying neurologic disease.

Stringhalt often begins as an abrupt onset of excessive flexion of one or both rear limbs. In some horses the condition may worsen and result in frequent episodes of the foot hitting the abdomen. The condition has been reported for a long time and in some areas of the world may occur as an outbreak.<sup>17</sup> The clinical syndrome is similar to the movement of a horse with a tibial neurectomy with unopposed flexion of the hock and extension of the digit. In the case of Australian stringhalt, the forelimbs and neck muscles may be involved. Stringhalt deserves mention in this chapter because when the examiner observes this gait, the examiner should be certain no other signs of neurologic gait deficits exist. The primary condition usually can be corrected by a tenectomy of the lateral digital extensor tendon, including a portion of the muscle belly. The underlying cause of the disease may be a sensory neuropathy, a myopathy, or primary spinal cord disease. The defect likely affects the neuromuscular spindle, as well as the efferent and afferent pathways controlling muscle tone.<sup>10</sup>

Fibrotic myopathy results from scar tissue formation after injury to the semitendinosus and semimembranosus muscles. One may confuse the characteristic foot placement coupled with the abrupt rearward movement of the affected limb with a spastic gait caused by spinal cord injury (SCI) or disease. With careful examination, a horse suffering from fibrotic myopathy likely will not go undiagnosed.

Upward fixation of the patella in horses with neurologic disease may result from weakness in the quadriceps muscle group. This weakness is thought to occur because of a lack of use of these muscles or may be caused by abnormal transmission of proprioceptive information to and from the muscles and joint capsule because of damage to the spinal cord.

Horses with profound ataxia may pace when they walk, which often is accompanied by circumduction of the outside rear limb while turning. These signs suggest general proprioceptive deficits. If the horse has these deficits while walking, then the examiner should observe the horse walking with its

TABLE 12-1

Localization of peripheral nerve injuries in horses		
Nerve	Clinical Signs	Common Causes of Injury
Suprascapular	Injury is termed sweeney. Eventual atrophy of supraspinatus and infraspinatus muscles. Lateral subluxation (popping) of the shoulder upon weight bearing. This may be caused by lack of lateral collateral support (suprascapular muscles) or by additional involvement of the pectoral nerve, subscapular nerve, caudal cervical nerve roots, or other muscular and tendinous supporting structures of the shoulder.	Collision of shoulder with objects.
Radial	Unable to bear weight on affected limb because of a lack of elbow extension. The shoulder is rested in an extended position and the limb rests with the dorsum of the pastern on the ground. The limb may be moved forward by the action of the pectoral girdle muscles while the horse walks.	Often damaged in conjunction with humeral fracture; Occasionally observed after recovery from general anesthesia.
Brachial plexus	Signs of radial nerve paralysis often predominate. Evidence of suprascapular involvement not uncommon. Involvement of other nerves and nerve roots may be confirmed with EMG. Possible long-term atrophy of triceps. May have diffuse hypalgesia of lower limb.	Compression of the brachial plexus and radial nerve roots between the scapula and the ribs.
Musculocutaneous	Paralysis not common. Gait not markedly altered. Elbow may be overextended. Hypalgesia of medial forearm. Ultimately biceps and brachial muscles atrophy.	Uncommon.
Median and ulnar	Stiff, goose-stepping gait with hyperextension of the carpal, fetlock, and pastern joints.	Uncommon.
Femoral	Unable to support weight as a result of lack of stifle extension. At a walk, the limb is advanced only with difficulty and the stride is markedly shortened. The limb buckles due to stifle, hock, and fetlock flexion if the horse attempts to bear weight. Quadriceps muscle will atrophy after 10-14 days. Patellar reflex is absent.	External blow to the limb; occasionally observed after recovery from general anesthesia.
Sciatic	Poor limb flexion with stifle and hock extended and fetlock flexed when the horse is not bearing weight. Weight can be supported if the foot is extended; otherwise weight is supported on the dorsal surface of the foot. Limb hypalgesia from stifle downward with the exception of the medial surface between stifle and hock.	Variety of injuries may be causal. Occasionally occurs secondary to intramuscular injections, especially in foals; occasionally observed after recovery from general anesthesia.
Tibial	Hypermetric or stringhalt-like gait with flexion of the hock (dropped hock) at rest. Hypalgesia of areas of caudal limb distal to the hock including most of the caudal and medial coronary band area.	Uncommon.
Peroneal	Frequently a component of sciatic nerve injury. Inability to flex the hock and extend the digits. Acutely there is hyperextension of the hock and hyperflexion of the fetlock and interphalangeal joints causing the horse to drag the fetlock along the ground. Short protraction phase to the stride. If the foot is placed in a normal position, the limb may bear weight. Hypalgesia of the craniolateral portion of the limb from the level of the hock to the fetlock.	Accessible to injury as it passes across the lateral surface of the tibia. Injury seen in horses after recovery from general anesthesia or secondary to a kick or blow to the lateral side of the pelvic limb.

head elevated and on a slope (these maneuvers often exaggerate a subtle problem).

If the horse shows signs only in the trunk and pelvic limbs, the neuroanatomic localization of the lesion is between T2 and S2 or involves the nerves and muscles of the pelvic limbs. However, horses with cervical spinal cord lesions often demonstrate signs in the pelvic limbs that are one grade worse than those observed in the thoracic limbs. Therefore a mild cervical spinal cord or brainstem lesion could show minimal

or no thoracic limb signs with grade 1 or subtle signs in the pelvic limbs.

Palpating the horse over its back, rump, and muscles of the rear limbs while being careful to detect any muscle atrophy is helpful. The author routinely stimulates the horse over the side of its body and observes for any twitching of the cutaneous trunci muscles. Such twitching usually is accompanied by a cerebral response and requires a fairly severe lesion to detect areas of analgesia.

A sway reaction performed while the horse is standing and walking is also necessary to assess the pelvic limb strength and proprioceptive functions. In addition, one may evaluate strength by slow but deliberate and forceful pressure along the back and sacral muscles. A normal horse should reflexively arch its back upward, whereas a horse with rear limb weakness may be unable to withstand this pressure and its rear limbs may even buckle.

To complete the neurologic examination, one must examine the tail and anus to determine whether damage has occurred to the sacrococcygeal nerve and muscle segments. A normal perineal reflex results in contraction of the anus and clamping of the tail in response to light stimulation of the skin in this region. Cauda equina neuritis or polyneuritis equi, trauma, and iatrogenic injury resulting from an alcohol tail block are some disorders that may affect this area.

The evaluation of the major peripheral nerves in the horse is also an important part of the neurologic examination (Table 12-1). The important points to remember are that damage to a peripheral nerve can result in sensory and motor deficits in the area supplied by the nerve and that focal muscle atrophy follows within a short time after damage to one of these nerves. The examiner is referred to other portions of this book for a more detailed anatomic description of these nerves in the horse; however, a dropped elbow joint with radial nerve paralysis, inability to fix the stifle with femoral nerve paralysis, and atrophy of the supraspinatus and infraspinatus muscles (sweeney) with damage to the suprascapular nerve are classic examples of what to expect with peripheral nerve injuries.<sup>1-3</sup>

## CONCLUSION

For a horse to be a good athlete, it must gather information from muscles, tendons, and nerves; process this information in the brain, brainstem, and spinal cord; and relay this information to the musculoskeletal system. The horse must accomplish all of this in a short time to perform complex maneuvers at a high rate of speed. When performing in a setting involving many other horses or when a rider or driver is involved, the horse needs to be able to control these movements in a coordinated fashion to protect itself, other horses, and especially those persons handling, riding, or driving the horse.

Beyond this, veterinarians must recognize which musculoskeletal and neurologic conditions occur together in order to assist prospective buyers with horse-purchasing decisions. Recognizing and understanding these things helps the veterinarian determine whether a particular horse with subtle neurologic gait deficits caused by trauma, infection, or compression may still be a safe and useful athlete.

## CEREBROSPINAL FLUID EVALUATION

Frank M. Andrews

Cerebrospinal fluid evaluation has diagnostic importance regarding neurologic disease in horses. Collection and analysis of CSF is indicated to make or confirm a diagnosis of neurologic disease, but this is not without limitations. CSF values may be normal in an animal with severe neurologic deficits because the lesion is extradural, collection occurred early or late in the course of disease, collection occurred too far from the lesion, or the ventral roots and peripheral nerve have been affected

by the disease. Even with its limitations, CSF provides valuable information about the CNS. However, one must emphasize that CSF evaluation is another piece of the diagnostic puzzle and together with the history, physical examination, neurologic examination, and other ancillary procedures may help in the diagnosis and prognosis of neurologic disease in horses.

## FORMATION, FLOW, AND FUNCTION OF CEREBROSPINAL FLUID

CSF is an actively transported ultrafiltrate of plasma that bathes the CNS.<sup>1</sup> The CSF is located in the ventricles of the brain and subarachnoid space of the spinal canal (Figure 12-2) and originates from the choroid plexus and ependymal lining of the ventricles.<sup>2</sup> CSF flows from the ventricular system up and over the cerebral hemispheres and through the subarachnoid space surrounding the spinal cord.<sup>1</sup> Pulsation of blood in the choroid plexuses forces the CSF in a caudal direction. The rate of CSF production varies between 0.017 ml/min in cats to 0.5 ml/min in human beings<sup>3</sup> and is independent of the blood hydrostatic pressure. The rate of CSF production for horses has not been determined. Osmotic and hypertonic solutions such as mannitol and dimethyl sulfoxide (DMSO), when added to blood, decrease CSF production and decrease CSF pressure and edema.<sup>1</sup>

Collections of arachnoid villi (arachnoid granulations) are located in the venous sinus or the cerebral vein and absorb CSF. CSF absorption is related directly to the pressure gradient between the CSF and venous sinus. When CSF pressure exceeds venous pressure, these villi act as one-way ball valves, forcing CSF flow to the venous sinus.<sup>4</sup>

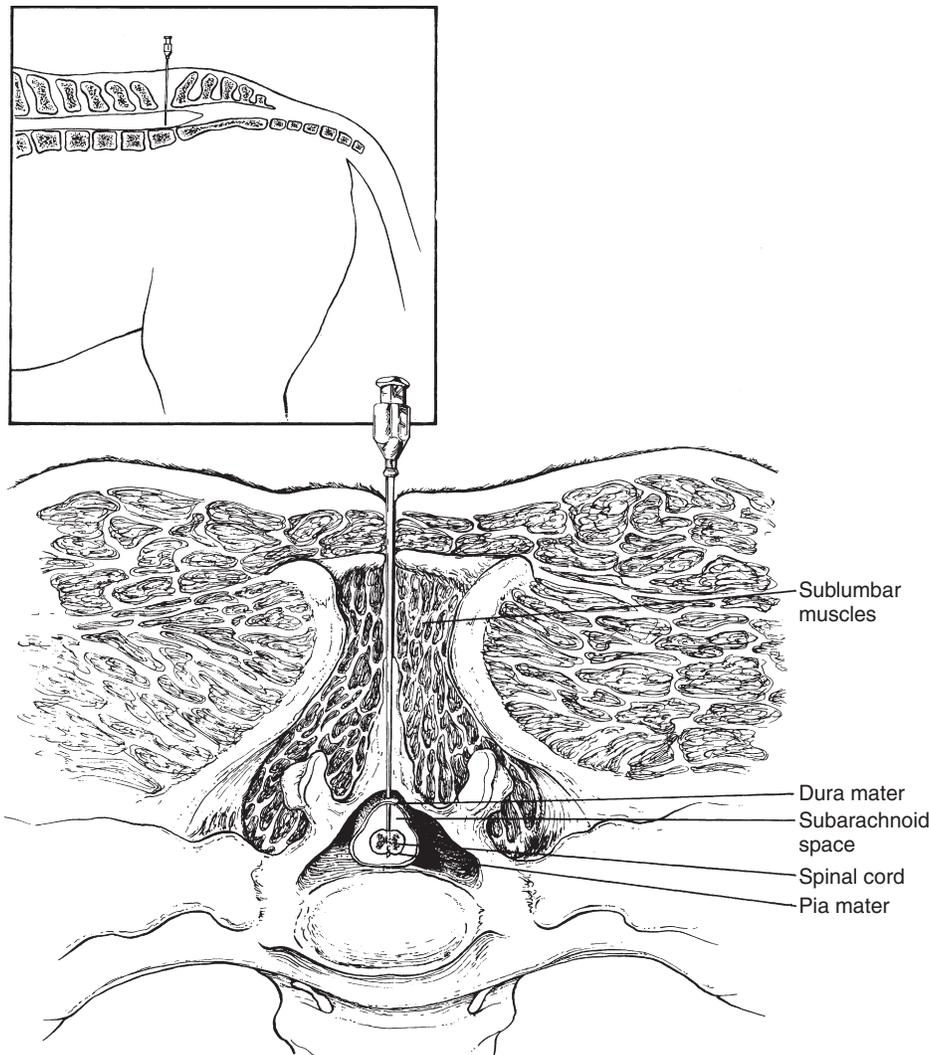

CSF functions to suspend the brain and spinal cord for protection, regulate intracranial pressure, and maintain the proper ionic and acid-base balance.<sup>1</sup>

## COLLECTION OF CEREBROSPINAL FLUID

Techniques for collecting CSF in horses have been described in detail elsewhere.<sup>1-5</sup> One may collect CSF from the lumbosacral site in a standing horse sedated with an intravenous injection of 0.2 to 0.5 mg/kg xylazine or 0.01 to 0.02 mg/kg butorphanol (or a combination of both drugs). Alternatively, one can collect CSF from the atlantooccipital site of an anesthetized horse. In foals and recumbent adult horses, one can collect CSF while the animal is restrained and heavily sedated with 1.0 mg/kg xylazine and 0.2 mg/kg butorphanol, both administered intravenously. If the lesion is localized to an area above the foramen magnum (at least cranial to the second cervical vertebra), then CSF collected from the atlantooccipital site will be more diagnostic. If the lesion is localized to an area below the foramen magnum (caudal to the second cervical vertebra), then CSF collected from the lumbosacral site will be more diagnostic. These differences result from the craniocaudal circulation of CSF. Collecting CSF from both sites at the same time and comparing the findings may be helpful in cases in which neuroanatomic localization of the lesion is difficult.<sup>5</sup>

## EXAMINATION OF CEREBROSPINAL FLUID

Reference values for CSF in horses have been reported,<sup>6-11</sup> but each laboratory should determine its own reference ranges. CSF determinations that are helpful in evaluating horses with

**FIGURE 12-2** Lumbosacral spinal fluid collection from a horse showing the various tissue layers that the spinal needle must pass through to obtain a sample. The spinal fluid is collected ventral to the spinal cord in the subarachnoid space. *Inset*, Lateral view of spinal needle placement in the lumbosacral space for collection of cerebrospinal fluid (CSF). (From deLahunta A, Glass EN: *Veterinary neuroanatomy and clinical neurology*, ed 3, St Louis, 2009, WB Saunders.)

neurologic diseases include pressure, appearance, cellular content, protein concentration (total protein, albumin, immunoglobulin G [IgG]), enzyme activity (creatinase [CK], aspartate aminotransferase [AST], lactate dehydrogenase), and lactic acid concentration.

## PRESSURE

One can measure opening CSF pressure before withdrawal of CSF by attaching a manometer tube with a three-way stopcock to a properly placed spinal needle, allowing the CSF to rise within it.<sup>12</sup> Because the cranial and vertebral cavities are enclosed in a rigid bony compartment, changes in blood pressure or volume can cause a concomitant increase in CSF pressure. Thus increased CSF pressure may occur from venous compression or jugular occlusion. Venous compression causes increased blood volume in the cranial cavity and compression of the CSF space, leading to increased CSF pressure. One can use jugular occlusion clinically to increase CSF pressure and facilitate collection of CSF fluid.<sup>13</sup> The jugular

compression maneuver, or Queckenstedt's phenomenon, can help one diagnose compressive lesions, neoplastic lesions, or an abscess along the spinal cord. With compression and obliteration of the subarachnoid space by a compressive lesion in the cervical or thoracic spinal cord, jugular vein compression does not cause a CSF pressure increase in the lumbosacral site.<sup>1</sup>

Increased CSF pressure may occur after injury, after systemic changes in blood pressure, and in the presence of an intracranial space-occupying mass such as a tumor, abscess, hemorrhage, or edema. One must provide an adequate airway after injury and during surgery to prevent hypoxia-mediated cytotoxic cerebral edema and vasogenic cerebral edema.<sup>14</sup> Cytotoxic edema is caused by inadequate cerebral oxygenation and leads to neuronal, glial, and endothelial cell swelling. Such reactions are especially important during long surgical procedures or recumbency in which respiratory hypoxia and poor alveolar ventilation (hypercapnia) may occur. Hypercapnia increases cerebral blood flow in the cranial cavity and CSF pressure and may worsen existing cerebral edema.<sup>1</sup>

Increased CSF volume may occur in hydrocephalus, which is defined as an increased volume of CSF and can be classified as *compensatory* or *obstructive*.<sup>15</sup> Compensatory hydrocephalus is an accumulation of CSF in areas in which brain tissue has been destroyed and may occur from brain injury or inflammation. Hydranencephaly is destruction of brain tissue from a viral or other infectious agent and results in severe accumulation of CSF.<sup>15</sup> CSF pressure in compensatory hydrocephalus usually does not increase.<sup>1</sup>

Obstructive hydrocephalus is an accumulation of CSF in the ventricles from an obstruction to CSF outflow or absorption. Cerebral aqueduct malformation may lead to obstruction of ventricular CSF outflow. Inflammatory lesions, especially of the arachnoid villi, result in decreased absorption of CSF and increased CSF pressure. The white matter is affected more severely than the gray matter in obstructive hydrocephalus, but the cerebral cortex usually is spared.<sup>1</sup> CSF pressure in obstructive hydrocephalus usually increases. The presence of an abnormally high opening pressure that drops by 25% to 50% after removing 1 to 2 ml of fluid suggests a space-occupying intracranial mass or spinal cord compression cranial to the site of collection. The removal of more fluid would risk causing tentorial herniation.<sup>12</sup>

## APPEARANCE

One can evaluate the appearance of CSF immediately after collection. Normal CSF is clear and colorless and does not clot, and newsprint is visible through it.<sup>16</sup> CSF may be red tinged from blood contamination after a traumatic tap or from preexisting trauma to the CNS. In the case of a traumatic tap, the CSF usually will clear if allowed to flow for several seconds (about 0.5 to 1.0 ml). With preexisting trauma and secondary hemorrhage, the supernatant of CSF after centrifugation is xanthochromic.

Other causes of CSF xanthochromia include increased protein concentration (150 mg/dl)<sup>16</sup> and direct bilirubin leakage from serum in horses with high serum bilirubin concentration. In addition, indirect bilirubin may leak across a damaged blood-brain barrier. Clots in the CSF are abnormal and may be caused by increased amounts of fibrinogen resulting from inflammation.<sup>1</sup>

Turbid CSF may indicate an increased number of white blood cells (>200/ $\mu$ l), an increased number of red blood cells (RBCs) (>400/ $\mu$ l), epidural fat, bacteria, fungal elements, or amebic organisms.<sup>1</sup> Cytologic evaluation and cultures can help differentiate causes of turbidity.

## CYTOLOGIC EVALUATION

One can use a standard hemocytometer to obtain a complete blood count (CBC). In addition, a sedimentation chamber requiring 0.5 to 1.0 ml of CSF is a rapid method for cytologic evaluation.<sup>17</sup> One must perform cell counts and cytologic evaluation within 30 minutes to avoid degeneration. If cell counts or cytologic evaluation cannot be performed immediately, then one can mix a portion of the sample with an equal volume of 50% ethanol to preserve cellular characteristics.<sup>12</sup> CSF from normal horses and foals usually contains fewer than 10 white blood cells per microliter. However, much variation occurs in CSF white blood cell counts in horses.<sup>9,10</sup>

Most studies show no differences in white blood cell counts in normal CSF samples obtained from the atlantooccipital

space as compared with samples obtained from the lumbosacral space.<sup>10</sup> However, one study did show a slightly higher total white blood cell count in CSF obtained from the lumbosacral site, but white blood cell counts in all of those horses were less than 10 per microliter.<sup>6</sup>

Small mononuclear cells (70% to 90%) and large mononuclear cells (10% to 30%) predominate in equine CSF. Rarely, one may see neutrophils in horse CSF. Increased CSF large mononuclear phagocytes are visible in horse CSF in diseases of axonal degeneration.<sup>9</sup> One may see increased CSF neutrophil numbers in encephalomyelitis, bacterial meningitis, parasitism, and diseases with extensive inflammation. Occasionally, in severe inflammatory diseases of the neurologic system or parasitism, eosinophils may be visible.<sup>9,17,18</sup> In some cases, cytologic evaluation of CSF may reveal specific agents causing neurologic disease such as fungal organisms,<sup>16</sup> bacteria, or tumor cells. Although CSF cytologic examination may support a diagnosis of neurologic disease, it may not yield a specific causative diagnosis.

## PROTEIN CONCENTRATION AND COMPOSITION

Normal total protein values range between 20 to 124 mg/dl, depending on the measuring method used<sup>1,6-10</sup> (Table 12-2). Total protein concentration is higher in lumbosacral CSF compared with atlantooccipital CSF.<sup>6</sup> A difference of 25 mg/dl of protein between the atlantooccipital and lumbosacral spaces may suggest a lesion closer to the space with greater spinal fluid protein.<sup>10</sup> Proteins in the CSF are derived from the peripheral blood and include albumin, IgG, and possibly other globulins. Increased CSF albumin and IgG concentrations may occur with damage to the blood-brain barrier or increased intrathecal production of IgG. One can determine CSF albumin and IgG concentrations by electrophoresis and radial immunodiffusion, respectively, and can compare these with serum concentrations.<sup>6</sup> Special low-level radial immunodiffusion plates (VMRD Inc, Pullman, WA) are available to quantify CSF IgG concentration. One can calculate the albumin quotient (AQ) ( $[Albc]/[Albs] \times 100$ ) and IgG index ( $[IgGc]/[IgGs] \times [Albs]/[Albc]$ ) to determine blood-brain barrier permeability and intrathecal IgG production.<sup>6</sup> Increased intrathecal IgG production (increased IgG index) may occur in inflammatory spinal cord disease such as equine protozoal myeloencephalitis (EPM), bacterial meningitis, some tumors, and EMND. Increased blood-brain barrier permeability (increased AQ) may occur in equine herpesvirus-1 (EHV-1) after necrotizing vasculitis.<sup>7</sup> Determining blood-brain barrier integrity is also important in planning therapy. If the blood-brain barrier is damaged, then pharmacologic agents such as penicillin that do not normally penetrate the blood-brain barrier will penetrate a disrupted blood-brain barrier and attain bactericidal CSF concentration.

## ENZYME DETERMINATION

CSF enzyme activity may be increased in neurologic disease. CK and AST activity may be increased in diseases with myelin degeneration and neuronal cell damage such as EPM, polyneuritis equi, equine degenerative myelopathy, and EMND. Increased CK activity also may occur in conditions that alter blood-brain barrier permeability, such as EHV-1. In diseases in which the blood-brain barrier is damaged, serum CK can leak

TABLE 12-2

**Cerebrospinal Fluid Values from Atlantooccipital and Lumbosacral Spaces of Normal Healthy Adult Horses\***

	<b>Atlantooccipital Space (Mean ± SD [Range])</b>	<b>Lumbosacral Space (Mean ± SD [Range])</b>
Red blood cell (RBC) count (per $\mu$ l)	51.0 ± 160 (0-558)	36.8 ± 59.7 (0-167)
White blood cell count (per $\mu$ l)	0.33 ± 0.49 (0-1)	0.83 ± 1.11 (0-3)
Total protein (mg/dl)*	87.0 ± 17.0 (53 ± 11.6) (59-118) (35-74)	93.0 ± 16.0 (58.0 ± 11.0) (65-124) (39-78)
Albumin (mg/dl)	35.8 ± 9.7 (24-51)	37.8 ± 11.2 (24-56)
Albumin quotient (AQ)	1.4 ± 0.4 (1.0-2.0)	1.5 ± 0.4 (1.0-2.0)
Immunoglobulin G (IgG) (mg/dl)	5.6 ± 1.4 (3-8)	6.0 ± 2.1 (3-10)
IgG index	0.19 ± 0.046 (0.12-0.27)	0.19 ± 0.5 (0.12-0.26)

\*Total protein concentration next to the mean ± SD in parentheses is the value expected using a total protein standard.

into the CSF and increase CSF CK activity. This increased CK activity is not associated with damaged myelin.

Increased CK activity also may suggest other diseases of the CNS. In one study, CK activity (>1 IU/L) most often was associated with EPM in horses and may be helpful in differentiating compressive spinal cord disease from EPM. Furthermore, persistently increased CSF CK activity may be associated with a poor prognosis in horses with EPM.<sup>19</sup> Lactate dehydrogenase activity may be increased in spinal lymphosarcoma.

## LACTIC ACID CONCENTRATION

CSF lactic acid concentration may be an indicator of neurologic disease (see Table 12-2). CSF lactic acid concentration increases in eastern equine encephalomyelitis (4.10 ± 0.6 mg/dl), head trauma (5.40 ± 0.9 mg/dl), and brain abscess (4.53 mg/dl). Lactic acid concentration may be the only CSF parameter increased in horses with brain abscess.<sup>20</sup>

## ☞ SUMMARY

Normal CSF findings do not always rule out the presence of neurologic disease. CSF values may be normal with lesions outside the CNS that are not bathed in the CSF, such as extradural, ventral root, and peripheral nerve lesions. Normal CSF values also may occur early or late in the disease process and in CSF samples obtained from a site distant from the lesion. Acute neurologic disease, especially if multifocal, may not have sufficient time to cause significant damage to the blood-brain barrier and alter CSF constituents, whereas in chronic CNS disease the blood-brain barrier may be repaired and functional but with nervous tissue replaced by fibrous tissue. Fibrosis of

nervous tissue may result in significant neurologic gait deficits and normal CSF constituents. CSF taken away from the site of the lesion shows normal findings despite significant neurologic gait deficits. For example, CSF in a horse with a cervical spinal cord abscess may show a suppurative inflammation in the lumbosacral CSF and a normal atlantooccipital CSF. This discrepancy is caused by the caudad flow of CSF.

CSF may be helpful in supporting the diagnosis of neurologic disease in horses and is part of the diagnostic workup. Because CSF evaluation is an ancillary diagnostic test, one should use it with, and not as a substitute for, a thorough history, physical examination, neurologic examination, and other diagnostic tests.

## ELECTRODIAGNOSTIC AIDS AND SELECTED NEUROLOGIC DISEASES

*Frank M. Andrews, V.A. Lacombe*

Localizing lesions to and within the nervous system can be difficult in some horses using only clinical and neurologic examinations. Generally, neurologic disease is characterized by changes in cell electric activity; because electric activity has amplitude and frequency, one can measure it by electronic equipment. The observed electric activity may be helpful in defining and localizing lesions of the nervous system.

Electromyography (EMG), auditory brainstem response (ABR) testing, and electroencephalography (EEG) are electrodiagnostic aids that may be helpful in the localization, diagnosis, and prognosis of neurologic disease in horses. Needle EMG and nerve conduction studies are helpful in localizing and

defining diseases of the lower motor neuron or motor unit. ABR testing is helpful in localizing lesions to cranial nerve VIII and auditory pathways along the brainstem. EEG is helpful in diagnosing focal and diffuse intracranial lesions. Use of these diagnostic aids as an extension of the neurologic examination, separately or collectively, can provide valuable information about nervous system function and help in diagnosing neurologic disease. These techniques are noninvasive and in many cases can be done on the awake horse with mild sedation. Even when these techniques do not provide the information necessary to arrive at a diagnosis, they may provide a more complete understanding of the disease process.

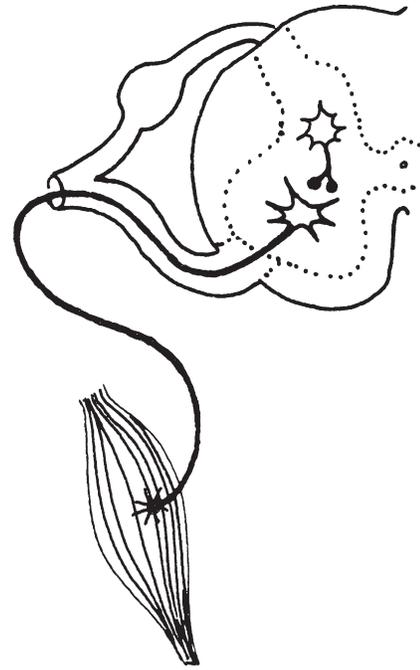

## ☞ ELECTROMYOGRAPHY

Needle EMG is the graphic recording of muscle cell electric activity during contraction or at rest from a recording electrode placed in the muscle. Electric activity is recorded by means of an amplifier on an oscilloscope.<sup>1-3</sup> Nerve conduction studies consist of stimulating a peripheral nerve with electric current and recording the resultant physiologic electric activity from other segments of the nerve or from the muscles innervated by those nerves.<sup>4</sup> Together, EMG and nerve conduction studies may help in the localization, diagnosis, and prognosis of diseases of the lower motor unit. The motor unit consists of the ventral horn cell bodies (located in the ventral horn of the spinal cord), its axon, the peripheral nerve, the myoneural junction, and the muscle fibers it innervates (Figure 12-3).

## ELECTROMYOGRAPHIC EXAMINATION

A history and physical and neurologic examination always should precede the EMG examination; these aid in localizing the lesion, shortening the examination time, and minimizing trauma to the horse. Initially, one examines the standing horse that is under mild sedation. One can tranquilize the horse with 0.2 to 0.5 mg/kg xylazine administered intravenously or 0.2 to 0.5 mg/kg xylazine and 2 to 10 mg butorphanol administered intravenously. Examination of the awake horse aids in evaluating individual motor unit action potentials (MUAPs), summated MUAPs, and interference pattern. One can evaluate normal and abnormal MUAPs and measure their amplitudes. Unfortunately, in the awake horse an interference pattern (many MUAPs) sometimes can obscure abnormal low-amplitude EMG potentials. In this case, further examination may require general anesthesia.

In the needle EMG examination, one should thrust the exploring electrode briskly into the muscle and hold it until the animal completely relaxes. To enable relaxation, one can force the animal to bear weight on the opposite limb. Once relaxation has occurred, one can evaluate the resting activity or any postinsertional activity of the muscle. One should evaluate at least four areas and depths of smaller skeletal muscles and six to eight areas and depths of larger skeletal muscles when possible. One should examine the horse systematically so as not to miss a lesion. Needle EMGs can also be performed in many of the major extrinsic muscles of the horse (Table 12-3). In addition, they can be performed on facial, laryngeal, esophageal, pectoral, and external anal sphincter muscles when indicated by neurologic examination. One may perform nerve conduction studies and collect muscle biopsy specimens to define suspected lesions further or confirm a diagnosis.

**FIGURE 12-3** Illustration of the motor unit, including the ventral horn cell in the spinal cord, ventral root, peripheral nerve, neuromuscular junction, and muscle.

## NERVE CONDUCTION STUDIES

The evaluation of nerve conduction velocities requires knowledge of the topographic anatomy of nerves and muscles, plus a stimulator capable of delivering up to 150 V at durations of 0.1 to 3.0 ms at variable frequencies, up to 100 Hz. Most standard EMGs have built-in stimulators with adequate parameters to do nerve conduction studies. The peripheral nerve to be assessed can be located by palpation or by anatomic landmarks and then can be stimulated. One can palpate or observe the resultant muscle contraction and can view the evoked muscle action potential, which has a thumping sound, on the oscilloscope.

Nerve conduction studies are difficult to do in horses and therefore are not done routinely. However, the technique for radial and median nerve conduction studies in the horse has been reported.<sup>5,6</sup> One must perform nerve conduction studies with the horse under general anesthesia and may use them to evaluate the speed of conduction of large myelinated motor nerves. To do this, the horse should be placed in lateral recumbency, with the affected side up. One stimulates the appropriate motor nerve by monopolar needle electrodes inserted at or near the nerve and records an evoked MUAP from an innervated muscle (Figures 12-4 and 12-5). The examiner may see or palpate the contraction of appropriate muscles and insert needle electrodes until a repeatable response is obtained. The unaffected limb can be used as a control.

In horses, one can obtain radial nerve recordings from the extensor carpi radialis and abductor digiti longus (extensor carpi obliquus) muscles (see Figure 12-4) and can obtain median nerve recordings from the humeral and radial heads of the deep digital flexor tendon<sup>5,6</sup> (see Figure 12-5). Facial nerve recordings can be obtained from the levator nasolabialis muscle by stimulating the buccal branch of the facial nerve

TABLE 12-3

<b>Muscles, Nerves, and Nerve Roots Evaluated during Routine Electromyographic Examination of Horses</b>		
<b>Muscles</b>	<b>Peripheral Nerve</b>	<b>Spinal Nerve Root</b>

Deep digital flexor	Ulnar and median nerve	C7-T1, T2

just ventral to the facial crest.<sup>7</sup> Often a supramaximal stimulus can be obtained at 70 to 90 V for 0.1-ms duration. Nerve conduction studies are helpful in diagnosing radial nerve, median nerve, and possibly facial nerve injury.

## ☞ NORMAL ELECTROMYOGRAPHIC POTENTIALS

Normally occurring EMG potentials and nerve stimulation studies are described next. One can examine the muscle at rest, under submaximal contraction, under maximal contraction, and after direct nerve stimulation.

### INSERTIONAL ACTIVITY

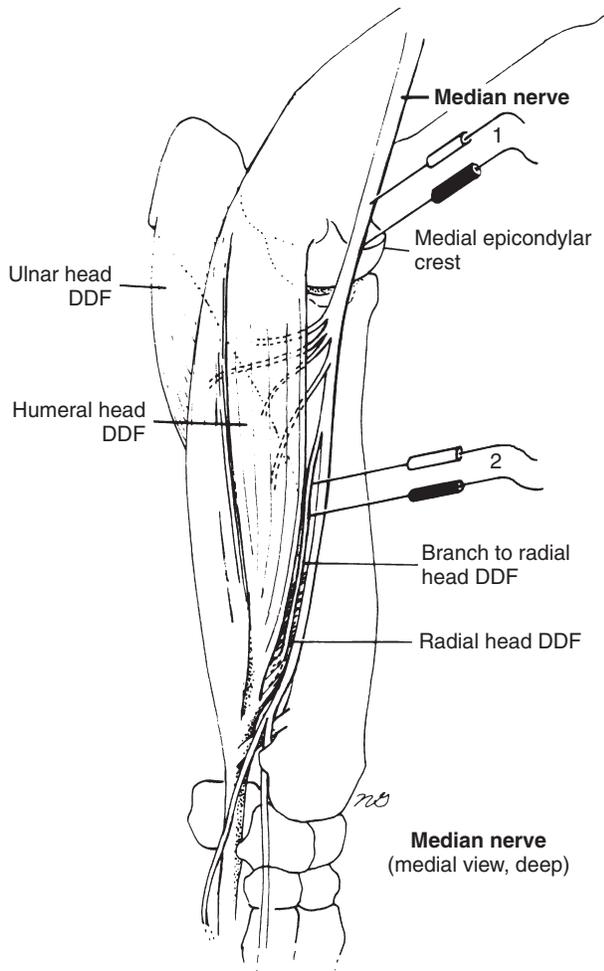

Insertional activity consists of short bursts of high-amplitude, moderate- to high-frequency (<200 Hz) electric activity after insertion or movement of the exploring electrode in the muscle (Figures 12-6 and 12-7). In normal skeletal muscle this activity stops a few milliseconds after cessation of needle movement. Insertional activity may be caused by mechanical stimulation, muscle fiber injury,<sup>3,8,9</sup> or depolarization of muscle fibers directly adjacent to the EMG needle.<sup>1</sup> Positive sharp waves and fibrillation potentials observed during (or associated with) needle insertion that stop after cessation of needle movement are considered normal. Damage to muscle fibers by needle insertion is probably the source of these potentials. However, positive sharp waves and fibrillation potentials persisting after needle insertion are considered abnormal and may suggest early muscle denervation.<sup>3</sup>

### RESTING ACTIVITY (POSTINSERTIONAL BASELINE)

Resting activity is observed in relaxed muscle and is characterized by electric silence. A flat line appears on the oscilloscope. When the needle comes to rest near a nerve twig or end plate, the needle may irritate small intramuscular nerve terminals, which results in the production of two characteristic potentials: (1) end plate noise and (2) end plate spikes. End plate noise produces a rippling of the baseline and a low-pitched continuous noise (Figure 12-8). End plate spikes, on the other hand, are high-amplitude intermittent spikes and make a popping sound. End plate noise and spikes can occur alone or together. The origin of end plate noise is thought to be extracellularly recorded miniature end plate potentials,<sup>10,11</sup> whereas end plate spikes are thought to be single muscle fiber contractions after needle electrode irritation of the nerve terminals.<sup>11</sup> In human beings, these potentials are associated with dull pain<sup>3</sup>; repositioning the needle often eliminates their activity.

### MOTOR UNIT ACTION POTENTIALS

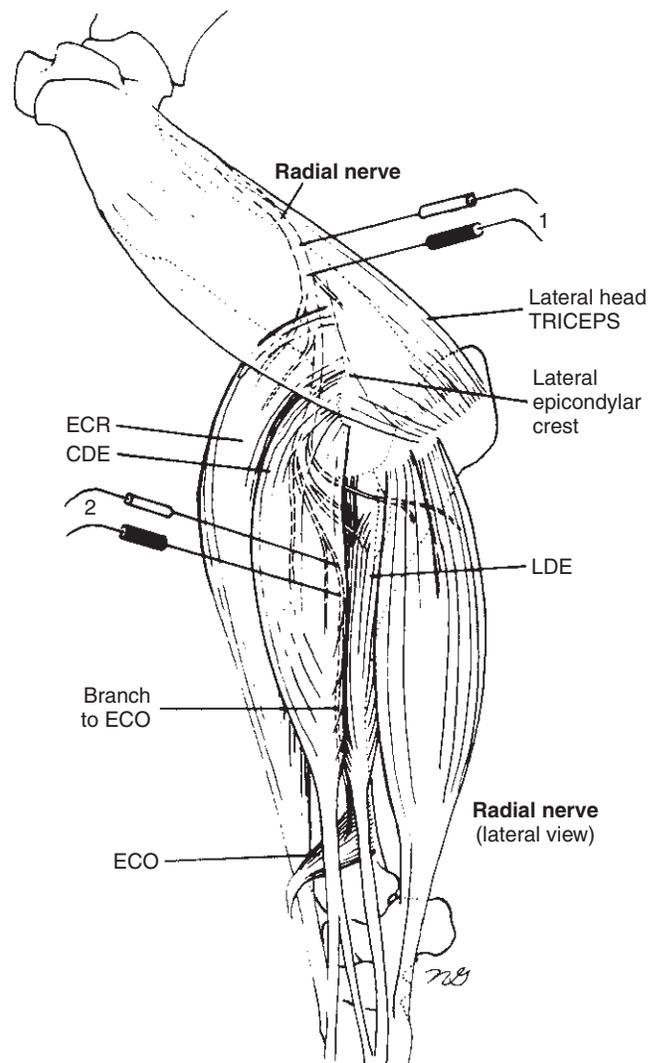

Motor unit action potentials (MUAPs) are voluntary or reflex muscle contractions observed after insertion of the needle electrode. They represent the sum of a number of single muscle fiber potentials belonging to the same motor unit. MUAPs are usually monophasic, biphasic, and triphasic. Because individual muscle fibers fire nearly synchronously, the prefixes refer to the number of phases above and below the baseline (see Figure 12-7). A few polyphasic potentials

**FIGURE 12-4** Illustration of anatomy and electrode placement used in median nerve conduction velocities. *DDF*, Deep digital flexor. (From Henry RW, Diesem CD, Wiechers MD: Evaluation of equine radial and median nerve conduction velocities, *Am J Vet Res* 40:1406–1410, 1979.)

(greater than four phases) may occur in normal muscle but usually do not exceed 5% to 15% of the population of MUAPs observed.<sup>3</sup> MUAPs have an amplitude ranging between 500 to 3000  $\mu\text{V}$  and a duration ranging between 1 to 15 ms. Examination of the conscious horse enhances the evaluation of the amplitude and number of phases of MUAPs in the muscle.

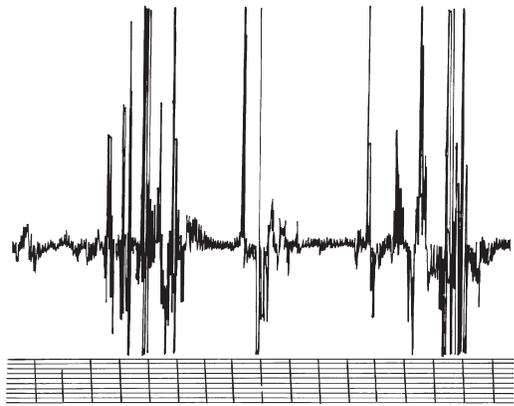

One may see these MUAPs when one forces the animal to bear weight on or retract a limb, resulting in contraction of that explored muscle. In lightly stimulated muscle, one may see single MUAPs, because single motor units are recruited (see Figure 12-7). As muscle contraction becomes more intense, more motor units are recruited and the greater frequency of MUAPs appears on the oscilloscope. Once MUAPs fill the screen, one observes an interference pattern. Clinically, the number of phases and the duration of MUAPs are of greater importance than amplitude, because amplitude may be influenced by species, the muscle explored, the age of the horse, and electrode position.<sup>9</sup> Furthermore, MUAP duration has been shown to increase with age in human beings.<sup>12</sup>

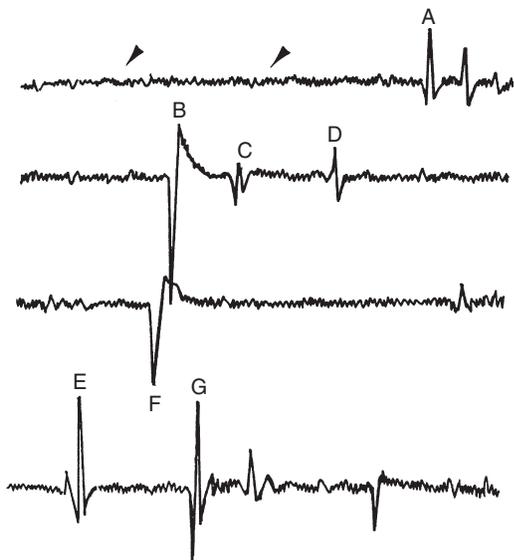

**FIGURE 12-5** Illustration of anatomy and electrode placement used in radial nerve conduction velocities. *ECR*, Extensor carpi radialis; *CDE*, common digital extensor; *LDE*, long digital extensor; *ECO*, extensor carpi obliquus. ## ⊕ EVOKED MUSCLE POTENTIALS

Stimulation of a mixed motor and sensory nerve results in two observed potentials: (1) the direct evoked muscle action potential (M wave) and (2) the reflex evoked muscle action potential (H wave). The M wave is the direct muscle action potential resulting from orthodromic conduction of direct nerve stimulation (Figure 12-9). The M wave is the most commonly used potential in veterinary medicine. This wave is usually biphasic or triphasic and is larger than the H wave. The amplitude of these evoked potentials depends on the number of motor units activated and on the size of the muscle, predominant fiber type, and type of recording electrode used.<sup>4</sup> With monopolar electrodes, amplitudes observed in the horse range between 5 to 60 mV for a 2- to 10-ms duration. Normal amplitudes and durations have been reported for several muscles in the horse. The time required for the potential to travel down the motor nerve, cross the neuromuscular

**FIGURE 12-6** Normal insertional activity in the infraspinatus muscle. Gain: 0.500 mV/division; time: 10 ms/division.

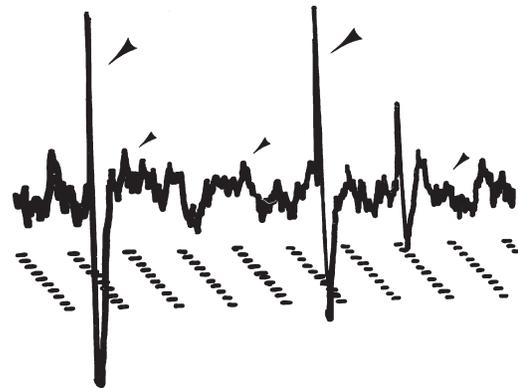

**FIGURE 12-7** Electromyogram of the middle gluteal muscle showing normal resting activity (*arrowheads*), fasciculation potentials (A, E, G), fibrillation potentials (C), positive sharp waves (B, F), and a small motor and action potential (D).

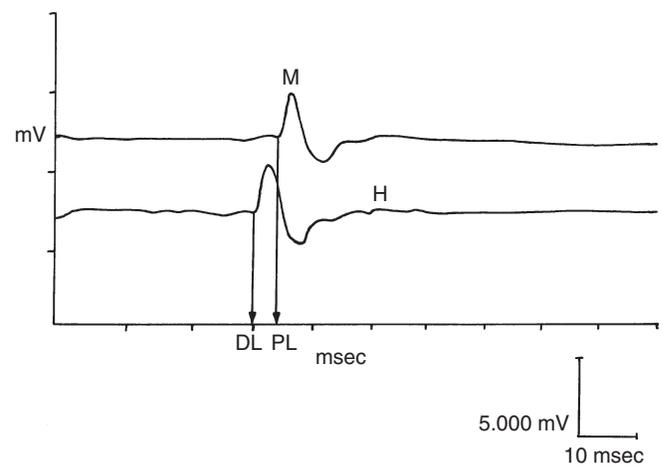

junction, travel down the muscle membrane, and stimulate a response in the muscle is called the *latency*. When two points along the motor nerve are stimulated, one can measure the distance between the stimulating electrodes (in millimeters) and divide it by the difference in latencies (in milliseconds). Normal median and radial nerve conduction velocities are 60 to 80 m/sec.<sup>5,6</sup> Normal facial nerve conduction velocities are 55 to 70 m/sec.<sup>7</sup>

## ⊗ ABNORMAL ELECTROMYOGRAPHIC POTENTIALS

Spontaneous activity in a relaxed muscle after cessation of needle movement may be clinically significant. Diseases affecting the motor unit can lead to altered muscle electric activity, such as prolonged or decreased insertional activity, postinsertional activity, altered waveforms, and complex repetitive discharges. Some abnormal EMG potentials are described next.

**FIGURE 12-8** Electromyogram from triceps brachii muscle showing end plate spikes (*large arrowheads*) and end plate noise (*small arrowheads*). Gain: 0.500 mV/stair step; time: 10 ms/division.

**FIGURE 12-9** Evoked muscle action potentials from the levator nasolabialis muscle after direct stimulation of the buccal branch of the facial nerve illustrating the M wave and H wave. Nerve conduction velocity: 66.0 m/sec. DL, Distal latency; PL, proximal latency.

## PROLONGED OR DECREASED INSERTIONAL ACTIVITY

Prolonged electric activity continuing 1 to 10 ms after needle insertion and placement in the muscle is considered abnormal and probably is caused by hyperirritability and instability of the muscle fiber membrane.<sup>9</sup> This activity is most prominent 4 to 5 days after denervation in dogs.<sup>13</sup> Increased or prolonged insertional activity usually precedes the onset of other denervation potentials (fibrillation potentials and positive sharp waves) and may suggest early denervation atrophy.<sup>9</sup> However, one also may see prolonged insertional activity in myotonic disorders and myositis.<sup>13</sup>

Decreased insertional activity (decreased amplitude, duration, or both) may be associated with a decreased number of functioning muscle fibers and may suggest a long-standing neuropathy or myopathy. Infiltration of connective tissue and fat in the muscle can lead to a decreased number of muscle fibers, which can decrease insertional activity. Complete

fibrosis of the muscle may result in loss of insertional activity. Insertional activity also may be absent when muscle fibers are functionally inexcitable, as occurs during attacks of familial periodic paralysis,<sup>3,14</sup> if one uses a faulty needle electrode, or if the EMG needle comes to rest in a normal muscle.<sup>3</sup>

### POLYPHASIC MOTOR UNIT ACTION POTENTIALS

Polyphasic MUAPs (myopathic potentials) have increased frequency (greater than four phases) and decreased amplitude and duration (Figure 12-10), which one observes during submaximal muscle contraction and which result from an increased number of action potentials for a given strength of contraction. Myopathic potentials result from a diffuse loss of muscle fibers<sup>15</sup> and indicate the need for extra motor units to perform the work normally done by fewer motor units.<sup>16</sup> Myopathic potentials are polyphasic and most often occur in primary myopathies such as myotonia-like syndromes, periodic paralysis, myositis, botulism, and myasthenia gravis-like syndromes. These potentials also have been reported in steroid-induced myopathies, pars intermedia pituitary dysfunction, and membrane defect myopathies.<sup>9</sup>

### NEUROPATHIC MOTOR UNIT ACTION POTENTIALS

Neuropathic potentials are MUAPs of decreased frequency and longer duration than myopathic potentials and may occur during minimal and maximal muscle contraction (see Figure 12-10). Thus one observes fewer MUAPs of increased amplitude than expected for the strength of contraction, which is more noticeable during maximal contraction and produces a sputtering or motorboat sound. Neuropathic potentials probably

are caused by a decreased number of functioning axons firing during maximal muscle contraction. These potentials are most often present in primary neuropathies in which collateral reinnervation has occurred.<sup>16</sup>

### FIBRILLATION POTENTIALS

Fibrillation potentials are the most commonly observed abnormal spontaneous electropotential in EMG (see Figure 12-7). These spontaneous discharges sound like frying eggs, crinkling cellophane, or frying bacon and have an initial positive deflection of 100 to 300  $\mu$ V in amplitude and 2 to 4 ms in duration. They are diphasic or triphasic in waveform. Fibrillation potentials strongly suggest denervation but have been observed in polymyositis, muscular dystrophy, and botulism. Their origin is uncertain, but fibrillation potentials are thought to be spontaneous discharges from acetylcholine-hypersensitive denervated muscle fibers<sup>1,17</sup> or may result from muscle necrosis,<sup>18</sup> muscle inflammation, and focal muscle degeneration. A few fibrillation potentials have been observed in normal healthy muscle, but they are usually not reproducible in other areas of the muscle.

The onset of fibrillation potentials after denervation depends on the size of the animal. The larger the animal, the later the onset of fibrillation potentials<sup>19</sup>; they have been reported between days 5 and 16 postdenervation in dogs<sup>20</sup> and human beings.<sup>18</sup> The author has observed fibrillation potentials 4 to 10 days after nerve injury in horses. Fibrillation potentials often occurred along with positive sharp waves; they increase and then decrease in amplitude as the muscle atrophies, with activity ceasing on complete muscle atrophy. Fibrillation potentials occurring alone denote a more severe disease process than the presence of positive sharp wave potentials alone.<sup>17</sup> Fibrillation potentials are helpful in evaluating

EMG FINDINGS

EMG steps	Lesion	Normal	Neurogenic lesion		Myogenic lesion		
			Lower motor	Upper motor	Myopathy	Myotonia	Polymyositis
1	Insertional activity	Normal	Increased	Normal	Normal	Myotonic discharge	Increased
2	Spontaneous activity	—	Fibrillation Positive wave	—	—	—	Fibrillation Positive wave
3	Motor Unit potential	0.5-3.0 mV 5-10 ms	Large unit Limited recruitment	Normal	Small unit Early recruitment	Myotonic discharge	Small unit Early recruitment
4	Interference pattern	Full	Reduced Fast firing rate	Reduced Slow firing rate	Full Low amplitude	Full Low amplitude	Full Low amplitude

**FIGURE 12-10** Differential electromyographic findings in neurogenic and myogenic conditions. (Modified from Kimura J: *Electrodiagnosis in diseases of nerve and muscle: principles and practice*, Philadelphia, 1984, FA Davis.)

the length of time muscle denervation has been present and are important in diagnosing denervation before clinical muscle atrophy. One also can use fibrillation potentials as a prognostic indicator (by monitoring fibrillation frequency and amplitude changes with serial examinations, one can assess the extent and progress of denervation). In addition, a decrease in fibrillation potentials followed by the recording of MUAPs may indicate reinnervation and may suggest a favorable prognosis.<sup>18</sup>

### POSITIVE SHARP WAVES

Positive sharp waves are potentials in which the primary deflection is downward, followed by a lower-amplitude, longer-duration negative deflection (see Figure 12-7). This waveform has been described as *resembling a sawtooth*.<sup>3</sup> Positive sharp waves occur with muscle denervation and muscular diseases such as myositis, exertional rhabdomyolysis (tying-up syndrome),<sup>21</sup> and spinal shock.<sup>16</sup> Sometimes one observes positive sharp waves in association with or shortly after insertional activity that persist after electrode placement. More than two positive sharp waves occurring after insertional activity may indicate early denervation. Positive sharp waves may occur in denervated muscle after chronic exertional rhabdomyolysis, myotonia,<sup>21</sup> EPM, laryngeal hemiplegia,<sup>22</sup> suprascapular nerve injury (sweeney),<sup>23</sup> and compressive myelopathies. Positive sharp waves often precede or appear along with fibrillation potentials in denervated muscle. One can observe these potentials singly or in trains (Figure 12-11), and they may sound like a machine gun. The origin of positive sharp waves is uncertain but may be associated with hyperexcitable muscle cell membranes.<sup>17</sup>

### FASCICULATION POTENTIALS

Fasciculation potentials are spontaneous discharges from a group of muscle fibers representing the whole or part of a motor unit<sup>3,17</sup> (see Figure 12-7). The source of fasciculation potentials has not been determined yet, but evidence suggests they originate from neural discharges in the spinal cord or along the peripheral nerve.<sup>24,25</sup> Fasciculation potentials occur in diseases of anterior horn cells and irritative-type lesions of root or peripheral nerve, such as radiculopathies and nerve entrapments in human beings.<sup>13</sup> Little significance is placed on isolated fasciculation potentials in horses. However, fasciculation potentials in the presence of fibrillation potentials or positive sharp waves may indicate lower motor neuron disease and may occur in suprascapular nerve entrapment (sweeney) in horses.

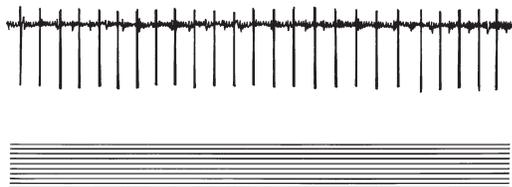

FIGURE 12-11 Electromyograph showing trains of positive sharp waves. Gain: 500 V/stair step.

### COMPLEX REPETITIVE DISCHARGES VERSUS MYOTONIC POTENTIALS

Complex repetitive discharges (bizarre high-frequency potentials) and myotonic potentials occur less frequently in horses. Both of these potentials are repetitive MUAPs induced by insertion of the needle electrode or percussion of muscle. Bizarre high-frequency potentials tend to be shorter in duration and end abruptly compared with myotonic discharges. Bizarre high-frequency potentials sound like a machine gun. However, myotonic potentials often wax and wane in amplitude, last 4 to 5 seconds,<sup>2,3,9</sup> and sound like a dive-bomber, hence the nickname *dive-bomber potential*.<sup>1,9</sup> (Figure 12-12). Myotonic and bizarre high-frequency potentials are thought to be associated with hyperexcitability of the muscle cell membrane.<sup>1</sup> Bizarre high-frequency potentials may occur in diseases of the lower motor unit such as muscular dystrophy,<sup>1,9,21</sup> steroid-induced myopathy,<sup>9</sup> polymyositis, chronic denervation,<sup>26</sup> and hyperkalemic periodic paralysis.<sup>14</sup> Myotonic potentials may occur in myotonia congenita and myotonia dystrophica<sup>21</sup> and may occur in hyperkalemic periodic paralysis in human beings, which may reflect abnormal muscle chloride or potassium conductance.<sup>3</sup> Myotonic potentials also have been observed in horses with hyperkalemic periodic paralysis, but some were obscured by concurrent complex repetitive discharges.<sup>14</sup>

### ☞ DISEASES AFFECTING THE MOTOR UNIT AND PERIPHERAL NERVES

Diseases of the motor unit and peripheral nerves can lead to changes in skeletal muscle electric activity or nerve conduction velocity (or changes in both). In these diseases, EMG may be a useful diagnostic aid in localizing the lesion.

### FOCAL AND MULTIFOCAL MYELOPATHIES

Compressive cervical myelopathies, cervical stenotic myelopathy (wobbler syndrome), and EPM are common causes of neurologic signs in the horse. These conditions are characterized by damage to the sensory pathways and in some instances damage to the ventral horn cells of the spinal cord, a component of the motor unit. Physical examination may reveal muscle atrophy and sweating over affected muscles. Needle EMG of the cervical axial musculature in horses with truncal, forelimb, and hindlimb ataxia, without cranial nerve deficits, may

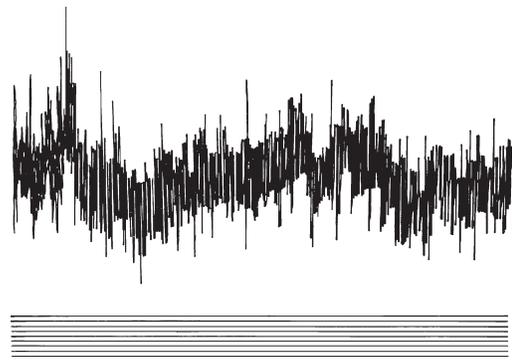

FIGURE 12-12 Electromyograph showing waxing and waning myotonic potentials. Gain: 500 V/stair step.

reveal increased insertional activity, fibrillation potentials, and positive sharp waves indicating compression of the ventral horn cells or ventral roots.<sup>27</sup> Abnormal postinsertional activity at the level of the spinal cord compression may allow the clinician to focus the radiographic examination.

In cases of EPM, needle EMG may reveal fibrillation potentials, positive sharp waves, and abnormal insertional activity in affected limb muscles in horses presented for obscure lameness. One also can examine horses with muscle asymmetry (Figure 12-13) via needle EMG to determine the extent of muscle involvement. The examination may lead to early diagnosis of EPM so that treatment can be prescribed. Serial needle EMG examination also may be helpful in monitoring the response to treatment and prognosis.

### RADIAL AND SUPRASCAPULAR NERVE INJURY

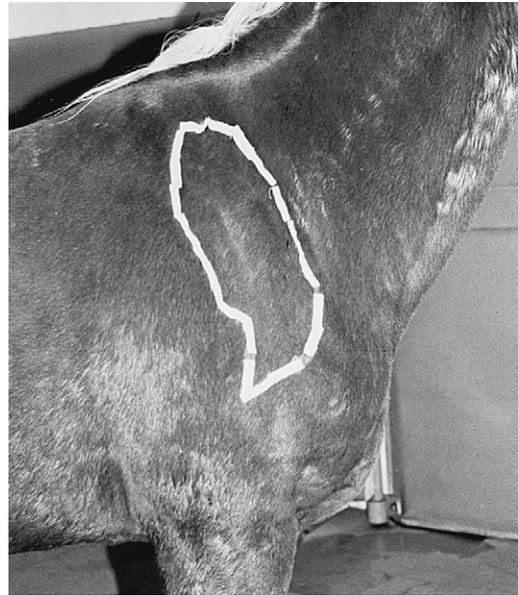

Damage to the peripheral nerves leads to muscle atrophy of the innervated muscle. Damage to the radial and suprascapular nerves can occur with trauma to the cranial aspect of the shoulder. Needle EMG and nerve conduction studies are helpful in evaluating the extent of damage to these and other peripheral nerves. Needle EMG and nerve conduction studies also may be able to differentiate lost or reduced limb function caused by nerve damage from painful conditions. Muscle groups that have atrophied because of disuse (disuse atrophy) caused by a painful condition show no postinsertional activity on needle EMG examination.

Positive sharp waves and fibrillation potentials in the triceps brachii and extensor carpi radialis muscles may suggest radial nerve injury. Positive sharp waves and fibrillation potentials in the supraspinatus and infraspinatus muscles may

suggest suprascapular nerve injury (Figure 12-14). Postinsertional activity in these muscle groups and the lateral head of the triceps suggests damage to the brachial plexus (Figure 12-15). Thus needle EMG may be helpful in differentiating suprascapular nerve injury from brachial plexus injury. Visible evidence of muscle atrophy may not be present until several weeks after injury. To confirm a radial nerve injury, one can calculate the radial nerve conduction velocity (Figure 12-16). If the nerve conduction velocity is less than 60 m/sec or significantly less than the opposite limb, then one may suspect radial nerve injury. Radial nerve injury also may lead

**FIGURE 12-13** Horse with gluteal muscle atrophy due to EPM showing distribution of abnormal electro myographic potentials.

**FIGURE 12-14** Horse with suprascapular nerve injury with characteristic electromyographic distribution of fibrillation potentials and positive sharp waves in supraspinatus and infraspinatus muscles.

**FIGURE 12-15** Horse with brachial plexus injury showing characteristic distribution of electromyographic charges, including fibrillations and positive sharp waves. The involvement of the supraspinatus, infraspinatus, triceps brachii, extensor carpi radialis, and pectoral muscles is notable.

to a decreased amplitude and duration of the evoked muscle action potential.

Needle EMG and nerve conduction studies may also be helpful in determining success of nerve decompression surgery. Once the nerve is decompressed surgically, serial needle EMG examinations may be helpful in determining if permanent nerve damage has occurred and the extent of return of nerve function.

### LARYNGEAL HEMIPLEGIA

Laryngeal hemiplegia has been described extensively in the literature as denervation of the intrinsic laryngeal musculature, specifically the recurrent laryngeal nerve.<sup>5</sup> One difficulty with this condition is that current diagnostic techniques (endoscopy, inspiratory stridor with exercise) are limited to recognizing laryngeal hemiplegia after onset of clinical signs.<sup>28</sup> However, fibrillation potentials and positive sharp waves in the dorsal cricoarytenoid muscle on needle EMG examination may appear before clinical signs. Thus needle EMG may be useful in the early detection of laryngeal hemiplegia in horses. Spontaneous EMG activity, including fibrillation potentials, positive sharp waves, or bizarre high-frequency discharges, have been reported in the dorsal cricoarytenoid muscle of horses affected with laryngeal hemiplegia. Fibrillation potentials and positive sharp waves are the most common abnormal electric potential observed in horses with laryngeal hemiplegia. Decreased insertional activity and bizarre high-frequency discharges were reported at a lesser frequency.<sup>22</sup>

### MYOPATHIES, MYOSITIS, AND MYOTONIA

Needle EMG may be helpful in evaluating horses with signs of primary muscle disease, such as muscle tremors, muscle fasciculations, muscle stiffness, weakness, and percussion dimpling. Myopathies generally are classified into *inflammatory* or *degenerative* types.<sup>29</sup> Degenerative myopathies are characterized by an intact motor unit but a loss of viable muscle fibers, which

results in an increased number of polyphasic MUAPs with decreased duration (see Figure 12-10). Inflammatory myopathies (myositis) are characterized by a subacute or acute degeneration of muscle fibers with active infiltrates of inflammatory cells. The characteristic potentials are increased insertional activity, brief low-voltage MUAPs, fibrillation potentials, and positive sharp waves. Needle EMG is a valuable aid in the diagnosis and localization of focal and diffuse myopathies. Primary myopathies such as exertional rhabdomyolysis and myositis can be differentiated from myotonia and myotonia-like syndromes by needle EMG examination.<sup>21</sup> Furthermore, fibrillation potentials and positive sharp waves have been observed on EMG examination in horses with chronic myositis, exertional rhabdomyolysis, shivers, and hyperkalemic periodic paralysis.<sup>14,21</sup> After completing the needle EMG examination, one may evaluate muscles with postinsertional activity further by muscle biopsy and microscopic evaluation.<sup>21,30</sup>

### MYOTONIA

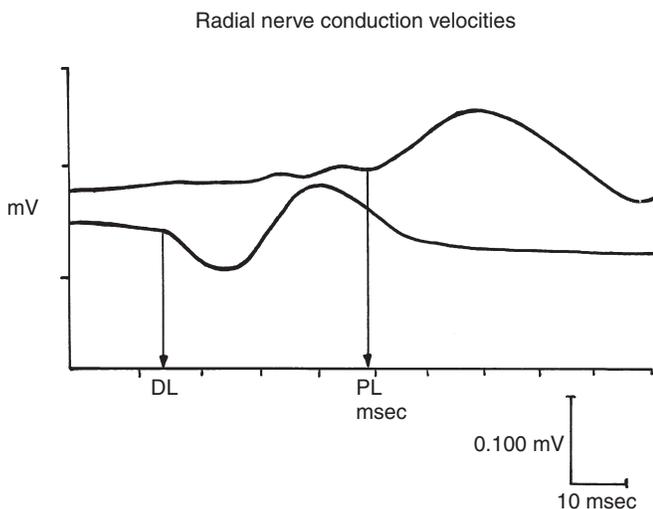

Myotonia is a disease characterized by an electrolyte conductance deficit in the skeletal muscle membrane.<sup>3</sup> One may observe fibrillation potentials, positive sharp waves, a train of positive sharp waves, and myotonic potentials on EMG examination in horses with myotonia congenita<sup>21</sup> and myotonia dystrophica.<sup>31</sup> Characteristic electrophysiologic findings include waxing-and-waning, high-frequency, spontaneous, and induced myotonic discharges (dive-bomber potentials) in many muscle groups, including the middle gluteal and semitendinosus muscles<sup>21,31</sup> (see Figure 12-12). One may use needle EMG to confirm the diagnosis of myotonia, to distinguish this condition from pseudomyotonia, and to localize areas for muscle biopsy (see Figure 12-10). Myotonia and myotonia-like syndromes also may present as tremors or even seizure activity. EMG along with a thorough physical and neurologic examination can help differentiate seizures from primary myopathy.

### ☞ BRAINSTEM AUDITORY EVOKED RESPONSE TESTING

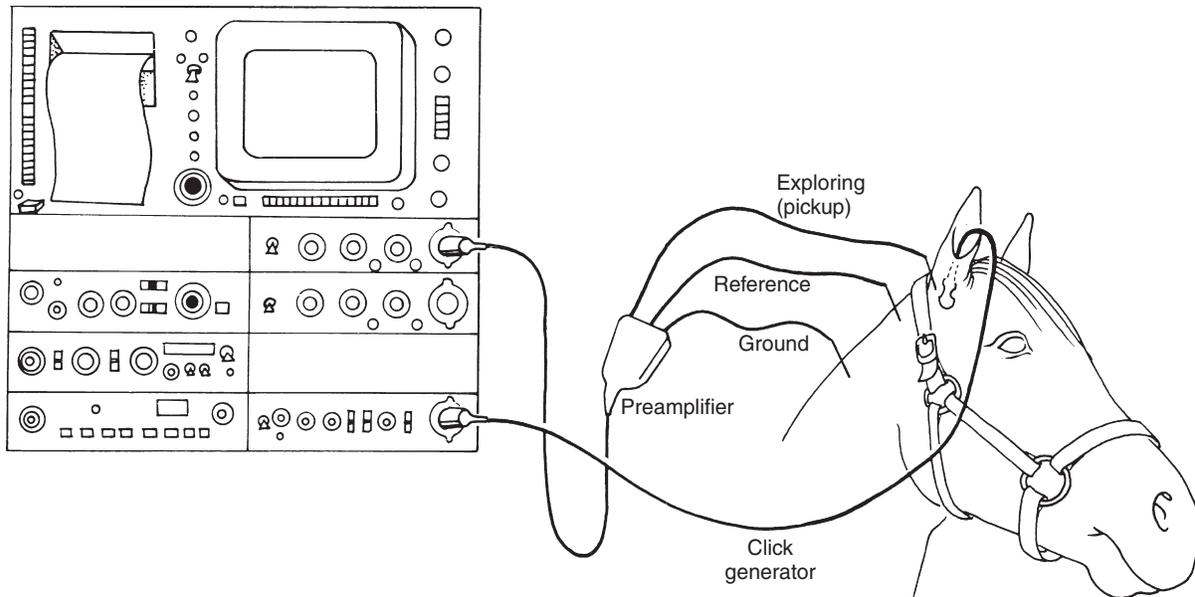

Brainstem auditory evoked response (BAER) testing is a method of recording potentials arising from the eighth cranial nerve and its projections in response to acoustic stimulation via surface or subcutaneously placed electrodes. The BAER is those evoked potentials, or waves, arising within the first 10 ms after delivery of an acoustic stimulus (clicks; Figure 12-17). In human beings, BAER is recognized as consisting of from five to seven waves, generally designated *I* through *VII*. Of these, waves *I* through *V* are the most common. In dogs and cats, fewer waves are observed.<sup>32,33</sup> In human beings and animals, a correspondence exists between these waves and certain anatomic generator sites<sup>33-39</sup>:

1. Wave *I* is generated by bipolar neurons of the eighth cranial nerve.
2. Wave *II* also may be generated partly by the eighth cranial nerve.
3. Waves *II* through *V* probably reflect more generalized activity in the auditory system in the medulla and pons and may represent neural activity ipsilateral and contralateral to the stimulated ear.

A wide range of clinical applications of BAER in human beings has been well described.<sup>19,34,37,39-46</sup> However, its use in the horse has been limited.<sup>47-53</sup>

**FIGURE 12-16** Evoked muscle action potential from the extensor carpi radialis muscle showing decreased amplitude and decreased nerve conduction velocity, suggesting radial nerve injury. *DL*, Distal latency; *PL*, proximal latency.

**FIGURE 12-17** System used for auditory brainstem response (ABR) testing in the horse. (From Rolf SL, Reed SM, Melnick W et al: Auditory brainstem response testing in anesthetized horses, *Am J Vet Res* 48:910–914, 1987.)

ABR testing is a method of assessing not only auditory function but also a variety of neurologic disorders involving the brainstem. ABR testing is unaffected by the state of arousal of the test subject, and responses are not degraded by sedation or general anesthesia.<sup>37,45</sup>

One can examine horses awake, with or without mild sedation, or anesthetized (see Electromyography). If a conscious awake horse is tested, then one stimulates each ear and records the resultant waveforms independently. If the patient is anesthetized, then one examines the uppermost ear first, turns the horse, and examines the lower ear.

One commonly observes five peaks, and these are considered analogous to waves I through V in human beings (Figure 12-18).<sup>\*</sup> Mean latencies have been reported previously in horses under general anesthesia.<sup>55</sup> As has been observed in dogs and cats,<sup>32,33</sup> latencies of the waves decrease as stimulus intensity increases. One can use the ABR clinically in horses with head tilts (Figure 12-19, A) to verify the presence of hearing loss (Figure 12-19, B), middle or inner ear infections, and stylohyoid osteomyelitis. ABR testing also may be helpful in the diagnosis and prognosis of traumatic, infectious, or inflammatory brainstem lesions such as vascular infarcts or anomalies, ischemic fibrocartilaginous emboli, basisphenoid bone fracture, and protozoal encephalomyelitis. One can assess the quantitative and qualitative characteristics of the ABR-generated waveforms. Persistent prolonged latencies suggest retrocochlear or conductive abnormalities.<sup>37</sup> Interaural latency differences of wave V may suggest unilateral brainstem disease, except when cochlear disease is present. Qualitative ABR changes are of greater use in equine medicine because quantitative measures of normal and abnormal horses are limited. In human beings, qualitative changes such as peak presence, waveform morphologic characteristics, and response stability are of greater use in the diagnosis of central disorders, particularly acoustic

neuromata and demyelinating diseases.<sup>37</sup> The limitations of ABR include a dependence on cochlear function; susceptibility to extraneous noise, which may affect waveform morphology; and the limits of the machinery in excluding 60-cycle interference.

## ELECTROENCEPHALOGRAPHY

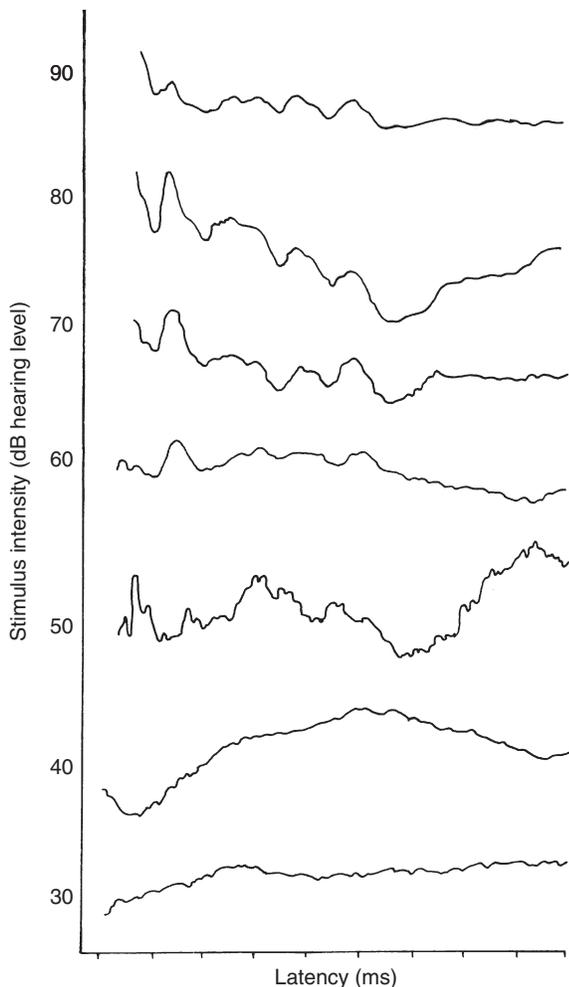

Electroencephalography is the graphic recording of electric activity arising from the cerebral cortex. The origin of this electric activity is not known but is thought to arise from pyramidal cell dendrites located within a 2-mm depth of the cerebral cortex. This electric activity may be modified by deeper structures such as the brainstem, reticular activating system, and thalamus. EEG is an extension of the neurologic examination and is a valuable tool for determining the presence of a cerebral disease, localizing it, determining its extent (focal or diffuse), differentiating between inflammatory and degenerative changes, and establishing a prognosis.

EEG has been used and reviewed extensively in human beings<sup>56,57</sup> and small animals,<sup>8,17</sup> but little work has been done in the horse.<sup>58-69</sup> This discussion presents a brief description of the use, interpretation, and limitations of EEG so that one may gain a better understanding regarding its use.

## NORMAL PATTERNS

One should evaluate the EEG for symmetry, waveform, morphology, frequency, and amplitude. The bipolar montage allows comparison of cortex to cortex. One can compare the potentials generated by the left occipital region with those of the right occipital cortex, the potentials generated by the left frontal cortex region with those of the right frontal area, and the potentials generated by the left side (left frontal-left occipital) with those of the right side (right frontal-right occipital; Figure 12-20). Normal EEG potentials in the horse consist of a dominant waveform in the awake alert

\*References 4, 17, 35, 37, 39-44, 54.

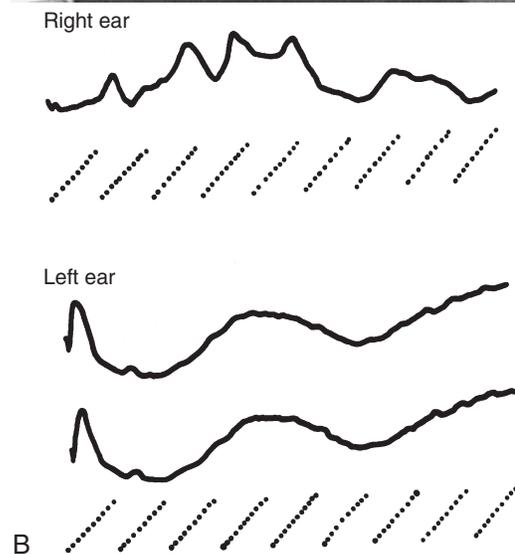

**FIGURE 12-18** Mean latency waves at 136 dB, sound pressure level (SPL) through 87 dB SPL. Five waves are present, except at 40 of 80 dB SPL. (From Rolf SL, Reed SM, Melnick W et al: Auditory brainstem response testing in anesthetized horses, *Am J Vet Res* 48:910-914, 1987.)

horse of low voltage (8 to 15  $\mu$ V) and fast activity (18 to 30 Hz) (Table 12-4). Usually this activity is superimposed over a low- to medium-voltage (10 to 40  $\mu$ V) and slow activity (5 to 10 Hz). Muscle artifact occasionally interrupts the baseline, when the animal shakes its head, moves its eyes, or twitches the facial muscles.

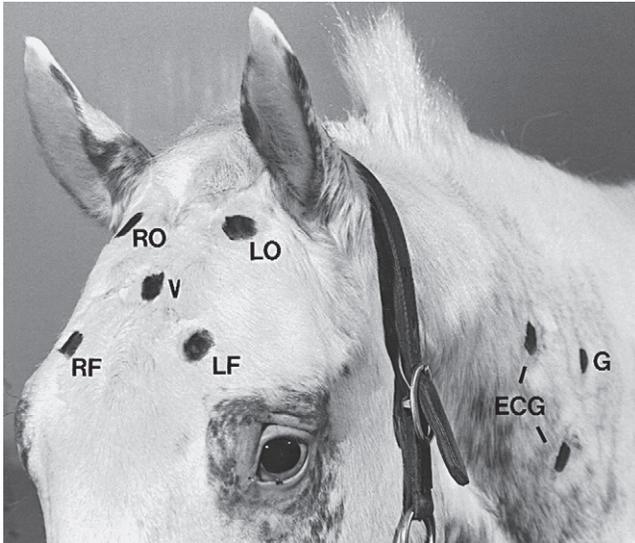

### ABNORMAL PATTERNS

Diseases of the cerebral cortex can alter frequency, amplitude, and symmetry of EEG patterns. Low-voltage, fast activity, and spikes may occur with ongoing irritative processes such as seizures or inflammation (Figure 12-21). High-voltage, slow activity indicates death of neurons in diseases such as brain abscess (Figure 12-22) and neoplasia. However, low-voltage, fast activity and high-voltage, slow activity are not pathognomonic for any disease process but suggest the various disease states previously discussed. Localized EEG changes indicate focal cortical disease such as infarcts, hemorrhage, early tumor, or abscessation (see Figure 12-22), whereas generalized EEG changes may indicate a diffuse cortical or subcortical disease

**FIGURE 12-19** A, Photograph of foal with a right head tilt and drooping of the right ear. B, Auditory brainstem response (ABR) (see Figure 12-20) shows a hearing loss in the left ear, the presumed cause of the head tilt. The right ear was normal.

such as infection (see Figure 12-21), trauma, space-occupying lesions (hydrocephalus, tumor), idiopathic epilepsy, or a systemic metabolic illness (hepatic encephalopathy). Serial recordings may be helpful in following therapy and the progress of disease. Generally, artifacts such as ocular movement and facial muscle twitches produce asymmetrical and symmetrical low-voltage, slow activity, whereas hypothyroidism may produce symmetrical low-voltage, medium-to-slow

**FIGURE 12-20** Photograph of horse illustrating bipolar montage for electroencephalography (EEG). RO, Right occipital; LO, left occipital; RF, right frontal; LF, left frontal; V, vertex; G, ground; ECG, electrocardiogram position.

activity.<sup>54</sup> The difficulty in EEG in the horse is differentiating artifact (muscle movement, eye movement, head shaking, EEG artifact) from true EEG changes. For reemphasis, EEG alone is only one part of the diagnostic workup. One always should interpret the EEG examination along with the history, clinical signs, and neurologic examination.

## MAGNETIC RESONANCE IMAGING

*Katherine S. Garrett*

Although magnetic resonance imaging (MRI) has been used for diagnosis of neurologic disease in human beings for decades, it has only come into clinical use for horses within the past 10 years. Imaging of the brain and spinal cord is essentially impossible without MRI or computed tomography, so this represents an exciting new imaging modality to aid in the diagnosis of neurologic disease in horses.

### PRINCIPLES

Magnetic field strength is measured in Tesla (T). The strength of the magnetic field varies between types of magnets, but is typically between 0.25 T and 1.5 T for most magnets currently in routine equine clinical use, although 3.0 T magnets will likely become more widely available in the near future.

Most MRI applications use hydrogen nuclei (protons) as the molecule of interest, but other nuclei can be used. Application of the strong magnetic field causes the magnetic moments of the protons within tissues to orient themselves parallel to the main magnetic field. A radiofrequency pulse at a specific frequency is then applied, which causes a change in the cumulative magnetic moment of the protons and synchronizes the phase of the protons' precessions (rotation about an axis). After the radiofrequency pulse is discontinued, the protons

**TABLE 12-4**

### Amplitudes and Frequencies Observed in Normal Electroencephalographic Patterns from Awake and Sedated Adult Horses

		NORMAL PATTERNS	
		Voltage ( $\mu$ V)	Frequency (Hz)
Awake	Primary pattern	8-15	18-30
	Secondary pattern	10-40	5-10
Sedated with xylazine	Dominant	10-70	1-3
		10-80	10-15
		10-90	0.5-4
		5-30	25-40
Sedated with acetylpromazine	Primary pattern	5-40	25-40
	Secondary pattern	5-10	1-4

From Reed SM, Furr M, editor: Equine neurology, Oxford, 2008, Blackwell; Data from Purohit RC, Mysinger PW, Redding RW: Effects of xylazine and ketamine hydrochloride on the electroencephalogram and the electrocardiogram in the horse, *Am J Vet Res* 42:615-619, 1981; and Mysinger PW, Redding RW, Vaughan JT, et al: Electroencephalographic patterns of clinically normal, sedated, and tranquilized newborn foals and adult horses, *Am J Vet Res* 46:36-41, 1985.

will return to the resting state governed by the main magnetic field alone and the precessional phase synchrony will degrade. Different tissues return to the resting state at different times and in different ways. In a basic sense, the time for the magnetic moment of a tissue to return to the direction of the main magnetic field is a description of the T1 time of the tissue and the time for the phase coherence to degrade is a description of the T2 time of the tissue. These are inherent properties, and the differences between tissues form the basis of MRI.

Different pulse sequences produce different types of contrast, based on each tissue's hydrogen content and its response. Proton density sequences have contrast determined by the proton content of each tissue. Cortical bone, tendons, ligaments, and air have low proton density, so they appear hypointense (dark) on all sequences, as well as on proton density-weighted sequences. T1-weighted sequences have contrast dominated by the T1 relaxation times of the tissues. Fat is hyperintense (bright) and fluid is hypointense. T2-weighted sequences have contrast dominated by the T2 relaxation time of the tissues. Fat is hypointense and fluid is hyperintense. Fluid attenuation inversion recovery (FLAIR) sequences have the signal from CSF specifically nulled using an inversion pulse. This allows abnormal fluid within the brain or spinal cord parenchyma to be more apparent. Intravenous contrast can also be used in MRI. Gadolinium compounds are typically used, which allow assessment of abnormal patterns of blood flow or delineation of anatomic structures, similar to the use of contrast in computed tomographic (CT) imaging.

Two major families of pulse sequences exist. Spin echo sequences use multiple radiofrequency pulses to generate a signal. Turbo or fast spin echo sequences are a subset of spin echo sequences that are faster than traditional spin echo sequences. Image contrast can be altered slightly; for example,

**FIGURE 12-21** Electroencephalograph from a horse with cryptococcal meningitis showing generalized low-voltage, high-frequency activity and frequent spikes. *RO*, Right occipital; *LO*, left occipital; *RF*, right frontal; *LF*, left frontal; *V*, vertex; *G*, ground; *ECG*, electrocardiogram position.

fat on T2-weighted turbo spin echo sequences is hyperintense instead of hypointense. Gradient echo sequences use a changing magnetic field gradient to generate a signal. Gradient echo sequences can be acquired more quickly than spin echo sequences but are more susceptible to magnetic field inhomogeneities.

For each series of slices, the operator must choose the orientation of the slices, as well as the type of pulse sequence used. A typical MRI examination will consist of many series, each with a different combination of orientation and pulse sequence. Unlike CT imaging, the orientation of the images obtained during each pulse sequence can be selected by the operator. These are typically 1- to 5-mm thick slices. A complete examination produces hundreds of individual images to be reviewed and usually takes between 1 and 2 hours to complete the acquisition of images. Some series are acquired in a way that permits reconstruction in multiple planes or in three dimensions.

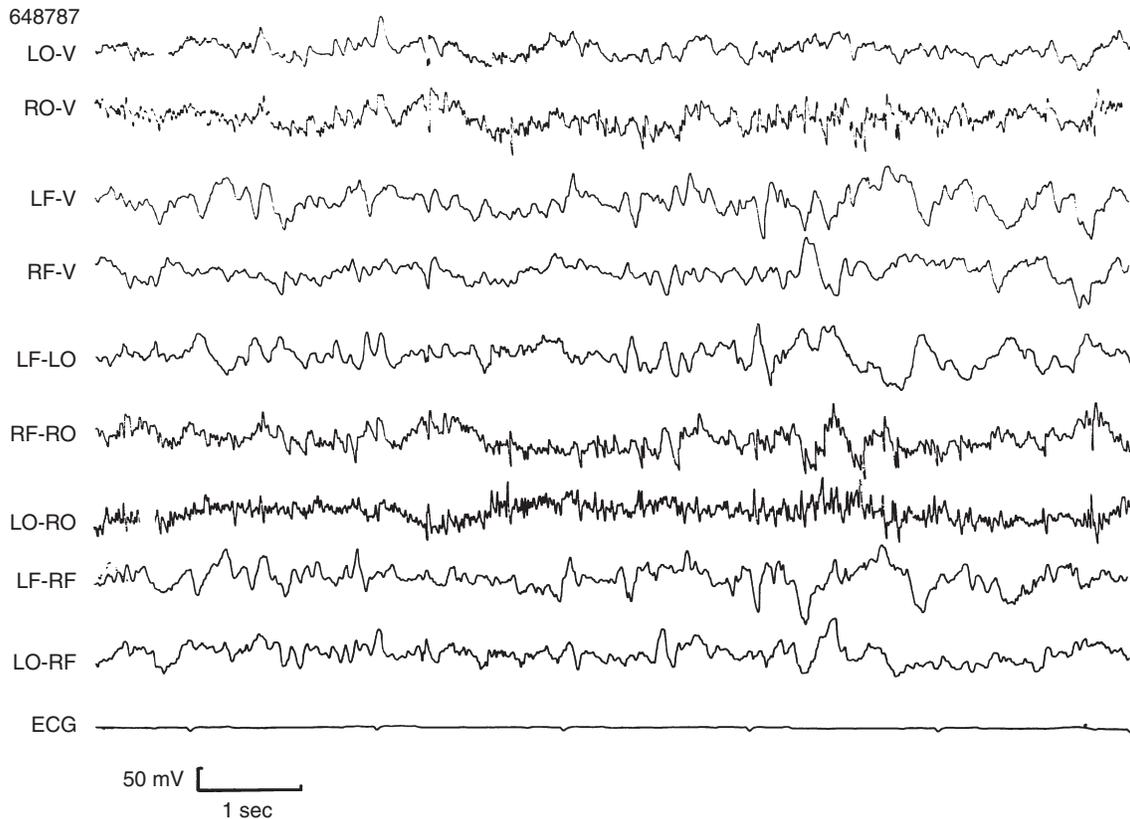

## ☞ EQUIPMENT

The main magnetic field can be generated in a variety of ways. Permanent magnets are used in lower field systems (<0.4 T). These magnetic fields are generated by using ferromagnetic materials of the same type as in everyday magnets. Stronger magnetic fields are produced using superconducting

electromagnets. These magnets use liquid helium to cool the electromagnetic coils and reduce the resistance, allowing much stronger magnetic fields to be generated. Liquid helium is expensive and requires periodic replenishment, but it is necessary to efficiently generate the stronger magnetic fields in clinical use. Regardless of the type of magnet, the room must be shielded to prevent any external radiofrequency pulses (e.g., radio signals, cellular phone transmission) from entering the room and introducing artifacts.

Two types of MRI systems are used for horses. One type consists of systems designed for use in human beings. These tend to be high field magnets with strengths  $\geq 1.0$  T of closed bore construction and require the horse to be under general anesthesia. The horse is positioned either in lateral or dorsal recumbency on a nonferromagnetic padded table with the body part of interest positioned into the bore. Foals can be imaged using the human patient table in any recumbency.

The other group consists of magnets that have been specifically designed for veterinary use. These magnets are generally low field magnets with a strength in the 0.25-T range. Many have an open bore design and can be positioned about a body part; some require general anesthesia and some only sedation. The images produced with these weaker magnets require longer scan times to obtain and are of lower resolution. Motion artifact in studies obtained on standing horses can significantly reduce image quality.

**FIGURE 12-22** Electroencephalograph from a horse with a space-occupying mass in the left frontal area of the brain. The generalized high-voltage, low-frequency wave and asymmetry of left cortex are notable. *RO*, Right occipital; *LO*, left occipital; *RF*, right frontal; *LF*, left frontal; *V*, vertex; *G*, ground; *ECG*, electrocardiogram position.

Examinations are limited to regions that can fit into the bore of the magnet to be positioned at or near the isocenter (center of the magnetic field). Depending on the type of magnet, this requires that either the horse be pushed into the center of the magnet bore or that the magnet be positioned around the region of interest. These limits will vary between magnets based on their construction.

## ⊕ SAFETY

Most safety hazards associated with MRI are related to the introduction of ferromagnetic objects into a strong magnetic field, as opposed to the existence of the magnetic field itself. No known adverse effects have been reported for MRI at field strengths currently used in equine clinical imaging. Any object that is magnetic (scissors, oxygen tanks, scalpel blades) will be attracted to the magnet; thus all the equipment in the room must be nonmagnetic or MRI compatible, including the anesthesia equipment. The strength of the magnetic field increases exponentially as the distance to the magnet decreases. In practical terms, this means that the pull of the magnet on any ferromagnetic object becomes quickly stronger as the object approaches the magnet (to prevent injury this is especially important to bear in mind when considering stronger magnets).

The strong magnetic field can also affect internal implants and is especially dangerous for people with cardiac pacemakers,

who should not enter a MRI room under any circumstances because of the potential for serious cardiac arrhythmias resulting from the effect of the magnetic field on the pacemaker. Metal shards in the cornea can also be affected by the magnet and can move within the cornea, causing ocular damage. The changing of the magnetic gradients can be quite loud. Any personnel who remain in the scan room during the examination should wear protective equipment to prevent hearing damage.

## ⊕ PATIENT PREPARATION

Horseshoes should be removed before the examination to eliminate the risk of potential magnetic attraction. Appropriate preparations should be carried out for images requiring general anesthesia. After induction to anesthesia but before entering the scan room, any metal objects (e.g., halters) should be removed from the horse. A specialized, nonferromagnetic table must be used to support the horse during the examination. After the horse is positioned in the bore of the magnet, it must remain completely motionless during image acquisition to prevent blurring of the image. Because MRI examinations typically take between 1 and 2 hours, urinary catheterization or some other means of urine collection is recommended to protect the equipment from contamination with fluid.

Because an MRI examination can be lengthy, it is extremely important that the primary region of interest be localized as

specifically as possible. MRI has proven particularly useful in areas that are not amenable to examination using other diagnostic imaging modalities.

## USE OF MAGNETIC RESONANCE IMAGING IN EQUINE NEUROLOGIC DISEASE

In adult horses, examination is limited to the brain and cranial cervical spine because of limitations of current magnet design. However, the trunk of foals up to approximately 500 lb may fit inside the bore of some magnets, enabling imaging of any part of the spinal column.

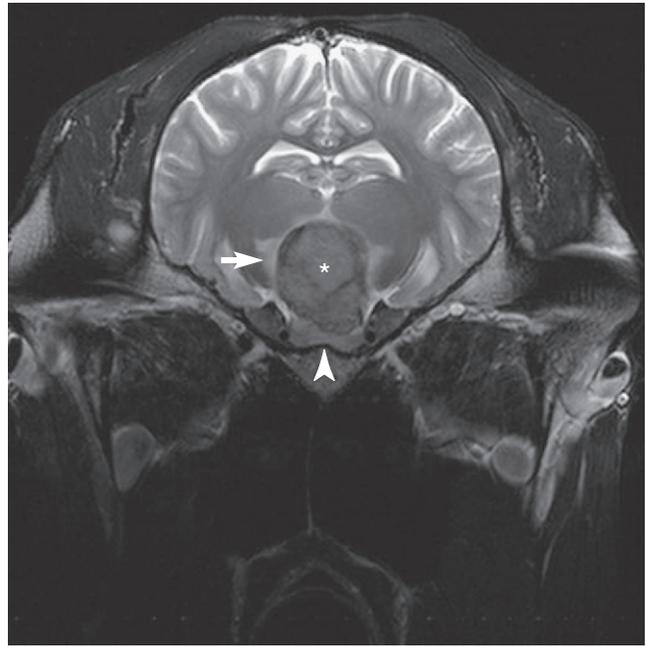

Few reports exist of clinical use of MRI in neurologic disease. Investigators at Washington State University described a case series of 12 horses with neurologic signs localized rostral to the foramen magnum imaged with MRI. Abnormal findings were seen in eight of these horses, and diagnoses included nigropallidal encephalomalacia, head trauma, cerebral abscess, stylohyoid bone fracture, pituitary mass, congenital hydrocephalus, and otitis media.<sup>1</sup> Additional case reports have described findings in cases of brain abscess,<sup>2,3</sup> cholesterol granuloma,<sup>4</sup> and EPM.<sup>5</sup> Diagnoses of equine protozoal myelitis, neoplasia, inflammatory disease, encephalomyelitis, meningitis, otitis media, hydrocephalus, and ischemic injury have been made at the author's clinic. In addition, substantial information has been gained regarding the extent of damage after traumatic injury. Although this clinic's experience with MRI of the nervous system is limited, the possibilities of this technique are exciting.

### PITUITARY ADENOMA

A 13-year-old Thoroughbred mare had decreased mentation, poor appetite, weight loss, and absence of normal estrous cycles. The decreased mentation had progressed to prolonged periods of somnolence, slow circling behavior, and an apparent decrease in vision. The mare had decreased menace and pupillary light responses and demonstrated slight weakness on a tail pull test. An anatomic diagnosis of a CNS lesion rostral to the foramen magnum was made. Endogenous adrenocorticotropic hormone, triiodothyronine (T3), and thyroxine (T4) levels were normal. A MRI examination was undertaken in an attempt to find the cause of the neurologic signs and to further investigate a possible pituitary lesion.

A mass was found on the median plane ventral to the diencephalon, with the ventral aspect of the mass within the sella turcica (Figure 12-23). A portion of the pituitary distinct from the mass can be identified in part of the sella turcica. The mass compresses the thalamus, hypothalamus, and optic chiasm. Portions of the mass appear hemorrhagic and regions of the thalamus, and hypothalamus surrounding the mass are edematous.

This horse was treated with pergolide and cyproheptadine in an attempt to ameliorate the signs of pituitary pars intermedia dysfunction (PPID), and improvement was seen for a brief period of time. Its condition then deteriorated after 6 weeks with progressive anorexia, weight loss, and depression despite aggressive supportive care. The mare was euthanized, and necropsy results showed a large pituitary mass with histologic features consistent with a pituitary macroadenoma of the pars intermedia.

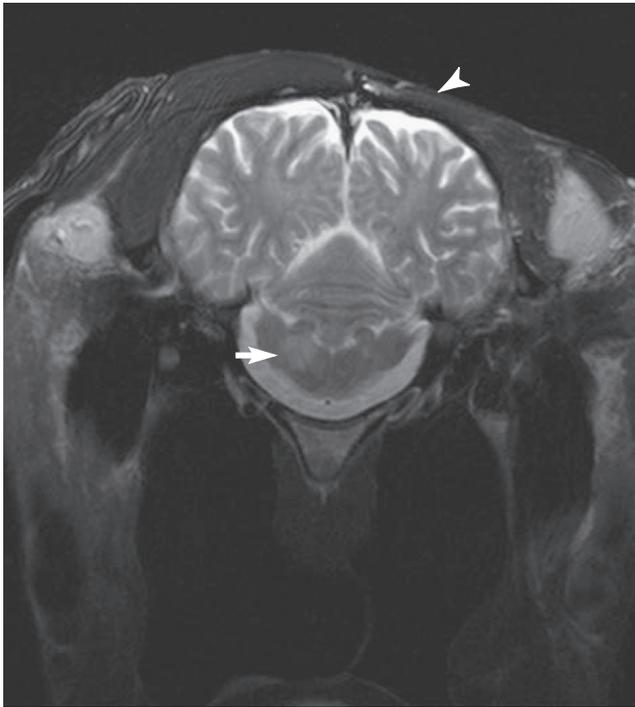

**FIGURE 12-23** Transverse T2-weighted fast spin echo image of the brain at the level of the sella turcica. The asterisk indicates a large mass of heterogeneous signal intensity displacing the diencephalon laterally. The arrowhead indicates normal pituitary tissue compressed by the mass. The arrow indicates high T2 signal (edema) within the diencephalon adjacent to the mass.

### EQUINE PROTOZOAL MYELOENCEPHALITIS

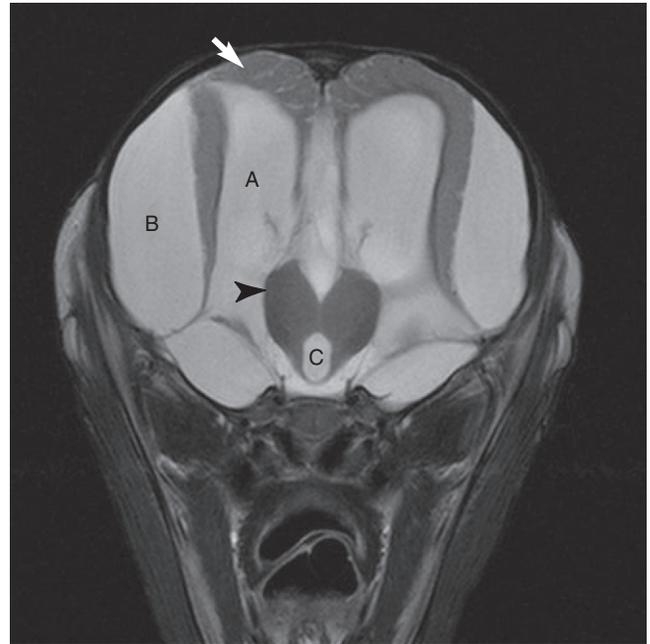

An 18-year-old Thoroughbred gelding became ataxic 9 months before presentation. Two months before presentation, the horse started to exhibit weight loss, dysphagia, and facial muscle wasting. The animal had been treated for equine protozoal myelitis twice before presentation and exhibited grade 3/4 ataxia in all limbs. In addition, the horse had atrophy of the left facial muscles, as well as the left temporalis and masseter muscles, muzzle deviation to the right side, and difficulty moving food to the pharynx with normal tongue tone, prehension, and ability to swallow. These neurologic signs suggested multifocal disease with involvement of cranial nerves V, VII, IX, and X, as well as the cervical spinal cord and brainstem. Equine protozoal myelitis Western blot was weakly positive on the CSF and positive on serum.

MRI findings consistent with inflammation and edema were seen throughout the right side of the medulla and caudal pons in areas including the nuclei of cranial nerves V, VII, VIII, and XII (Figure 12-24). These findings are consistent with those seen in a previously reported case of EPM.<sup>5</sup>

Nitazoxanide (NTZ), vitamin E, and flunixin meglumine were administered. Supportive care, including intravenous fluid therapy and enteral feeding via nasogastric tube, was also performed. The horse became progressively more depressed and developed pleuropneumonia 1 week after admission, likely secondary to aspiration because of dysphagia. The next day, the horse became acutely more ataxic, was unable to rise, and died. On postmortem examination, neuronal degeneration, inflammation, and protozoal organisms consistent with *Sarcocystis neurona* were identified in the nuclei and nerves of cranial nerves V, VII, and VIII.

**FIGURE 12-24** Transverse T2-weighted fast spin echo image of the brain at the level of the pons. The arrow indicates an area of T2 hyperintensity in the region of the nuclei of the seventh and eighth cranial nerves. The arrowhead indicates temporalis muscle atrophy.

**FIGURE 12-25** Transverse T2-weighted turbo spin echo image of the brain at the level of the thalamus. The lateral (A) and third (C) ventricles are massively dilated with cerebrospinal fluid (CSF) present outside of the brain (B). The arrow indicates the cerebral cortex and the arrowhead indicates the thalamus.

## HYDROCEPHALUS

A 1-month-old Quarter Horse filly was noticed by the owners to have a dome-shaped head, blindness, and obtundation. A congenital brain lesion was suspected.

MRI images showed severe communicating hydrocephalus with a specific location of obstruction not identified (Figure 12-25). The ventricles were enlarged and filled with CSF. The parenchyma of the cerebral hemispheres was thinned, and the cerebellum was compressed and herniated through the foramen magnum. A meningocele and an open fontanelle were noted at the junction of the left and right frontal and parietal bones.

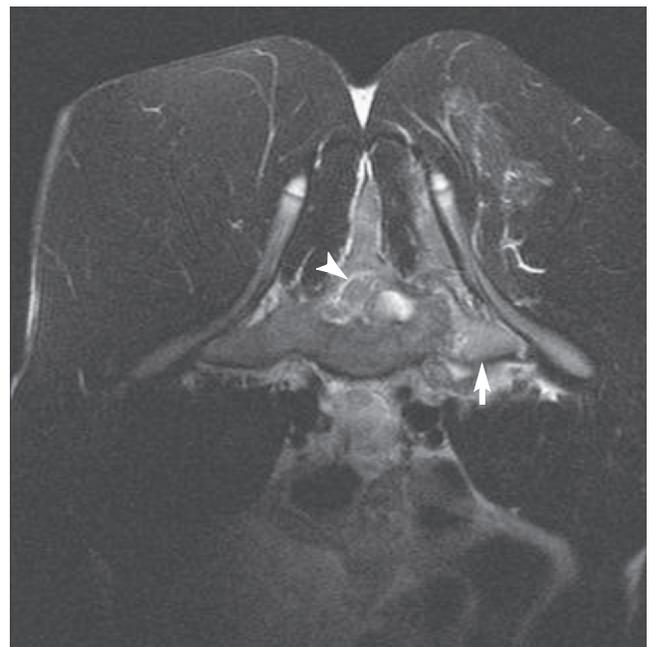

Treatment was not pursued, although the possibility of placement of a ventriculoperitoneal shunt was discussed with the owners. The foal remained alive and was weaned successfully.

## SPINAL CORD COMPRESSION

A 4-month-old Thoroughbred colt had a 2-day history of pyrexia and “knuckling over” of the left hind fetlock. Ultrasound examination of the lumbar, sacral, and gluteal regions showed an abscess within the musculature. The extent of the abscess could not be determined but was suspected to involve the pelvis, so MRI examination was undertaken.

Severe compression and inflammation of the spinal cord in the sacral region was seen on MRI (Figure 12-26). The left side of the sacrum had heterogeneous signal intensity suggestive of osteomyelitis.

The foal was treated with anti-inflammatory and antimicrobial medication and establishment of drainage of the

**FIGURE 12-26** Transverse T2-weighted turbo spin echo image of the spinal canal at the level of the sacroiliac joint. The arrowhead indicates the laterally compressed spinal cord and the arrow indicates a region of edema and proteinaceous fluid accumulation within and around the sacrum (osteomyelitis).

intramuscular portion of the abscess. The foal's condition improved and it was discharged on long-term antimicrobial therapy. During follow-up MRI examination 2 months later, the compression of the spinal cord had been relieved and the intramuscular abscess had decreased in size. The heterogeneous signal intensity within the sacrum had improved but not resolved completely.

## CONCLUSION

Although MRI of equine neurologic disease remains in its infancy, veterinarians are increasingly able to use this technology to make more specific and timely diagnoses. As the knowledge base regarding MRI progresses, practitioners will be able to advance their care and treatment of equine patients to new levels.

### SEIZURES, NARCOLEPSY, AND CATAPLEXY\*

Véronique A. Lacombe\*

## SEIZURES

### TERMINOLOGY

Seizures (from the Latin *sacire*, "to take possession of") may be referred to as fits, attacks, strokes, convulsions, or epilepsy and were first described around 500 - 700 B.C. Seizures are a common problem in both human and veterinary medicine but are less common in horses compared with other species. True seizures (i.e., "epileptic") are clinical manifestations of rapid excessive and/or hypersynchronous abnormal neuronal activity from the cerebral cortex that result in involuntary alterations of motor activity, consciousness, autonomic functions, or sensation.<sup>1-4</sup> Therefore, an epileptic seizure has a specific neural origin and can occur as a single event or be recurrent. Epileptic seizures can be further classified as primary (i.e., idiopathic), secondary (as the result of structural cerebral abnormalities), or reactive (reaction of the healthy brain to transient systemic insult). Epilepsy specifically refers to reoccurring epileptic seizures from a chronic brain disorder, which may be genetic (primary) or acquired (secondary). Epilepsy has been rarely documented in horses, except for juvenile idiopathic epilepsy in Arabian foals.<sup>5</sup> Finally, convulsions refer to seizures accompanied by tonic-clonic muscle activity and loss of consciousness.

Similar to standardized classifications described in small animals and humans, seizures in horses can be classified as being partial (simple and complex), generalized (primary or secondary), or as status epilepticus.<sup>2</sup> Seizures, which involve a discrete area of the cerebral cortex, are classified as simple partial seizures when consciousness is not impaired and complex partial seizures when consciousness is impaired. Partial seizures result in localized clinical signs, such as facial or limb twitching, compulsive running in a circle, or self-mutilation. One

may observe a partial seizure following a procedure such as collection of cerebrospinal fluid, cervical myelography, anesthesia, or cranial trauma that may spread throughout the cerebral cortex and produce a secondary generalized seizure. A generalized seizure involves the entire cerebral cortex and results in generalized tonic-clonic muscle activity over the whole body, with loss of consciousness. Seizures generalized from the onset are defined as primary generalized seizures. Secondary generalized seizures could originate from both types of partial seizures. Status epilepticus has been defined as more than 30 minutes of continuous seizure activity or 2 or more sequential seizures without a full recovery of consciousness, and is uncommon in horses. The most common types of seizures observed in an equine referral center were partial seizures (simple or complex, 30%) and secondary generalized seizures (30%).<sup>6</sup> This is in agreement with data in dogs, for which partial seizures with or without secondary generalization appear to be the most common type of seizures observed. Complex partial seizures are commonly observed in neonatal foals, and are referred as "chewing-gum fits", jaw chomping, and lip smacking.<sup>7</sup>

### ETIOLOGY/PATHOGENESIS

Adult horses have a high seizure threshold. In most cases severe damage must occur to the brain before adult horses have seizures. Foals, however, have a lower seizure threshold and are more susceptible to conditions causing seizures.

Etiologies of seizures in horses include intracranial and extracranial diseases (for which the healthy brain is reactive to the insult) (see Tables 12-5 and 12-6). The most common causes of seizures in foals under 2 weeks of age are neonatal maladjustment syndrome or hypoxic-ischemic encephalopathy, trauma, and bacterial meningitis.<sup>8</sup> The most common causes of seizures in foals less than 1 year of age are trauma, idiopathic epilepsy in Arabian foals and hyperammonemia in young Morgan horses.<sup>2,9</sup> The most common causes of seizures in adult horses older than 1 year of age are brain trauma, hepatoencephalopathy and toxicity.<sup>2</sup> Tumors, especially pituitary adenoma, may cause seizures and blindness in horses older than 7 years.<sup>2</sup>

Irrespective of the etiology, the pathogenesis of epileptic seizure is caused by an abnormal hypersynchronous electrical activity of neurons, caused by an imbalance between excitation and inhibition in the brain.<sup>10</sup> If the balance shifts toward excessive excitation (theory of excitatory post-synaptic potentials), a prolonged depolarization of neuronal aggregate will occur, a phenomenon known as "paroxysmal depolarization shift", which may generate an epileptic seizure.<sup>11</sup> Several mechanisms are thought to cause paroxysmal depolarization shifts and include increased excitatory neural transmitters (e.g., glutamate), decreased inhibitory neural transmitters (e.g., gamma-aminobutyric acid), alteration in neural transmitter receptor sites, or a derangement in the internal cellular metabolism of the neuron.<sup>12</sup> Notably, much research has focused on glutamate, the principle excitatory neurotransmitter in the brain, and its receptor complex, the N-methyl-D-aspartate (NMDA) receptor. Glutamate binds to NMDA receptors, which open sodium and calcium channels, leading to entry of these ions in the neuron and to postsynaptic depolarizations.<sup>13</sup> In addition, NMDA receptors have been implicated in the pathogenesis of seizures in infants and foals because if exacerbated (e.g., during perinatal asphyxia), intracellular calcium overload causes neuronal necrosis by activation of lytic enzyme systems

\*The authors wish to acknowledge Frank M. Andrews and Hilary K. Matthews, whose original work has been incorporated into this section.

TABLE 12-5

### Known and Suspected Causes of Seizures in Horses Less Than 1 Year of Age

DIFFERENTIAL DIAGNOSIS			
Classification	Extracranial	Intracranial	Diagnostic Aids
Anomalies (congenital)		Hydrocephalus	
		Hydranencephaly	1-6, 8
		Benign epilepsy	1, 10
Metabolic	Hypoxia, hyponatremia, hypoglycemia, hyperkalemia		2-6
Toxic	Organophosphates	Moldy corn	2-6
	Strychnine	Locoweed	9-11
	Metaldehyde		
Traumatic		Brain trauma	2-6, 8
		Lightning	2-5
Vascular		Neonatal maladjustment syndrome (vascular accidents)	2-6
Infectious	Septicemia	Bacterial meningitis	2-6
	Hyperthermia	Cerebral abscesses	5, 6, 8
		Rabies	2, 3, 11
		Viral encephalitis	6, 7

1, Breed; 2, onset; 3, clinical course; 4, physical examination; 5, neurologic examination; 6, clinical pathology (e.g., cerebrospinal fluid analysis); 7, serologic testing; 8, radiology (computed tomography scan, ultrasound, radiographs); 9, toxicologic testing; 10, electrodiagnostics (electroencephalography, electromyelography); 11, pathologic examination.

and nitric oxide synthase with generation of free radicals.<sup>14,15</sup> Conditions leading to the summation of excitatory postsynaptic potentials include excessive excitations and also loss of inhibitions without normal regulatory feedbacks. In response to the sudden depolarization shift of a neuronal aggregate, local surround inhibitory zones are established to try to prevent the spread of the epileptogenic activity. Gamma-aminobutyric acid (GABA) is the major inhibitory neurotransmitter of the central nervous system (CNS). GABAergic inhibition can be pre-synaptic (release of GABA from the GABAergic nerve terminal into presynaptic nerve terminals causing a reduction of neural transmitter release) or postsynaptic (caused by the interaction of GABA with specific postsynaptic receptors).<sup>11</sup> In GABA-system dysfunction, an abnormal neuronal hypersynchronous activity will spread, resulting in depolarization of more neurons.<sup>11</sup> Once a “critical mass” of neurons has fired, uncontrolled spread of electric activity may occur over the cerebral cortex, which may precipitate an epileptic seizure. Thus, these seizures can be blocked by use of agents that potentiate inhibitory neural transmitters, such as phenobarbital. In brief, seizures may develop because of a summation of synchronous excitatory postsynaptic potentials in large groups of neurons that may be precipitated by an increase in excitatory neurons, a decrease in inhibitory neurons, a decrease in inhibitory neurotransmitters, or any combination of these mechanisms.

Alterations in the neuronal cell microenvironment may also lead to seizure generation. Systemic and local neuronal electrolyte abnormalities may disturb excitatory neuron homeostasis and lead to spontaneous and excessive action potentials.<sup>4</sup> Intracellular potassium released during neuronal activity may reach

sufficient concentration to move the resting membrane potential toward the threshold and generate a seizure focus. Spontaneous action potentials generated by alteration in intracellular potassium concentration may spread to other parts of the cerebral cortex, causing a generalized seizure. Alterations in one intracellular neuronal electrolyte may alter the homeostasis of other intracellular electrolytes. Increased intracellular potassium concentration, and decreased intracellular calcium, magnesium, and chloride concentrations, are observed during interictal epileptogenesis and the transition from interictal to ictal activities.

Alterations in sodium conductance have also been implicated in the onset of seizures. Rapid influxes of sodium into the neuron may lead to hyperexcitability of the neuron and rapid firing. Phenytoin, a hydantoin derivative, blocks these rapid influxes of sodium into neurons and suppresses repetitive firing by hyperexcitable neurons.<sup>16</sup> Thus a complex interaction may occur between these electrolytes and the internal cell homeostasis that precipitates seizure formation.

### CLINICAL SIGNS AND DIAGNOSIS

Seizure activity is manifested clinically in a variety of ways depending on the area and the extent of the cerebral cortex involved. In partial seizures, asymmetric twitching of a limb, facial twitching, excessive chewing, compulsive running, or self-mutilation may occur.<sup>2</sup> A localized seizure may develop into a generalized seizure. One may observe three distinct clinical periods in a generalized seizure. Just before the seizure (aura), horses may exhibit signs of anxiety and uneasiness. During the seizure (ictus), horses may become recumbent, unconscious,

TABLE 12-6

### Known and Suspected Causes of Seizures in Horses More Than 1 Year of Age

#### DIFFERENTIAL DIAGNOSIS

Classification	Extracranial	Intracranial	Diagnostic Aids
Metabolic	Hepatoencephalopathy, hypocalcemia, uremia, hyperlipidemia		2-6, 8
Toxic	Organophosphates	Moldy corn	2-6
	Strychnine	Locoweed	9, 11
	Metaldehyde	Bracken fern	
		Lead, arsenic, mercury	
Traumatic		Rye grass	
Vascular		Brain trauma	2-6, 8
		Strongylus vulgaris	2-5
		Cerebral thromboembolism	5, 6, 11
		Intracarotid injection	2, 3
Tumor		Neoplasia	2-5, 8, 10, 11
		Hemarthroma	6, 8, 10, 11
		Cholesterol granuloma	8, 11
Infectious		Cerebral abscess	5, 6, 8
		Rabies	2, 3, 11
		Arbovirus encephalitis	6, 7
		Mycotic cryptococcosis	5, 6
		Equine Protozoal myeloencephalitis	6, 7

1, Breed; 2, onset; 3, clinical course; 4, physical examination; 5, neurologic examination; 6, clinical pathology (e.g., cerebrospinal fluid analysis); 7, serologic testing; 8, radiology (computed tomography scan, ultrasound, radiographs); 9, toxicologic testing; 10, electrodiagnostics (electroencephalography, electromyography); 11, pathologic examination.

and have symmetric clonic muscle contractions (contractions and relaxations of muscles occurring in rapid succession), followed by symmetric tonic muscle contractions (continuous unremitting muscle contractions).<sup>2,9</sup> Horses also may show deviation of eyeballs, dilated pupils, ptialism, trismus or jaw clamping, opisthotonos, lordosis or kyphosis, violent paddling movements of the limbs, uncontrolled urination and defecation, and excessive sweating. A generalized seizure may last from 5 to 60 seconds.<sup>2</sup> After the seizure (postictus), horses may show depression and blindness for hours to days.<sup>2,9</sup>

Diagnosis of seizure is based on history, clinical signs, and ancillary diagnostic tests to determine an underlying cause, whenever possible (see Tables 12-5 and 12-6). Diagnosing seizures in horses can be very challenging due to the non-specific clinical expression coupled with a rapid return to normal activity without persistent neurological signs in many affected horses. Since many horses are unobserved for long periods of the day, the presence of a seizure might be suspected after recognition of unexplained trauma to the head or legs, and disruption of the stall or outside paddock. At other times, the caretaker may identify a change in attitude or behavior of the horse such as restlessness or a "far-off" appearance, which might be a prodromal sign (aura) of an impending seizure. Careful and thorough questioning of the caretaker should be performed to determine the duration and frequency of the episodes, date(s), the time of day, the relationship to feeding, any event(s) associated with the episode (e.g., injection in

the carotid and traumatic event), any unusual environmental circumstances (stimuli such as thunderstorms, fireworks, changes in housing), recent trauma, febrile episodes, exposure to drugs or toxins, recent behavioral changes, and the seizure history of the dam, sire, and other siblings. The veterinarian should always consider rabies in the list of differential diagnoses, even if the horse has been vaccinated and especially in endemic areas.

A complete physical examination should be performed to rule out non-cerebral clinical conditions that mimic epileptic seizures, including painful conditions (colic, limb fractures, exertional myopathy), tetanus, botulism, and hyperkalemic periodic paralysis (HYPP). In these conditions, horses do not lose consciousness but remain bright and alert. Horses with HYPP may show prolapse of the nictitating membranes of the eye and muscle fasciculations but remain anxious, alert, and have normal pain perception. Cardiac disorders may precipitate syncopal episodes, which could be confused with seizures. Auscultation of the heart may help identify the presence of murmurs and electrocardiography may help determine the presence of arrhythmias. One can also confuse narcolepsy and cataplexy with seizures. Most narcoleptic horses (except for some ponies) remain standing with the head hanging close to the ground. If recumbency occurs, loss of muscle tone and rapid eye movement (REM) sleep may follow.<sup>4</sup> Icteric mucous membranes may be apparent in horses with hepatoencephalopathy and diarrhea may be evident in horses after toxin ingestion. A fundic

examination may reveal papillary edema, detached retina, or active inflammation suggestive of trauma or an infectious cause. Blindness may also occur during or after an episode of seizure.

One should perform a complete neurologic examination to help determine the presence of a central nervous system lesion and its localization. Neurologic examination should be performed during the interictal period, since an immediate postictal examination may reveal depression, weakness, blindness, and crossed extensor reflex, which may lead to false anatomic localization of lesions.<sup>1,2,9</sup> Any sedatives or anticonvulsants given to control the seizures may affect subsequent neurological examination.

A complete blood cell count (CBC) and serum biochemistry analysis should elucidate the presence of systemic, extracranial disease, which may predispose to seizures. CBC and fibrinogen may suggest inflammation (leukocytosis and hyperfibrinogenemia) or viral infection. A complete serum biochemistry profile should be performed to rule out metabolic abnormalities that may trigger seizures. Although rare in horses hypoglycemia may indicate a cause for seizures in both neonates and adults. Renal disease and hyperlipidemia should be ruled out as both of these conditions could create metabolic imbalance and precipitate a seizure. An arterial blood gas evaluation is indicated to rule out hypoxia or metabolic derangements. Liver function tests, liver biopsy, and determination of serum ammonia concentration should be performed if hepatic encephalopathy is suspected.

Cerebrospinal fluid (CSF) evaluation may be helpful in determining the underlying etiology of seizures, such as an active structural cerebral abnormality, although normal fluid analysis can be seen in many conditions. The site of choice is the atlanto-occipital cistern, but this may be contraindicated if the horse is showing signs of increased CSF pressure (such as mydriasis or papilledema) or if general anesthesia is not appropriate. Alternatively, CSF fluid collection from the lumbosacral space could be performed, providing that it can be safely done in the standing and sedated animal. Interpretation of equine CSF abnormalities is described previously in this chapter.

Electroencephalography (EEG), which is defined as the graphic recording of the rhythmic bioelectrical activity arising predominantly from the cerebral cortex, is the most important paraclinical test in humans suffering from epilepsy. Similarly, this diagnostic test has been useful in dogs and horses with seizures, and has been used as a screening procedure in patients with seizures because of its excellent sensitivity.<sup>17,18</sup> Accurate interpretation of the EEG recording can provide information supporting the presence and type of cerebral disease (e.g., acute vs. chronic; focal vs. diffuse; inflammatory vs. degenerative). One should assess the background of the EEG recording for abnormal frequency and amplitude, the presence of asymmetrical patterns between regions, and for the presence of paroxysmal activity.<sup>18</sup> Although normal EEG patterns for foals and adult horses have been described, the establishment of normal values remains difficult because frequency and amplitudes are state-dependent (awake, drowsy, sleeping, sedated, anesthetized), vary with age (foal vs. adult), and chemical restraint influences EEG patterns.<sup>17,18</sup> When possible, the recording should be attempted on standing horses with chemical restraint. Please refer to Table 12-4 for description of normal patterns in awake and sedated horses. In epileptic patients, an increase toward low voltage-fast activity or high voltage-slow activity may be observed, and are suggestive of ongoing irritative processes or neuronal death, respectively. Epileptiform paroxysmal activity, defined as abnormal paroxysmal transient events (such as spikes, sharp

waves, and spike-and-wave discharges), supports the diagnosis of seizures.<sup>17,18</sup> Focal, multifocal or generalized epileptiform activity can be recorded on EEGs of epileptic patients, depending on the localization of the discharges and the extent of the cerebral cortex involved.<sup>17,18</sup> The lack of recording of epileptiform activity does not rule out seizures.<sup>18</sup> The proximity of a seizure to the EEG examination may influence the amount of epileptiform activity present in the EEG. Therefore, one should consider repeating EEG examination in an animal suspected of having seizures and for which the first EEG recording was normal.<sup>17,18</sup> Horses suffering from extracranial diseases may also have abnormal EEG recording such as during metabolic diseases.<sup>17,18</sup>

Skull radiographs may help determine the presence of traumatic skull fractures. Computed tomography (CT) has superior capabilities for imaging bony structures and could reveal potential skull fractures that may remain undetected by conventional radiographs, due to superimpositions of bony structures. Brain lesions detectable by CT include intracranial masses such as cholesterol granulomas, neoplasia and abscesses, calcification, acute hemorrhage, ischemia, hydrocephalus, and brain malformation.<sup>19,20</sup> Although the presence of seizures in horses (independent of the type and frequency) is significantly negatively associated with the presence of intracranial lesions detectable with CT, the procedure is warranted to rule out structural lesions, especially if other neurologic signs such as cranial nerve deficits or abnormal mentation are present.<sup>6</sup> The use of contrast did not help in identifying cerebral lesions by CT in horses presented for evaluation of neurologic deficits.<sup>6</sup>

Magnetic resonance imaging has become the gold standard for diagnosis of structural intracranial abnormalities in small animals. Unfortunately, access for horses is limited. MR imaging is discussed in more detail previously in this chapter.

## TREATMENT

The goals of treatment for adult horses or foals with a seizure disorder are to stop ongoing seizures, correct underlying diseases, and prevent future seizure activity.

### INITIAL THERAPY: CONTROLLING SEIZURES

Prompt control of seizures is a priority as prolonged or recurring seizures may result in increased intracranial pressure and neuronal necrosis and result in trauma to the patient or caregivers.<sup>13</sup> The best initial treatment for controlling seizures in horses is diazepam, a benzodiazepine anticonvulsant, and phenobarbital sodium. Benzodiazepines hyperpolarize neuronal cells by binding to GABA receptors resulting in change of the chloride conductance pathways and making cells resistant to depolarization. The overall result is a decrease in the electrical activity of the seizure focus and an increase in the seizure threshold.<sup>21</sup> Although quite effective, the half-life of diazepam is short, 10 to 15 minutes, making repeated doses sometimes necessary. Caution is warranted as prolonged usage may cause respiratory depression/arrest and drug accumulation in foals as its clearance is slower in this age group.<sup>22</sup> In addition, diazepam should be used with caution in horses or foals with hepatoencephalopathy, as it may exacerbate clinical signs due to the upregulation of benzodiazepine receptors. In patients that do not respond to the initial bolus doses of diazepam, a constant rate infusion of diazepam can be implemented at an initial rate of 0.1 mg/kg/hr.<sup>13,23</sup> Midazolam is a potent short-acting benzodiazepine that can be used in foals at 0.05-0.1 mg/kg intravenously or intramuscularly or as a continuous rate infusion.<sup>24</sup>

Intravenous phenobarbital rapidly (within 20 minutes) provides a high serum concentration and will quickly stop seizures and reduce cerebral metabolic rate, which is particularly important if cerebral edema is suspected. The mechanisms of action of phenobarbital include: 1) facilitation of inhibitory neurotransmission via GABA receptors; 2) inhibition of postsynaptic potentials produced by glutamate; and 3) inhibition of voltage-gated calcium channels at excitatory nerve terminals. In foals, a loading dosage of 20 mg/kg intravenously (diluted in 30 ml of saline and infused IV over a 30 min period), followed by maintenance dosages of 9 mg/kg intravenously q8h is recommended.<sup>25</sup> In adult horses, a parenteral loading dosage of 12 mg/kg IV followed by 6.65 mg/kg IV (20 min infusion) q12h, is adequate to reach appropriate therapeutic concentrations.<sup>26</sup> Maintenance therapy is administered by the oral route, with a recommended dosage of 10-12 mg/kg once daily.<sup>27,28</sup>

Although not a true anticonvulsant, sodium pentobarbital could be used for the short-term management (1-3 days) of seizures in neonatal foals because of its anesthetic effects. Although this anesthetic agent has little use in the management of seizures in adult horses, general anesthesia with continuous infusion of pentobarbital (for up to 24 hours) may be required for horses suffering from status epilepticus, which may not be controlled effectively with regular anticonvulsant therapy. Maintenance phenobarbital therapy should be administered throughout anesthesia.

Although not routinely used as anticonvulsants in horses, primidone and phenytoin may be considered as an alternative therapy if previous drugs are ineffective. Primidone is metabolized to phenobarbital (main active metabolite) and to a smaller extent to phenylethylmalonamide (metabolite which may potentiate the anticonvulsant effects of phenobarbital).<sup>23</sup> Primidone has been reported anecdotally for treating foals with seizures.<sup>29</sup> Phenytoin inactivates voltage-dependent neuronal sodium channels, preventing depolarization of the presynaptic neuronal membrane at the excitatory nerve terminal, and thus reducing release of glutamate. Adverse effects of phenytoin include prolonged depression in foals, as well as mild atrioventricular block and decrease in blood pressure in adults.<sup>24</sup>

Some sedative drugs, such as acetylpromazine, xylazine, and ketamine, should be used with caution for emergency seizure management. Although acetylpromazine has been used to control seizures in foals, this drug is contraindicated because of its ability to lower the seizure threshold.<sup>2,9</sup> Xylazine decreases cerebral blood flow and increases intracranial pressure, which may exacerbate cerebral hypoxia and worsen seizures. However, giving xylazine may be necessary in an emergency situation until a more appropriate drug becomes available. Ketamine may exacerbate seizures because it increases cerebral blood flow, oxygen consumption, and intracranial pressure. However, ketamine also antagonizes NMDA receptors and thus, appears helpful in a rodent model of status epilepticus as well as in some neonatal foals with seizures, although further studies are required.<sup>30</sup>

### MAINTENANCE THERAPY: PREVENTING SEIZURES

The goal of long-term anticonvulsant therapy is to reduce the frequency, duration, and severity of seizures without intolerable side effects associated with such therapy. Therefore, the initiation of long-acting anticonvulsant therapy depends on consideration of the underlying cause, frequency, and severity of the episodes. Client factors such as owner preference and compliance, and the long-term expense of medication should

also be considered. The owners should be aware that therapy for the control of seizures, particularly in adult horses, may continue for months or years. In addition, the initiation of treatment does not guarantee elimination of seizures, and it may be not safe to ride or handle affected horses. With identified intracranial diseases, the therapy should be initiated at the onset of seizures. When no etiology has been determined, the decision to place the horse on long term maintenance therapy is based on recognition of either a cluster of seizures (>3-4 times per year or 2 seizures per month), or severe generalized seizures that results in injury to the horse and danger to those in the environment regardless of frequency. Foals with idiopathic epilepsy that have several seizures over 1 to 3 days also may require short-term (1 to 3 months) anticonvulsant therapy.<sup>2,9</sup>

One should select a single anticonvulsant medication for maintenance; the choices include phenobarbital, bromide, phenytoin, and primidone. Phenobarbital is the drug of choice for long-term maintenance in horses. Tables 12-7 and 12-8 list therapy guidelines.<sup>2,4,9</sup> Phenobarbital is well absorbed following oral administration and is metabolized in the liver. It induces hepatic cytochrome P450 enzyme complex with resultant increase in its own rate of metabolism, often resulting in the need to adjust the dose over time. Trough levels of phenobarbital should be measured 4 to 5 days after initiation of treatment, aiming for a concentration of 15 to 45 µg/ml.<sup>27</sup> Trough phenobarbital concentrations should be determined at initiation of therapy, whenever the dose has been adjusted, or whenever seizure control is inadequate. One must tailor the treatment dosage to fit the individual, using the lowest concentration effective at controlling seizures, in conjunction with monitoring of serum drug concentration. Once the seizure activity is under control, phenobarbital monitoring approximately every 60 days is usually adequate. Although phenobarbital is well tolerated in horses, potential adverse effects include excessive sedation, respiratory depression, bradycardia, hypotension and hypothermia in neonatal foals. Veterinarians should avoid using other drugs with known interactions, such as ivermectin, a GABA agonist. Tetracyclines and chloramphenicol inhibit hepatic microsomal enzymes, thereby prolonging the effects of phenobarbital. If the adverse effects are unacceptable and seizures are not controlled with one anticonvulsant therapy, one could consider reducing the dose by 20% or to nontoxic level, and beginning a second anticonvulsant therapy, such as potassium bromide.<sup>9,31</sup>

Bromide (sodium or potassium) appears to compete with chloride to hyperpolarize neuronal membranes, as well as enhancing GABA-activated chloride conductance. Because the elimination half-life of this drug in horses is 3 to 5 days, it often takes several weeks to reach a steady state level in horses. Because of the long elimination half-life, potassium bromide should not be used alone to treat ongoing seizures, but in combination with phenobarbital, with an initial dose of 25-40 mg/kg/day PO.<sup>32,33</sup> When used as monotherapy, a loading dose of 120 mg/kg daily for 5 days followed by a daily oral dose of 40 mg/kg achieved a serum level of 1 mg/ml, which has been reported to be within the therapeutic window of other species. Adverse effects appear to be rare in horses.<sup>33</sup>

Newer antiepileptic drugs have been introduced in veterinary medicine, with improved therapeutic indices (i.e., effective dose compared to toxic dose) with a reduction of the sedative and organ-toxic adverse reactions. These drugs include felbamate, gabapentin, clorazepate, topiramate, and zonisamide, and can be used as monotherapy or in combination.<sup>23</sup> Gabapentin, a

TABLE 12-7

Guidelines for Treating Seizure Disorders in Foals				
Regimen	Drug	Dosage	Route	Frequency
Control seizures: initial therapy	Diazepam	0.1-0.4 mg/kg slow	IV	As needed
	Midazolam	0.05-0.1 mg/kg	IV or IM	As needed
	Phenobarbital	9-20 mg/kg loading dose (30 ml saline)	IV	
		5-10 mg/kg		
	Phenytoin	20-40 mg/kg	IV	
		2-4 mg/kg		
	Primidone	2-4 mg/kg	PO	To effect
		66.6-222.2 mg/kg		
Chloral hydrate	To effect	IV	To effect	
	Guaifenesin			IV
Prevent seizures: maintenance therapy	Phenobarbital	a. 4-10 mg/kg	PO	q12 h
		b. 2-10 mg/kg	IV	q8-12 h
	Phenytoin	1-5 mg/kg	PO, IM	q2-4h for 12 h, then q6 h or q12h
		15 mg/kg	PO	q12h
Control cerebrocortical edema	Prednisolone	50-10 mg/kg	IV	
	DMSO	0.5-1.0 g/kg diluted in 10% solution	IV	q12h
Anti-oxidant and NMDA-receptor blockade therapy (Efficacy not established)	Alpha-tocopherol (Vit E)	500-4,000 units per foal	PO	q24h
	Ascorbic acid (Vit C)	50-100 mg/kg	IV	q24h
	Allopurinol	40 mg/kg	PO	within first 4 h
	Magnesium sulfate (HIE)	50 mg/kg/h for the first hour diluted to 1% as a loading dose, then 25 mg/kg/h CRI	IV	CRI q24-48h
Provide respiratory support (if needed)	Oxygen supplementation	5-10 L/min	nasal	
	Caffeine	loading dose: 10 mg/kg	PO	
		maintenance dose: 2.5-3.0 mg/kg	PO	q24h
Provide proper hydration and nutritional support	Positive pressure Ventilation			
	Cautious fluid therapy	Maintenance: 4-5 ml/kg/h	IV	
	Oral feeding (if tolerated)	Milk: 10-25% of foal's bw/day		
	Parenteral nutrition			
Provide metabolic support	Support body temperature			
	Glucose supplementation	—	IV	
	Electrolyte supplementation	—	IV or PO	
Minimize chances of trauma	Thiamine (HIE)	10 mg/kg	IV	q12h
	Provide thick bedding, heavy padding and head helmets, leg wrap	—	—	—

\*IV, Intravenously; IM, intramuscularly; PO, by mouth; HIE, hypoxic ischemic encephalopathy.

structural analog of GABA, has been used as adjunctive therapy in humans and dogs for the treatment of partial seizures refractory to phenobarbital and bromide therapy. Currently, there is one pharmacokinetic study on the use of gabapentin in horses.<sup>34</sup> After a single oral dose (5 mg/kg), gabapentin was rapidly absorbed with a plasma elimination half-life similar to dogs (3.4 h).<sup>34</sup> However, the clinical efficacy of gabapentin and other new anticonvulsant drugs is currently unknown in horses.

It is difficult to provide recommendation for when to terminate anticonvulsant therapy. If no adverse effects are seen, the dose should not be altered for most horses until the patient has been seizure free for at least one month or at least 3 times the duration of the seizure cycle. If one needs to discontinue anticonvulsant therapy, this should be done slowly since sudden withdrawal of drugs may precipitate seizures. In neonates, the

dose can be decreased by one-fourth to one-half each day for a minimum of 3 days then discontinued. In the adult which has been on anticonvulsant maintenance therapy long term, a longer weaning period is suggested, decreasing the dose by 20% every other day for 1 week before stopping.<sup>9,23,31</sup> Serial EEGs may provide valuable information on the progression or resolution of the disease in horses, and may help the clinician in determining if continued maintenance anticonvulsant therapy is necessary.<sup>23</sup>

#### ANCILLARY THERAPY

The goal of ancillary therapy is to: 1) control cerebrocortical edema, CNS inflammation, and intracranial pressure; 2) decrease the production of oxygen-derived free radicals; 3) prevent post-traumatic autodestruction of nervous tissue; and 4) provide appropriate supportive care.<sup>23</sup>

TABLE 12-8

Guidelines for Treating Seizure Disorders in Adult Horses				
Regimen	Drug	Dosage	Route	Frequency
Control seizures: initial therapy	Diazepam	0.05-0.2 mg/kg in 25-100 mg doses	IV or IM	As needed
	Phenobarbital	12-20 mg/kg initial dose (diluted in saline over 30 min), then 1-9 mg/kg	IV	q8-12h after initial dose
	Phenytoin	1-5 mg/kg	IV or PO	q4h for up to 24h
	Pentobarbital	2-10 mg/kg	IV	To effect
	Chloral hydrate	33.3-133.3 mg/kg	IV	To effect
	Guaifenesin	88.9-133.3 mg/kg	IV	To effect
Prevent seizures: Maintenance therapy	Phenobarbital	5-11 mg/kg	PO	q12-24h
	Potassium bromide	25-40 mg/kg	PO	q24h
	Phenytoin	1-5 mg/kg	PO	q12h
Control cerebrocortical edema	Dexamethasone	0.1-0.25 mg/kg	IV	q6-24h
	Methylprednisolone	a. 30 mg/kg followed by 15 mg/kg 2 and 6 h later, followed by a CRI (2.5 mg/kg/h)	IV	1 <sup>st</sup> dose within 4 h after trauma CRI for 48 h
	DMSO	1.0 g/kg diluted as a 10% solut.	IV	q12-24h
	Mannitol	0.25-2g/kg as a 20% solution	IV	q12-24h
	Furosemide	1 mg/kg	IV, IM, SQ	q12h
	Anti-oxidant and NMDA-receptor blockade therapy (Efficacy not established)	Alpha-tocopherol (Vit E)	a. 2,000 IU/adult b. 5,000-20,000 IU/adult	IM PO
Ascorbic acid (Vit C)		20 mg/kg	PO	q24h
Allopurinol		5 mg/kg	PO	q12h
Magnesium sulfate		50 mg/kg	IV slow	once
Provide proper hydration and nutritional support		Cautious fluid therapy Oral feeding (if tolerated)		IV
Correct metabolic derangements (if needed)	Oxygen therapy		Nasal	
	Glucose supplementation		IV	
Minimize chances of trauma	Provide thick bedding, heavy padding, helmet and leg wraps.			

\*IV, Intravenously; IM, intramuscularly; PO, by mouth.  
From Equine neurology<sup>24</sup>-reprint with permission

Steroidal or non-steroidal anti-inflammatory drugs could be an effective ancillary therapy to reduce CNS inflammation and pressure.<sup>21</sup> Corticosteroids may stabilize neuronal membranes and decrease seizure foci.<sup>21</sup> Dexamethasone is the most commonly used corticosteroid for treating horses with neurological diseases. One should give a single dose of 0.1 to 0.2 mg/kg dexamethasone intravenously initially and should reevaluate the horse the next day. Short-acting glucocorticoids, such as prednisolone sodium succinate, may be used in foals instead of long-acting corticosteroids.

Dimethyl sulfoxide scavenges free oxygen radicals released in damaged tissue and helps maintain cerebral blood flow by reducing thromboxane production, which may result in vasoconstriction and platelet aggregation.<sup>35</sup> Adult horses and foals in seizure may benefit from 1 g/kg dimethyl sulfoxide given intravenously as a 10% solution with lactated Ringer's solution or 5% dextrose. Mannitol is recommended to control cerebrocortical edema, however it is contraindicated in horses with intracranial hemorrhage as it may exacerbate bleeding.<sup>23</sup> Alpha-tocopherol (vitamin E), ascorbic acid (vitamin C) and allopurinol (a xanthine oxidase inhibitor) have also been recommended to reduce the production of oxygen-derived free radicals in the CNS.<sup>36</sup>

Supportive care is an important aspect of the treatment of convulsing horses. One must 1) provide proper hydration and nutritional support; 2) ensure proper cerebral perfusion by careful administration of intravenous fluid; and 3) provide adequate delivery of nutrients and oxygen to the brain.<sup>23</sup> Magnesium sulfate, an NMDA receptor antagonist, may be beneficial for the treatment of seizures in foals suffering from hypoxic ischemic encephalopathy and for brain injury after head trauma in adults at a dose of 50 mg/kg (25 g/500-kg horse administered in the first 5-10 L of IV fluid).<sup>14,36</sup> Thiamine, which is an essential coenzyme in glucose utilization by the brain, may also prevent glutamate-induced and NMDA receptor-mediated cell death in foals with hypoxic ischemic encephalopathy.<sup>37</sup>

Finally, one must treat skin trauma and limit injury associated with seizures or recumbency, by maintaining the horse in a proper environment to enhance delivery of medication, ensure safety of attending personnel, and provide protection for the horse. The horse should be placed in a padded stall with heavy bedding, and a protective helmet should be placed (if tolerated) especially on recumbent animals, which will prevent eye and head injuries. The immediate environment should be quiet and the intensity of the lighting should not be suddenly increased to minimize the potential effects of outside stimuli.<sup>23</sup>

## NARCOLEPSY

True narcolepsy is an incurable non-progressive sleep disorder of the central nervous system characterized by excessive daytime sleepiness with pathologic manifestations of Rapid Eye Movement (REM) Sleep. These manifestations also include uncontrolled episodes of loss of muscle tone (cataplexy), although narcolepsy may also occur without cataplexy.<sup>1,3,9,38</sup>

Narcolepsy has been recognized in humans and in a variety of domestic animals, affecting 0.02% of adults worldwide and over 17 breeds of dogs.<sup>38,39</sup> Although its prevalence is not known in horses, narcolepsy appears to be rare and is breed specific. Both familial and sporadic cases of narcolepsy have been observed in horses. The disease has been reported in Suffolk and Shetland foals (the fainting disease)<sup>40</sup>, Welsh ponies, Miniature horses, Thoroughbred, Quarter Horse, Morgan, Appaloosa, and Standardbred horses.<sup>1,3,9,40</sup> A familial occurrence is thought to exist in affected Suffolk and Shetland pony foals, and in American Miniature horses.<sup>9,41</sup> In general, narcolepsy is identified in two distinct groups: in foals (for which the onset occurs at approximately 6 months of age) and in adult horses.

A condition of excessive daytime sleepiness with episodes of collapse or near-collapse is described in horses that have been deprived of recumbent sleep for a period of time.<sup>42,43</sup> This may be the result of medical conditions inhibiting recumbency, housing and environmental factors, or social and behavioral factors. While this problem closely resembles narcolepsy in its clinical presentation, it is a result of sleep deprivation rather than the biochemical abnormalities suspected in horses with true narcolepsy.<sup>42,43</sup>

## PATHOPHYSIOLOGY

Four components of narcolepsy are apparent in human beings and include excessive daytime sleepiness associated with short periods of REM sleep, cataplexy, hypnagogic hallucinations, and sleep paralysis.<sup>4</sup> Cataplexy or sudden collapse with complete inhibition of skeletal muscle tone occurs in horses with narcolepsy.<sup>1,4,9</sup> Respiratory and cardiac muscles are spared.<sup>1</sup>

With narcolepsy and cataplexy, a biochemical abnormality of the brainstem or sleep-wake center may be present. In people, evidence suggests that narcolepsy with cataplexy is related to an underlying deficiency in the hypothalamic orexin/hypocretin system.<sup>44</sup> Although their physiological roles are not fully understood, hypocretins are hypothalamic-specific neuropeptides, which are involved in various functions such as sleep, feeding, energy homeostasis, and neuroendocrine and autonomic nerve functions. A mutation in the hypocretin receptor 2 gene has been identified in Dobermans and Labrador Retrievers, with secondary impairment in postsynaptic hypocretin neurotransmission. In acquired canine narcolepsy, the concentration of hypocretin-1 in the brain and CSF was undetectably low, suggesting a loss of production of hypocretin peptides, similar to the pathophysiological mechanisms reported in humans.<sup>39</sup> Although the role of hypocretins in equine narcolepsy is unknown, horses with pituitary pars intermedia dysfunction and narcolepsy-like episodes had low concentration of hypocretin-1 in the CSF.<sup>45</sup>

## CLINICAL SIGNS

Cataplectic episodes are triggered by strong emotions (usually positive), such as laughing or anger in humans, and excitement associated with play or the presentation of food in dogs.

In horses, the initiation of eating or drinking, petting or stroking of the head and neck, hosing with cold water after exercise, and leading out of a stall may precipitate a cataplectic episode.<sup>4</sup> The episodes have also been reported during riding. However, one may observe narcolepsy in horses in a stall or at pasture, without any obvious precipitating events. Tight whole-body restraint may induce a cataplectic state in neonatal foals. This response is thought to be an inherent in utero mechanism that prevents violent movements, especially during parturition.

Clinical signs of narcolepsy vary from mild muscle weakness to complete collapse. Adult horses may drop their heads, buckle at the knees, and stumble.<sup>1,4,9</sup> If forced to walk, the horse may be ataxic. Pony breeds are more likely to become recumbent.<sup>4</sup> Horses and ponies that collapse may show absent spinal reflexes and REM sleep. Occasional sudden contraction of a limb or trunk muscle can occur resulting in a spasmodic motion. Episodes may last from a few seconds to 10 minutes.<sup>1,4,9</sup> The horse maintains eye and facial responses, normal cardiovascular function, and normal respiratory function during the attack. Horses can be aroused from the attack with varying degrees of difficulty, and most recover and rise quietly without incident.<sup>9</sup> A predictable pattern of duration and frequency of attacks is set within the first 1 to 2 weeks following the onset of disease.<sup>1</sup> Affected horses are neurologically normal between attacks.<sup>1,4</sup>

## DIAGNOSIS

Diagnosis of narcolepsy is based on history, clinical signs, pharmacologic testing, and the absence of other diseases. Careful questioning of the caretaker should be performed to determine any event(s) associated with the episode and video documentation of the episode(s) is optimal. Physical examination may reveal the presence of superficial trauma, particularly over the dorsal aspect of the fetlocks and carpi in most, but not all, cases. A complete blood count and serum biochemical profile are normal in affected horses, and may help to exclude underlying systemic and metabolic abnormalities. Cerebrospinal fluid is normal in affected horses.<sup>4</sup> Electroencephalography and needle electromyography during an attack may reveal fast waves of REM sleep and the absence of postinsertional activity of resting muscle.<sup>1</sup>

A provocative test may be useful in diagnosing true narcolepsy or cataplexy in horses. Physostigmine salicylate, an anticholinesterase drug given at 0.05 to 0.1 mg/kg slowly intravenously, precipitates a cataplectic attack within 3 to 10 minutes after administration in affected horses.<sup>4</sup> This compound crosses the blood-brain barrier. Careful monitoring of the horse after physostigmine administration is necessary because of untoward effects such as colic and cholinergic stimulation. In addition, lack of positive response to physostigmine does not rule out a diagnosis of narcolepsy since individual response to the drug is quite variable and some affected horses failed to respond to this provocative testing.

Atropine sulfate, a muscarinic blocker, given at 0.04 to 0.08 mg/kg intravenously, reduces the severity of cataplectic attacks minutes after administration and can prevent their reoccurrence for 12 to 30 hours following administration.<sup>4,9</sup> Response to atropine sulfate supports a possible cholinergic mechanism for causing cataplexy. One must monitor horses given atropine sulfate for ileus and colic.

Neostigmine, a cholinesterase inhibitor given at 0.005 mg/kg intravenously, does not cross the blood-brain barrier and therefore has no effect on cataplectic attacks. However, neostigmine may help rule out conditions causing muscle

weakness such as myasthenia-like syndromes and botulism. Horses with muscle weakness show increased muscle tone and a favorable response to neostigmine.

## DIFFERENTIAL DIAGNOSIS

Cataplexy, which is specific to narcolepsy, is the best diagnostic marker of this disease and should be distinguished from other causes of episodic weakness. One should also consider other causes of acute collapse in the horse. Ruling out collapse secondary to prolonged sleep deprivation is important as it may be common in horses. This disorder may be caused by chronic pain, environmental factors, or social/behavioral factors. In these cases, administering non-steroidal anti-inflammatory drugs to animals with chronic pain and/or providing the horse with a comfortable environment (to encourage the horse to lay down) may resolve the clinical signs.<sup>42</sup> Acute collapse without premonitory signs is characteristic of cardiovascular collapse or syncope, and unlike narcolepsy, is not preceded by gradual lowering of the head and drowsiness. Atrial fibrillation, ruptured chordae tendineae, myocardial infarction, myocardial fibrosis, aortic endocarditis, and pericarditis have been associated with syncope in horses. Cerebral hypoxia may occur in these conditions and may lead to coma, with or without signs of cardiac failure. One should differentiate seizures from narcolepsy/cataplexy. One should also consider botulism (shaker foal syndrome, forage poisoning), myasthenia-like syndrome, postanesthetic neuromyopathy, exertional rhabdomyolysis, and metabolic causes such as hyperthermia, shock, hypoglycemia, hypocalcemia, hypo- or hyperkalemia, endotoxemia, anaphylaxis, and snakebite. Horses with HYPP also may have attacks similar to those in horses with narcolepsy. These horses typically have muscle tremors and may become recumbent with hyporeflexia but are alert and anxious. Attacks in horses with hyperkalemic periodic paralysis may last up to 15 minutes, and the horse usually stands without incident.

## TREATMENT AND PROGNOSIS

In general, drugs that stimulate monoamine systems (e.g., dopamine) in the brain are effective suppressors of narcolepsy, whereas drugs that stimulate cholinergic activity in the brain exacerbate narcolepsy. Imipramine, a tricyclic antidepressant drug, has been recommended to control narcolepsy and cataplexy.<sup>1,4,9</sup> The drug blocks the uptake of serotonin and norepinephrine and decreases REM sleep.<sup>4</sup> Oral administration (250 to 750 mg orally) produces inconsistent results.<sup>4</sup> Potentially serious adverse effects including muscle fasciculations, tachycardia, hyperresponsiveness to sound, and hemolysis may be seen in horses receiving intravenous dosages of imipramine that exceed 2 mg/kg.<sup>46</sup> Adverse effects are not seen when the drug is administered orally, but that is likely because of very poor bioavailability. Anecdotally, tyrosine, which may increase dopamine concentration, may improve clinical signs of narcolepsy in some horses.<sup>47</sup> Atropine sulfate can provide relief from acute attacks for up to 30 hours, but one must weigh its use against potential adverse gastrointestinal effects.

The prognosis for narcolepsy or cataplexy varies. Some newborn Thoroughbreds and Miniature horses may have severe attacks but recover fully.<sup>9</sup> In Shetland and Suffolk ponies the disease may persist throughout life, as is true with the adult-onset form.<sup>1,4,9</sup>

## CENTRAL NERVOUS SYSTEM TRAUMA

Yvette S. Nout\*

Trauma to the CNS is the most common cause of neurologic disease in horses. A recent study from Europe reported CNS trauma to account for 22% of neurologic disorders,<sup>1</sup> which is consistent with the findings from an older report out of Australia that indicated CNS trauma to account for 24% of neurologic cases.<sup>2</sup> Both studies reported trauma to the spinal cord to be more prevalent than brain injury. Feige et al.<sup>1</sup> reported a diagnosis of traumatic brain injury (TBI) in 5 out of 22 (23%) horses that were presented for traumatic neurologic disease, whereas 17 of the 22 (77%) were diagnosed with SCI. Tyler et al.<sup>2</sup> reported 47 cases of TBI and cranial nerve disease in 107 (44%) horses examined, whereas 60 horses in this group had SCI (56%). One study examining head fractures in 21 horses demonstrated that 24% had neurologic deficits secondary to their injuries.<sup>3</sup> Although mechanisms of CNS cell damage, to a certain degree, are similar after TBI and SCI, a few different processes exist with regards to cause and pathophysiology. Clinical syndromes as a result of traumatic injury to the CNS can vary tremendously, but the most common are coma; vestibular disease; tetraparesis, paraparesis, or tetraplegia; and cauda equina syndrome. Treatment regimens for CNS injury are aimed toward reducing inflammation and swelling, halting secondary injury mechanisms, and promoting regeneration and recovery of function. Prognosis depends primarily on severity of primary injury and on the extent and neuroanatomic location of CNS damage.

## TRAUMATIC BRAIN INJURY

### PATHOPHYSIOLOGY

Head trauma is typically caused by incidents such as collision with an immovable object such as a fencepost or another horse, falling down, flipping over backward, being kicked by another horse, and, although rare, impact by a projectile (e.g., gunshot). A recent study involving 34 horses with TBI showed that the most common cause (44%) of injury was rearing and falling backwards resulting in poll injury.<sup>4</sup> Another type of head injury that may lead to CNS damage is fracture of the petrous temporal bone associated with THO.<sup>5,6</sup>

Although traumatic injury to the head is reported to be common in horses, subsequent TBI occurs only in 25% to 50% of cases.<sup>3,7</sup> The remaining horses typically present for fractures of the orbit, periorbital rim, and zygomatic, mandibular, or maxillary bones.<sup>3,7,8</sup> TBI may occur with or without fracture of the calvarium; however, some of the most severe injuries to the brain occur when the injury is contained within the closed calvarium (i.e., no skull fractures).<sup>9</sup> Within the closed calvarium, the sum of the intracranial volumes of the brain, blood, and CSF are constant; volume or pressure changes within one of these compartments will affect volume (anatomy) or pressure of the other compartments.

\*The authors wish to acknowledge Hilary K. Matthews, whose original work has been incorporated into this section.

Consequences of impact sustained to the poll in horses that flip over backward, include fracture of the bones on the side and base of the calvarium such as the petrous temporal, squamous temporal, and parietal bones. However, more commonly these bones remain intact and more serious injury occurs to the basilar bones as a result of strong traction forces from the rectus capitis ventralis muscles (Figure 12-27).<sup>6,10,11</sup> In addition, adjacent large vessels are lacerated, and hemorrhage into the retropharyngeal spaces or guttural pouches can occur. In severe cases, transverse fracture of the basilar bones at the level of the basioccipital-basisphenoidal suture can occur. Young horses may be more susceptible to this type of injury because the joint between the basilar bones fuses by 5 years of age.<sup>11</sup> In most cases the fracture site is stable and minimal displacement occurs. The cerebellum is seldom severely damaged after poll impact,<sup>6</sup> but the cerebral parenchyma is more commonly injured after being subjected to rapid acceleration-deceleration forces. Moreover, optic nerves and other attachments may be torn from the cerebral hemispheres.<sup>12</sup> Impact to the dorsal surface of the head may result in damage to the frontal or parietal bones, with subsequent cerebral cortical injury or, more commonly, damage to the cervical vertebrae with subsequent SCI.<sup>6</sup> In addition, cranial nerve XII may be injured as it exits the hypoglossal foramen. Furthermore, occipital cortical injury may occur and, as described for poll impact injuries, with frontal injuries the optic nerves may be stretched.

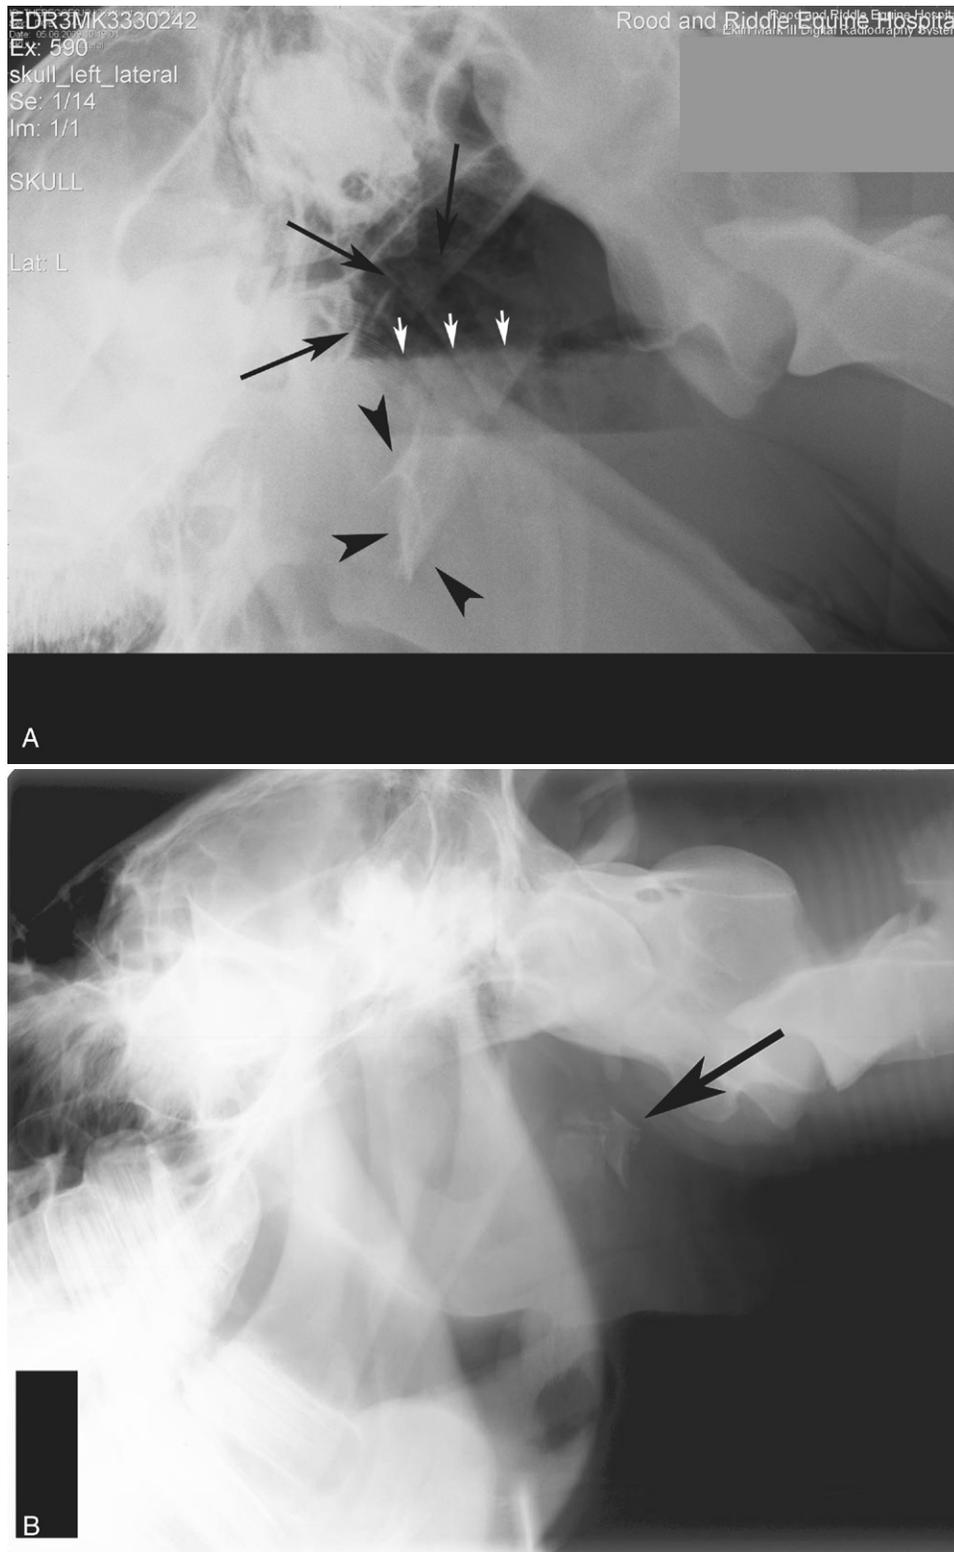

After trauma, most severe damage generally takes place at the place of impact (coup), opposite to the side of impact (contrecoup), or in both locations. Additionally, the brain is subjected to other forces after trauma, such as rotational and shock wave forces. TBI is a result of both direct, immediate mechanical disruption of brain tissue (primary injury) and indirect, delayed (secondary) injury mechanisms. The primary damage is a result of the biomechanical effects of the injury and is characterized by immediate and often irreversible damage to neuronal cell bodies, dendritic arborizations, axons, glial cells, and brain vasculature. This initial brain injury may be focal, multifocal, or diffuse.<sup>13</sup> Secondary injury is a complex cascade of molecular, cellular, and biochemical events that can occur for days to months after the initial insult, resulting in delayed tissue damage. In addition, systemic alterations further contribute to the tissue damage. Hypoxia, ischemia, brain swelling, alterations in intracranial pressure, hydrocephalus, infection, breakdown of blood-brain barrier, impaired energy metabolism, altered ionic homeostasis, changes in gene expression, inflammation, and activation and release of autodestructive molecules occur and exacerbate the initial injury.

Principles of raised intracranial pressure are described in the Monro-Kellie doctrine, which states that once the fontanelles and sutures of the skull are closed, the brain is enclosed in a nonexpandable case of bone, the brain parenchyma is nearly incompressible, the blood volume in the cranial cavity is therefore nearly constant, and a continuous outflow of venous blood from the cranial cavity is required to make room for continuous incoming arterial blood.<sup>14</sup> Blood flow to the brain is controlled by changes in diameter of resistance blood vessels, and cerebral blood flow is controlled by autoregulation whereby the perfusion pressure is maintained within a range of approximately 50 to 150 mm Hg.<sup>15</sup> Beyond these limits, cerebral blood flow decreases at pressures below the lower limit and increases at pressures above the higher limit. Cerebral perfusion pressure (mean arterial blood pressure minus intracranial pressure) is the stimulus to which

the autoregulatory response of the vasculature occurs. Cerebral autoregulation is altered unpredictably after TBI, and it appears that the minimum acceptable cerebral perfusion pressure is higher than normal after trauma. Increased intracranial pressure leads to a decreased cerebral perfusion pressure and subsequently reduces cerebral blood flow. Reduced cerebral blood flow results in areas of ischemia and subsequent restriction of delivery of substrates such as oxygen and glucose to the brain. Reduced cerebral blood flow has been associated with an unfavorable neurologic outcome in human beings and has been implicated in increased susceptibility of the brain to secondary injury.<sup>16,17</sup> Brain swelling after TBI because of edema formation and hematoma formation within the skull are the most common causes of increased intracranial pressure. Vascular damage that occurs after head injury can occur epidural (between dura mater and the skull), subdural (between the dura mater and arachnoid mater), subarachnoid (between arachnoid mater and pia mater), superficial (vessels immediately under the pia mater), intraparenchymal, and intraventricular. Subarachnoid hemorrhage, or hemorrhage into the CSF, occurs commonly in horses.<sup>8</sup>

The cascade of secondary injury that results in necrotic and apoptotic cell death is described in more detail in the section on pathophysiology of SCI. Uncontrolled glutamate release and failure of energy systems in neuronal and supporting tissues lead to elevated intracellular calcium concentrations and subsequent cell death. Hemorrhage, ischemia, and the primary tissue damage lead to sequestration of vasoactive and inflammatory mediators at the injury site and are thus involved in the secondary injury cascade. Inflammation and endothelial damage cause derangements in normal cerebrovascular reactivity and contribute to a mismatch of oxygen delivery to tissue demand, resulting in local or diffuse ischemia.

A major consequence of ischemia is reduced delivery of oxygen and glucose. Blood flow interruption is responsible for disruption in ion homeostasis (especially calcium, sodium, and potassium), and a switch to anaerobic glycolysis resulting in lactic acid production and acidosis. Cell membrane lipid peroxidation with subsequent prostaglandin and thromboxane synthesis, formation of reactive oxygen species (ROS), nitric oxide, and energy failure also ensue. Because of the high metabolic rate and oxygen demand of the brain, disruption of blood flow rapidly compromises the energy-supplying processes and leads to impaired nerve cell function and even cell death. Impaired mitochondrial function with subsequent energy depletion leads to a loss in maintenance of membrane potentials resulting in depolarization of neurons and glia.<sup>18</sup> Cytotoxic edema develops through the failure of the sodium-potassium ATPase-dependent pump in the presence of hypoxia and the subsequent influx of water that passively follows sodium and chloride. This type of edema occurs in gray and white matter and decreases the extracellular fluid volume.<sup>19</sup> If capillary endothelial cells are edematous, then the capillary lumen size will diminish, creating an increased resistance to arterial flow. Capillary permeability is usually not directly affected in cytotoxic edema. Major decreases in cerebral function occur with cytotoxic edema, with stupor and coma being common signs.<sup>19</sup> In addition to cytotoxic edema, vasogenic edema develops as a result of disruption of the blood-brain barrier, which includes damage of endothelial cells, degeneration of pericytes, and loss of astrocytes. Extravasation of blood components and water occurs resulting in increased extracellular fluid accumulation. This is referred to as *vasogenic edema*.<sup>19</sup> Understanding the complex pathophysiologic events

**FIGURE 12-27, A**, Radiograph from a 3-year-old thoroughbred colt that flipped while playing on the end of the lead shank. The horse hit its head on a small board along the side of the walkway and was unconscious for 3 to 5 minutes. The horse had blood coming from the nostrils, paralysis of the right eyelid, a corneal ulcer on the right eye, and weakness in all four limbs. The radiograph shows a fluid line in the guttural pouch (*small white arrows*), a basisphenoid fracture (*large black arrows*) with a large fragment (*arrowheads*) visible in the guttural pouch area. **B**, This is a radiograph taken from a horse after head injury and subsequent rupture of the longus capitis muscle and an avulsion fracture from the basisphenoid bone. The arrow is pointed at the avulsed bone located behind the guttural pouch. Image from The Ohio State University. FIGURE 12-28 Flow chart for localizing a lesion in the nervous system in a recumbent horse.

that take place after TBI is important for development of effective monitoring and treatment strategies.

## NEUROLOGIC EVALUATION

Clinical signs associated with TBI range from inapparent to recumbency with unconsciousness or death (Figure 12-28). A complete physical examination is very important in head trauma cases, because fractures and other concurrent injuries are not uncommon and require identification and treatment. Physical examination findings as a result of head trauma can include fractures; hemorrhage from the nostrils, mouth, and

ears; CSF draining from the ear (Figure 12-29); respiratory distress; cardiac arrhythmias; and hypo- or hypertension.<sup>6,8,10</sup>

Hemorrhage from the nose typically presents as dark-colored (venous) blood and originates from a paranasal sinus, ethmoid turbinates, or nasal cavity. Occasionally, blood is bright red and then usually originates from larger vessels in the guttural pouches.<sup>6,20</sup> Respiratory distress can occur associated with significant throat swelling after profuse hemorrhage into the guttural pouches. Furthermore, neurogenic pulmonary edema has been reported to occur. Acute elevation of intracranial pressure may result in the Cushing's reflex, which is a hypothalamic response to brain ischemia and is characterized

**FIGURE 12-29** Blood and cerebrospinal fluid (CSF) draining from the ear after a basilar skull fracture.

by hypertension and secondary baroreceptor-mediated bradycardia. Continued elevation of intracranial pressure and reduction of cerebral blood flow results in increased sympathetic discharge (catecholamines), with subsequent myocardial ischemia and development of cardiac arrhythmias. This is referred to as the *brain-heart syndrome*.

Life-threatening injuries should be attended to first, and then a complete neurologic examination should be performed. Horses may be recumbent, intractable, or both after a traumatic incident; examination and management of these horses can be difficult and dangerous (see [Figure 12-28](#)).<sup>21</sup> Signs of focal brain injury are listed in [Table 12-9](#). Sedation may be necessary for examination. Although  $\alpha_2$ -agonists may transiently cause hypertension, which may potentiate intracranial hemorrhage,<sup>22</sup> xylazine has been found to cause a minor decrease in cerebrospinal pressure in normal, conscious horses.<sup>23</sup> Xylazine is probably a safe sedative to use in horses with head trauma, if the horse's head is not allowed to drop to such a low position that postural effects could lead to physiologic increases of intracranial pressure.<sup>7</sup>

The complete neurologic examination should include an assessment of the horse's mentation, cranial nerve function, posture, and ability to coordinate movements, as well as its ability to regulate rate and range of motion. In addition, reflex and nociceptive testing should be performed to investigate any concurrent SCI. Serial neurologic examinations, particularly during the first hours, are important for diagnostic purposes and to allow prediction of a more accurate prognosis. Furthermore, serial examinations are important to assess response to therapy.<sup>7,21</sup> Pupil size, symmetry, and response to light should be assessed in all horses and followed carefully, particularly in recumbent horses. A change from bilateral pupillary constriction to bilateral dilation with no response to light is a poor prognostic indicator.<sup>7</sup>

The most common neurologic syndromes after head trauma are a result of hemorrhage into the middle and inner ear cavities. Signs are those of central or peripheral vestibular disease and facial nerve damage and include recumbency, head tilt, neck turn, body lean, and circling, all toward the side of the lesion. The ipsilateral eye may be rotated ventrally and laterally, and there may be horizontal or rotary nystagmus with the fast phase away from the lesion.<sup>6,22</sup> Facial paralysis on the same side as the lesion is seen with cranial nerve VII damage. Central vestibular disease is suspected when signs of brainstem disease or other cranial nerve deficits are present. Central vestibular lesions can result in a paradoxical vestibular syndrome, in which the lesion is located on the side opposite to that which is expected from the clinical signs.<sup>6</sup> More serious trauma can lead to alterations of mentation, behavior, or both.

The level of consciousness is affected by the degree of damage to the cerebrum and reticular activating system in the brainstem. Immediately after cerebral injury, a period of concussion occurs, with unconsciousness for various periods of time, or even coma. Usually a horse recovers from this in minutes to hours. Comatose horses may have an irregular breathing pattern with periods of either Cheyne-Stokes breathing or hyperventilation. In some horses, seizures can occur after initial concussion; these are typically generalized seizures. Level of mentation and responsiveness to reflexes should be assessed and recorded. Injury to the occipital cortex can result in impairment of vision and menace response of the eye contralateral to the lesion. Pupillary light reflex, however, should remain intact. Injury to the parietal cortex can result in decreased facial sensation on the contralateral side. Another sign of cerebral damage is dementia, or altered behavior, such as walking in circles (toward the side of the lesion), head pressing, hyperexcitability, or aggression.<sup>6,7,22</sup>

Severe rostral brainstem injuries (mesencephalon) can be associated with coma and depression because of damage to the reticular activating system. Strabismus, asymmetrical pupil size, and loss of pupillary light response can be present because of damage to cranial nerve III. Apneustic or erratic breathing reflects a poor prognosis, and bilaterally dilated and unresponsive pupils indicate an irreversible brainstem lesion. These lesions can occur immediately after injury, secondary to herniation of components of the cerebrum or cerebellum, or after hemorrhage. Severe brainstem injuries may result in a decorticate posture, characterized by rigid extension of neck, back, and limbs.<sup>6</sup> Injury to caudal parts of the brainstem (pons and medulla) result in dysfunction of multiple cranial nerves in addition to depression and limb ataxia and weakness. To make a distinction between a cranial cervical spinal cord and caudal brainstem lesion, careful assessment of the horse's mentation and function of cranial nerves X and XII is important.<sup>6,7</sup>

Signs of cerebellar injury occur infrequently and include intention tremor, broad-based stance, spastic limb movements, and absent menace response with normal vision. If multiple areas of the brain are damaged, then this will be reflected in the different clinical signs. Multifocal damage or progression of disease through hemorrhage, secondary injury mechanisms, or both is suggested when clinical signs become more widespread.

Diagnostic tools that are helpful in further defining cranial trauma include radiography, computed tomography, MRI, endoscopy, electrodiagnostics, and CSF analysis. Radiographs are used to determine the presence and severity of fractures, hemorrhage in cavities, or thickening of stylohyoid bone or bulla (or both). A recent study determined that of the horses

TABLE 12-9

Signs Characteristic of Focal Brain Injury				
Levels	Consciousness	Motor Function	Pupils	Other Sign
Cerebrum	Behavior change, depression, coma	Circling	Normal	Blindness
Cerebellum		Ataxia and hypermetria, intention tremor		Menace response deficit without blindness
Diencephalon (thalamus)	Depression to stupor	Normal to mild tetraparesis, "aversive syndrome" <sup>**</sup>	Bilateral, nonreactive pupils with visual deficit	None
Midbrain	Stupor to coma	Hemiparesis, tetraparesis or tetraplegia	Nonreactive pupils, mydriasis, anisocoria	Ventrolateral strabismus
Pons	Depression	Ataxia and tetraparesis, tetraplegia	Normal	Head tilt, abnormal nystagmus, facial paralysis, medial strabismus
Rostral medulla oblongata (including inner ear)	Depression	Ataxia or hemiparesis to tetraplegia	Normal	Same
Caudal medulla oblongata	Depression	Ataxia, hemiparesis to tetraparesis, abnormal respiratory patterns	Normal	Dysphagia, flaccid tongue

From Robinson NE, editor: Current therapy in equine medicine, ed 6, St Louis, 2009, WB Saunders.  
<sup>\*</sup>Deviation of the head and eyes with circling toward the side of a unilateral lesion.

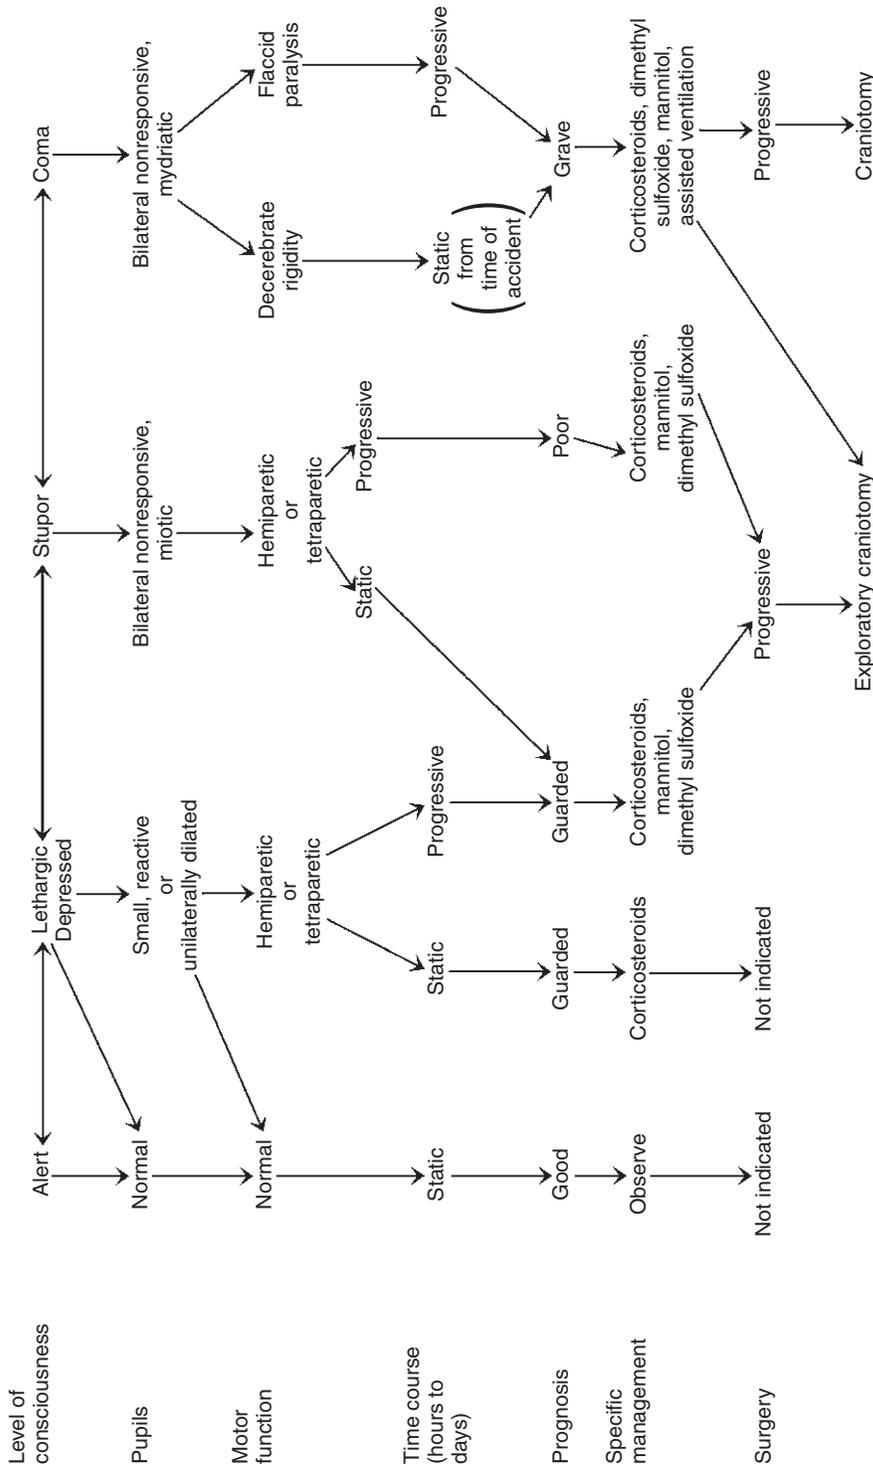

with bony fractures of the calvarium (22), only 50% were confirmed radiographically.<sup>4</sup> Computed tomography is very sensitive for detection of bony abnormalities and also provides some information on soft tissues and brain matter.<sup>24-26</sup> Soft tissue changes seen after TBI, for example, are change in the size, shape, and position of the ventricles, deviation of the falx cerebri, and focal changes in brain opacity.<sup>6</sup> In human beings, CT findings may include midline shift and obliteration of sulci and cisterns, for which a grading system exists that can be used in combination with other diagnostics for prognostication purposes.<sup>27</sup> Enhancement of areas of injury or hemorrhage is possible with iodinated contrast agents. MRI offers a higher sensitivity for examination of soft tissue structures and has the ability to acquire images in all planes. However, the use of MRI is not yet possible for all equine clinicians.

Upper respiratory endoscopy is an important diagnostic procedure for evaluation of cranial nerve function, stylohyoid bones, retropharyngeal area, and appearance of guttural pouches. Use of electrodiagnostics is typically not indicated immediately after TBI; however, after stabilization or during recovery these techniques will provide information about certain levels of (dys)function. For example, electroencephalograms are used for assessment of seizure activity, BAER is used for examination of vestibular function, and visual function is examined with visual-evoked potential in combination with electroretinography. CSF analysis may not always be indicated after acute trauma, but it may be useful for excluding other diseases. Cisternal CSF collection is contraindicated if increased intracranial pressure is suspected because of the possibility of brain herniation through the foramen magnum. Lumbosacral collection is a safer alternative but can be normal despite a traumatic episode, especially in the acute phase, and because the sample is not obtained closest to the lesion, it may not reflect the changes that have occurred. CSF lactate concentrations are increased after trauma in horses.<sup>28</sup>

More invasive diagnostic and monitoring modalities are available. Methods to measure and monitor intracranial and cerebral perfusion pressures have been described for use in foals<sup>29</sup> and adult horses.<sup>30,31</sup> However, these techniques have thus far not been scientifically evaluated in clinical cases. In human medicine, development of advanced bedside neuro-monitoring devices has been an important focus in neurocritical care. The four most important parameters to be determined are (1) intracranial pressure, (2) cerebral blood flow, (3) information on brain metabolism, and (4) functional outcome. In human beings, catheters may be placed into the brain tissue to determine glucose, glycerol, and glutamate concentrations, indicators of secondary ischemia,<sup>32,33</sup> by microdialysis. In addition, probes may be placed to determine brain tissue oxygen tension. It appears that use of multimodality monitoring techniques, in which complementary regional neuro-monitoring tools may measure tissue pH, cerebral blood flow, or biochemical metabolites would be part of an optimal overall strategy.<sup>34</sup>

## TREATMENT AND PROGNOSIS

Based on the pathophysiology of events that occur after TBI, it is likely that single drug intervention would not be effective. Treatment of TBI is aimed at optimizing delivery of oxygen and substrates to brain tissue to salvage brain tissue that is undamaged or reversibly damaged. This requires optimizing cerebral blood flow (i.e., optimizing mean arterial blood pressure and hemoglobin concentration; ensuring intracranial pressure is not elevated). Emergency surgical treatment (although not commonly performed) is warranted in open cranial fractures and in the face of deterioration despite medical therapy. A recent report describes the surgical and medical treatment of a horse with severe and unfortunately fatal TBI.<sup>35</sup> In Figure 12-30 a flow chart is shown that can serve as a guide to the management of cranial trauma in horses. Evaluation of

**FIGURE 12-30** Flow chart for management of cranial trauma. (From Robinson NE, editor: Current therapy in equine medicine, ed 6, St Louis, 2009, WB Saunders; modified from Kirk KW, editor: Current veterinary therapy VII, Philadelphia, 1980, WB Saunders.)

potential treatment strategies affecting secondary injury pathways has recently been reviewed.<sup>36</sup>

Methods to reduce intracranial pressure include hyperventilation, CSF drainage, treatment with hyperosmolar agents or barbiturates, head elevation, and decompressive surgery. Hyperventilation reduces the partial pressure of carbon dioxide in blood and subsequently leads to cerebral vasoconstriction. Reduced cerebral blood volume reduces intracranial pressure. However, cerebral vasoconstriction may lead to reduction of cerebral blood flow to ischemic levels. Hyperventilation could be considered in cases of increased intracranial pressure in horses. Proper hyperventilation requires monitoring of arterial blood gases and may require use of neuromuscular blockers if the horse is not comatose and is resisting the ventilator. CSF drainage is commonly used in people to reduce intracranial pressure; however, it is therapeutic only if CSF outflow obstruction is noted. If these methods are ineffective, then repeat imaging is pursued to investigate the presence of mass lesions before medical treatments are commenced such as administration of hyperosmolar substances and induction of barbiturate coma. Hyperosmolar treatment is commonly used in horses with neurologic signs attributable to TBI. This is discussed later in this section.

Mean arterial blood pressure should be maintained within normal limits. Blood transfusion may be indicated in cases of severe hemorrhage. Crystalloid fluids are recommended as fluid therapy of choice, particularly in light of findings of the serum versus albumin fluid evaluation (SAFE) study<sup>37</sup> that determined no difference between outcomes between administering albumin versus normal saline in the intensive care unit (and in which subgroup analysis demonstrated an increased mortality in TBI patients that were treated with albumin). However, isotonic crystalloid fluids administered in typical shock doses of 40 to 90 ml/kg/hr may produce worsening of cerebral edema and increased intracranial pressure.<sup>38</sup> Comparison of isotonic crystalloid fluids with hypertonic saline solutions has shown hypertonic saline to be the fluid of choice for fluid support of head trauma patients in shock.<sup>39</sup> Hypertonic saline is associated with significant decreases in intracranial pressure and cerebral water content compared with isotonic fluid treatment. Furthermore, hypertonic saline has positive effects on cerebral blood flow, oxygen consumption, and inflammatory response at a cellular level.<sup>40</sup> Hypertonic saline can be administered intravenously to head trauma horses in shock as 5% or 7% sodium chloride (NaCl) solutions (4 to 6 ml/kg) over 15 minutes. Isotonic fluids can then be used for maintenance if needed. Contraindications to the use of hypertonic saline include dehydration, ongoing intracerebral hemorrhage, hyponatremia, renal failure, hyperkalemic periodic paralysis, and hypothermia. Systemic side effects include coagulopathies, excessive intravascular volume, and electrolyte abnormalities. Monitoring central venous pressure and maintaining it within normal limits (5-7 cm H<sub>2</sub>O) is therefore important, as well as monitoring serum sodium and potassium concentrations if hypertonic saline is used frequently.<sup>39</sup>

The use of carbohydrate-containing intravenous solutions should be avoided early in the treatment of head trauma patients. Glucose suppresses ketogenesis and may increase lactic acid production by the traumatized brain, limiting the availability of nonglycolytic energy substrates.<sup>41</sup> Furthermore, carbon dioxide liberated from glucose metabolism could cause vasodilation and worsening of cerebral edema. It has been well established that maintaining blood glucose concentrations at

80 to 110 mg/dl through intensive insulin therapy reduces morbidity and mortality in human critical care patients.<sup>42</sup> However, neurointensivists have shown that intensive insulin therapy increases markers of cellular distress in the brain and suggest that systemic glucose concentrations of 80 to 110 mg/dl is too low in TBI and may lead to cerebral hypoglycemia.<sup>43</sup> Recommendations now are to maintain blood glucose concentrations at 120 to 140 mg/dl in TBI.

Treatment with anti-inflammatories is likely the most commonly used treatment in equine TBI. Indications for use of anti-inflammatory treatment are to combat the inflammatory pathways of secondary injury mechanisms (cytokine release, free radicals), improve comfort level, and reduce fever. Fever is extremely common after TBI, and it has been well documented in animal models and in human beings to negatively affect outcome after TBI (e.g., by augmenting secondary injury mechanisms).<sup>44,45</sup> Researchers have proposed that a proactive approach should be taken toward reducing fever. In fact, hypothermia has been shown to be neuroprotective. Hypothermia results in decreased cellular metabolism and has been proven efficacious as a treatment for TBI in experimental and clinical settings.<sup>46</sup> The neuroprotective effects include reduced release of excitotoxins, reduction of free radical and inflammatory mediator formation, and reduction of blood-brain barrier disruption. However, long-term benefits and improved functional outcome has not been adequately demonstrated.<sup>47,48</sup> Therapeutics with anti-inflammatory properties that are common to equine practice include corticosteroids, NSAIDs, DMSO, and vitamin E. These drugs are discussed in more detail in the section pertaining to SCI.

Controlling seizure activity is very important after TBI, because seizure activity increases cerebral metabolic rate and is detrimental to secondary injury. It is not unusual for horses sustaining cranial trauma to develop seizures. Diazepam, midazolam, phenobarbital, or pentobarbital are drugs that can be used to control seizures. Intractable seizures may necessitate general anesthesia. Agents useful for general anesthesia include guaifenesin, chloral hydrate, barbiturates, and gas anesthesia. Ketamine is not recommended as part of a balanced anesthesia regimen because it increases cerebral blood flow and intracranial pressure.

Barbiturate treatment or coma may decrease cerebral metabolism, thereby providing a protective effect against cerebral ischemia. Barbiturates may also limit lipid peroxidation. However, the actual benefits of barbiturate use on the neurologic outcome remain controversial. The effects of barbiturates on lowering intracranial pressure are enhanced by concurrent hyperventilation. An exact dosage regimen for barbiturate treatment in horses has not been investigated, but 5 to 10 mg/kg intravenous to effect is reported to be useful. The major adverse effect of barbiturates is hypotension, especially if mannitol and furosemide have been administered, so they must be used with caution and adequate blood pressure monitoring. Barbiturates should be reserved for those cases in which elevated intracranial pressure is refractory to other treatments. Other methods to lower intracranial pressure include elevation of the head by 30 degrees if no cervical fractures are present<sup>49</sup> and decompressive craniectomy. Rationale for use of the latter is comparison of the effect of a durotomy for compartment syndrome of the brain to that of a fasciotomy in muscle compartment syndrome.<sup>50,51</sup> This technique has been used in normal dogs and was effective at reducing intracranial pressure.<sup>52</sup>

Furosemide has experimentally been found effective in decreasing intracranial pressure.<sup>53</sup> A 1 mg/kg bolus intravenous dose was administered at 5-hour intervals and a 0.5 mg/kg/hr dose was administered intravenously as a continuous rate infusion for 4 hours, 1 hour after the initial bolus. Normal hydration status is required before furosemide is administered. Furosemide may also be used concurrently with mannitol to increase the duration of intracranial pressure reduction provided by mannitol, and to diminish the potential for rebound intracranial pressure elevation. Hyperosmolar therapy forms the mainstay of treatment for elevated intracranial pressure.

Mannitol has been the primary osmotherapeutic drug for the last four decades. Mannitol induces changes in blood rheology and increases cardiac output, leading to improved cerebral perfusion pressure and cerebral oxygenation. Improved cerebral oxygenation induces cerebral artery vasoconstriction and subsequent reduction in cerebral blood volume and intracranial pressure. Mild dehydration after osmotherapy is desirable and may improve cerebral edema; however, severe dehydration can lead to hyperosmolality and renal failure. Mannitol also decreases CSF production by up to 50%, which can lead to prolonged intracranial pressure decrease.<sup>39</sup> In horses, 20% mannitol can be administered at 0.25 to 2.0 mg/kg intravenously over 20 minutes. Horses receiving osmotic diuretics should be adequately hydrated. The use of osmotic substances is warranted in any horse with worsening mental status, abnormal pupillary size or inequality indicating transtentorial herniation, or development of paresis. Although mannitol administration is very effective in reducing intracranial pressure, several limitations to its use exist. Hyperosmolality can be associated with renal and CNS effects. Furthermore, administration of multiple doses of mannitol may lead to intravascular dehydration, hypotension, and reduction of cerebral blood flow. Therefore current research is focused on the use of substitutes for mannitol, of which the most promising is hypertonic saline.

Hypertonic saline has a number of beneficial effects in TBI. The permeability of the blood-brain barrier to sodium is low. Hypertonic saline produces an osmotic gradient between the intravascular and the interstitial-intracellular compartments, leading to shrinkage of brain tissue and subsequent reduction of intracranial pressure. The reflection coefficient of NaCl is more than that of mannitol, making it potentially a more effective osmotic drug. As described previously, hypertonic saline augments volume resuscitation and increases circulating blood volume, mean arterial blood pressure, and cerebral perfusion pressure. Other beneficial effects include restoration of neuronal membrane potential, maintenance of the blood-brain barrier integrity, and modulation of the inflammatory response by reducing adhesion of leukocytes to endothelium.<sup>39,54</sup> Hypertonic saline typically is used as 3.0%, 5.0%, or 7.5% solutions, but a recent study showed beneficial effects of using small-volume 23.4% hypertonic saline to reduce intracranial pressure.<sup>55</sup>

Antibiotic treatment is usually warranted in cases of head trauma, especially when fractures are involved. The presence of hemorrhage increases the possibility of septic meningitis. Antibiotic choice should be based on culture and sensitivity testing. Good empiric choices for broad spectrum coverage include trimethoprim-sulfamethoxazole and penicillin in combination with gentamicin. Appropriate monitoring for aminoglycoside toxicity should be undertaken with their use. Owing to disruption of the blood-brain barrier, other antimicrobials probably penetrate into the CNS, and therefore their use may also be efficacious.

Nutritional support plays a role in the outcome after neurologic injury. In human beings, neurologic recovery from head injury occurs faster in patients receiving early adequate nutritional support.<sup>56</sup> If the horse is able to eat and the gastrointestinal tract is functioning normally, then water and good-quality hay should be available at all times. Small amounts of grain should be fed three to four times a day to boost caloric intake. The amount of grain fed should be based on the horse's condition and ability to tolerate grain feeding. Horses with a poor appetite or those unable to swallow may have to be tube fed using a gruel of alfalfa and complete feed pellets.<sup>21</sup> Horses in which enteral feeding is not possible are candidates for total parenteral nutrition. Thiamine may be of benefit in treating head injuries because thiamine aids in metabolism of lactic acid and is a necessary coenzyme in brain energy pathways.

The prognosis for cranial trauma is dependent on severity of insult and early treatment, and it is gauged by response to treatment. An early prognosis based on initial findings is important to establish for owners and thus can influence clinical decisions. However, in a study performed in human TBI patients, even with sophisticated clinical and radiologic technologies, it was not possible to predict outcome on the first day after the accident with sufficient accuracy to guide early management.<sup>57</sup> Here again, it is important to highlight the value of repeated neurologic evaluations. In general, basilar fractures and severe brainstem injuries carry a grave prognosis.<sup>4,10</sup> Recumbency, tetraparesis, and severe dementia carry a poor-to-grave prognosis.<sup>8</sup> A recent retrospective confirmed that recumbency of more than 4-hours duration after the initial onset of trauma and the presence of basilar skull fractures were associated with non-survival having odds ratios of 18 and 7.5, respectively.<sup>4</sup> Time, good nursing care, and adequate nutritional support, especially in the recumbent horse, are vital for a positive outcome.

## ☞ SPINAL CORD AND VERTEBRAL INJURY

### PATHOPHYSIOLOGY

Trauma to the vertebral column is typically caused by incidents, such as collision with an immovable object or falling down. Injury to the vertebral column can occur at all sites, but trauma to or fractures of the cervical vertebrae are the most common.<sup>1,2,9,22</sup> Foals appear to be more susceptible to vertebral trauma than adults and frequently suffer injury to the cranial cervical (C1-3), and caudal thoracic (T15-18) regions.<sup>9</sup> Fractures elsewhere along the vertebral column occur as well.<sup>58</sup> Vertebral fracture with subsequent SCI, not as a result of trauma but secondary to osteomyelitis, has been reported.<sup>59</sup> Predilection sites for vertebral trauma in adult horses are the occipital-atlanto-axial region, the caudal cervical region (C5-T1), and the caudal thoracic region.<sup>9,22</sup> Reports also exist of injuries at the sacral<sup>60,61</sup> and coccygeal<sup>62,63</sup> regions.

Typically, the more severe the insult is, the more damage occurs to the vertebral column (and the more severe clinical signs are due to soft tissue damage and osseous fragments compressing the spinal cord; [Table 12-10](#)). With very severe injury, soft tissue structures supporting the vertebral column may be disrupted, resulting in dislocation of vertebrae. Both subluxation and luxation of vertebrae have been reported in horses.<sup>64</sup> An increased incidence of luxations, subluxations,

TABLE 12-10

Common Types of Vertebral Trauma				
Level of Injury	Age	Type of Vertebral Trauma	Common Traumatic Injury	Syndrome
Cervical	Foal to yearling	Fracture of dens, luxation C1-C2	Hyperflexion (e.g., somersault)	Tetraparesis, respiratory depression, death
Cervical	Young adult	Epiphyseal fracture	Hyperextension	Tetraparesis to tetraplegia
Cervical	Adult	Compression fracture	Head-on collision	Tetraparesis to tetraplegia
Cranial thoracic	Usually young	Fracture of dorsal spinous process	Flipping over backward	Often none
T2-S1	Any	Transverse fracture of vertebral arch, with dislocation	Somersaulting or falls	Paraparesis
Sacroiliac subluxation	Adult	Subluxation	Falls or slipping on ice	None
Sacral fracture	Any	Compression	Fall over backward or dog sitting when backed	Urinary and fecal incontinence with or without posterior paresis, paralysis of the tail and anus

From Robinson NE, editor: Current therapy in equine medicine, ed 6, St Louis, 2009, WB Saunders.

and epiphyseal separations is seen in young horses, which is likely because cervical vertebral growth plate closure does not occur until 4 to 5 years of age.<sup>9</sup> Compression injuries are associated with shortening of the vertebral body and result from a head-on collision with an immovable object.

SCI secondary to trauma is a dynamic process of which the severity is related to the velocity, degree, and duration of the impact. Cord concussion with transient neurologic deficits is a result of local axonal depolarization and transient dysfunction, whereas permanent paralysis is a result of primary tissue injury followed by spreading of secondary damage that expands from the injury epicenter.

Primary injury is the initial mechanical damage to the components of the spinal cord that follows acute insult. Blood vessels are broken, axons are disrupted, and neuron and glial cell membranes are damaged. Ensuing pathophysiologic processes involving ischemia, release of chemicals from injured cells, and electrolyte shifts alter the metabolic milieu at the level of the lesion and trigger a secondary injury cascade that substantially compounds initial mechanical damage. These secondary injury processes do not necessarily coincide with the clinical picture, because pathologic changes may progress in severity for weeks to months, even in the face of clinical improvement.

Secondary injury involves both necrotic and programmed cell death, and although mechanisms involved in this are not fully understood, some aspects of this process are well described. Disruption of cellular and subcellular membranes of glia, neurons, and vascular endothelial cells is believed to be the initiator of this autodestructive cascade of events, and it is likely that multiple mechanisms are involved such as ischemia, inflammation, free radical-induced cell death, excitotoxicity, cytoskeletal degradation, and induction of apoptotic pathways. The consequence of secondary injury is enlargement of the area of cell death. The phase of secondary injury is widely studied because this process progresses from minutes to months after injury and is thus considered to be a target for therapeutic interventions. Minimizing secondary injury through protection of neural elements that initially survived the mechanical

injury would increase the quantity of spared tissue and could lead to reduced functional impairment.

Acute injury results in immediate hemorrhage and cell destruction within the central gray matter. Loss of microcirculation and cord swelling within minutes of injury occurs mainly because of hemorrhage and development of edema. The initial hemorrhage, edema, and hypoperfusion of the gray matter extends centripetally within minutes to hours of injury and results in central necrosis, white matter edema, and eventually, demyelination of axons through secondary injury processes. Spinal cord ischemia develops over several hours after injury and is considered one of the most important contributors to secondary injury.<sup>65,66</sup> Mechanical disruption of the microvasculature, vasospasm of intact vessels, and edema together lead to profound local hypoperfusion and ischemia. Cord swelling that exceeds venous blood pressure results in secondary ischemia, and ischemia is further exacerbated by cessation of autoregulation of spinal cord blood flow and systemic hypotension.

During the ischemic hypoxic state, cell metabolism is altered such that a shift occurs from aerobic to anaerobic metabolism, which is a less efficient method of energy production. Anaerobic metabolism results in lactic acid accumulation, causing acidosis in nervous tissue, thus decreasing glucose and oxygen consumption. Furthermore, lactic acid stimulates prostaglandin production, adenosine diphosphate release, platelet aggregation, thromboxane A<sub>2</sub> release, vasospasm, vasoconstriction, and the inhibition of neurotransmitter release. In addition, in hypoxic states, the sodium-potassium ATPase-dependent cell pump is inhibited or damaged, resulting in the cell's inability to maintain its electric polarity. Damage to this pump allows for accumulation of potassium extracellularly and sodium intracellularly, which contributes to the development of edema.<sup>67</sup>

Free radicals can cause progressive oxidation of fatty acids in cellular membranes (lipid peroxidation) through reactions with their unpaired electrons. Furthermore, oxidative stress can disable key mitochondrial respiratory chain enzymes, alter DNA/RNA and their associated proteins, and inhibit sodium-potassium ATPase. These changes can induce metabolic

collapse and necrotic or apoptotic cell death and are considered important during the initial period of hypoperfusion (and perhaps even more important during the period of reperfusion). In addition to oxidative stress and membrane damage, nitric oxide production and excitatory amino acid-induced calcium entry are considered important mediators of necrotic and apoptotic cell death.<sup>68</sup>

*Excitotoxicity* refers to the deleterious cellular effects of excess glutamate and aspartate stimulation of ionotropic and metabotropic receptors. Extracellular concentrations of both of these excitatory amino acids are increased after acute SCI, which occurs through release from damaged neurons, decreased uptake by damaged astrocytes, and through depolarization-induced release. Ionotropic receptors include the NMDA and alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)/kainite receptors through which extracellular calcium and sodium can pass down a massive concentration gradient into the cell or, when activated, can result in release of calcium from intracellular stores. Metabotropic glutamate receptors are coupled to G proteins that act as secondary intracellular messengers to mediate a wide spectrum of cellular functions. Furthermore, elevation of intracellular calcium concentration can occur through direct membrane damage and voltage-gated calcium channels triggered by membrane depolarization. Elevated intracellular calcium concentrations can trigger a multitude of calcium-dependent processes that can lethally alter cellular metabolism, such as activation of lytic enzymes (calpains, phospholipase A<sub>2</sub>, proteases, and lipoxygenase), generation of free radicals, impairment of mitochondrial function, spasm of vascular smooth muscle, and binding of phosphates with subsequent depletion of cell energy sources. Sodium dysregulation is thought to be important in the pathophysiology of damage to axonal and glial components in the white matter through similar mechanisms that lead to elevated intracellular calcium concentrations.

Controversy exists surrounding the role of inflammation in acute SCI, mainly because the effects of inflammatory cells can be both cytotoxic and protective. After SCI, the injury site is rapidly infiltrated by blood-borne neutrophils, which can secrete lytic enzymes and cytokines. Later, blood-borne macrophages and monocytes are recruited, as well as locally activated resident microglia, both of which subsequently invade to phagocytose the injured tissue. These and other reactive cells produce cytokines, such as tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ), interleukins (ILs), and interferons, that mediate the inflammatory response and can further damage local tissue and recruit other inflammatory cells. Among the cytokines involved in secondary SCI, TNF- $\alpha$  is perhaps the most extensively studied. It is produced by a range of different cell populations, including neutrophils, macrophages and microglia, astrocytes, and T cells and has been shown to accumulate quickly at the site of SCI. It has been suggested that the early inflammatory phases are deleterious in nature, whereas the later inflammatory events appear to be protective.<sup>65</sup>

Currently much research is being performed on the role of apoptosis, or programmed cell death, in secondary injury. This slowly spreading form of cell death is induced by the injury and is characterized by apoptotic neurons at the lesion margins and, even later, apoptosis of oligodendrocytes in areas with degenerating axons that were injured at the original lesion site.<sup>68,69</sup> Apoptosis can thus occur at quite remote distances from the point of impact. Oligodendrocytes appear vulnerable to apoptosis, and death of these cells can result in demyelination of otherwise spared axons, thus contributing to the loss of distal neurologic function.

## NEUROLOGIC EVALUATION

Clinical signs seen as a result of SCI reflect the extent and location of the injury. Neurologic signs are usually observed immediately after the accident but may occur weeks to months after the initial insult because of delayed damage to the spinal cord caused by instability, arthritis, or bony callus formation at the site of impact. Clinical signs depend on the neuroanatomic location of injury and range between inapparent to severe incapacitating tetraparesis or tetraplegia (see Figure 12-28). Lesions causing recumbency are mostly found in the caudal cervical or thoracic spinal cord, whereas lesions of nonrecumbent horses are mostly found further cranial in the cervical spinal cord or in the lumbosacral cord.<sup>1</sup>

Initial evaluation of the patient should be directed toward stabilization and correction of any life-threatening problems such as airway obstruction, hemorrhage, cardiovascular collapse, and pneumothorax. In addition, major long-bone fractures must be identified, because these may be the limiting factor for survival of the horse. All affected horses may be nervous or agitated as a result of pain and the inability to stand. A systematic neurologic evaluation should then be performed to localize the site of injury.<sup>9,21,70</sup> In recumbent horses the use of a sling to assist standing may be a valuable diagnostic tool for localizing the site of injury and for assessing progression of disease and prognosis.<sup>21,70</sup>

In animals, SCI usually occurs as a solitary lesion and the level of the lesion can be diagnosed by neurologic examination.<sup>71</sup> Depression or loss of a segmental spinal reflex implies damage to either the afferent, efferent, or connecting pathways of the reflex arc. However, after acute SCI a phase of spinal shock can occur in which profound depression is noted in segmental spinal reflexes caudal to the level of the lesion, even though reflex arcs are physically intact.<sup>71-73</sup> Spinal shock occurs in all species; however, it appears to be of much shorter duration in dogs, cats, and rabbits when compared with primates.<sup>71,74</sup> Another syndrome that occurs infrequently and is short-lived in the horse is Schiff-Sherrington syndrome, in which extensor hypertonus is present in otherwise normal thoracic limbs in patients with severe cranial thoracic lesions.<sup>74</sup>

Cord injury typically results in damage that is worse in the large myelinated motor and proprioceptive fibers compared with the smaller or nonmyelinated nociceptive fibers. Therefore ataxia and loss of proprioception and motor function will occur before the loss of deep pain.<sup>9</sup> Flaccid paralysis with hypo- or areflexia, muscular hypotonia, and neurogenic muscle atrophy are characteristic of a lower motor neuron lesion. Signs resulting from an upper motor neuron spinal cord lesion include loss of voluntary motor function, whereas muscle tone may be increased and spinal reflexes may be normal to hyperactive.

In horses, lesions in the C1 to T2 region are most common and result in varying degrees of dysfunction ranging from tetraparesis to recumbency. Thoracolumbar SCI can result in paraparesis to recumbency and horses may dog sit. Sacral cord damage can result in fecal and urinary incontinence, loss of use of tail and anus, muscle atrophy, and mild deficits of pelvic limb function. Sacrococcygeal cord injury can produce hypalgesia; hypotonia and hyporeflexia of the perineum, tail, and anus; or total analgesia and paralysis of those structures. In addition to these clinical signs, loss of sensation can occur distal to the level of SCI. Furthermore, diffuse sweating can be seen as a result of loss of supraspinal input to the

preganglionic cell bodies of the sympathetic system in the thoracolumbar intermediate gray matter. Patchy sweating can be seen with damage to specific preganglionic or postganglionic nerve fibers.<sup>9,74</sup>

Ancillary diagnostics that may aid in diagnosing or localizing SCI include radiography, myelography, computed tomography, MRI, nuclear scintigraphy, CSF analysis, nerve conduction velocities, EMG, and transcranial magnetic stimulation. Radiography may demonstrate fractures, luxations, subluxations, and vertebral compression. As presented previously, computed tomography or radiography are the diagnostic aids of choice to evaluate skeletal injury, whereas MRI is more sensitive for evaluation of soft tissue structures such as the spinal cord and ligaments. With respect to imaging the vertebral column with computed tomography and MRI devices, however, the size of the horse, the size of the equipment aperture, and the cost of the equipment aperture limit its use to investigations of the cervical and cranial thoracic spinal cord. Myelography may be required to confirm spinal cord compression and can be used at the level of the cervical, cranial thoracic, and sacral-coccygeal spinal cord. Nuclear scintigraphy can be useful in diagnosing nondisplaced or occult fractures and soft tissue lesions. Common CSF abnormalities after SCI include xanthochromia and mild-to-moderate increased total protein concentrations.<sup>9</sup> CSF analysis may be normal, especially in very acute or chronic cases. Nerve conduction velocity and electromyographic studies evaluate the lower motor neuron and aid in lesion localization. Electromyographic changes, however, may not develop until 4 to 5 days after nerve damage.<sup>75</sup> Transcranial magnetic stimulation allows detection of functional lesions in descending motor tracts through recording of magnetic motor-evoked potentials. This method has been validated and used to distinguish motor tract disorders from other causes of recumbency in clinical cases.<sup>76-78</sup>

## TREATMENT AND PROGNOSIS

Treatment to reverse primary SCI does not currently exist, and it is the assortment of pathophysiologic processes that occur during the period of secondary injury that are considered the target for pharmaceutical intervention. The period of secondary injury can be divided into three therapeutic windows.<sup>79</sup> The first 48 hours after acute SCI are dominated by the vascular and biochemical changes that occur within the spinal cord. The second period is a result of the effects of inflammatory cells and occurs within hours of injury, peaking around 4 days after injury. The third period occurs approximately 1 week after injury and is characterized by axonal regeneration and lesion repair. The goals of treatment are to stop the cascade of cellular events initiated by the traumatic insult, to protect spared neural tissue, and to promote regeneration. Surgical intervention is warranted when the need exists for stabilization or fracture repair, as well as when a compressive lesion is evident; however, this is not routine practice. The use of medical treatment to stabilize the patient should always be instituted before surgery is performed.

Acute SCI often results in impaired cardiopulmonary function such as impaired ventilation, bradycardia, and hypotension. This is particularly the case in lesions cranial to C5 (respiratory center affected) and cranial to T2 (origin of sympathetic outflow = thoracolumbar spinal cord). Systemic hypotension may exacerbate spinal cord hypoperfusion and ischemia, and maintaining systemic blood pressure has been

shown to improve spinal cord perfusion. Volume resuscitation is clearly indicated in shock and for restitution of tissue perfusion. The current recommendation is to maintain euvolemic normotension; because of sympathetic outflow disruption after cranial SCI, pressor therapy is commonly indicated in the treatment regimen. Maintaining normal mean arterial blood pressure is also important to consider during stabilization of the acutely injured horse, and it is particularly important when horses are placed under general anesthesia for various diagnostic and therapeutic procedures.

Similar to TBI, SCI has a complex multifactorial pathophysiology and likely requires a combinational treatment intervention for successful outcome. Many agents, which could target different aspects of the secondary injury mechanisms, have been investigated for use in SCI and have been reviewed.<sup>65,80,81</sup> Until now only methylprednisolone sodium succinate (MPSS) was shown to be efficacious in both animal models and human beings<sup>82-87</sup>; however, based on conflicting reports and small neurologic improvements, a number of reviews of the data have been published expressing concern with regards to the true beneficial effect of MPSS in acute SCI.<sup>88-91</sup> MPSS is a synthetic glucocorticoid with four times more anti-inflammatory activity and 0.8 times less mineralocorticoid action compared with cortisol.<sup>92</sup> Beneficial effects of MPSS on neural tissue include inhibition of lipid peroxidation, eicosanoid formation, and lipid hydrolysis, including arachidonic acid release, maintenance of tissue blood flow and aerobic energy metabolism, improved elimination of intracellular calcium accumulation, reduced neurofilament degradation, and improved neuronal excitability and synaptic transmission. MPSS was selected for human clinical trials rather than dexamethasone because the succinate radical has been shown to cross cell membranes more rapidly than other radicals.<sup>85</sup>

In 1984 the first National Acute Spinal Cord Injury Study (NASCIS I) was performed, and subsequent studies led to the conclusion that high-dose (30 mg/kg bolus followed by infusion at 5.4 mg/kg/hr for 23 hours) MPSS treatment within 8 hours of SCI improved neurologic recovery, and the use of naloxone in SCI was not recommended.<sup>85,93,94</sup> The dose of MPSS used exceeds that necessary for activation of steroid receptors, suggesting that MPSS acts through mechanisms that are unrelated to steroid receptors and apparently it is the cell membrane antilipid peroxidation effect of MPSS that is most beneficial.<sup>85,94</sup> In a fifth trial of MPSS (NASCIS III), using essentially the same protocol for drug administration and neurologic assessment as NASCIS II, no significant benefit was found when the NASCIS II regimen of 24-hour therapy was extended to 48 hours.<sup>87,93</sup> In addition, the NASCIS II and III studies have received intense criticism on several important methodological, scientific, and statistical issues that have been reviewed elsewhere.<sup>91</sup> Moreover, others have not been able to reproduce results obtained with NASCIS II and III.<sup>91</sup> Although there has been no report on increased incidence of adverse effects after MPSS treatment in human beings, a recent report in animals has shown that MPSS administration according to the doses recommended in the NASCIS II and III studies resulted in lymphocytopenia, intestinal necrosis, and eosinophilic pulmonary infiltrates.<sup>95</sup> Experts have suggested that a multinational study should be undertaken to review the current recommendation of MPSS administration.<sup>91</sup> The usefulness of high-dose MPSS treatment for spinal cord trauma in the horse remains to be investigated.

In horses, corticosteroids, alone or in combination with other drugs, are likely the most commonly used drugs for acute CNS trauma. Reported dosages of dexamethasone for horses range between 0.1 to 0.25 mg/kg intravenously every 6 to 24 hours for 24 to 48 hours. A favorable response is expected within 4 to 8 hours after administration. Horses on corticosteroid therapy should be monitored closely for the development of laminitis or *Aspergillus* spp. pneumonia. If improvement in clinical signs is observed, then the horse may be placed on oral prednisolone therapy (0.5 to 1.0 mg/kg tapered over 3 to 5 days) to decrease the chance of laminitis. The neuroprotective effect of corticosteroids is thought primarily to be mediated by free radical scavenging but may include decreased catecholamines and glutamate, as well as decreased apoptosis-related cell death.<sup>96</sup> Other potential beneficial effects of corticosteroids include reduction in the spread of morphologic damage, prevention of the loss of axonal conduction and reflex activity, preservation of vascular membrane integrity, and stabilization of white matter neuronal cell membranes in the presence of central hemorrhagic lesions.<sup>67</sup> Furthermore, their anti-inflammatory properties may be useful in reducing edema and fibrin deposition, as well as their ability to reverse sodium and potassium imbalance because of edema and necrosis. Another beneficial effect of corticosteroids is maintenance of normal blood glucose concentrations while maintaining electrolyte balance.<sup>67</sup>

As mentioned for TBI, the use of NSAIDs such as flunixin meglumine and phenylbutazone may decrease the inflammation associated with a traumatic episode. In addition, they may be beneficial in maintaining a normal rectal temperature. These compounds work by inhibiting cyclooxygenase, which converts arachidonic acid to inflammatory mediators (endoperoxides). In addition, the potential beneficial properties of DMSO, 1 g/kg intravenously as a 10% solution for 3 consecutive days followed by three treatments every other day, likely warrant inclusion of this drug in the treatment of CNS trauma.<sup>78</sup> Pharmacokinetic evaluation of DMSO in horses indicates that twice-daily dosing is necessary to maintain adequate blood levels.<sup>97</sup> Reported benefits of DMSO include increased brain and spinal cord blood flow, decreased brain and spinal cord edema, increased vasodilating prostaglandin E<sub>1</sub> (PGE<sub>1</sub>), decreased platelet aggregation, decreased prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) and prostaglandin F<sub>2</sub> (PGF<sub>2</sub>), protection of cell membranes, and trapping of hydroxyl radicals.<sup>67</sup> The exact mechanism of DMSO remains unknown, and this treatment remains controversial because some researchers have found no positive effects on neurologic outcome from the use of DMSO.<sup>98</sup> Although the free radical scavengers vitamin E and selenium have been shown to be beneficial in SCI, these antioxidants do not appear useful in the acute management because of the length of time required to achieve therapeutic concentrations in the CNS.<sup>79</sup>

Similar as is stated for TBI, antibiotics are not always necessary in the treatment of vertebral or spinal cord trauma; however, they are indicated in treating open fractures and secondary complications associated with a recumbent horse, such as pneumonia and decubital sores.

Physical therapy is important in the rehabilitative process in spine-injured horses. Controlled exercise allows the unaffected parts of the nervous system to compensate for the affected parts by increasing strength and conscious proprioception. Exercise is especially helpful in improving weakness, ataxia, spasticity, and hypermetria. In recumbent

horses, massage, therapeutic ultrasound, and hydrotherapy of affected muscle groups for 10 to 15 minutes at least twice a day is important. These measures help combat necrosis and muscle atrophy of the horse's dependent muscle groups. Passive flexion and extension of all limbs is helpful in maintaining full range of motion in recumbent horses. Furthermore, experimental studies have shown that exercise enhances functional recovery after SCI.<sup>99</sup>

Prognosis is based on response to therapy and is directly related to the time from injury to the institution of treatment. Horses that show rapid neurologic improvement have a fair-to-good prognosis. Recumbent horses or horses suffering from fractures or luxations have a guarded-to-poor prognosis. Horses that have lost deep pain sensation have a functional or anatomic spinal cord transection and have a grave prognosis. The longer the time from loss of deep pain to treatment, the poorer the prognosis. Partial or complete recovery of horses with spinal cord trauma may take weeks to months, so time and nursing care are required.

## VESTIBULAR DISEASE

Bonnie R. Rush

The vestibular system is a special proprioceptive system responsible for maintenance of balance and reflex orientation to gravitational forces. This system functions to maintain appropriate eye, trunk, and limb position in reference to movements and positioning of the head.<sup>1,2</sup>

## ☞ VESTIBULAR APPARATUS

The afferent unit of the vestibular system comprises the receptor organ within the inner ear and the vestibulocochlear nerve (the eighth cranial nerve). The vestibulocochlear nerve processes auditory and vestibular input through a common physiologic mechanism. Acoustic stimuli and acceleration forces result in mechanical deformation of hair cells in the cochlea and vestibular receptor organs, which transform physical forces into electric impulses.<sup>3</sup> The inner ear is located in the petrous temporal bone and consists of the bony and membranous labyrinth. The membranous labyrinth is suspended within the bony labyrinth by perilymph, fluid similar to and likely derived from CSF.<sup>2</sup> The membranous labyrinth comprises the cochlea, the saccule, the utricle, and the three semicircular canals.<sup>4</sup> The cochlea is responsible for auditory functions and has no input to the vestibular system.<sup>5</sup> Endolymph fills the membranous labyrinth and is derived from blood vessels along one side of the cochlea.<sup>2</sup>

The three semicircular canals are oriented at right angles to one another, which allows for detection of rotation in any plane at any angle. At one end of each semicircular canal is a dilation of the canal called the *ampulla*. A ridge of connective tissue called the *crista* is located on one side of the ampulla. The internal surface of the crista is lined with hair cells (neuroreceptor cells) and sustentacular cells (support cells) that are oriented perpendicular to the flow of endolymph.<sup>2,6</sup> These cells are covered with a gelatinous protein-polysaccharide material called the *cupula*, which extends across the lumen of the ampulla.<sup>5</sup> Rotation of the head in any plane causes endolymph to flow in one or more of the semicircular

ducts. Each hair cell has 40 to 80 stereocilia and a single modified kinocilium. Movement of endolymph causes the cupula to move across the stereocilia. Deformation of the stereocilia by the flow of endolymph toward the kinocilia results in increased neuronal activity of the vestibular nerve. Inhibition of vestibular neurons occurs with deviation of stereocilia away from kinocilia.<sup>5</sup> The semicircular canals are responsible for dynamic equilibrium and respond only to changing forces such as acceleration and deceleration but not to constant velocity or stationary positioning.<sup>2</sup> The semicircular canals can detect changing forces at a rate of 1 degree/sec.<sup>2,5</sup>

A similar receptor organ called the *macula* is located in the wall of the saccule and the utricle. The organ consists of a 2-mm oval plaque of dense connective tissue lined by neuroepithelial cells and covered with a gelatinous substance, termed the *otolithic membrane*. Calcium carbonate crystals called *statoconia* (*otoliths*) lie on the otolithic membrane, and their movement initiates stimulation of the vestibular neurons.<sup>7</sup> The macula sacculi is oriented vertically, and the macula utriculi is oriented horizontally. Gravitational forces continuously affect the position of otoliths in at least one of the maculae, supplying constant information regarding the static position of the head.<sup>8</sup> These receptor organs can detect changes in head position of one-half degree from the stationary plane.<sup>5</sup> The maculae of the saccule and utricle also detect linear acceleration and deceleration and are responsible for maintenance of static equilibrium.<sup>8</sup>

The hair cells of the crista ampullaris and maculae synapse with sensory neurons of the vestibular nerve. The cell bodies of these bipolar neurons are located within the petrous temporal bone and constitute the vestibular ganglion.<sup>5</sup> Axons leave the petrous temporal bone through the internal acoustic meatus adjacent to the cochlear portion of the eighth cranial nerve. Fibers course to the lateral aspect of the rostral medulla and penetrate the brainstem between the caudal cerebellar peduncle and the spinal tract of the trigeminal nerve. The majority of fibers of the eighth cranial nerve terminate in the four vestibular nuclei (rostral, medial, lateral, and caudal) located in the lateral wall of the fourth ventricle of the rostral medulla oblongata.<sup>1</sup> Some of these fibers form the vestibulocerebellar tract and directly enter the caudal cerebellar peduncle to terminate in the fastigial nucleus and flocculonodular lobes of the cerebellum. The afferent supply to the vestibular nucleus is primarily from the maculae, the crista ampullaris, and the cerebellum. These sensory fibers synapse with second-order neurons in the vestibular nuclei that extend fibers to the motor neurons of the spinal cord, the nuclei of the cranial nerves that control eye position, the cerebellum, the autonomic nervous system, the reticular formation, and the cerebral cortex.<sup>2,5</sup>

The vestibulospinal tract courses in the ipsilateral ventral funiculus and terminates in interneurons of the ventral gray column. Stimulation of the vestibulospinal tract is facilitatory to  $\alpha$ - and  $\gamma$ -motor neurons of the ipsilateral extensor muscles, inhibitory to the  $\alpha$ -motor neurons of the ipsilateral flexor muscles, and inhibitory to contralateral extensor muscles.<sup>2</sup> The net result is ipsilateral extensor tonus and contralateral flexor tonus that act as an adaptive mechanism against gravity by catching the body and preventing a fall in the direction of vestibular stimulation.<sup>6</sup>

Axons from the medial vestibular nucleus project through the medial longitudinal fasciculus. The ascending portions of the medial longitudinal fasciculus course to the motor nuclei of the third, fourth, and sixth cranial nerves (oculomotor,

trochlear, and abducens).<sup>4,9</sup> These fibers coordinate conjugate eye movement with changes in head position. This pathway, along with cerebellar input, controls physiologic (vestibular) nystagmus.<sup>2</sup> Physiologic nystagmus is a normal reflex that allows the eyes to remain fixed on a stationary object while the head moves.<sup>5</sup> Nystagmus is characterized by involuntary, conjugate, rhythmic eyeball oscillations with a fast and slow phase. The direction of nystagmus is defined by the direction of the fast phase and is induced by rapid movements of the head. Rapid dorsiflexion of the neck results in vertical nystagmus, whereas side-to-side movement of the head induces horizontal nystagmus. Turning the head to the left results in a horizontal nystagmus with the fast phase to the left. The accompanying slow phase is in a direction opposite to body motion and allows the eyes to fix on a stationary image. The fast phase is initiated when the eyeball reaches the lateral limit of ocular movement and allows the eyeballs to jump forward and focus on a new image.<sup>5,6</sup> The slow phase is controlled by vestibular input, and the fast phase is a function of the brainstem.<sup>2</sup> Physiologic nystagmus induced by rapid manipulation of the head is called the *oculocephalic reflex*. This reflex occurs independent of vision.<sup>10</sup> Descending portions of the medial longitudinal fasciculus travel in the ventral funiculus of the cervical and cranial thoracic spinal cord segments and control the position and activity of the limbs and trunk in coordination with head position.<sup>2,5</sup>

Fibers from the vestibular nuclei that project to the reticular formation provide afferent nerves to the vomit center, which is the pathway for the development of motion sickness. Reticulospinal tracts also aid in the maintenance of extensor tone to support the body against gravity.<sup>2,5</sup>

Vestibular impulses enter the cerebellum via the caudal cerebellar peduncles. Fibers of the vestibulocerebellar tracts terminate primarily in the flocculonodular lobe and fastigial nucleus.<sup>2</sup> The flocculonodular lobe appears to be linked closely to the semicircular canals in the control of dynamic equilibrium.<sup>5</sup> The cerebellum functions to coordinate antagonistic, antagonistic, and synergistic muscle groups for controlled responses to gravity. The vestibular apparatus provides information to the cerebellum, dictating the relative degree of contraction necessary to maintain equilibrium.<sup>5</sup>

Vestibular signals travel through to the contralateral medial geniculate nuclei of the thalamus to the cerebral cortex. In addition to proprioceptive information from other parts of the body, the cerebral cortex facilitates conscious perception of orientation.<sup>2</sup>

The vestibular system is capable only of detecting movement and orientation of the head in relationship to the rest of the body. Afferent pathways from the neck allow the head to be cognizant of the orientation of the rest of the body.<sup>5,8</sup> Proprioceptive receptors in the joints of the neck that transmit signals to the reticular formation are essential to the righting reflex.<sup>7,8</sup> Exteroceptor receptors of the skin and proprioceptive receptors in other joints also are integrated in the cerebellum and reticular formation to aid in the maintenance of equilibrium. These signals allow the vestibular system to know if the body remains in an appropriate position with respect to gravity while the head is bent. Visual images can help to maintain balance by visual detection of the upright stance. In addition, slight linear or angular movement of the head shifts the image on the retina, which relays directional information to equilibrium centers. Visual compensation may be capable of maintaining balance in the face of complete vestibular destruction, if the eyes are open and motions are performed slowly.<sup>5</sup>

The seventh cranial nerve (the facial nerve) emerges from the lateral medulla ventral to the vestibulocochlear nerve at the level of the trapezoid body. The two nerves are associated closely with the petrous temporal bone and enter the internal auditory meatus together.<sup>11</sup> Within the internal auditory meatus, the facial nerve separates from the vestibular nerve and courses through the facial canal of the petrosal bone. The facial nerve exits the cranium from the stylomastoid foramen located immediately caudal to the external auditory meatus. Because of the proximity of the facial and vestibular nerves, a single disease process commonly affects both nerves simultaneously.<sup>12</sup>

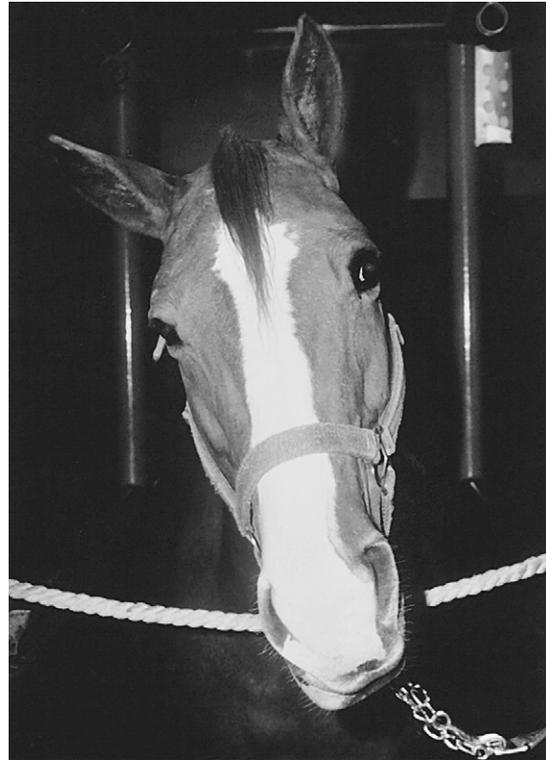

Sympathetic innervation to the eye also is associated anatomically with the petrous temporal bone. Damage to this nerve (Horner's syndrome), along with vestibular and facial nerve deficits, frequently occurs with petrous temporal bone trauma and otitis media in small animals.<sup>10</sup> The association of Horner's syndrome, facial nerve paralysis, and vestibular disease rarely is documented in the horse.<sup>2</sup>

## CLINICAL SIGNS

Knowledge of the anatomy and function of structures related to the peripheral and central vestibular system aids in neuroanatomic localization of the lesion.<sup>10</sup> Differentiation of central versus peripheral vestibular disease is important for establishing a list of differential diagnoses, initiating therapy, and formulating a prognosis. A thorough physical and neurologic examination of a horse with vestibular disease may identify nonvestibular neurologic signs, lending significant insight into the location of the lesion. Historical information, including duration of condition, rate of onset, and disease progression, also may aid in differentiation of central from peripheral vestibular disease.

Signs of acute peripheral vestibular system dysfunction include head tilt, nystagmus, falling, circling, reluctance to move, and asymmetrical ataxia with preservation of strength.\* Horses affected with peracute vestibular disease are often violent because of disorientation.<sup>1</sup> A true head tilt is a consistent sign of vestibular disease and is characterized by ventral deviation of the poll of the head toward the affected side<sup>4,14</sup> (Figure 12-31). The horse prefers to lie on the side of the lesion and may lean on the wall toward the affected side when standing. When forced to move, the horse takes short, uncoordinated steps in a circle toward the direction of the lesion. The body may be flexed laterally with a concavity toward the lesion.<sup>4,6</sup> Extensor hypotonia ipsilateral to the lesion, and mild hypertonia and hyperreflexia of the extensor muscles of the contralateral side result in asymmetrical ataxia.<sup>15</sup> Extensor hypotonia occurs from loss of facilitatory neurons of the vestibulospinal tract to ipsilateral extensor muscles.

Contralateral extensor hypertonia occurs from loss of inhibitory neurons and unopposed extensor tone of the contralateral vestibulospinal tract.<sup>2,6,14</sup> Central vestibular disease has similar clinical signs, but general proprioceptive deficits, weakness, and multiple cranial nerve deficits also may be present, resulting from damage to the surrounding neurologic structures. The onset of vestibular signs in a horse with an expanding space-occupying central lesion is not as dramatic as peripheral nerve damage; adjustments by compensatory mechanisms occur during slow development of the lesion.

**FIGURE 12-31** Thoroughbred with right-sided peripheral vestibular disease caused by a temporohyoid osteoarthropathy (THO) and acute fracture. The head tilt, dropped pinna, and eyelid droop occur on the affected side, whereas the muzzle is pulled toward the contralateral side.

These lesions, however, are not likely to show significant clinical improvement after the onset of clinical signs, as may occur with peripheral vestibular lesions.

Pathologic nystagmus is involuntary, rhythmic oscillations of the eyes occurring while the head is in a normal position and indicates a lesion in the vestibular system or cerebellum.<sup>12</sup> As in physiologic nystagmus, one can identify a fast and a slow phase. The direction of nystagmus is defined by the direction of the fast phase.<sup>2,5,12</sup> Pathologic nystagmus may be spontaneous, occurring with the head in the resting position, or positional, which is induced by elevation or lateral flexion of the head.<sup>2</sup> Nystagmus usually appears with the onset of other peripheral vestibular signs but may last only 2 to 3 days because of central compensation.<sup>4,15</sup> Concomitant blinking of the eyelid may hinder detection of nystagmus.<sup>2</sup>

Peripheral vestibular dysfunction may result in horizontal or rotary nystagmus. The fast phase of nystagmus is directed away from the lesion and does not change with changing head position.<sup>2,3,6</sup> The direction of rotary nystagmus is defined by the direction the limbus moves from the 12 o'clock position during the fast phase.<sup>2</sup> Horizontal, rotary, or vertical nystagmus can result from a central vestibular lesion. In addition, the type of nystagmus observed may change with changing head position in a patient with central vestibular disease.<sup>1,12,14</sup> Often the fast phase is directed away from the central lesion, but this is not a consistent finding.<sup>2</sup>

In the healthy animal a constant stream of electric stimulation arises in each vestibular end organ and transmits signals that control ocular position via the medial longitudinal fasciculus. These signals normally drive the eyes toward the opposite

\*References 2, 4, 8, 10, 12, 13.

direction. The eyes are maintained centrally, however, because vestibuloocular pathways are opposed in an equal and opposite manner. Unilateral vestibular disease upsets this balance, resulting in slow deviation of both eyes toward the lesion. REM returns the eyes to midposition. Individuals that are blind at birth or have been blind for an extended time may exhibit irregular eyeball oscillation with no slow or fast component.<sup>16</sup>

Ataxia and dysmetria are often severe with peripheral vestibular disease; however, strength is maintained. Postural reactions remain normal with the exception of the righting reflex. The motor system is unable to accurately control movement and identify the location of different parts of the body at a given time. Therefore the horse makes an exaggerated response toward the side of the lesion as it attempts to stand.<sup>2</sup>

Loss of hearing is a common finding with peripheral vestibular disease because of the proximity of the cochlea to the vestibular receptor organs. In the CNS, diffuse pathways control auditory signals and extensive central disease would be necessary to cause hearing loss.<sup>14</sup>

If vestibular signs are accompanied by depression, weakness, or conscious proprioceptive deficits, a central vestibular system lesion is likely. With a central lesion, abnormal conscious proprioception occurs because of damage within the brainstem of the descending upper motor neuron tracts to the limbs.<sup>2</sup> Damage to the spinocerebellar tracts or caudal cerebellar peduncles results in abnormal unconscious proprioception and hypermetria.<sup>1</sup> The nuclei of the trigeminal (fifth cranial nerve) and the abducens nerves (sixth cranial nerve) are in anatomic proximity to the vestibular nuclei and are damaged readily in a common disease process. Trigeminal nerve paralysis creates a loss of sensation to the head and atrophy of the muscles of mastication. Trochlear nerve damage results in medial strabismus.<sup>10</sup>

Destructive space-occupying lesions in the cerebellopontine angle or flocculonodular lobe may result in paradoxical central vestibular disease.<sup>1,17</sup> This syndrome is manifested by vestibular ataxia and a head tilt contralateral to the side demonstrating general proprioceptive ataxia and postural reaction deficits. When this unusual combination of neurologic signs is present, the side of general proprioceptive deficits defines localization of the lesion.<sup>2,10</sup>

Central or peripheral vestibular disease may produce strabismus. One observes ventrolateral strabismus ipsilateral to the vestibular lesion with elevation of the head and extension of the neck.<sup>2,10</sup> One observes mild ventral deviation of the eyes in normal horses when the head is elevated, but the finding is symmetric. Ventrolateral strabismus of vestibular disease is not a sign of a cranial nerve deficit of the extraocular muscles<sup>2</sup> but is a reflection of abnormal upper motor neuron influences on the oculomotor nucleus from the ipsilateral vestibular nucleus via the medial longitudinal fasciculus. If the strabismus is purely vestibular in origin, then normal ocular mobility is visible with manipulation of the head.<sup>14</sup>

Signs of vestibular disease may improve rapidly 2 to 3 weeks after onset because of visual and central accommodation.<sup>2,13</sup> Central vestibular lesions are slower to compensate than peripheral vestibular lesions; signs may even progress if the central lesion is an expanding space-occupying mass.<sup>14</sup> Human beings compensate satisfactorily for unilateral disease but are not required to be coordinated athletes performing at high speed.<sup>4</sup> Blindfolding a horse with compensated disease results in ataxia and a head tilt (Romberg's test). Blindfolding eliminates visual and limb proprioceptive orientation; the body is forced to rely on the impaired vestibular system for

equilibrium.<sup>2,10,11</sup> This test is unreliable for localizing the side of the lesion.<sup>3</sup> Horses may decompensate dramatically when the blindfold is placed over the eyes, resulting in anxiety, disorientation, and falling.<sup>2</sup> One should perform the test with caution on a padded surface with good footing.

Horses affected with bilateral peripheral disease demonstrate no head tilt, circling, or pathologic nystagmus, and one cannot induce physiologic nystagmus by rapid manipulation of the head (the oculocephalic reflex) or by caloric testing. The head may sway with wide excursions from side to side.<sup>4</sup> As with all peripheral vestibular disease, strength is preserved.<sup>2</sup> Clinically, horses affected with bilateral vestibular disease exhibit more symmetrical ataxia similar to generalized cerebellar disease.<sup>1</sup>

Facial nerve (seventh cranial nerve) paralysis frequently occurs concurrently with peripheral vestibular disease because of its proximity to the vestibular nerve within the petrous temporal bone. Facial nerve paralysis worsens the long-term prognosis and complicates the management of vestibular disease patients. The facial nerve innervates the muscles of facial expression, and damage to this nerve results in muzzle deviation away from the affected side, lack of menace and palpebral response, ear droop, decreased nostril flare impeding air flow, and buccal impaction of feed.<sup>4,11,12</sup> Keratitis and corneal ulceration are common because of the inability to blink and decreased tear production.<sup>4,18</sup> Decreased tear production results from damage to parasympathetic fibers to the lacrimal gland. Preganglionic fibers travel with the facial nerve through the internal auditory meatus and separate in the facial canal proximal to the geniculate nucleus.<sup>12</sup> The fibers split from the facial nerve to join the superior petrosal nerve, which carries fibers to the sphenopalatine ganglion. Postganglionic fibers join the sympathetic fibers to the eye and travel with the vasculature to the lacrimal gland.<sup>2,12</sup> Corneal ulcerations occur in the inferior portion of the cornea and are slow to heal because of ongoing exposure.<sup>11</sup> Lack of tear production aids in localization of the lesion, indicating the damage is within the petrous temporal bone, proximal to the geniculate nucleus.<sup>2,12</sup> Clinical signs of facial nerve paralysis may not appear for several days after the onset of vestibular disease, because damage to the nerve may result from hematoma, callus, or an extension of inflammation and secondary neuritis.<sup>4</sup> Because of the proximity of the nuclei of the facial and vestibular nerves, extensive lesions of the medulla may involve both nerves. If no improvement of facial nerve deficits occurs within 3 to 4 months after the onset of disease, then the prognosis is poor for recovery. If one notes even mild improvement in the first 4 months, then facial nerve function may return.<sup>4</sup> Horses may learn to retract the globe, allowing the eyelid and nictitating membrane to slide across the surface of the cornea, distributing lubrication and protecting the eye from trauma.<sup>11</sup> Careful observation is necessary to differentiate this adaptation from improvement of lid function.

## PERIPHERAL VESTIBULAR DISEASE

Acute onset of peripheral vestibular disease and facial nerve paralysis is not a rare occurrence in the horse.<sup>15,19</sup> Damage to the temporal bone is the most likely anatomic location when these nerves are affected concurrently. THO and traumatic skull fractures are the most common causes of these signs in large animals.<sup>1</sup> THO is the most common cause of peripheral vestibular disease in horses and should be the number one rule out for horses with acute onset of vestibular dysfunction, especially if accompanied by facial nerve palsy.

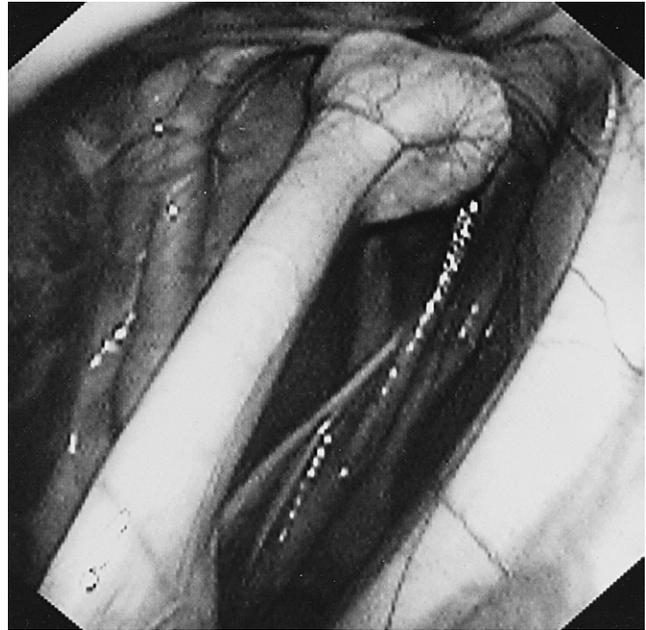

## TEMPOROHYOID OSTEOARTHROPATHY

Temporohyoid osteoarthropathy is one of the most common causes of acute onset peripheral vestibular disease, facial nerve paralysis, or both in horses.<sup>4,11,20-22</sup> Varying causes for the disorder have been suggested, including extension of inflammation and infection from otitis media-interna or guttural pouch infection, repetitive trauma, and nonseptic osteoarthritis. Much of the older veterinary literature refers to this disorder as *otitis media-interna*, whereas newer references use the designation *THO* because of the uncertainty concerning underlying cause in most horses.\* The earlier presumption of underlying otitis media-interna hypothesized that rather than rupturing the tympanic membrane, the inflammatory process might extend ventrally to involve the bones of the tympanic bulla and temporohyoid joint. However, this theory remains speculative, and relatively few horses with THO have evidence of otitis or guttural pouch infection at the time of diagnosis or historically. Some or all cases of THO are quite likely the result of primary degenerative joint disease rather than an extension of a bacterial ear or guttural pouch infection.

Regardless of initial cause, inflammation induces bony proliferation at the articulation of the stylohyoid bone with the petrous temporal bone, resulting in loss of the joint space and fusion of the temporohyoid joint. The hyoid apparatus is attached to the tongue and larynx; fusion of the temporohyoid joint results in impaired flexibility of the unit. A stress fracture of the petrous temporal bone, the stylohyoid bone, or both may result from eating, vocalization, or any activity associated with normal tongue movement.<sup>6,15</sup> Occasionally, fracture and acute onset of severe neurologic signs (collapse and seizure) may be associated with passage of a nasogastric tube or other veterinary procedure.<sup>20</sup> The fracture line may extend into the cranial vault at the level of the internal auditory meatus, resulting in direct neural tissue trauma and hemorrhage into the middle and inner ear.<sup>1,15</sup>

Neurologic signs are rarely apparent during the formation of proliferative osteitis and temporohyoid joint fusion. The onset of neurologic signs corresponds with the occurrence of the stress fracture. Early signs, before fracture, might include head shaking, resistance to the bit, ear rubbing, resentment of manipulation of the head or ears, or pain on pressure at the base of the ear. Occasionally more overt signs of otitis externa or otitis media-interna may be present, including evidence of exudate from the external ear canal.

Most horses exhibit acute onset of cranial nerve VII or VIII abnormalities (or both) at the time of fracture. Fractures can tear or stretch the facial or vestibulocochlear nerves as they exit the skull or within the skull, respectively. Some fractures extend into the cranial vault with resultant seizures, bacterial meningitis, or death.<sup>15,20,23</sup> Vestibular signs can vary between mild head tilt to circling with severe loss of balance and horizontal nystagmus or recumbency. Auditory abnormalities are evident in most affected horses when assessed by brainstem auditory-evoked responses.<sup>25</sup> If the facial nerve is damaged, then ptosis, muzzle deviation away from the side of the lesion, a drooping lower lip and ear on the side of the lesion, and accumulation of feed within the cheek occurs. Preganglionic parasympathetic fibers in the facial nerve that innervate the lacrimal gland may also be damaged with resultant keratoconjunctivitis sicca.

**FIGURE 12-32** Endoscopic view of the right guttural pouch of a horse with acute onset of right-sided vestibular disease and facial nerve paralysis. Bony proliferation of the proximal stylohyoid bone is consistent with chronic THO.

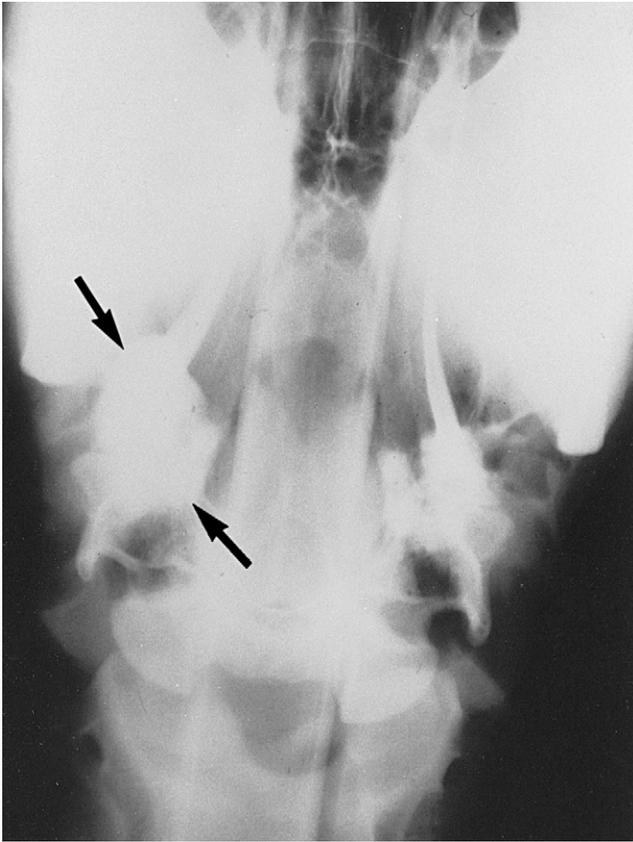

Many affected horses have corneal ulceration varying between mild to severe. Corneal disease is secondary to decreased tear production and facial nerve dysfunction that diminishes the horse's ability to effectively close the eyelids and spread the tear film across the eye. Rarely, horses may have intermittent acute episodes of vestibular disease with intervening periods of apparent normal neurologic function. Occasionally, the fracture extends to the foramen lacerum, caudal to the petrous temporal bone, where the glossopharyngeal and vagus nerves exit the skull. Trauma to these nerves may result in dysphagia.<sup>11</sup>

A diagnosis of THO may be confirmed by imaging of the stylohyoid bone or petrous temporal bone by endoscopy, radiography, nuclear scintigraphy, computed tomography, or MRI.<sup>20-22</sup> Although most affected horses have acute onset of unilateral neurologic signs, it is not uncommon for imaging to identify bilateral THO and bony proliferation.

Endoscopy of the pharynx and guttural pouch is one of the most sensitive diagnostic tests for THO in horses.<sup>20</sup> One should perform this noninvasive procedure on every horse suspected of having proliferative osteitis, because one often can identify bony proliferation of the proximal stylohyoid bone within the guttural pouch<sup>1,24</sup> (Figure 12-32). Many horses also have evidence of hyperemia, bruising, or hematoma formation in the dorsal mucosa of the guttural pouch, near the head of the stylohyoid bone.

Dorsoventral radiographs of the caudal skull should reveal the characteristic periosteal proliferation and sclerosis of the stylohyoid bone and petrous temporal bone<sup>4,11,18</sup> (Figure 12-33). The fracture line is often difficult to identify because of minimal displacement of the fracture fragments. Lateral oblique radiographs obtained at varying angles may aid in localization of a fracture of the basisphenoid, occipital, or petrous temporal bones. Moderate bony proliferation may not occur for several weeks and must be present to diagnose the condition radiographically.<sup>18</sup>

\*References 4, 11, 15, 18, 23, 24.

**FIGURE 12-33** Ventrodorsal skull radiograph demonstrating bony proliferation of the proximal left stylohyoid and petrous temporal bones (arrows) associated with THO.

Bone scintigraphy is a noninvasive technique that may allow for an immediate identification of early lesions of the petrous temporal bone. Radiography can identify only structural abnormalities of bone. Bone scintigraphy is capable of detecting dynamic characteristics of bone. Increased metabolic activity and blood supply to the bone, caused by infection or fracture, results in increased uptake of the radiolabeled compound (technetium-99m-labeled phosphate) before radiographic evidence of bony proliferation.<sup>26-28</sup>

When available, computed tomography and MRI are extremely sensitive diagnostic tests for identification of inflammation, bony proliferation, and fracture.<sup>20-22</sup> However, CT and MRI of the skull of horses requires general anesthesia. The risks associated with recovery from general anesthesia, when a horse has compromised neurologic function and possible skull fracture, should be considered seriously before recommendation of these procedures.

One may consider analysis of CSF in affected horses.<sup>1,2</sup> Cytologic evaluation, culture, and sensitivity may help to reveal the presence of secondary bacterial meningitis and can be used to direct the selection of an appropriate antimicrobial treatment plan.<sup>15</sup>

Treatment of horses with acute onset of neurologic dysfunction secondary to THO should focus on four areas<sup>22</sup>:

1. Stabilization of the horse and decreasing inflammation near the fracture site
2. Treatment with broad spectrum antimicrobials for either extension of a possible otitis interna-media or secondary infection in the hemorrhage that follows the fracture

3. Treatment of exposure keratitis and keratoconjunctivitis sicca
4. Surgical procedures to remove pressure on the temporohyoid articulation to decrease pain and to decrease the likelihood of repeated petrous temporal bone fracture

Medical therapy usually includes anti-inflammatory medications as described elsewhere in this text for treatment of acute head trauma. Trimethoprim-sulfonamide antimicrobials for 30 days are often recommended to treat potential bacterial infection. If culture and sensitivity of CSF or other diagnostic sample are available, then those results may direct alternative antimicrobial choices. Treatment of corneal ulceration and keratoconjunctivitis sicca is described elsewhere in this text.

Surgical treatment of THO may take the form of either a partial stylohyoid osteotomy or a ceratohyoidectomy.<sup>22,29,30</sup> Surgical removal of a 2- to 3-cm segment of the midbody of the stylohyoid bone results in a fibrous nonunion of the stylohyoid bone that should interrupt the transmission of hyoid forces to the temporohyoid joint. Reported complications include transection of the lingual artery, injury to the hypoglossal or facial nerve, and regrowth of the stylohyoid osteotomy site.<sup>29,30</sup> The goal of ceratohyoidectomy is also to remove mechanical stress on the fused temporohyoid joint, but the surgery is technically easier to accomplish without the risk of many of the more serious complications that may be seen with partial stylohyoidectomy.<sup>30</sup>

Diagnosis of THO before the acute onset of neurologic signs is difficult because most horses exhibit few, if any, clinical signs before fracture. Some horses may demonstrate ear rubbing, head tossing or shaking, chomping movements, and sensitivity or pain on palpation at the base of the ear.

Prognosis for life in horses with THO is fair to good if the horse survives the immediate fracture episode.<sup>20</sup> However, it may take up to 2 years for maximum neurologic improvement after fracture and the majority of affected horses have long-term, probably permanent, deficits. Some degree of facial nerve paralysis is common and persistent or recurrent corneal ulceration may result. However, many horses eventually learn to retract the globe to assist in eyelid closure to spread the tear film across the eye, lessening the severity and frequency of corneal ulceration. Many horses return to some level of athletic function after THO.<sup>20</sup> However, owners of horses with THO should be cautioned regarding the potential for acute onset of severe neurologic signs with no warning as a result of refracture. Therefore affected horses pose a risk to human beings in the environment and recognition of this risk is important. Surgical treatment may possibly diminish the risk for subsequent fracture; however, currently no long-term follow-up studies of large numbers of affected horses exist to quantify or compare risk with or without surgery.

## HEAD TRAUMA

Traumatic fractures of the petrous temporal bone result in damage to the vestibular and facial nerves. Profuse aural hemorrhage or loss of CSF from the external ear canal frequently is observed. Bleeding from the nose occurs if the fracture extends to the cribriform plate.<sup>4</sup> Clinical signs usually appear immediately after trauma and include vestibular disease, facial nerve paralysis, recumbency, or coma. Damage to nervous tissue may be caused by hematoma, callus formation, or displacement of fracture fragments resulting in delayed

onset of clinical signs. Signs from brainstem contusion or concussion may be more severe than vestibular dysfunction. If blindness is present, then the prognosis worsens because of the loss of visual compensation of vestibular disease in the future. If one cannot elicit the oculocephalic reflex (physiologic nystagmus), then the examiner should suspect damage to the medial longitudinal fasciculus, indicating extensive brainstem damage; a poor prognosis is indicated.<sup>2</sup> One may recall that bilateral peripheral vestibular disease also results in loss of the oculocephalic reflex; however, this is an unlikely scenario for trauma.

Fractures of the basioccipital and basisphenoid bones occur most frequently in horses that rear over backward and strike the poll of the head. This fracture does not result from referred impact from the poll but is thought to be an avulsion fracture from the pull of the powerful ventral straight muscle of the neck (rectus capitis ventralis) on its insertion on the basioccipital bone.<sup>31</sup> Basioccipital fractures result in neurologic signs associated with damage to the brainstem; signs of vestibular disease are common.

Petrous temporal bone fractures are difficult to identify radiographically; tympanosclerosis appears as early as 20 days after trauma and obscures the fracture line.<sup>4</sup> One often can identify basioccipital fractures easily but can confuse them with the suture lines in the base of the skull.<sup>31</sup> Treatment of vestibular signs after head trauma is similar to that of any acute head trauma as described previously in this chapter.

## DRUG TOXICITIES

Drug toxicities can result in unilateral or bilateral peripheral vestibular disease and deafness. Degeneration of the hair cells within the peripheral receptor organs of the auditory and vestibular system occurs with prolonged administration of aminoglycoside antibiotics. Severely affected animals also develop neural degeneration.<sup>3</sup> A more common manifestation of aminoglycoside toxicity is renal failure. As renal clearance of the aminoglycoside decreases, the ototoxic effects of the antibiotics are potentiated.<sup>1,10,23</sup> Clinical signs of vestibular disease appear before deafness. Early vestibular disease may be reversible or centrally compensated, but loss of auditory function is permanent.<sup>2,10,23</sup> Streptomycin preferentially affects the vestibular system, whereas dihydrostreptomycin, kanamycin, gentamicin, neomycin, and vancomycin are more toxic to the auditory system.<sup>2,15</sup> Vincristine, a vinca alkaloid, can cause bilateral cochlear nerve damage in human beings. Auditory function improves several months after discontinuation of the drug.<sup>3</sup> This antimetabolic drug is a common component of multiagent chemotherapy protocols in the treatment of lymphosarcoma in the horse.<sup>32</sup> Vincristine also is used for immunosuppression and stimulation of platelet function in refractory cases of immune-mediated thrombocytopenia.<sup>33</sup> One should carefully monitor auditory function when using this drug.

Sudden loud noises can result in degeneration and necrosis of the sensory hair cells of the inner ear.<sup>23</sup> A lightning strike, although usually fatal, is reported to cause acute onset of unilateral vestibular disease in the horse. Facial nerve paralysis may or may not accompany the vestibular signs. Documentation of histopathologic findings in one case revealed hemorrhage and necrosis of the temporal bone, vestibular nerve, and adjacent tissue. Whether the mechanism of damage is electrocution or noise trauma is unknown.<sup>1</sup>

## ☪ CENTRAL VESTIBULAR DISEASE

Any inflammatory disease or space-occupying mass of the CNS may damage the vestibular nuclei and related tracts. Clinical signs vary with the type and extent of the disease process. One should suspect a CNS disease if abnormal mentation, seizures, blindness, or multiple cranial nerve abnormalities are seen with general proprioceptive deficits. One should perform an electroencephalogram to detect the location and extent of the CNS lesion. The electroencephalogram can detect only cerebral damage and cannot identify lesions of the brainstem. Inflammatory, parasitic, and neoplastic diseases have been implicated in central vestibular disease of the horse.

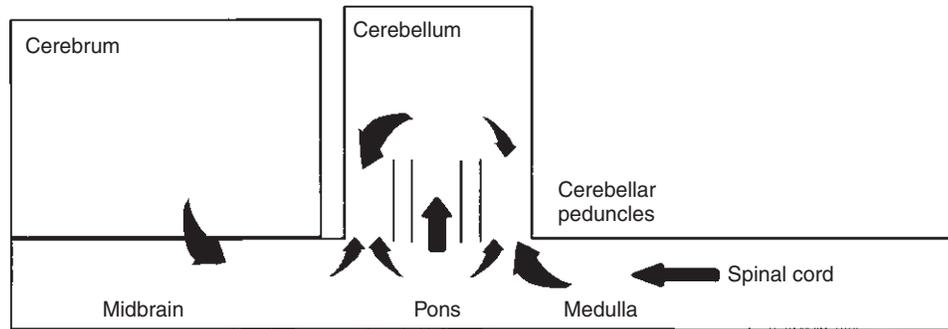

Inflammatory disease affecting the CNS includes bacterial abscess, equine protozoal myelitis, polyneuritis equi, and viral encephalitis. One should perform CSF analysis to identify the inflammatory process. In the case of brain abscessation, a culture of the CSF may identify the causative organism; *Streptococcus equi* subsp. *equi* is a common causative agent.<sup>34,35</sup> EPM is a common neurologic disease in the United States and Canada and should be suspected if multifocal disease is present.<sup>1</sup> For polyneuritis equi to occur with vestibular dysfunction is common, but the signs of cauda equina neuritis predominate.<sup>2</sup> Rabies may present as an encephalitis or spinal cord disease and should be considered in the differential diagnosis of any horse with neurologic disease. Spinal ataxia is the primary neurologic deficit observed in horses affected with equine herpesvirus (EHV) myelitis, but the presence of concurrent vestibular disease is reported.<sup>36</sup> The major clinical signs observed with a togavirus (eastern, western, and Venezuelan encephalitis) infection are depression and seizure, although cranial nerve deficits are observed.<sup>6,35</sup> Horses with West Nile virus (WNV) infection may display cranial nerve signs, including vestibular disease. Concurrent behavioral and mentation changes, ataxia, fever, and muscle fasciculations are common.

Aberrant parasite migration of the CNS in horses results in acute onset of neurologic signs. Clinical signs vary, but progression of clinical signs occurs in most instances. Neurologic signs are generally asymmetrical because of the random nature of migration. Neurologic disease secondary to parasite migration is discussed in detail later in this chapter. Fungal granulomata caused by *Aspergillus* spp. and *Cryptococcus neoformans* have been reported as space-occupying masses within the cranium of a horse.<sup>1,37</sup> Cholesteatoma (cholesterol granuloma) could involve the vestibular system by extending from the choroid plexus of the fourth ventricle of the brain.<sup>1</sup> Neoplastic diseases of the CNS are rare in the horse. Any tumor affecting the cerebellomedullary angle could result in vestibular signs.<sup>2</sup> Lymphosarcoma, ependymoma, meningeal melanoma, and melanotic hamartoma have been reported to affect the CNS of the horse.<sup>2,38</sup>

## ☪ ANCILLARY DIAGNOSTIC TESTS

### CALORIC TESTING

The caloric test is a diagnostic aid that may be helpful in differentiating central from peripheral vestibular disease. The test is able to assess each peripheral vestibular sensory organ separately. In the normal animal, irrigation of ice-cold water (12° C) into the external auditory canal for 3 to 5 minutes induces a horizontal nystagmus with the fast phase away from the tested labyrinth.<sup>2,3,5,6</sup> The water cools endolymph closest to the tympanic membrane, increasing its density. A density

**FIGURE 12-34** Schematic diagram of cerebellar efferent and afferent information pathways via the cerebellar peduncles. The arrow size reflects the relative contribution of each pathway (see text for details).

gradient is created within the semicircular canal and the cooled endolymph sinks, causing displacement of the hair cells. Warm water (45° C) irrigation of the external auditory canal results in horizontal nystagmus with a fast phase toward the tested labyrinth. The warm-water test is less reliable.<sup>10,16</sup> The test does not induce nystagmus in a nonfunctional labyrinth. Animals may resist the procedure, making the test difficult to interpret, and in some animals, one cannot induce nystagmus. If an asymmetrical response is obtained, then the depressed reaction indicates the abnormal labyrinth.<sup>2</sup> The test is difficult to perform and not entirely reliable, although it may be a helpful diagnostic aid in the anesthetized or comatose horse.<sup>6</sup>

### BRAINSTEM AUDITORY EVOKED RESPONSE

The cochlea is damaged by trauma or inflammation of the peripheral vestibular receptor organs, and detection of hearing loss may help to differentiate central from peripheral vestibular disease. Unilateral hearing loss is difficult to assess subjectively in the horse. BAER is a method of objective assessment of auditory function in the horse. This noninvasive, electrodiagnostic test stimulates the auditory system with a series of clicks. Far-field potentials of the brainstem auditory components are recorded via cutaneous electrodes and a signal-averaging system.<sup>6,39</sup> The response is a series of evoked potentials occurring within 10 ms after the stimulus. In the horse the evoked potentials appear on the oscilloscope as a series of five waveforms.<sup>40</sup> In human beings, five to seven waveforms are present, and each corresponds to a specific neurologic structure.<sup>39,40</sup> Abnormalities of the specific waveforms can identify a lesion of the corresponding neurologic structure. In the horse, functional loss of the cochlea or eighth cranial nerve results in the loss of the entire waveform on the side of injury, and the presence or absence of the waveform can differentiate a central from a peripheral vestibular lesion. General anesthesia is not necessary to perform the test, but sedation is recommended.<sup>39</sup>

## DISEASES OF THE CEREBELLUM

Barbara A. Byrne

Cerebellar abnormalities reported in horses consist primarily of neurodegenerative disorders confined primarily to a small number of breeds including Arabians and Gotland pony foals.

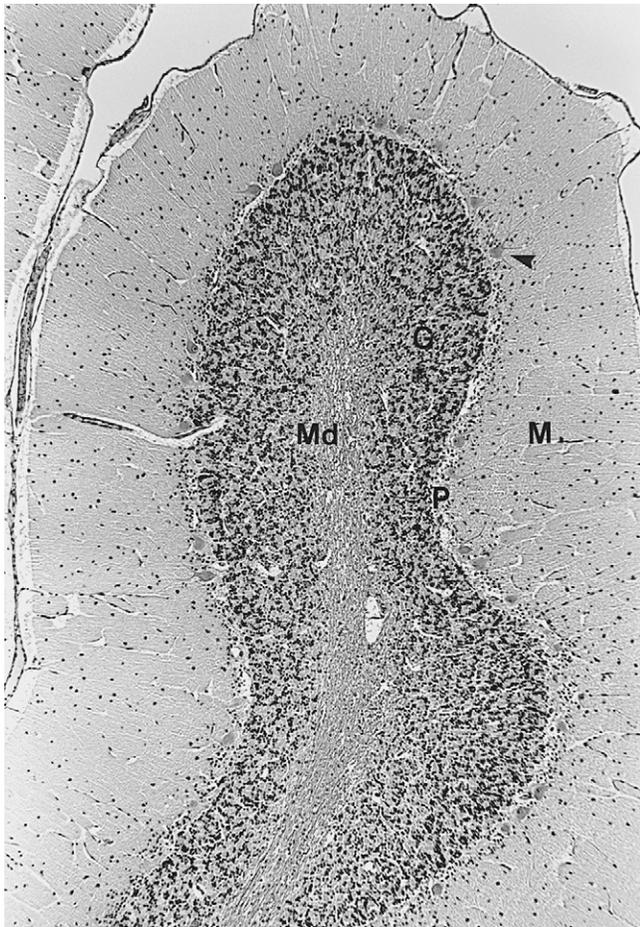

The cerebellum is essential for the coordination of movement. Afferent information arises from the general and special (vestibular) proprioceptive systems and the special somatic (auditory and visual) systems. The cerebellum is responsible for regulation of the rate, range, and strength of movement, as well as integration and coordination for balance and posture. Cerebellar abnormalities in horses are unusual; however, when present, they can have a profound effect on gait and posture.

### STRUCTURE AND FUNCTION

Knowledge of the structure and development of the cerebellum is important for understanding cerebellar function in health and disease. The cerebellum is located in the metencephalon dorsal to the pons and is attached to the pons via three cerebellar peduncles (Figure 12-34). The caudal peduncle is composed primarily of afferent fibers arising from the medulla, the vestibular nuclei via the vestibulocerebellar tracts, and the spinal cord via the spinocerebellar tracts. The middle cerebellar peduncle contains only afferent fibers to the cerebellum that arise from the transverse fibers of the pons. The rostral cerebellar peduncle is the primary connection to the mesencephalon and carries the majority of cerebellar efferent fibers, although a few afferent fibers arise from the spinocerebellar tracts. The cerebellum consists of two hemispheres and a central region known as the *vermis*.<sup>1</sup> The extensive convolutions of the cerebellar cortex are termed *folia*. The cortex covers the surface of the cerebellum. On cut section, the cerebellar medulla is a central region of white matter with multiple projections called *arbor vitae*. These branches extend to the cerebellar cortex and form the white matter portion adjacent to the cerebellar cortex.

The cerebellar medulla has three nuclei: (1) the fastigial, (2) the interpositional, and (3) the lateral nuclei from medial to lateral on each side of the cerebellum. The cerebellum also can be divided into three bilateral longitudinal regions in association with these nuclei.<sup>1,2</sup> The medial zone, containing the vermis and the fastigial nucleus, primarily regulates the tone, posture, and equilibrium of the body in general. The intermediate zones contain the interpositional nucleus and cortex adjacent to the vermis and adjust the orientation of limbs in space, maintaining balance, posture, and muscle tone during complex movements. The lateral zones, consisting of the lateral nuclei and lateral portions of the cerebral hemispheres, have a similar function but do not influence posture or muscle tone directly.<sup>2</sup>

The cerebellum arises from the alar plate region of the metencephalon and originates initially as a proliferation of

**FIGURE 12-35** Photomicrograph of a normal cerebellum. M, Molecular layer; P, Purkinje layer; G, granular layer; Md, medulla; arrowhead, a Purkinje neuron. (Hematoxylin-eosin stain;  $\times 55$ .) (Courtesy the Washington Animal Disease Diagnostic Laboratory, Pullman, WA.)

cells in the rhombic lip that extend dorsally and medially to form the dorsal portion of the metencephalon. Germinal cells proliferating in the rhombic lip eventually migrate into the cerebellum and differentiate to form the specialized neurons of the cerebellar cortex. The cerebellar cortex has three layers: (1) the outer molecular layer, (2) the middle Purkinje layer, and (3) the inner granular layer (Figure 12-35). The molecular layer is acellular and consists primarily of the dendritic zones of the Purkinje cells and axons of the granular cells.<sup>1</sup> The Purkinje layer is only one cell thick and consists of Purkinje neurons. The granular layer is densely cellular with granular neurons. All layers must be present and aligned in proper orientation for normal function.

Organization of the specialized structure of the cerebellar cortex allows integration and coordination of movement. The cerebellum primarily provides regulation of skeletal movement, allowing coordinated movement; it does not initiate muscular activity. Afferent information regarding movement and balance arising from the mesencephalon, the brainstem, and the spinal cord enters the cerebellum via the cerebellar peduncles, and regulation of movement is coordinated by the inhibitory influence of Purkinje neurons on the cerebellar nuclei. Information enters the cerebellum via the cerebellar peduncles and is carried on two major afferent nerves termed *mossy fibers*

and *climbing fibers*.<sup>1</sup> Mossy fibers originate from the brainstem and spinal cord. Mossy fibers send collateral fibers to synapse with the cerebellar nuclei; they terminate by synapsing with granule neurons in the cerebellar cortex. These fibers are facilitatory at these synapses. The axons that granule neurons send to the molecular layer course transversely through this layer to synapse with the dendritic zone of multiple Purkinje cells and also provide facilitatory influence at these synapses. Climbing fibers originate in the olivary nucleus, which provides most of the extrapyramidal projections to the cerebellum. Similar to mossy fibers, climbing fibers send collaterals to synapse on neurons in the cerebellar nuclei; however, the axon continues through the cerebellar cortex to synapse with the dendritic zone of the Purkinje neurons in the molecular layer. As with mossy fibers, climbing fibers provide a facilitative influence at the synapses.

Purkinje neurons provide the sole efferent fibers from the cerebellar cortex. The majority of Purkinje cell axons terminate on neurons in the cerebellar nuclei, although direct projections from these neurons to the vestibular nuclei occur via the caudal cerebellar peduncle. Purkinje neurons are inhibitory and use the neurotransmitter GABA.<sup>1</sup> Efferent nerves from the cerebellum are primarily from the cerebellar nuclei that facilitate activity of upper motor neurons originating in the brainstem.

Thus much of the influence of the cerebellum on skeletal muscle activity is to modulate the upper motor neuron. Information regarding movement and balance enters the cerebellar cortex via the cerebellar peduncles. This afferent activity stimulates inhibitory Purkinje neurons by climbing or mossy fibers. Purkinje neurons in turn modulate the activity of the cerebellar nuclei to regulate movement and muscular tone. Purkinje neurons also provide direct inhibitory input to the vestibular nuclei.

## CLINICAL SIGNS

Clinical signs associated with cerebellar disease generally reflect the loss of coordination. Mentation is normal in horses with cerebellar disease, provided that other regions of the brain are unaffected and metabolic disturbances such as septicemia or endotoxemia are not present. Cerebellar disturbances result in ataxia and inability to regulate the rate, range, and force of movement.<sup>1</sup> *Dysmetria* refers to alterations in the range of gait. *Hypermetria* is an exaggerated range of movement. When moving, the limb has a higher or longer flight compared with normal. *Hypometria* is a diminished movement; for example, the arc of flight of a limb in motion may be lower. Horses showing hypometria tend to hit objects with the limb when stepping over them and may fail to extend the limb far enough to set the foot down on a step. Initiation of movement may be jerky and awkward, and the trunk may sway from side to side when the horse moves. Spasticity is caused by hypertonia and results in a jerky stiff gait. Paresis is not a feature of cerebellar disease because the cerebellum does not initiate voluntary motion, although a horse that is unable to regulate rate and range of motion sometimes may appear weak and drag its toes. Diffuse cerebellar disease results in bilateral signs. In general, unilateral lesions result in signs ipsilateral to the lesion.

Intention tremor is another prominent sign of diffuse severe cerebellar disease. Tremor is most obvious as vertical or horizontal head motions and can be observed readily as a horse approaches feed or attempts to nurse. The tremor is

present only when a movement is initiated and tends to become more exaggerated as the horse approaches an object.

Cerebellar disease also may cause loss of the blink reflex and vestibular abnormalities. The horse may fail to blink in response to an ocular menace. The exact mechanism for this deficiency is unknown; however, a portion of the visual pathway from the visual cortex to the facial nucleus (which initiates the blink) likely travels through the cerebellum. Disruption of the flocculonodular lobe, located in the ventral cerebellum, or the fastigial nucleus may result in vestibular signs characterized by disequilibrium; a variable nystagmus, which may be positional; and positioning difficulties.<sup>1</sup> Unilateral lesions may result in a head and body tilt toward the side of the lesion and nystagmus with the fast phase away from the lesion. Paradoxical vestibular syndrome, characterized by a head tilt away from the lesion and nystagmus with the fast phase toward the lesion, is apparent with unilateral lesions involving the cerebellar peduncle.<sup>1,2</sup>

## ☞ DISEASES OF THE CEREBELLUM

### CEREBELLAR ABIOTROPHY AND DEGENERATION

Cerebellar abiotrophy is the most commonly reported cerebellar disease in horses.<sup>3-10</sup> *Abiotrophy in the nervous system* refers to premature degeneration of neurons caused by some intrinsic abnormality in their structure or metabolism.<sup>11</sup> Cerebellar abiotrophy has been reported in Arabian, Gotland pony, and Oldenburg horse breeds. Degenerative cerebellar lesions have been observed in one Thoroughbred and two Paso Fino newborn foals.<sup>12</sup> Arabian and part-Arabian horses in North America are affected most frequently and the disorder is believed to be inherited as an autosomal recessive trait in this breed.<sup>3-6,8-10</sup> The incidence in some Arabian horse herds has been reported to be as high as 8%. In one report, colts were affected more frequently than fillies, although subsequent reports have not substantiated this finding.<sup>5</sup> The cerebellar abiotrophy that occurs in Oldenburg horses is progressive and fatal, with atypical histologic lesions compared with the syndrome that occurs in Arabian foals, in which the degeneration is characterized by apoptosis of Purkinje cells.<sup>13</sup> Cerebellar abiotrophy generally affects foals less than 1 year of age and occurs most frequently in 1- to 6-month-old foals. Adult-onset cerebellar abiotrophy has been reported in other species such as the dog and has been observed in two horses.<sup>1</sup> Many foals are born with no abnormalities and later develop disease; however, occasionally they are affected at or shortly after birth.<sup>5,6,9</sup>

Clinical signs associated with cerebellar abiotrophy include intention tremors of the head, ataxia, wide-based stance and gait, dysmetria, and spasticity.<sup>3-10</sup> The most frequently reported initial signs noted by owners are an intention tremor of the head, vertical or horizontal, or a hypermetric forelimb gait.<sup>3,9</sup> The neurologic examination reveals no change in mentation. One almost never observes nystagmus, which has been reported in only one case of abiotrophy in a Gotland pony.<sup>7</sup> A menace reflex frequently is absent or diminished.<sup>6,9</sup> One must interpret this finding with caution because normal foals may lack or have a depressed menace reflex until at least 2 weeks of age.<sup>14</sup>

Stance and gait abnormalities seen with cerebellar abiotrophy generally consist of a wide-based stance or gait and

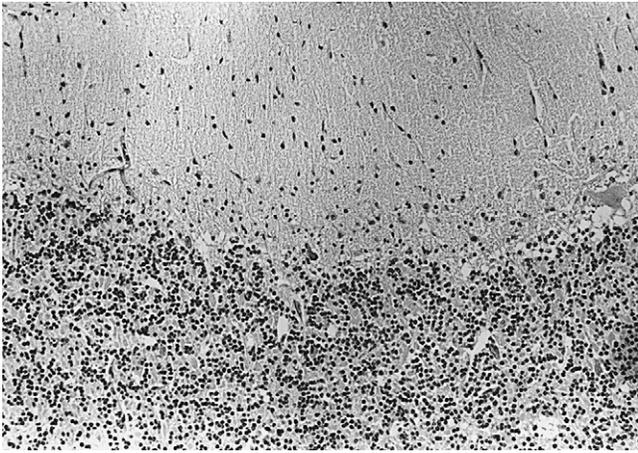

ataxia.<sup>6,8,9</sup> The foal may move stiffly and have a high goose-stepping gait. The horse may protract the limb when walking, resulting in slamming of the foot to the ground. Movement may be spastic with circumduction. Walking on an incline, asking the foal to step over obstacles, and blindfolding the foal exacerbate gait abnormalities. Generally, gait abnormalities are symmetric, although in a Welsh Cob and Arabian cross foal the initial signs were characterized by a stiff motion in the left front limb. Signs in this foal progressed to severe ataxia.<sup>4</sup> Foals affected at birth may have difficulty rising.<sup>5-7</sup> Despite this finding, weakness is not a feature of the clinical signs associated with cerebellar abiotrophy. Spinal reflexes are usually normal. Some affected animals fall when startled or when raising their heads. Signs are generally progressive for several months after diagnosis. Once the animal has reached maturity, the condition becomes static, although mild improvement has been observed.<sup>10</sup>

Ancillary testing is of limited value in diagnosing cerebellar abiotrophy but can be helpful to rule out other causes of ataxia. The CBC and serum biochemistry profile are normal in affected foals. Abnormalities in CSF are detectable. In one study, three of four foals had an elevated CSF CK activity. Values in affected foals ranged between 6.6 to 62 IU/ $\mu$ l (normal range, 0 to 8 IU/ $\mu$ l).<sup>9</sup> CSF CK elevations generally are associated with neural necrosis or degeneration, although they are not associated specifically with a particular disease.<sup>15-17</sup>

In addition, CSF total protein may be elevated. In the study cited previously, three foals had elevated total protein with an average of 226 mg/dl (normal, 0 to 100 mg/dl) in all foals with cerebellar abiotrophy. As with CK, total protein elevations are not specific for abiotrophy and may occur with disruption of the blood-brain barrier or with CNS inflammation or degeneration. Many foals with cerebellar abiotrophy have normal CSF analysis. Electroencephalographic abnormalities, including increased synchrony and increased number of abrupt frequency changes, also may be detectable in affected foals.<sup>9</sup> In this study, these abnormalities were not observed in normal foals anesthetized under similar conditions. Skull and cervical radiographs are unremarkable. However, because mentation is normal in foals with cerebellar abiotrophy, electroencephalographic examination is not necessary to make a diagnosis and is primarily useful to exclude seizure disorders as a cause of the tremors observed.

Antemortem diagnosis of cerebellar abiotrophy is based on a typical history and the clinical signs of intention tremor, lack of menace, failure to blink to bright light, and ataxia in Arabian, part-Arabian, or Gotland pony foals. The differential diagnoses for cerebellar abiotrophy include cranial malformations; congenital spinal malformations, including atlanto-axial malformations and stenotic myelopathy; inflammation or infection of the cerebellum; and trauma. One can rule out these conditions based on the neurologic examination, CSF analysis, and radiography. The signs of characteristic ataxia and head tremor without weakness in the appropriate breed is nearly pathognomonic.

Postmortem examination provides a definitive diagnosis of this disorder. Generally, no gross abnormalities are notable; however, careful examination of the cerebellum may reveal an increased lobular pattern with prominent folia. In the Gotland pony, the weight ratio of the cerebellum to the cerebrum is reduced significantly in foals with cerebellar abiotrophy.<sup>7</sup> Normal foals had a 13% ratio, and affected foals had a 10% ratio. In the degenerative cerebellar condition in the Paso Fino

**FIGURE 12-36** Photomicrograph of the cerebellum from a 9-month-old foal with cerebellar abiotrophy. The decreased number of Purkinje neurons is notable. (Hematoxylin-eosin stain;  $\times 139$ .) (Courtesy the Washington Animal Disease Diagnostic Laboratory, Pullman, WA.)

and Thoroughbred foals, a decrease in the cerebellar-to-whole brain weight ratio was evident.<sup>12</sup> This ratio in normal foals was 8% and in affected foals was 6%.

Histologic abnormalities are consistent in cases of cerebellar abiotrophy. The most prominent finding is the widespread loss of Purkinje neurons<sup>3-10</sup> (Figure 12-36). Degenerative changes, such as shrunken and angular neurons with hyperchromasia and dispersion of Nissl's substance, are apparent. One may observe occasional "baskets" or clear spaces where the Purkinje neuron is lost. Thinning of the molecular layer occurs with gliosis. The granular layer is also thin with a loss of cellularity. Similar histologic findings were found in Thoroughbred and Paso Fino foals with vacuolation and proliferation of Bergmann's glia in the Purkinje cell layer.<sup>12</sup>

The pathogenesis of cerebellar abiotrophy is unknown. Viral, toxic, and genetic causes have been investigated.<sup>3,5,6,9</sup> To date no evidence has been found to support an infectious cause. No virus has been isolated from the CSF or brain of affected foals, and no viral inclusions have been observed on histologic examination. No toxin has been associated consistently with cerebellar abiotrophy of Arabian foals. Experimental breedings of Arabian horses indicate an autosomal recessive mode of inheritance but an exact genetic basis for disease has not been determined. A pedigree analysis of Gotland ponies similarly suggests an autosomal recessive mode of inheritance<sup>7</sup>; however, a high degree of inbreeding was noted, making definitive conclusions difficult. Attempts to breed affected individuals in this study were unsuccessful.

No treatment exists for cerebellar abiotrophy. As noted previously, signs may be progressive until the foal reaches maturity. Signs may stabilize or improve slightly with time.

## GOMEN DISEASE

Gomen disease is a degenerative cerebellar condition recognized in the northwest part of New Caledonia.<sup>18</sup> Gomen disease is a progressive cerebellar disease that causes mild to severe ataxia. Horses that are indigenous or are introduced to the region may be affected. The disease occurs only in horses

that are allowed to roam free, and signs may take 1 to 2 years to develop once a horse is introduced into an endemic area. Horses that are confined generally are unaffected. Clinical signs consist of ataxia, which is most prominent in the hindlimbs; toe dragging; and a wide-based stance. As the disease progresses, weakness becomes prominent and horses may have difficulty rising. The signs are primarily referable to involvement of the cerebellum; however, weakness likely is caused by brainstem or spinal cord involvement. Nystagmus is not observed. Ataxia is progressive over 3 to 4 years until the horse dies or is euthanized.

Mild cerebellar atrophy may be apparent on gross examination of the brain. Histologically, severe depletion of Purkinje neurons is evident throughout the cerebellum.<sup>19</sup> Purkinje neurons may contain lipofuscin pigment and vacuoles. One horse examined had moderate loss of granule cells. Moderate to severe lipofuscin pigmentation of neuron cell bodies occurs throughout the brain and spinal cord. Although lipofuscin accumulation may be considered a normal variation of aging, the degree of pigment accumulation is far more severe than that in horses of similar age.

The pathogenesis of this disease is unknown. Pedigree analysis has not revealed any genetic component for susceptibility to development of disease.<sup>18</sup> A condition of neuronal lipofuscinosis in dogs has some similarities to this disease.<sup>19</sup> The accumulation of lipofuscin pigment and association with free-ranging horses suggests a metabolic disorder, perhaps resulting from toxicity.<sup>18,19</sup>

## DEVELOPMENTAL ABNORMALITIES

Dandy-Walker syndrome is characterized by a midline defect of the cerebellum and cystic dilation of the fourth ventricle, which separates the cerebral hemispheres.<sup>20</sup> Frequently, all or portions of the cerebellar vermis fail to form, and the corpus callosum may be absent. The condition is rare in horses and has been observed in Thoroughbred and Arabian foals.<sup>21,22</sup> Foals with this syndrome may be abnormal neurologically from birth, with difficulty rising, seizures, and absence of the suckle reflex.<sup>21</sup> The forehead may be domed excessively. Ataxia, nystagmus, aggression, and difficulty in training may persist as the foal ages.<sup>21,22</sup> Diagnosis generally is made at post-mortem examination; however, one case was diagnosed ante-mortem using computed tomography.<sup>21</sup>

Several individual cases of equine developmental cerebellar abnormalities have been described. Cerebellar hypoplasia has been described in a Thoroughbred foal that had difficulty rising and developed seizures shortly after birth.<sup>23</sup> This report did not describe the histologic findings of cerebellar hypoplasia in detail; thus the relationship between this finding and cerebellar abiotrophy or degeneration in Arabian foals is unknown. Bilateral focal cerebellar cortical hypoplasia has been reported in a 6-year-old Thoroughbred gelding.<sup>24</sup> No gait abnormalities were detected in this horse, although it had fallen over repeatedly before euthanasia. The relationship between falling and the cerebellar abnormality is unclear. Possibly the abnormality in this adult horse resulted from a secondary problem, such as vascular injury, rather than a developmental defect.<sup>13</sup>

A single case of cerebellar dysplasia has been described in a 4-year-old Thoroughbred horse.<sup>25</sup> This horse had a 7-month history of circling and collapsing to the left side. In this case the horse had hyperplasia of the right side of the cerebellum with no associated central white matter. Histologically, the

granule layer was thinning, with increased thickness of the molecular layer and cavitation of the white matter.

Additional reported developmental disorders include cerebellar hypoplasia with internal hydrocephalus and cerebellar aplasia with hydranencephaly in two fetuses from Haflinger mares with hydrops allantois.<sup>26</sup> Mild cerebellar degenerative changes consisting of Purkinje neuron granularity has been noted in a Standardbred filly with a chromosomal abnormality.<sup>27</sup> This abnormality was accompanied by mild spongiotic degeneration of the cerebrum. Abnormal neurologic signs in this filly included difficulty standing at birth, mental dullness, and a head tilt. Growth retardation, small inactive ovaries, and a consistently wrinkled muzzle accompanied these signs.

## INFECTIOUS CONDITIONS

Unlike in many other large animals, no infectious agents have the cerebellum as their primary target; however, a number of agents may affect the cerebellum. Any agent that targets the CNS, especially those that have a multifocal distribution, also may involve the cerebellum.

Equine protozoal myelitis is a protozoal disease caused by *Sarcocystis neurona*. This agent causes multifocal inflammation and necrosis of the CNS. The most common signs associated with *S. neurona* infection are spinal ataxia, weakness, and muscle atrophy, although this agent also can affect the cerebellum. Clinical signs associated with cerebellar involvement may reflect diffuse or focal involvement. A head tilt or asymmetrical ataxia without weakness or lower motor neuron signs may be associated with focal disease. Diagnosis is based on multifocal neurologic disease and the presence of antibody to *S. neurona* in the CSF. Additional information regarding this disease is found elsewhere in this chapter.

EHV-1 causes multifocal meningoencephalitis resulting from vasculitis, vascular thrombosis, and ischemia of nervous tissue. Although the primary signs associated with this agent include spinal ataxia, cranial nerve abnormalities, and signs associated with involvement of the cauda equina, this agent also may affect the cerebellum. As with equine protozoal myelitis, involvement may be focal, multifocal, or diffuse.

Occasionally, disseminated *Streptococcus equi* subsp. *equi* infection (bastard strangles) may result in a cerebellar abscess.<sup>28</sup> Neurologic abnormalities in one reported case included proprioceptive deficits in the right forelimb, nystagmus, and a head tilt. Meningitis contributed to other CNS signs such as depression, blindness, and recumbency. Diagnosis of this condition can be based on a history of previous *S. equi* subsp. *equi* infection, evidence of severe suppurative inflammation in the CSF, and culture of *S. equi* subsp. *equi* from the CSF. Treatment consists of penicillin. The prognosis is guarded; however, successful surgical drainage of a cerebellar *S. equi* subsp. *equi* abscess has been reported.<sup>29</sup>

Focal involvement of the cerebellum has been associated with aberrant parasite migration in the horse.<sup>4,30</sup> In a 6-year-old pony, infection with *Halicephalobus deletrix* resulted in severe ataxia.<sup>30</sup> Histologic study showed lesions scattered throughout the cerebellum, brainstem, thalamus, and pituitary gland, and nematodes were observed throughout the lesions. A second case involving a 1-year-old Thoroughbred colt had a sudden onset of severe ataxia.<sup>4</sup> Multifocal malacia with numerous eosinophils was observed throughout the cerebellar white matter. No nematode was detected, although

parasitic involvement was suspected based on the eosinophilic inflammation.

## MISCELLANEOUS CONDITIONS

A familial neurologic condition in newborn Thoroughbred foals has been reported.<sup>31</sup> This syndrome affected three of five foals of a Thoroughbred mare. The foals were normal at birth and developed signs of severe incoordination, a wide-based stance, and recumbency at 2 to 5 days of age. The condition appeared more severe when the foals became excited or struggled; consequently, they were treated symptomatically with diazepam. The signs would improve with this treatment and return as the sedation diminished. These foals improved with stall rest over 7 to 10 days. The cause of the clinical signs in these foals is unknown; however, the authors suggested possible viral or toxic causes.

Cerebellar ataxia in two Thoroughbred fillies has been associated with hematoma in the fourth ventricle.<sup>32</sup> These two horses demonstrated fever, dysmetria, spasticity, and weakness. Clinical signs most likely resulted from compression of the adjacent cerebellum. CSF analyses in these cases revealed xanthochromia, elevated RBC and white blood cell counts, and elevated total protein concentrations. The cause of the hematomas was not identified; damage to regional small vessels and a vascular anomaly were suspected.

Chronic methylmercurial poisoning in horses can cause a number of clinical abnormalities, including cerebellar ataxia.<sup>33</sup> Severe poisoning can result in incoordination, dysmetria, and gross head nodding in the experimental setting. Associated clinical signs include lethargy, anorexia, exudative dermatitis, and laminitis. Lesions in the cerebellum consisted of focal atrophy and cellular depletion in the granular layer with little to no involvement of Purkinje cells. Additional abnormalities included neuronal necrosis and gliosis in the cerebrum, lymphocytic perivascular cuffing, and swollen axons in the spinal cord. Preferential accumulation of inorganic mercury in the brain and resulting cell injury most likely led to the neurologic signs observed. Diagnosis of methylmercurial poisoning can be based on clinical signs and measurement of mercury in the liver and kidney (see Chapter 22).

## CERVICAL VERTEBRAL MALFORMATION

Caroline N. Hahn\*

Cervical vertebral malformation (CVM) is the most common cause of ataxia in horses in Europe and Australia and is an important differential diagnosis in regions affected by inflammatory diseases such as EPM and WNV. Differentiating CVM from other conditions that cause ataxia is important because some horses with vertebral malformation may be amenable to surgery.<sup>1</sup>

CVM resulting in spinal cord compression stems from bone and joint malformations and is seen as two broad categories. Younger lightbreed and warmblood horses and

\*The authors wish to acknowledge Randolph H. Stewart and Bonnie R. Rush, whose original work has been incorporated into this section.

foals are predisposed to deformation of the vertebral bodies with malarticulation on flexion secondary to developmental bone disease (type 1 CVM). In older horses, spinal cord compression more commonly occurs secondary to vertebral malformation because of osteoarthritis of caudal cervical articular process joints (type 2 CVM),<sup>2</sup> although there is some overlap in this classification. Spinal cord compression has traditionally been separated into two further categories: (1) dynamic vertebral compressions, whereby the spinal cord compression is intermittent and occurs when the cervical vertebrae are flexed (more cranial vertebral) or extended (more caudal vertebrae), and (2) static compressions, in which spinal cord compression is continuous regardless of cervical position. Both syndromes are likely to occur in individual cases, and differentiating the two is probably not clinically important other than to remind clinicians of the risks associated with extreme neck manipulation under myelography.

## 🌀 CLINICAL SIGNS

Cervical vertebral malformation is characterized by symmetrical ataxia, upper motor neuron paresis, and dysmetria, which are usually worse in the pelvic limbs than thoracic limbs.<sup>3</sup> Physical examination sometimes reveals palpable cranial cervical vertebral flexion-fixation, and affected horses tend to be large for their age and breed. Male animals appear to be more frequently affected. Often a history of increased clumsiness occurs, and mild to moderately affected horses show symmetrical ataxia with circumduction of the pelvic limbs, especially when the animal is made to walk in small circles. Proprioceptive deficits, toe dragging (flexor paresis), and varying degrees of upper motor neuron extensor paresis (assessed by pulling on the horse's tail at a walk) are also present. Thoracic limbs often have a hypometric, stiff (spastic) component to the strides, especially while walking the horse down a slope and with the head elevated. Thoracic limb deficits are usually less severe than pelvic limb deficits because of the more superficial location of pelvic limb spinocerebellar proprioceptive tracts in the spinal cord. Horses with chronic disease tend to show less paresis than those with recent onset clinical signs.<sup>4</sup> Neck pain or stiffness may be present in some older horses. An accident or injury to the neck is sometimes in the history, and clinical signs may have an abrupt onset or indeed the horse may be tetraplegic, especially if external trauma plays a major role. The ataxia, however, was likely present before the traumatic incident.

Clinical signs of concurrent developmental orthopedic disease of the appendicular skeleton, such as physal enlargement of the long bones, joint effusion after osteochondrosis, and flexural limb deformities, are often present in young horses with CVM.<sup>3</sup> It is worth remembering that sometimes horses affected with CVM may have another concurrent neurologic disease such as equine protozoal encephalomyelitis.

## 🌀 PATHOGENESIS

Neurologic signs result from progressive spinal cord compression secondary to structural changes to vertebral and surrounding tissues. Pathologic changes of the cervical vertebrae leading to spinal cord compression consist of vertebral malformation

with stenosis of the vertebral canal, abnormal formation of, and alterations to, the articular processes associated with osteochondrosis, angular deformity of vertebrae and cranioventral or, more commonly, caudal extension of the dorsal aspect of the vertebral arch (Figure 12-37).<sup>3,4</sup> Histopathologic examination of the spinal cord reveals wallerian-like degeneration, loss of axons and fibrosis at the sites of spinal cord compression, and axon loss in the ascending and descending white matter tracts within adjacent segments of the spinal cord cranial and caudal to the site of spinal cord compression.<sup>3,5</sup>

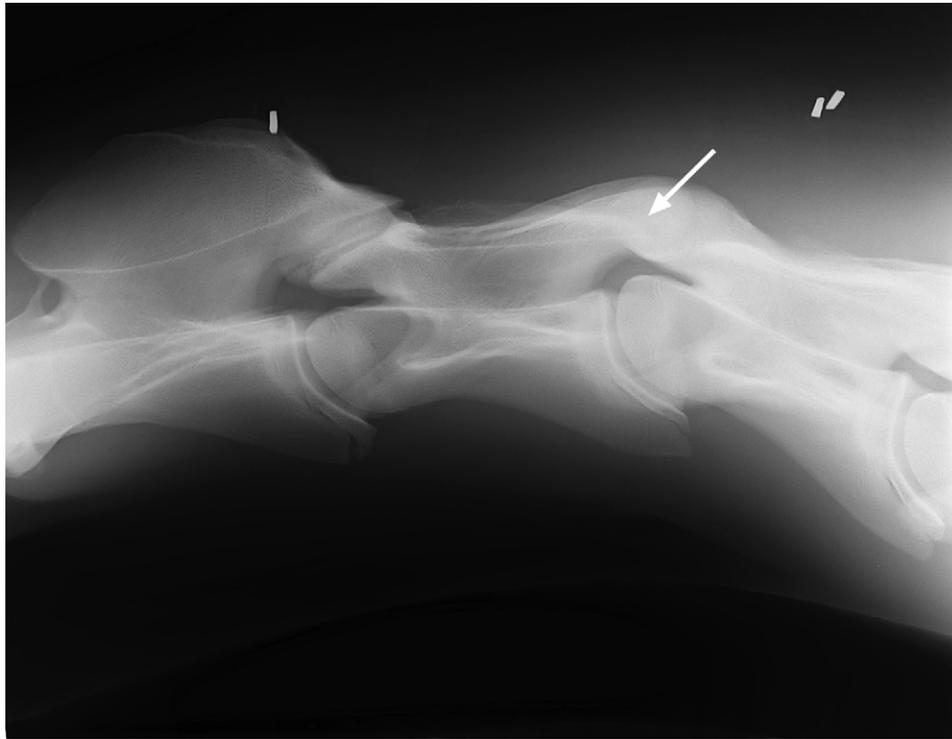

Type 1 CVM is a disease seen in young horses and may be a form of a developmental orthopedic disease (i.e., related to rapid skeletal growth in genetically predisposed horses). Cervical vertebrae in affected horses have lesions of osteochondrosis and epiphysitis similar to those seen in the limbs, found most commonly in more cranial cervical vertebrae, particularly C3, C4, and C5. A high dietary energy intake is almost certainly necessary for expression of the disease and trauma to the neck probably plays a role as young, large, fast-growing animals (often male animals) are most commonly affected. Type 1 CVM almost certainly has a genetic basis; however, a breeding trial using horses with CVM that had had corrective surgery resulted in offspring that did not have CVM but did have a higher frequency of developmental orthopedic diseases than expected.<sup>6</sup>

Type 2 CVM more commonly occurs in older horses without evidence of developmental orthopedic disease but with arthritis of the caudal (C6-T1) cervical vertebrae. External injury is likely to play a part in the onset of the disease. Compression of the spinal cord is due to vertebral malformation at C5, C6, and C7, resulting in cone-shaped caudal cervical vertebrae with a reduction in a cross-sectional area of the vertebral canal and resultant impingement on the spinal cord by proliferating articular and periarticular soft tissues. There may be concurrent formation of epidural and periarticular cysts, which can result in sudden onset of symmetrical or asymmetrical signs without a contemporaneous episode of external injury. Bleeding into one of these cysts has been observed and adds to the compression. Occasionally these cause acute onset severe clinical signs that can abate within a few hours only to reappear later.

## 🌀 DIAGNOSIS

Fortuitously, the narrowing of the cervical vertebral canal and associated spinal cord compressive lesions in horses are most commonly in a dorsoventral in orientation, allowing the diagnosis to be made with good-quality, standing plain lateral radiographs of C1 to T1 vertebrae. However, it should be remembered that the lack of dorsoventral radiographic projections effectively makes this an incomplete diagnostic series. The horse should be sedated and the head pulled forward manually, thus straightening each vertebra along the median plain giving the best alignment of vertebral bodies. The assessment of qualitative features of vertebral malformation, including physisitis of the caudal vertebral body, caudal extension of the dorsal arch of the vertebral body, intervertebral malalignment, and arthropathy of the articular processes, is useful; however, alone these findings offer poor positive and negative predictive values.<sup>7</sup>

The most important factor in the diagnosis of CVM in adult horses and foals is the identification of a decrease in the diameter of the vertebral canal, be it within a vertebra or, more commonly, between two vertebrae.<sup>8</sup> Corrected intravertebral and particularly intervertebral sagittal ratios (SRs) from C2-C7

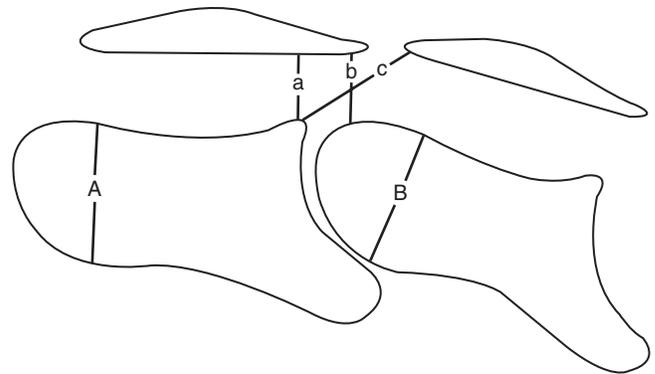

**FIGURE 12-37** Cervical vertebrae 2, 3, and 4 of a horse with cervical vertebral malformation (CVM) showing stenosis of the vertebral canal subjectively obvious at C3-4, intervertebral malalignment of C3 and C4, and caudal extension of the dorsal aspect of the vertebral arch of C3 (arrow).

calculated from lateral standing cervical radiographs can be used to accurately diagnose CVM in horses.<sup>9</sup> The intra- and intervertebral sagittal diameter of the vertebral canal are measured at the narrowest points and corrected for radiographic magnification and size of horse by being expressed as a ratio of the maximal height of the cranial vertebral physis (Figure 12-38). The minimum intravertebral diameter is measured at the point along the vertebral canal where the diameter is at a minimum, whereas the minimum intervertebral sagittal diameter is made from the caudal aspect of the dorsal lamina of the vertebral arch of the more cranial vertebra to the dorsocranial aspect of the body of the more caudal vertebra, or from the caudal vertebral body of the more cranial vertebra to the cranial dorsal lamina of the vertebral arch of the more caudal vertebra, whichever was smaller. For vertebrae C2-C3 to C5-C6, the minimum diameter is invariably found to be the former measurement (see Figure 12-38).

Reference figures for intra- and intervertebral SR in a limited number of horses are shown in Tables 12-11 and 12-12. A specific site can be considered very likely to be compressed if it is more than two standard deviations smaller than the reference values. As a general rule of thumb, horses with signs of cervical spinal cord disease that have SR values at any inter- or intravertebral site that are less than 50% of reference values have a greatly increased risk of having cervical vertebral canal stenosis.

In horses with type II CVM, spinal cord compression is most often the result of coning of affected caudal cervical vertebrae. The measurements can be difficult to perform on caudal cervical vertebrae, particularly if the radiographs in large horses are underexposed. In addition, these horses have enlarged and remodeled intervertebral joints of the caudal cervical vertebrae. Many horses without neurologic signs have

**FIGURE 12-38** Two cervical vertebra showing sites for measuring the intra- and intervertebral sagittal diameter and the width of the vertebral body (A) (B). For a particular vertebra, the minimum intravertebral diameter could be anywhere along the vertebral canal (a), and the minimum intervertebral sagittal diameter is the smallest of the two measurements (b) or (c) compared with the diameter of the more caudal vertebral diameter (B).

degrees of cervical vertebral osteoarthritis and considerable arthritic enlargement of articular processes that can occur well lateral and dorsal to the vertebral canal with no spinal cord compression.<sup>4</sup> Cervical scintigraphic examinations similarly cannot determine if active arthritis is actually causing spinal cord compression. Spinal magnetic motor evoked responses<sup>10-14</sup> may be used more in the future to objectively grade the degree of electric conductivity across a spinal lesion site.

Before deciding on surgical decompression or vertebral fusion, positive contrast myelographic evidence of spinal

Summary Data for Sagittal Diameter Ratio by Vertebral Site in Eight Horses with Cervical Vertebral Malformation											
Site	INTRAVERTEBRAL						INTERVERTEBRAL				
	C2	C3	C4	C5	C6	C7	C2-3	C3-4	C4-5	C5-6	C6-7
Mean	6.3	4.8	4.8	4.9	4.8	4.8	7.0	5.5	5.7	5.8	5.9
Standard Deviation	1.19	0.33	0.37	0.26	0.44	0.17	1.93	1.28	0.59	1.14	0.68

cord compression is mandatory. It should be remembered, however, that myelography under general anesthesia is not an innocuous procedure in the horse.<sup>15,16</sup> Myelography has traditionally been considered the gold standard antemortem diagnostic test; however, sagittal diameter ratio analysis may be more sensitive and specific than myelography, at least if the 50% or 2-mm reduction of the dorsal contrast medium myelographic rules are used.<sup>17</sup> Myelography can result in acceptable sensitivity and specificity for detecting sites of compression by using a 20% reduction of the total dural diameter reduction on a neutral myelographic view for the midcervical sites, and a 20% reduction of the same measurement at C6-7 with the neck in either neutral or flexed position.<sup>18</sup> In some horses with CVM, particularly those with caudal cervical arthropathy, spinal cord compression may occasionally occur in a lateral or transverse plane with no dorsoventral compression. In these cases, more subjective assessments, such as observing a blanching of the contrast column or split dorsal margins, may be the only myelographic abnormalities.

## TREATMENT

Stall rest, glucocorticoids, DMSO, and other anti-inflammatory drugs may provide transient improvement in clinical signs in horses with CVM, especially if acute exacerbation of disease secondary to trauma is seen. However, continued compression of the spinal cord is inevitable, and clinical signs will persist. In a controlled field study, in which growing foals with CVM were fed a diet restricted in protein and energy (65% to 75% of National Research Council recommendations), clinical signs and radiographic lesions resolved in some foals and significantly improved in others.<sup>19</sup> For most horses for which surgical treatment is not an option or with multiple intervertebral site involvement and severe, chronic clinical signs, the prognosis is poor to grave and humane destruction is advised.

Young patients with mild clinical signs of short duration and with only one site of cervical spinal cord compression have a good prognosis for return to athletic function with surgery. No controlled trials have been performed; however, it is estimated that more than 60% of such horses return to athletic function.<sup>20-23</sup> Ventral intervertebral fusion using a stainless steel fenestrated basket or threaded cylinder can allow expansion of the vertebral canal, atrophy of articular enlargements, and resolution of some or all the clinical signs in selected cases.<sup>24</sup> This procedure has been most successful in horses with acute clinical signs resulting from spinal cord compression at only one intervertebral site between C2 and C6 and in horses with absolute stenosis and enlarged articular processes of the caudal cervical vertebrae. Horses with persistent neck pain associated with cervical osteoarthritis but no evidence of fractures to the bodies of the vertebrae are also well suited to cervical intervertebral fusion surgery.

## EQUINE DEGENERATIVE MYELOENCEPHALOPATHY

Yvette S. Nout\*

Equine degenerative myeloencephalopathy (EDM) is a non-compressive, diffuse, symmetrical, degenerative neurologic disease characterized by ataxia, weakness, and spasticity (hypometria) in young horses of many breeds and both genders. Mayhew first described the disease in 1976, and it has been subsequently diagnosed in many other breeds of horses.<sup>1-3</sup> In addition, identical syndromes have been observed in Mongolian wild horses (*Equus przewalskii*)<sup>4</sup> and Grant's zebras.<sup>5</sup> The

\*The authors wish to acknowledge Hilary K. Matthews, whose original work has been incorporated into this section.

pathogenesis of the disease is likely to be multifactorial. Currently it is thought that the combination of dietary vitamin E deficiency and genetic predisposition are the most important contributors to disease development.<sup>5-8</sup> A familial tendency to develop EDM has been suggested in the Arabian,<sup>2</sup> Thoroughbred,<sup>8</sup> and wild horses,<sup>4</sup> and it has been demonstrated in Morgans,<sup>6</sup> Appaloosas,<sup>9</sup> Standardbreds, and Paso Finos.<sup>8</sup> Although a familial occurrence is suggestive of a genetic cause, this is so far unproven.

Neuroaxonal dystrophies (NADs) are a group of neurodegenerative diseases described in human beings and animals that are characterized by the formation of dystrophic axons. NAD can be considered a specific form of EDM and is clinically indistinguishable from EDM.<sup>10</sup> The disease has been described in Morgan horses.<sup>6,11</sup> Histologic lesions in NAD are confined to the cuneate and gracilis nuclei of the caudal myeloencephalon; in horses with EDM, lesions are found throughout the spinal cord and brainstem.

Equine degenerative myelopathy was one of the most prevalent causes of spinal cord disease in horses in the United States during an approximate 15-year span after it was first recognized. Although no recent epidemiologic surveys exist, the prevalence of EDM appears to have declined since about 1990.<sup>12</sup> In Europe the disease has been reported only sporadically, and just one recent report describes a cluster of five horses on one farm that were diagnosed with EDM.<sup>13</sup>

## CLINICAL SIGNS

The age of onset of clinical signs varies between less than 1 month to several years, with most horses manifesting signs within the first year of life. However, in one study of 128 horses with EDM, age of onset ranged between 1 month to 20 years, with 16% of the horses showing signs at older than 28 months of age.<sup>6</sup>

Onset of signs may be abrupt but is usually insidious.<sup>2</sup> Signs are referable to upper motor neuron and general proprioceptive deficits and include symmetrical ataxia, weakness, and spasticity of all four limbs, often worse in the pelvic limbs.<sup>2,12</sup> Signs may begin in the pelvic limbs and progress to the thoracic limbs. Postural placing reactions may show conscious proprioceptive deficits. The gait is characterized by dysmetria and stabbing of the ground with the limbs. Horses may walk with a two-beat lateral gait, referred to as *padding*, as also sometimes seen in horses with any spinal cord disease.<sup>12</sup> Often, hindlimb interference and dragging or scuffing of the toes are present. When walking backward, the horse may resist or rock back on the pelvic limbs and dog sit. When circling, affected horses often pivot on the inside hindlimb and circumduct the outside limb. Affected horses may have trouble stopping, and it is not unusual for them to fall while running in the pasture or being worked. Cranial nerve involvement, muscle atrophy, or changes in skin sensation or tail tone are absent in EDM.<sup>2</sup> Lower motor neuron signs such as hyporeflexia over the neck and trunk with diminished-to-absent cervical, cervicofacial, cutaneous trunci, and laryngeal adductor reflexes may be found, especially in severe and long-standing cases.<sup>8,9</sup>

Neuroaxonal dystrophy in Morgan horses has similar clinical signs; however, even in very severely affected horses, only pelvic limb deficits may be seen. Pelvic limb dysmetria, asynchrony, and ataxia are generally less severe than in EDM.<sup>9</sup>

## PATHOLOGY

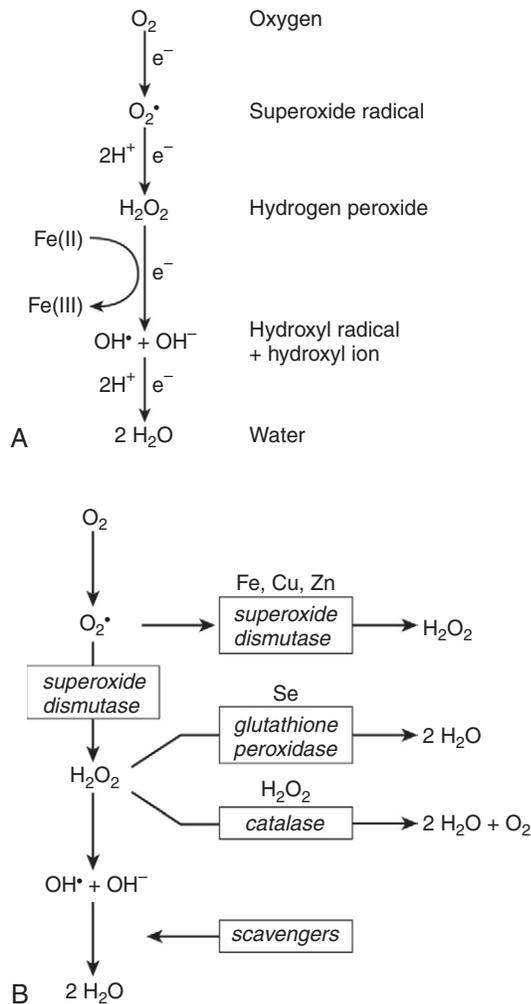

Gross necropsy findings in EDM are unremarkable.<sup>2,3</sup> Classic histologic changes are evident in the caudal brainstem nuclei (medulla oblongata) and especially the spinal cord and include diffuse neuronal fiber degeneration (dystrophy) of the white matter.<sup>2,3</sup> Generally, the lateral and medial cuneate nuclei, gracile nucleus, lateral cervical and thoracic nuclei, and lumbosacral and cervical intermediate gray columns are affected.<sup>2,3</sup> Astrocytosis, astrogliosis, vacuolization, myelin loss, spheroid formation (axonal swelling), and lipofuscin-like pigment accumulation are present in these areas.<sup>2,3</sup> With chronicity, the dorsal and ventral spinocerebellar tracts and the medial part of the ventral funiculi of the thoracic segments are more severely affected.<sup>2,3</sup> Neurochemical studies of the spinal cord show a significant loss of myelin and component lipids.<sup>3</sup> Demyelination occurs to a greater extent than axon loss.<sup>3</sup>

Histologic changes in NAD of Morgan horses lack the diffuse nature of the changes seen in EDM. In NAD, histologic changes may be confined to the accessory cuneate nuclei.<sup>6</sup>

## PATHOPHYSIOLOGY

The pathogenesis of EDM is unknown. However, it is most likely because of a complex interaction of many factors. Degenerative myelopathy in other species, which bears clinical and histopathologic similarities to EDM, has been linked to vitamin E and copper deficiencies, hereditary factors, and toxic insults.<sup>14</sup> Three risk factors associated with the development of EDM were identified in a study involving 56 affected and 179 control horses: (1) use of insecticides, (2) exposure to wood preservatives, and (3) spending frequent time on a dirt lot.<sup>15</sup> Spending time on green pastures was found to be a protective factor. Additionally, a foal was 25 times more likely to develop EDM if its dam had any other foals diagnosed with EDM.<sup>15</sup> These factors alone probably do not cause EDM but may interact with other factors to produce disease. In addition, these factors should be considered in preventing or minimizing the risk of developing EDM.

A hypothesis for the pathophysiology of EDM is exposure of genetically predisposed young foals to environmental oxidants and lack of antioxidants, including vitamin E. Oxidative stress is caused by the imbalance between production of prooxidants and the antioxidant defenses. ROS (e.g., superoxide anion, hydrogen peroxide, hydroxyl radical) are formed during the reduction of oxygen to water in normal cellular metabolism (Figure 12-39, A). Aerobic cells have antioxidant defense mechanisms that protect them from oxidative stress (Figure 12-39, B). The brain's high consumption of oxygen, high metabolic activity, and high concentration of polyunsaturated fatty acids, which can easily be oxidized to ROS, makes the CNS extremely vulnerable to oxidative attack by ROS.<sup>14,16,17</sup> Another source of ROS is through the metabolism of excitatory amino acids and neurotransmitters such as glutamate and aspartate. When present in excess, excitatory amino acids can trigger a series of events including an increase in intracellular calcium, which can lead to the production of free radicals and subsequent neuronal damage and death. Other sources of free radicals that arise from brain metabolism include cytochrome P-450 electron transport, monoamine oxidase activity, and endogenous guanidine compounds. Lipid peroxidation of cellular membranes and the direct oxidation of amino acids

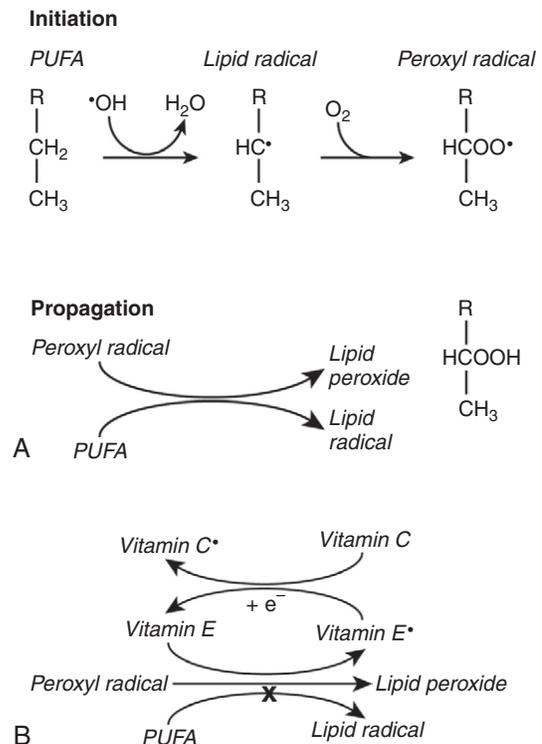

**FIGURE 12-39** **A**, Physiologic metabolism of molecular oxygen to water. **B**, The mechanisms of action of four antioxidant systems. Superoxide dismutase may act as a pro-oxidant by increasing the formation of hydrogen peroxide and as an antioxidant by decreasing the superoxide radical concentration. Co-factors for superoxide dismutase are iron, zinc, and copper. The co-factor for glutathione peroxidase is selenium.

leading to inactivation of enzymes, receptors, and structural proteins are the main consequences of oxidative injury (Figure 12-40, A). Increased evidence exists for a role of redox signaling by oxygen radicals that targets mitochondrial cytochrome *c* release, DNA repair enzymes, and transcriptional factor nuclear factor- $\kappa$ B. Neuronal damage occurs once these physiologic systems are disrupted.<sup>18</sup>

The main endogenous antioxidants are superoxide dismutase, catalase, glutathione peroxidase (that contains selenium),  $\alpha$ -tocopherol (vitamin E), and ascorbic acid (vitamin C) (see Figure 12-39, B; Figure 12-40, B).<sup>16,17</sup> Another protective mechanism is the existence of iron-binding proteins that keep iron in a less reactive form and prevent iron from catalyzing free radical reactions. Vitamin E reacts directly with OH<sup>•</sup> and prevents oxidant injury to polyunsaturated fatty acids and thiol-rich proteins in cellular membranes (see Figure 12-40, B).

Vitamin E deficiency has received much attention as a possible cause of EDM. This association is based on the similarities between EDM and vitamin E deficiency in human beings and

**FIGURE 12-40** **A**, Mechanism of peroxidation of polyunsaturated fatty acids in cell membranes. **B**, Antioxidant mechanisms of  $\alpha$ -tocopherol (vitamin E) and ascorbic acid (vitamin C). Polyunsaturated fatty acids are spared from oxidation because vitamin E is oxidized to a free radical instead. This prevents the propagation of lipid peroxidation in cell membranes and is referred to as the *chain-breaking action of vitamin E*. Vitamin C is a reducing agent that donates electrons to free radicals.

other animals, the reduced incidence of EDM seen after prophylactic treatment with vitamin E,<sup>8</sup> and the response to treatment with vitamin E in affected horses.<sup>9</sup> One study reported a high incidence of EDM on two breeding farms in which low serum vitamin E concentrations were found. Vitamin E supplementation decreased the incidence from 40% to less than 10%. However, affected and unaffected horses on both farms were found to be vitamin E deficient.<sup>8</sup> Another study found no significant differences in serum vitamin E and blood glutathione peroxidase concentrations between EDM affected horses and control horses.<sup>19</sup> A third study documented significantly lower vitamin E concentrations and clinical signs compatible with EDM in eight of nine foals sired by an EDM-affected stallion. Age-matched control foals raised in the same environment had normal serum vitamin E concentrations and no signs of EDM. Oral vitamin E absorption tests were performed on both groups, and no significant differences were found between the groups.<sup>20</sup> Thus an inability to absorb vitamin E from the gastrointestinal tract does not appear to be a factor in the low serum vitamin E concentrations in EDM-affected horses.<sup>20</sup> Two other trials involving three<sup>21</sup> and nine<sup>22</sup> horses, respectively, support a role for vitamin E in the pathogenesis of EDM. Three foals developed neurologic disease and had low serum vitamin E concentrations after being housed on a dry lot. Two were examined post mortem at 6 months of age and had prominent neuroaxonal dystrophy. The third foal was put onto grass pasture and recovered.<sup>21</sup> Nine horses with a

presumptive diagnosis of EDM improved after treatment with vitamin E at 6000 IU/day.<sup>22</sup> The role of vitamin E or glutathione peroxidase in the development of EDM remains unclear. The role of copper in the development of EDM is unclear. Although histologic changes and clinical signs consistent with degenerative myeloencephalopathy have been observed in copper-deficient animals, such as sheep, goats, calves, guinea pigs, pigs, and rats, no significant differences in plasma and liver copper concentrations between horses with confirmed EDM and age-matched control animals were found.<sup>23</sup>

Hereditary factors must also be considered in the pathogenesis of EDM and NAD in horses, as the diseases have been observed in familial clusters.<sup>6,8,9</sup> However, the mode of inheritance has so far not been identified in EDM- or NAD-affected horses. Toxic compounds such as organophosphates, diethylthiocarbamate, and cycad palm have been reported to cause histologic changes and clinical signs similar to NAD in horses or other animals.<sup>3</sup> Their effect is due to the neurotoxic properties of the compounds. No direct association of toxic compounds with EDM or NAD in horses has been shown.

Recent research has shown that disruption of axonal transport plays a role in the pathogenesis of dystrophic axons in EDM.<sup>24</sup> Similar to what has been shown in canine NAD,<sup>25</sup> abnormal accumulation of synaptic proteins within dystrophic axons was demonstrated in horses with EDM in addition to altered presynaptic terminal attachment to swollen neurons. Furthermore, enhanced immunoreactivity to ubiquitin was demonstrated, implying activation of the ubiquitin system. Activation of this system would cause lysis of altered proteins within swollen neurons and finally result in dystrophic axons.

## ☞ DIAGNOSIS

Definitive diagnosis of EDM can be made only with histopathologic examination of the spinal cord and brainstem. Antemortem diagnosis is based on clinical signs and ruling out other neurologic diseases (especially CVM and EPM). In EDM, CSF analysis and cervical spinal radiographs are usually within normal limits, although increased CSF creatine kinase (CK) levels have been found in horses affected with EDM.<sup>3</sup>

Measuring serum vitamin E concentrations may be unreliable when the animal is examined after the critical deficient period. Moreover, it should be noted that a single serum vitamin E sample may not adequately reflect the true vitamin E status of the horse, because up to 12% variation in concentrations can occur normally.<sup>26</sup> However, a low serum-plasma vitamin E concentration (<1.5 mg/ml) is supportive of the diagnosis.

## ☞ TREATMENT AND PREVENTION

No specific treatment exists for EDM in horses. Affected horses may benefit from oral vitamin E supplementation coupled with monitoring of serum vitamin E concentrations. The earlier vitamin E treatment is instituted, the better the chance for a response. Horses with clinical signs of EDM may benefit from large doses of vitamin E (6000 to 10,000 IU/day) for an extended period of time.<sup>27</sup> Horses with very low serum vitamin E concentration may also benefit from 1000 (foals and yearlings) to 2000 (adults) IU of vitamin E in oil given intramuscularly every 10 days.<sup>27</sup> Dietary vitamin E levels should be maintained at 500 to 1000 IU/kg dry weight. Heat-treated pellets, stored oats, and sun-baked forages have marginal vitamin E concentrations (0 to 5 IU/kg dry weight).<sup>8</sup>

Horses fed a diet of these should have frequent access to fresh green forage or vitamin E supplementation at 600 to 1800 mg or tocopheryl acetate 1.5 to 4.4 mg/kg/day to meet their reported needs.<sup>28</sup> To date, vitamin E toxicity associated with supplementation has not been reported. In addition, farms with a high incidence of EDM may benefit from prophylactic vitamin E supplementation.<sup>8,13</sup>

## ☞ PROGNOSIS

EDM is generally progressive, necessitating euthanasia. Once clinical signs are evident, no improvement or remission occurs. However, signs may plateau.<sup>8</sup> Generally, horses with EDM do not progress to a state of recumbency.<sup>3,8</sup> Severely affected horses usually have an earlier age of onset and rapid disease progression, whereas mildly affected horses usually have a later age of onset, and the disease has a less rapid course.<sup>29</sup>

## EQUINE PROTOZOAL MYELOENCEPHALITIS

Martin Furr\*

Equine protozoal myeloencephalitis is a commonly diagnosed condition of the horse, which J. Rooney originally described in 1964 and termed *segmental myelitis*. Later descriptions used the terminology *focal myelitis encephalitis*, recognizing that lesions within the brain occurred.<sup>1</sup> Eventually, an organism that resembled toxoplasma was seen in histologic sections, and the term *toxoplasma-like encephalitis* was coined.<sup>2-4</sup>

In 1976, Dubey first suggested that EPM was caused by a member of the genus *Sarcocystis*.<sup>5</sup> A *Sarcocystis* organism was eventually cultured from the spinal cord of an affected horse and named *Sarcocystis neurona* because it often develops within neurons.<sup>6</sup> Since that time, *S. neurona* or *S. neurona*-like organisms have been cultured from several ataxic horses, as well as numerous other animals including the zebra,<sup>7</sup> domestic cat,<sup>8</sup> Canadian lynx,<sup>9</sup> sea otter,<sup>10,11</sup> straw-necked ibis,<sup>12</sup> mink, raccoon, and skunk.<sup>13-15</sup>

Recently, another protozoan parasite (*Neospora hughesi*) has also been shown to be a cause of EPM in the horse; however, its role likely is limited.<sup>16-21</sup>

## ☞ EPIDEMIOLOGY

EPM is one of the most commonly diagnosed neurologic diseases of the horse in the Western Hemisphere. It was reported that 25% of all equine neurologic disease submissions to the New York State Veterinary College were caused by EPM.<sup>22</sup> Similarly, EPM was diagnosed in 25% of all horses presented to the Ohio State University Veterinary Teaching Hospital with spinal ataxia in the early 1990s.<sup>23</sup> Given the complexity of clinical diagnosis, and the difficulty of finding conclusive lesions in the CNS, the true incidence is difficult to state conclusively. Based on a recent national study conducted by the United States Department of Agriculture (USDA), the

\*The authors wish to acknowledge William J. Saville and David E. Granstrom, whose original work has been incorporated into this section.

average incidence of EPM was 14 + 6 cases per 10,000 horses per year. The lowest incidence was in farm and ranch horses (1 + 1 cases/10,000 horses), with 6 + 5 cases/10,000 horses for pleasure horses. A much higher incidence of 51 + 39 and 38 + 16 cases/10,000 horses was seen for competition and racing horses, respectively. An intermediate incidence of 17 + 12 cases was reported for breeding animals.<sup>24</sup> This is similar to the findings of other studies showing racing and showing animals to have a higher risk than breeding and pleasure horses.<sup>25</sup>

EPM is a disease of the Western Hemisphere, with cases reported from many states within the United States, as well as Canada, Mexico, Panama, Argentina, and Brazil. Most horses with a diagnosis of EPM outside this region appear to have spent some time in the endemic area. EPM has been reported in England among horses imported from the Eastern United States and in an 8-month-old Arabian horse in South Africa that had been imported from the United States approximately 5 months before the onset of signs.<sup>26</sup> The most recent report was a horse from California that developed clinical signs of EPM after 10 months in Hong Kong.<sup>27</sup> These cases demonstrate the probability of persistent, subclinical, latent infections.

However, a few reports exist of neurologic horses with consistent clinical signs, positive immunoblot test results, and no history of travel in the American continent.<sup>28,29</sup> The nature of the infection in these horses is unclear and may be because of cross-reacting antigens. Epidemiologic data of 364 horses with histologically confirmed EPM taken from across the United States and Canada revealed that Thoroughbreds, Standardbreds, and Quarter Horses were most commonly affected, although many other breeds were represented.<sup>30</sup> Standardbreds and Thoroughbred horses have also been reported to be over-represented in some studies<sup>24,31,32</sup>; however, this is not consistent and may reflect selection bias. Alternatively, this may reflect management, environment, or use of these breeds rather than an innate breed characteristic.<sup>32</sup> For example, neurologic disease would be difficult to discern in an animal not used for riding or strenuous athletic activity, unless the signs were severe.

All horses are susceptible to the development of EPM, but epidemiologic surveys have suggested that the average age of affected horses is 4.4 years in one study<sup>31</sup> and 3.6 years in another report.<sup>32</sup> More than 60% of cases were less than 4 years old. This bias toward younger animals being affected has been reported by other investigators<sup>25,30,32</sup>; however, one study also found an increased risk in horses older than 13 years of age.<sup>33</sup> It is unclear if the young age of most affected individuals reflects some specific physiologic effect or is rather a reflection of the animals use, because they are more likely to be involved in strenuous physical activity. The age range of reported cases is from 2 months<sup>34</sup> to 24 years<sup>35</sup>; no gender predilection exists. Most cases appear to be individual cases, and "outbreaks" of EPM appear to be very rare.<sup>36</sup> A report from Ohio, however, did find that previous diagnosis of the disease on the farm increased a horse's risk of subsequently developing EPM (>2.5 times higher).<sup>25</sup> This finding suggests clustering of cases may occur when all the risk factors for EPM are present. One author has described an epizootic of EPM on a single farm.<sup>37</sup>

After the development of the immunoblot test for *S. neurona*, numerous seroprevalence studies were performed, casting light on the distribution of the infection and life cycle of the organism.

Horses in the United States have a variable but generally high seropositive incidence to *S. neurona*, ranging between

10% among wild mustangs in Utah, 22% in the arid regions of Oregon, 45% in Pennsylvania, 53% in Ohio, and 60% in Michigan.<sup>38-42</sup> The Ohio study demonstrated increasing prevalence with increasing age, as well as differences from Southern to Northern Ohio. The authors concluded that this difference was the result of differences in the number of days of freezing temperature within the different regions, affecting parasite viability.<sup>25</sup> These results were confirmed by a different study in Colorado, showing increased incidence with increasing age and also associated with temperature (seroprevalence lowest in the colder months).<sup>43</sup>

Additional risk factors for EPM have been described. Risk increased if opossums were seen on the farm or if woods were present on the farm. The risk decreased if a creek or river was present on the farm and if the feed was kept protected from wildlife access.<sup>25</sup> Additional risk factors included an increased risk with increased numbers of horses, purchased versus home-grown grain, use of wood chips or shavings as bedding, presence of rats and mice on the premises, and increased human population density. A protective effect was apparent when woods were within 5 miles of the premises and where surface water was the primary drinking source. The National Animal Health Monitoring System (NAHMS) study also found the highest risk for disease was in the fall of the year.<sup>24</sup>

The seroprevalence for *Neospora hughesi*, in contrast to that for *Sarcocystis neurona*, is generally low and varies with the method of assay. Using an indirect immunofluorescence assay and a titer of 1:100 as the cutoff for a positive test, a seroprevalence of 37% in California, 20% in Montana, and 5% in New Zealand is noted.<sup>44</sup> In another study of horses in California, the *N. hughesi* seropositive rate was 1.7%/year of age.<sup>45</sup> A seroprevalence of 23.3% was found in an abattoir survey in the United States; the incidence was 0% in Argentina and Brazil.<sup>46-48</sup>

## ☞ LIFE CYCLE

*Sarcocystis* spp. belongs to the phylum Apicomplexa, which includes several genera of coccidia that use an obligatory predator-prey or scavenger-carrion life cycle.<sup>49,50</sup> *Sarcocystis* spp. produce sporulated oocysts by sexual reproduction (gametogony) in the gut wall of the appropriate predator or definitive host. Infective sporocysts are introduced into the food and water supply of the prey animal or intermediate host by fecal contamination from the predator. In the *S. neurona* life cycle, the definitive host is the opossum, whereas the intermediate hosts are skunks, raccoons, and armadillos, among others. Once ingested by the intermediate host, sporocysts excyst, releasing four sporozoites that penetrate the gut and enter arterial endothelial cells in various organs. Meronts develop rapidly and eventually rupture the host cell, releasing merozoites into the bloodstream, which usually is followed by a second round of merogony in capillary endothelial cells throughout the body. Second-generation merozoites are released into the bloodstream and usually enter skeletal muscle cells, where they develop into specialized meronts known as *sarcocysts*. Mature *sarcocysts* contain bradyzoites, which are able to complete the life cycle only when ingested by the appropriate predator or scavenger.

*S. neurona* has been cultured from CNS lesions of several horses from different geographic locations within the United States and Central America.<sup>6,51-55</sup> Preliminary morphologic, immunologic, and DNA comparisons detected only minor

differences among isolates<sup>53,54</sup>; however, more recent studies have demonstrated differences among isolates in the expression of surface receptors, which has substantial implications for immunodiagnosis.<sup>56-58</sup>

*S. neurona* may infect a large number of intermediate hosts aberrantly, unlike most *Sarcocystis* spp. Several species of animals and birds have been reported to exhibit signs similar to those in horses with EPM. This feature made the experimental elucidation of the *S. neurona* life cycle quite challenging. At the present time, domestic cats (*Felis domesticus*), nine-banded armadillos (*Dasypus novemcinctus*), striped skunks (*Mephitis mephitis*), raccoons (*Procyon lotor*), and sea otters (*Enhydra lutris nereis*)<sup>59-62</sup> are considered to be viable intermediate hosts. Feeding studies, as well as epidemiologic and seroprevalence data, have determined this. Initially the domestic cat was thought to be only a laboratory intermediate host; however, several epidemiologic studies have now incriminated domestic cats as natural intermediate hosts.<sup>63-65</sup> The life cycle of *S. neurona* has been completed in a laboratory setting.<sup>61</sup> The horse has traditionally been considered an aberrant, dead-end host, in that sarcocysts have never been reported.<sup>50</sup> One report, however, describes mature sarcocysts that were well characterized as *S. neurona* and found in the tongue of a horse suffering from EPM.<sup>66</sup> This suggests that horses can be intermediate hosts but requires further confirmation.

Some evidence suggests that the organism may be transmitted by methods other than direct contact with opossum feces. It has been suggested that birds may mechanically disseminate sporocysts<sup>67</sup> and secondary transmission via “pass-through” of infective sporocysts in the feces of budgerigars, canaries, mice, and chickens fed opossum feces has occurred. At least some organisms appeared to retain viability and infectivity after transit through the digestive tract.<sup>68</sup> This is most likely to be a laboratory phenomenon; its importance in nature is unknown but likely to be small.

The life cycle of *Neospora hughesi* in horses is understood poorly. The definitive host of *N. caninum* has been demonstrated to be the dog,<sup>69</sup> but whether the dog is the definitive host of *N. hughesi* is not known. Tachyzoites, as well as tissue cysts, have been found in other horse tissues in two of the horses reported to have EPM caused by *Neospora* spp.<sup>70</sup> In one case of neosporosis, a foal was determined to have been infected congenitally, whereas congenital infections have not been demonstrated in horses infected with *Sarcocystis neurona* up to the present time.

## ☉ PATHOGENESIS

Despite the often high rate of exposure to the organism, only a small percentage (perhaps <1%) of horses develop clinical illness.<sup>24</sup> This suggests that immune clearance of the parasite is very effective but that unknown factors must exist in certain cases to allow clinical disease to be expressed. Parasite dose is likely to be a factor, and in fact this has been experimentally demonstrated.<sup>71</sup> Strain-related variance in virulence may also be involved, although this has not been examined critically. Other factors that have been considered to have a role in the induction of EPM include physiologic stress associated with shipping, training, showing, and pregnancy that may make animals more susceptible to EPM.<sup>25</sup> Indeed, one reliable model of inducing EPM incorporates long-range shipping as a stressor, performed immediately before infection.<sup>72</sup> Other attempts to induce EPM using the oral infection route and that do not

incorporate stressors such as shipping have lead to inconsistent and only mild illness.<sup>73</sup> The assumption is that these stressors lead to some degree of immune suppression, which is a commonly implicated factor in protozoan parasite infections. However, treatment of horses with immunosuppressive doses of steroids associated with oral infection with *S. neurona* did not result in significantly worse histopathologic changes in the CNS, although clinical signs were slightly more severe than in non-steroid-treated horses.<sup>73</sup> Additional evidence for the role of physiologic stress is found in the observation that stressed horses develop more severe clinical signs than naturally infected (nonstressed) horses.<sup>74</sup> It thus appears likely that stress has a role in the development of EPM; however, the interaction is complex and not fully understood at this time.

After infective sporocysts of *S. neurona* are passed from the definitive host and subsequently ingested by a horse, infection proceeds. Clinical disease results from the inflammation and neuronal necrosis associated with infection of the CNS with live organisms.

The mechanism (or mechanisms) by which *S. neurona* transits the blood-brain barrier and enters the CNS is unclear. One hypothesis is that *S. neurona* organisms that have been phagocytosed by leukocytes in the periphery are transported across the blood-brain barrier in the process of normal immune surveillance. Once within the CNS, the organisms proliferate. This “Trojan horse” hypothesis of CNS infection is attractive and has support from experimental work in which clinical disease can be induced by administering horses autologous lymphocytes, which have been infected with *S. neurona*.<sup>75</sup> When Arabian foals with severe combined immunodeficiency, lacking B and T lymphocytes, are infected with *S. neurona* they develop significant widespread parasite replication in visceral tissues, but parasites cannot be found within the CNS.<sup>76</sup> Alternatively, organisms enter the CNS by hematogenous dissemination, or directly through the cytoplasm of endothelial cells. Hematogenous dissemination is supported by the observation of a transient parasitemia in immunocompetent horses that have been experimentally challenged with *S. neurona*.<sup>77</sup>

There does not appear to be “targeting” of the CNS by the organism; rather the organism is not cleared from the CNS tissue while it is cleared elsewhere. Once organisms enter the CNS, it is likely that the immunosuppressive environment of the CNS plays a role by diminishing clearance of the organism in this immune-privileged tissue. The parasite itself may also induce some immunosuppression.<sup>78</sup> Placental transmission with subsequent infection of the fetus is not believed to occur.

Resistance to *Sarcocystis neurona* is presumed to be the result of the combined effects of humoral and cellular immunity. After infection, a relatively rapid production of antibodies occurs. In horses challenged with live *S. neurona* organisms orally, all horses seroconverted within 32 days,<sup>73</sup> whereas in another study, horses challenged with a larger number of organisms seroconverted by day 13 after infection (if stressed by transport) and by day 30 if unstressed.<sup>72</sup>

It has been demonstrated with various apicomplexan parasites that antibody is at least partially protective. Research with *S. neurona* has demonstrated that antibodies to the Sn14 and 16 surface proteins block target cell penetration, while blocking the Sn30 surface protein had no effect.<sup>79</sup>

Although the effects of circulating antibody are likely to be very important, cell-mediated immunity is necessary for the elimination of intracellular forms of most organisms.

Mouse studies have confirmed the importance of CD8+ T cells in protection against *S. neurona* encephalopathy in that species; it is presumed to be similar in horses. Endothelitis and meningoencephalitis developed in CD8 knockout mice after challenge with *S. neurona*, highlighting the importance of this cell subset in protection against *S. neurona*,<sup>80</sup> at least in the mouse. The CD8+ T cell is one important source of interferon gamma (IFN- $\gamma$ ), which is critical for protection against *S. neurona* induced neurologic disease in mice.<sup>81</sup> Infection of IFN- $\gamma$  knockout mice leads to fulminant neurologic disease. These findings support the critical importance of IFN- $\gamma$  in protection against *S. neurona*.

## 🌀 PATHOLOGY

*Sarcocystis neurona* probably causes few pathologic changes in immunocompetent intermediate hosts. However, CNS lesions in the horse are often extensive.<sup>2-4,22</sup> Multifocal areas of hemorrhage to light discoloration of the brain or spinal cord may be visible on gross examination. Lesions may be microscopic to several centimeters wide. The brainstem and spinal cord are affected most often; however, lesions have been seen in peripheral nerves. Microscopically, lesions are characterized by focal to diffuse areas of nonsuppurative inflammation and necrosis with perivascular infiltration of mononuclear cells, including lymphocytes, macrophages, and plasma cells. Giant cells, eosinophils, and gitter cells also are present in inflammatory infiltrates. Gray or white matter (or both) is affected. Organisms have been found in neurons, leukocytes, and vascular endothelium, although they tend to develop most often in neurons.

## 🌀 CLINICAL SIGNS

The clinical signs associated with *S. neurona* infection are variable and exclusively related to neurologic dysfunction. This variability reflects the random distribution of the lesions that may occur within the nervous system. Usually the physical examination is within normal limits, and the horse appears bright and alert, although one may observe focal muscle atrophy. A typical history is a slowly progressive ataxia, which may initially have been identified as a musculoskeletal disorder. Occasional acute and rapidly progressive disease is seen; empirically this presentation seems more commonly associated with brainstem disease, although this has not been formally evaluated. Neurogenic gait deficits seen with EPM are characteristically asymmetrical and may involve a single limb or multiple limbs. The presence of ataxia, asymmetry, and atrophy (the “three A’s of EPM”) suggests multifocal or diffuse disease, which is characteristic of, although not pathognomonic for, EPM. Less commonly observed are diseases of the cerebrum, cerebellum, or brainstem resulting in a variety of cranial nerve deficits including dysphagia, head tilt, tongue or master paralysis, or masseter atrophy.

At least three horses have been observed with seizures as the only clinical signs of EPM.<sup>82</sup> Visual deficits and behavioral abnormalities have been reported in some horses with EPM.<sup>83</sup> A recent case series reported head shaking in three horses diagnosed with EPM that resolved after treatment for EPM.<sup>84</sup> The clinician needs to recognize that all of the clinical signs listed previously may be caused by conditions other than EPM, all of which should be considered in the differential diagnosis

## 🌀 DIAGNOSIS

An important point to remember is that EPM is an easy diagnosis to make but difficult to substantiate and confirm in a live patient. Experts recommend that at least three criteria be met before a diagnosis of EPM is rendered. First, the horse must have clinical signs arising from disease of the nervous system and that are consistent with EPM as described previously. Second one must confirm exposure to the causative agent by immunodiagnostic testing. Third, other conditions that could give rise to the clinical signs observed should be ruled out to the degree possible.

Ruling out other diseases may require radiographs of the cervical spine or head, nuclear scintigraphy, CSF evaluation, or testing for EHV, for example. These tests will be determined based on a careful physical and neurologic examination, as well as a consideration of the horse’s history and progression, risk factors, and related information. The third component of the diagnostic triad is confirmation of exposure to the organism.

At the present time a number of tests are available to confirm exposure to the causative agents of EPM. An important consideration is that all currently available tests are intended to determine if antibodies to the causative agent are present, even though the test platforms may differ. Hence it is likely that the results obtained from such tests will be similar.

The first test developed to aid in the diagnosis of EPM was immunoblot analysis (Western blot) of serum and CSF to provide antemortem information regarding exposure to *Sarcocystis neurona*.<sup>85</sup> The test uses cultured merozoites to detect antibodies directed against proteins considered unique to *S. neurona*. Antibodies produced to proteins shared with *S. fayeri* or other organisms found in North America can be differentiated with this test.

Immunoblot testing of CSF samples has demonstrated greater than 90% specificity and sensitivity among approximately 100 horses with neurologic disease that received post-mortem examination.<sup>86</sup> Approximately one half of the cases were histologically confirmed as EPM. Positive serum (specific antibody present) indicates exposure only; however, greater than 90% of histologically confirmed cases have tested seropositive. Given the widespread seroprevalence of this disease, however, this is not unexpected.

It was commonly believed for many years that the blood-brain barrier was impermeable to antibodies; hence it was thought that antibodies present in CSF confirmed that parasites had crossed the blood-brain barrier, entered the CNS parenchyma, and stimulated a local immune response. This has been shown not to be true. In fact, passive movement of antibodies into the CSF is readily demonstrated (the magnitude of the antibody in the CSF is directly related to serum concentrations of the same antibody).<sup>87</sup> When infection of the CNS occurs, the antibody titer is much higher because of local production of antigen-specific antibodies, however. Many of the false-positive CSF immunoblot tests probably arise from passive movement of antigen-specific antibody across the blood-brain barrier. In these cases, however, the immunoblot test is usually quite weakly reacting. Alternatively, blood contamination of the CSF sample at collection can lead to false-positive tests. Bleeding within the CNS, after trauma or infection, for example, will also lead to a false positive. In an effort to differentiate false-positive CSF antibody tests, a number of techniques have been described. The AQ is a measure

of blood-brain barrier permeability and has been evaluated in horses as an aid in interpretation of the CSF immunoblot result. The normal AQ is  $1.5 \pm 0.4$  in CSF of adult horses from the lumbosacral space and  $1.86 \pm 0.28$  in CSF collected from the atlantooccipital space of neonatal foals.<sup>88,89</sup> Values greater than this suggest damage to the blood-brain barrier. Clinical experience and empiric evaluation of the value of the AQ has demonstrated a very low sensitivity for this test, however, and its use is no longer recommended as an aid in the diagnosis of EPM.<sup>90</sup> Determination of the IgG index was proposed as a method to differentiate intrathecal production versus passively acquired CSF antibodies. The range for IgG index in the CSF collected from the atlantooccipital space of normal horses is  $<0.27$ ; values greater than this suggest intrathecal antibody production, consistent with CNS infection.<sup>88</sup> In one study the IgG index was found to be increased at the beginning of treatment and to drop slightly after treatment for EPM.<sup>91</sup> Unfortunately, the sensitivity of this test appears to be too low, and the use of the IgG index is no longer recommended as a diagnostic aid for EPM.<sup>90</sup>

False-negative results have been rare but may occur. The possible causes of false-negative responses are important to consider so that one does not misdiagnose affected horses. Some horses simply may fail to respond to the *Sarcocystis neurona*-specific proteins identified by the immunoblot. Horses that initially tested positive have become negative after several weeks of treatment and apparently have recovered. A chronically affected horse may test negative and still be infected, or the horse still may exhibit neurologic signs. Persistent neurologic damage (i.e., scarring) may be present in some cases, resulting in permanent neurologic damage in the absence of active infection. One should retest acute cases that initially test negative in 2 to 3 weeks. However, the incubation period appears to be sufficiently long to allow production of detectable amounts of IgG before the onset of clinical signs in most cases.

The original, conventional Western blot test has been modified at one testing laboratory (Michigan State) by blocking the 30-kD band with pooled serum with a high anti-*Sarcocystis cruzi* antibody titer.<sup>91</sup> This is considered by them to be a cross-reacting antigen. This modified Western blot was reported to have a sensitivity and specificity approaching 100%.<sup>91</sup> However, this study was performed on only a small number of EPM positive horses (6), and subsequent evaluation of the test by other investigators has found a much lower sensitivity and specificity of 89% and 69%, respectively.<sup>92</sup> A further modification of the Western blot has been proposed by another testing laboratory (Neogen Inc), in which the intensity of the staining reaction of the 17-kD band is reported as a unitless number referred to as the *relative quotient* (RQ). This number ranges between 0 to 100, with a higher value implying a more robust antibody response. The use of the RQ has not been found to improve diagnostic efficiency, although in one study the RQ did decrease slightly during treatment.<sup>91</sup>

A whole organism indirect fluorescent antibody test (IFAT), has been developed and is currently available from the University of California Diagnostic Laboratory.<sup>93</sup> Diagnostic performance of the IFAT was tested and compared with the Western blot tests and was reported to have a (slightly) better diagnostic efficiency than either test.<sup>92</sup> Serum titers of greater than 1:100 and CSF titers of greater than 1:5 were considered positive and diagnostic of active infection. This test is considered to be robust in the presence of blood contamination of the CSF sample. However, previous attempts using an indirect

fluorescent test were disappointing, and the IFA was unable to distinguish between related *Sarcocystis* organisms.<sup>94</sup> This finding was further supported using the California IFAT, when it was demonstrated that the test was unable to differentiate between *S. neurona* and *S. fayeri* (a nonpathogenic *Sarcocystis*) infections.<sup>95</sup> Therefore the superiority of the IFAT as a diagnostic for EPM is not clearly established and awaits further evaluation.

Another diagnostic test described for EPM is an enzyme-linked immunosorbent assay (ELISA) for antibodies to the snSAG-1 protein. This test (currently commercially available from Antech Inc) provides a titer, and values greater than 1:100 in serum are considered to indicate active infection.<sup>96</sup> Use of this test is not without concern, however. The test has not been rigorously evaluated for sensitivity and specificity, and the cutoff values for a positive diagnosis appear to be arbitrary. Further, it has been clearly demonstrated that not all *S. neurona* isolates produce the SAG-1 protein<sup>58</sup>; hence false-negative results are possible with this test.

A stall-side ELISA test that uses the snSAG-1 protein is also available (Endocrine Technologies, Newark, CA); however, it has not been evaluated for accuracy. It does not appear at this time that any of these tests are clearly superior; the final diagnosis should not hinge on the results of the immunodiagnostic test alone.

Immunodiagnostic testing for *Neospora hughesi* (IFAT) is also available from the University of California. The accuracy of this test has not been rigorously evaluated in a large number of clinical patients, but in a small challenge study (14 total animals) demonstrated perfect assignment of infected and control horses when a serum IFAT cutoff of  $>1:640$  was used.<sup>97</sup>

As previously noted, most horses with EPM do not show constitutional signs of illness, such as fever, depression, or anorexia. Changes in the CBC are not recognized, and changes in serum biochemistry analysis are not noted, unless the severity of the neurologic signs is such that the horse falls or is recumbent, or it is dysphagic and cannot drink or eat. In these horses, secondary changes in the serum biochemistry panel may be seen.

Collection and analysis of CSF is a common component of the neurologic evaluation and should not be ignored in evaluating the EPM suspect. The observation that CSF false-positive tests can occur has led some to question the value of analyzing CSF in horses being evaluated for EPM. An important point to remember is that the CSF is not collected for the sole purpose of doing an EPM test; additional information is obtained from the sample. Although it is true that some false-positive tests occur using CSF, this should not preclude the use of this diagnostic test. Horses exposed to *Sarcocystis neurona* will not necessarily and invariably develop a false-positive test on CSF. This appears to be associated with a high serum titer and is often transient. A negative CSF test has great value in eliminating EPM in most cases. A weak or suspect positive reaction in CSF is not compelling evidence for a diagnosis of EPM, whereas a stronger test reaction on immunoblot (or a titer exceeding the reference laboratory's high cutoff) is strong support for the diagnosis.

A key part of the diagnosis of EPM is ruling out other conditions that may be present; evaluation of CSF is necessary for this process. The author has identified conditions such as intrathecal hemorrhage, neoplasia, meningitis, and verminous encephalitis when evaluating EPM suspects (and would have been missed had the CSF analysis not been done). Hence the

author considers CSF analysis a key part of the full diagnostic evaluation of horses with CNS disease.

Most horses with EPM have normal CSF. Early work identified the occasional increase in RBC count; however, in more recent times this finding has been considered to be spurious and a result of unrecognized blood contamination from the collection. The severe and fulminant case may have a mildly increased total protein or white blood cell count, but these situations are rare.

## ☞ DIFFERENTIAL DIAGNOSIS

Given the variety of clinical abnormalities that may be expressed in horses with EPM, the differential diagnosis includes virtually all diseases of the equine CNS. However, the results of a careful history, physical examination, and neuro-anatomic localization help to limit the number of rule outs and guide further diagnostic efforts. The most common and likely rule out is probably cervical compression. In contrast to EPM, cervical compression usually results in symmetrical gait deficits, which are worse in the pelvic limbs and are characterized by spasticity and hypermetria, with good retention of strength and no muscle wasting.

Infectious diseases such as WNV encephalitis, equine encephalitis (eastern equine encephalitis [EEE] and western equine encephalitis [WEE]), and equine herpesvirus-1 (EHV-1) may all cause neurologic disease that could resemble EPM. Horses affected with these conditions are typically systemically ill, demonstrating fevers and alterations in the leukogram. The neurologic deficits of EHV-1 are fairly characteristic in that dysuria is a common component that is not often seen in horses with EPM. CSF is abnormal in most such cases (e.g., WNV, EEE, EHV-1), in contrast to EPM, and a variety of specific diagnostic tests exist for each of these conditions, such as IgM capture ELISA for WNV and PCR testing for EHV-1.

Polyneuritis equi and equine degenerative encephalomyelitis may also be confused with EPM and can have signs of multifocal disease, ataxia, and muscle atrophy. Less common conditions, such as verminous encephalitis, bacterial meningitis or CNS abscessation, can be seen, but alterations in the leukogram and the CSF are usually present, distinguishing these cases from EPM.

## ☞ TREATMENT

The cornerstone of treatment for horses with EPM is antiprotozoal medication. At the present time the Food and Drug Administration (FDA) has approved a number of compounds for the treatment of EPM. The first compounds used for the treatment of EPM were the sulfonamide drugs combined with pyrimethamine to achieve a synergistic effect. Clinical efficacy studies have been performed using sulfadiazine (20 mg/kg) and pyrimethamine (1 mg/kg) orally once per day, marketed as Re-Balance. Using this dose in well-characterized cases of EPM, the overall success rate (e.g., improvement by one clinical grade) was 61.5%. The duration of treatment varied between 90 to 270 days.<sup>98</sup> Complications of this drug regimen have been reported as anemia (22%), leukopenia (19%), and neutropenia (5%).<sup>98</sup> These signs are usually self-limiting and resolve with cessation of treatment. Folic acid supplementation has been advised by some authors to limit the degree of anemia; however, no support for this practice exists, and research has demonstrated increased toxicity when folic acid

supplementation is provided. Hence its use is discouraged. Use of sulfadiazine in breeding animals is controversial, although one study has shown no effect on pregnancy rates or early embryonic death. Mild signs of ataxia associated with mounting and ejaculation were noted in a group of pony stallions treated with sulfamethoxazole and pyrimethamine.<sup>99</sup> At the time of this writing, Re-Balance was no longer commercially available.

The first FDA-approved drug for the treatment of EPM was ponazuril (Marquis, Bayer Animal Health). Ponazuril is well absorbed orally, and within 3 days achieves a therapeutic, steady-state concentration in the CSF of horses treated with 5 mg/kg body weight.<sup>100</sup>

A field efficacy study of 101 horses with well-characterized EPM and treated with ponazuril demonstrated successful treatment in 60% of treated animals, success defined as improvement by at least one neurologic grade. A 90-day relapse rate of 8% after the termination of treatment was found.<sup>91</sup> Animals typically responded within 10 days and often continued to improve even after treatment stopped at 28 days.

Safety studies have found ponazuril to be very safe, with no systemic toxicity, even at high doses (30 mg/kg body weight) for up to 56 days.<sup>101</sup> Treatment of breeding stallions with 10 mg/kg body weight ponazuril did not affect androgenic hormone production nor spermatogenesis.<sup>102</sup> Ponazuril has been used without obvious problems in pregnant mares, but the use of ponazuril in pregnant animals is off label, and owners should be made aware of this fact. Feeding 2 oz of corn oil immediately before the ponazuril is given results in blood concentrations that are 25% higher than if no corn oil is given.<sup>103</sup>

Diclazuril is chemically similar to ponazuril and has been investigated for the treatment of horses with EPM. In one study, treatment of EPM-affected horses with diclazuril resulted in improvement in 58% of the treated animals, when given for 28 days. Diclazuril is administered orally, once per day, at the rate of 5 mg/kg for 28 days.<sup>98</sup> At the time of this writing, diclazuril has been approved by the FDA to be administered as a top-dress pellet; however, the drug has not become commercially available. Diclazuril, like ponazuril, appears to be very safe. No adverse events attributable to the drug were reported during the efficacy study, but a specific target animal safety study has not been reported.

NTZ (Navigator, Idexx Pharmaceuticals) is a member of the 5-nitrothiazol class of antimicrobials and is currently approved for the treatment of EPM. NTZ also demonstrated a success rate of about 60% in horses in a well-controlled clinical field trial, which was scrutinized by the FDA and that was comparable in design to the ponazuril study.<sup>98</sup> A second study (open, uncontrolled field trial) reported a success rate of 81%. The standards for diagnosis, case inclusion, and definition of case success were very different from the FDA-regulated studies, however. The results of this study cannot logically be compared with the results of the FDA-controlled studies.

In safety testing, horses became very ill at two times the dose (and some deaths occurred at three times the dose after only a few doses).<sup>98</sup> Modification of the dosing schedule has reduced the apparent adverse effects; however, some diarrhea, depression, and laminitis has been seen. Results of the two reported efficacy studies for NTZ also demonstrate that only 51% to 59% of enrolled horses completed the study.<sup>98</sup> Although not confirmatory, this poor completion rate and study compliance raises the question of unreported toxicity.

This is particularly noticeable in comparison with a completion rate of 68% for diclazuril and 90% for the ponazuril studies. To minimize toxicity, horses are given one half the dose each day for 1 week, then the dose is increased for the final 21 days of treatment. NTZ must be carefully dosed to minimize toxicity, which may occur even at the standard dosage. If toxic signs are observed, then withdrawal of the compound usually results in resolution of toxicity-related clinical signs. As of the writing of this chapter, NTZ is no longer available commercially in the United States.

Regardless of the drug used, the duration of treatment necessary and when to stop treatment is a consideration in all EPM cases. Definitive treatment durations are hard to define. Even successfully treated cases will remain immunoblot positive for long periods, so attempting to treat until the horse is seronegative is not a logical goal. The triazine-based drugs (Ponazuril [PNZ], Diclazuril [DCZ]) and NTZ are licensed to be given for only 28 days. Longer duration of treatment of clinical cases is often necessary; the need for this being determined by repeat examination after the first month of treatment. No response at all suggests misdiagnosis, and the case should be re-evaluated and further tested. If there has been a clinical response, yet the horse remains abnormal, then a second month of treatment is recommended. If finances are limited, then treatment can stop after 28 days, but the horse should be re-examined in 1 month to ensure that no deterioration occurs.

Relapses are a concern, and relapse rates of up to 25% have been suggested by one author when horses are treated with sulfadiazine and pyrimethamine; this was an empiric estimate, however.<sup>104</sup> The occurrence of a relapse is probably dependent on a number of factors, including the exact drug and dose used and the duration of treatment. Extended dosing may reduce the occurrence of relapse.<sup>98</sup> The relapse rate for horses treated for 28 days with ponazuril was 8%, when examined 90 days after cessation of therapy.<sup>91</sup> Relapse rates for the other drugs are not reported.

Relapse implies that the horse responded well to the initial drug treatment; hence horses that relapse can be treated with the same drug that was initially used but for a longer period. The author typically recommends 2 months of ponazuril, followed by a minimum 90-day course of sulfadiazine-pyrimethamine. Failure with a longer course of ponazuril usually prompts a change to a different medication from within a different chemical class. Other authors have recommended an immediate switch in drug class or indefinite intermittent therapy with sulfadiazine-pyrimethamine, 2 days per week at the standard dose.<sup>98</sup> The value of these strategies is currently unproven and purely anecdotal.

No studies have been conducted to determine the effectiveness of the currently approved antiprotozoal medications against *N. hughesi*. In vitro reports suggest effectiveness of NTZ against *N. caninum*,<sup>105</sup> yet treatment of one horse with culture positive *N. hughesi*-induced EPM did not result in improvement.<sup>106</sup> Ponazuril has also demonstrated in vitro effectiveness against *N. caninum*.<sup>107,108</sup> Ponazuril (5 mg/kg body weight, once per day for 28 days) was used in three horses with *N. hughesi* EPM. All three horses showed clinical improvement, and one showed complete resolution.<sup>109</sup>

In addition to specific antiprotozoal medication, ancillary treatment modalities are sometimes useful. In horses that are severely affected, the use of NSAIDs is recommended at standard dosages. Some practitioners routinely give NSAIDs

during the first 1 to 2 weeks of treatment because of a concern that clinical signs might worsen as the parasite is killed and inflammation worsens transiently. This “treatment crisis” is occasionally observed but is only rarely of clinical significance; however, a modest course of NSAIDs is unlikely to be harmful. Intravenous DMSO (0.5-1.0 g/kg IV as a 10% solution) is widely recommended. Although specific studies showing effectiveness of this drug in horses is lacking, a substantial body of evidence in laboratory animals indicates that it lowers CSF pressure; clinical experience also indicates improvement in neurologic status after treatment. This treatment is usually reserved for more severely affected horses and is not necessary in the majority of cases.

The use of anti-inflammatory corticosteroids in horses with EPM is debated, with no universal agreement. Concern about immunosuppression and the observation that stress may be a risk factor for development of EPM has led some to conclude that steroids should be scrupulously avoided because they may make the condition worse. There seems little support for this position, however. In experimental models, large doses of steroids have not appeared to substantially increase the severity of the illness and, in fact, in some cases appear to lessen it. A critical aspect of the illness is the degree of neuroinflammation that occurs. Hence in severely affected horses that are in danger of becoming recumbent, a short course (2-5 days) of dexamethasone (0.05 mg/kg q12h) may be useful in stabilizing the patient until the antiprotozoal medications can take effect. Long-term use of corticosteroids should probably be avoided.

Immunomodulators have been recommended in an effort to “boost” the immune response in EPM-affected horses. No empiric research has been done in this area, and the clinical impression is that most nonspecific “immune enhancers” have no obvious effect. Levamisole (1 mg/kg PO q24h) has been recommended because it influences T cell-mediated immunity and enhances phagocytosis. More recently a parapox ovis virus (PPOV) immunomodulator (Zylexis, Pfizer Animal Health, Kalamazoo, Mich) has become available. This product is intended for use in the aid of treatment of horses with EHV-1 and EHV-4. PPOV has been demonstrated in a number of species (although not horses) to upregulate the secretion of numerous cytokines,<sup>110</sup> specifically IFN- $\gamma$ , which is believed to be critical for clearance of *S. neurona*. For this reason, inclusion of PPOV vaccine in the treatment protocol for horses with EPM is logical, although unproven. It is possible, although unlikely, that immunomodulators or immunostimulants may enhance the immunopathologic effects associated with CNS infection.

Some clinicians recommend the use of additional supplements such as vitamin E and thiamine that may facilitate healing of nervous tissue when treating horses with EPM. Clinical trials have not been performed to establish the efficacy of this supplementation and it is unlikely to have significant effect, yet it is unlikely to be harmful.

In very ataxic animals, it is important to provide a stall with deep bedding and good footing. The best footing is a grassy field, and if the area is level with no obstacles, then turnout in such an area may be advisable. Turnout with other horses should be done carefully, because the ataxic horse cannot protect itself and may slip and fall when trying to get away from aggressive herd mates. Recumbent animals, or animals in slings, require additional care.

The prognosis for horses diagnosed with EPM appears to be similar regardless of the treatment used, because most reports

suggest an approximate improvement rate of 60% to 75% with the standard therapy.<sup>98</sup>

## ☞ PREVENTION

The widespread distribution of the parasite and the variety of intermediate hosts make control of EPM complicated. A vaccine was available; however, it has been removed from the market because of failure to demonstrate efficacy.

Monitoring high-risk age groups such as young and old horses closely for evidence of neurologic disease may help detect EPM early. That EPM may be the cause of the clinical signs when horses are presented for treatment of neurologic disease in the warmer months should raise the index of suspicion. Because many major horse competitions take place in the fall of the year, monitoring of horses before transport and competition may be helpful. Wildlife such as opossums and pests should be denied access to feed by using rodent-proof containers to help limit the contamination of feed with the infectious organism. One also should protect forages from wildlife access by storage in enclosed facilities. Close monitoring of broodmares close to foaling and horses that develop a major illness or injury is important, because it may help early diagnosis of EPM cases.

Prophylactic treatment with ponazuril has reduced the incidence and severity of clinical signs in one study.<sup>111</sup> Although unlikely to be financially viable in most situations, this suggests that treatment of horses with ponazuril before and during persistently stressful events such as long-distance shipping or a heavy travel and showing period, may reduce the risk of clinical illness. Alternatively, interval treatment with ponazuril (20 mg/kg PO every 7 days) significantly reduced *S. neurona* antibody in the CSF of challenged horses. This may also be a reasonable option for some specific circumstances.<sup>107</sup> Products have been marketed that are top-dressed on feed in an effort to kill the infective stage of the organism before ingestion. No empiric evaluation of these products exists, and they are highly unlikely to have any effect.

## EQUINE HERPESVIRUS-1 MYELOENCEPHALOPATHY

W. David Wilson, Nicola Pusterla

EHV-1 is an economically important pathogen of horses and exerts its major effect by inducing abortion storms or sporadic abortions in pregnant mares, early neonatal death in foals, and respiratory disease in young horses.<sup>1-8</sup> Myeloencephalopathy is an uncommon manifestation of EHV-1 infection but can cause devastating losses during outbreaks on individual farms, racetracks, veterinary hospitals, or boarding stables.<sup>9-11</sup> Although EHV-4 rarely causes clinical manifestations of disease in organs other than the respiratory tract, isolated cases of myeloencephalopathy and sporadic abortions have been reported in EHV-4 infections.<sup>1-3,12,13</sup> Clinical signs of neurologic disease reflect a diffuse multifocal myeloencephalopathy after vasculitis, hemorrhage, thrombosis, and ischemic neuronal injury. Sudden onset and early stabilization of signs including ataxia, paresis, and urinary incontinence; involvement of multiple horses on the premises; and a recent history of fever, abortion, or viral respiratory disease in the affected

horse or herd mates are typical features, although considerable variation exists between outbreaks concerning epidemiologic and clinical findings.<sup>14</sup> Prevention is difficult because many horses are latently infected with EHV-1, allowing the virus to circulate silently in horse populations, and current vaccines do not confer protection against neurologic manifestations of infection.<sup>8,15</sup> The distribution of lesions that can result after infection with neurotropic EHV-1 results in the need to include many conditions on the differential diagnosis list, including EPM, cervical vertebral instability, cervical stenotic myelopathy, vertebral or CNS trauma, polyneuritis equi, fibrocartilaginous emboli, aberrant parasite migration, degenerative myelopathy, togaviral encephalitis, rabies, botulism, toxins, and other disorders.

## ☞ VIROLOGIC FINDINGS

Of the five distinct herpesviruses that are known to infect horses, three are typical  $\alpha$ -herpesviruses with a double-stranded DNA genome and are designated EHV-1 (equine abortion virus, formerly known as *EHV-1, subtype 1*), EHV-4 (equine rhinopneumonitis virus, formerly known as *EHV-1, subtype 2*), and EHV-3 (equine coital exanthema virus), and two are  $\gamma$ -herpesviruses, designated *EHV-2* (formerly called *equine cytomegalovirus*) and *EHV-5* (which has recently been associated with interstitial pulmonary disease).<sup>2,3,16-18</sup> In addition, three asinine  $\alpha$ -herpesviruses (AHV1, AHV2, and AHV3) have been isolated from donkeys. Of these, AHV3 has been shown by many criteria to be related closely to EHV-1. Indeed, EHV-1 and AHV3 are related more closely to each other than either is to EHV-4.<sup>2,18-20</sup> Phylogenetic analysis and epidemiologic evidence suggest that EHV-1 recently has been derived from AHV3 and that donkeys may remain an alternate host for EHV-1, serving as a reservoir to infect horses.<sup>16,18</sup>

EHV-1 and EHV-4 are distinguishable from EHV-2, EHV-3, and EHV-5 by biologic properties and virus neutralization tests (and distinguishable from each other by restriction endonuclease fingerprinting of DNA, DNA sequences, and several immunologic tests based on monoclonal antibodies to each virus).<sup>1-3,16,17,21</sup> EHV-1 and EHV-4 produce eosinophilic intranuclear inclusion bodies in infected cells in vivo and in vitro. Several strains have been identified within EHV-4 and EHV-1, although the epidemiologic, immunologic, and pathogenic significance of this finding is not known. The 1-p and 1-b subtypes of EHV-1 likely are capable of inducing neurologic disease. Apart from differences in endotheliotropism, genetic and antigenic fingerprinting and experiments in baby mice have not yielded clear markers distinguishing EHV-1 strains that induce neurologic disease or abortion (or both).<sup>16,22-26</sup> However, a recent analysis of EHV-1 isolates from neurologic and non-neurologic disease outbreaks revealed a point mutation within the DNA polymerase gene that was strongly associated with neuropathogenic disease.<sup>27,28</sup> Recently, a hamster model has been described showing some potential for discrimination between abortigenic and neuropathogenic EHV-1 strains.<sup>29</sup>

## ☞ EPIDEMIOLOGY AND IMMUNITY

EHV-1 and EHV-4 are enzootic in most horse populations, and the majority of horses show serologic evidence of exposure to these viruses. Most horses become infected via the respiratory tract with EHV-1 or EHV-4 (or both) during the first year of

life. After an incubation period of 2 to 10 days, clinical signs of respiratory disease of variable severity develop and resolve within 1 to 2 weeks in uncomplicated cases.<sup>1-3</sup> Resolution of clinical signs is coincident with development of virus-specific neutralizing antibody directed primarily against surface viral glycoproteins. The development of cell-mediated responses is probably critical for recovery.<sup>30</sup> Resistance to reinfection with homologous virus is demonstrable after recovery but generally persists for only 3 to 4 months. Subsequent infections typically induce milder clinical signs or subclinical infection, although virus shedding from the nasopharynx occurs.<sup>1,2</sup> The immune response frequently is not successful in clearing herpesviral infection, and the majority of clinically recovered horses remain latently (asymptomatically) infected with EHV-1 or EHV-4 (or both) for life.<sup>1,2,31,32</sup> Recently, EHV-1 has been shown to evade the host immune system in part by downregulating major histocompatibility complex class I expression at the cell surface. This process may be a prerequisite to the establishment of latency.<sup>33</sup>

Recrudescence of latent infection is important in the epidemiology of EHV-1 and EHV-4 and explains why these diseases can occur in closed populations without the introduction of new horses.<sup>1,2,32,34</sup> Signs of EHV-1 infection may occur in the horse in which stress-associated recrudescence of infection has occurred, or the horse may remain asymptomatic but shed infectious virus in nasal secretions to infect other horses. Natural infection with EHV-1 occurs by inhalation or ingestion of aerosolized infective virus or by direct contact with virus shed in the products of abortion or in the nasal and ocular discharges and saliva of horses with overt clinical disease, subclinically infected horses, or shedding carrier horses.<sup>1,2,21</sup> Infectious EHV-1 virus was detected in the feces of experimentally infected foals that developed diarrhea, suggesting that fecal spread is a possibility.<sup>35</sup> Virus may be shed by clinically affected and inapparently infected horses for 3 weeks or more, and EHV-1 may remain infective in the environment for up to 14 days and on horse hair for 35 to 42 days.<sup>2,36,37</sup>

The first definitive association between EHV-1 and myeloencephalopathy was made in 1966 in Norway with the isolation of the virus from the brain and spinal cord of a horse that showed signs of severe neurologic dysfunction.<sup>38</sup> The myeloencephalopathic form of EHV-1 infection now is considered to have a worldwide distribution, having been recognized in Denmark, The Netherlands, Germany, Sweden, Austria, Britain, Ireland, Australia, India, the United States, and Canada.<sup>9,10,14,25,39,61</sup> In view of the ubiquitous occurrence of EHV-1 infection in horse populations, outbreaks of EHV-1 myeloencephalopathy are rare. In many instances, cases of neurologic EHV-1 infection occur in association with outbreaks of abortion or respiratory disease, although some outbreaks occur in the absence of other manifestations of EHV-1 infection and without the introduction of new horses into the group.<sup>21,34,62,63</sup>

The myeloencephalopathic form of EHV-1 infection may occur as sporadic individual cases or, more often, as outbreaks involving multiple individuals over a period of several weeks on one or more premises within a limited geographic region.\* Secondary or tertiary waves of clinical disease may occur as previously unexposed horses become infected from a common source over a short period.<sup>10,21,44,60</sup> Recently there has been an

increased reporting of occurrences of EHV-1 myeloencephalopathy<sup>65</sup> in congregations of horses around the United States. Most of these outbreaks have been associated with a mutant strain of herpesvirus, which appears to replicate rapidly, leading to a very high level of viremia and an apparent increased incidence of neurologic manifestations of this disease.<sup>27,28,66</sup> Morbidity rates ranging between less than 1% to almost 90% of exposed individuals and mortality rates ranging between 0.5% to 40% of in-contact horses have been reported.† Neurologic EHV-1 infection can occur at any time of year, but the highest incidence is in the late winter, spring, and early summer, perhaps reflecting the seasonal occurrence of abortigenic EHV-1 infections during the same months.<sup>52</sup>

The neurologic form of EHV-1 infection has been observed in pregnant mares, barren mares, geldings, stallions, and foals, although foals frequently do not show neurologic manifestations of infection during outbreaks that involve severe neurologic disease in adult horses.<sup>9,44</sup> The disease also appears to less commonly affect pony breeds. Pregnant mares and mares nursing foals appear to be at increased risk for developing neurologic manifestations of EHV-1 infection, and the stage of gestation may be important in determining the outcome of infection in pregnant mares.<sup>9,43,44,50,51</sup> Mares infected during the first 2 trimesters of gestation appear to be more likely to develop neurologic signs without abortion, whereas mares infected during the last trimester are more likely to abort without showing neurologic signs.<sup>21,41,43,51,58</sup>

All breeds of horses are susceptible to the neurologic form of EHV-1 infection, and other Equidae also may be affected. EHV-1 was the suspected cause of myeloencephalopathy that developed in a zebra 1 week after an in-contact onager (*Equus hemionus onager*) aborted an EHV-1 infected fetus.<sup>68</sup> The authors are unaware of reports of neurologic EHV-1 affecting donkeys and mules, although donkeys and mules have shown seroconversion indicating infection with EHV-1 while in contact with affected horses during outbreaks.<sup>56,57,64</sup> Indeed, donkeys and mules returning from a show were thought to be responsible for dissemination of EHV-1 and propagation of multiple outbreaks of neurologic EHV-1 infection in Southern California in 1984 (and in several subsequent years), suggesting that a donkey-adapted variant of EHV-1 with an increased neuropathogenicity for horses may have been involved.<sup>64</sup>

A modified live EHV-1 vaccine of monkey cell line origin was associated with neurologic disease in 486 of 60,000 recipients, prompting its withdrawal from the U.S. market in 1977.<sup>33</sup> No reports of EHV-1 myeloencephalopathy have been associated with use of the modified live vaccine currently approved for use in horses in the United States.

## ☪ PATHOGENICITY AND PATHOGENESIS

Natural infection with EHV-1 occurs by inhalation or ingestion, after which the virus attaches to and rapidly replicates in cells of the nasopharyngeal epithelium and associated lymphoreticular tissues, causing necrosis, exudation, and infiltration of phagocytic cells. Bronchial and pulmonary tissues also become infected, particularly in foals, thus predisposing them to secondary bacterial pneumonia.<sup>1,2,21,30,69</sup> Migration of virus-infected phagocytes into the circulation results in viremia

\*References 9, 10, 25, 38, 45, 49, 52, 54, 61, 64.

†References 9, 10, 25, 38, 45, 49, 52, 54, 61, 64, 67.

associated with mononuclear cells (primarily T lymphocytes) of the buffy coat.<sup>1,2,21,70</sup> The immunologically privileged intracellular location of the virus appears to protect it from inactivation by circulating antibody and permits dissemination to other tissues, including the CNS, even in the presence of high levels of antibody.<sup>71</sup> EHV-1 is capable of spreading directly from one infected cell to contiguous cells without an extracellular phase.<sup>21</sup> Vascular endothelium is the initial site of infection in the CNS and appears to be the predilection site for replication of EHV-1 after transfer of the virus from circulating leukocytes.<sup>51,72,73</sup> Viremia, which may be of prolonged duration, can occur during primary and all successive infections with EHV-1, even when no clinical signs are apparent; thus all EHV-1 infections pose a threat of inducing neurologic disease or abortion.<sup>1,9</sup>

The acute onset of clinical signs of EHV-1 myeloencephalopathy appears to result from vasculitis and thrombosis of arterioles in the brain and especially the spinal cord. This causes functional impairment of blood flow and metabolic exchange and, in severe cases, hypoxic degeneration and necrosis (malacia) with hemorrhage into adjacent neural tissues of the white and, to a lesser extent, gray matter.\* This proposed pathogenesis, based primarily on interpretation of the prominent vasculitis seen histopathologically in infected horses and the lack of definitive evidence of viral multiplication in neural tissues, contrasts greatly with the well-established pathogenesis of encephalitis caused by herpesviruses in other species.<sup>16</sup> The propensity of certain EHV-1 isolates to induce myeloencephalopathy does not appear to reflect specific neurotropism but rather a significant endotheliotropism.<sup>†</sup> The finding of chorioretinopathy and neural lesions in experimentally infected specific pathogen-free ponies, however, suggests that at least some strains of EHV-1 may exhibit neurotropism.<sup>75</sup> Furthermore, strong evidence indicates that in addition to circulating T lymphocytes, epithelial cells of the respiratory tract, and lymphoid tissues draining the respiratory tract, trigeminal ganglia are important sites for establishing and maintaining the lifelong state of latency that occurs in most, if not all, horses during primary infection with EHV-1 and EHV-4.<sup>75-78</sup> The ubiquitous EHV-2 has been proposed to play an important role in promoting reactivation of EHV-1 and EHV-4 from these sites in latently infected horses.<sup>31</sup>

No satisfactory explanation exists as to why some outbreaks of EHV-1 infection are associated with a high incidence of neurologic disease, whereas others are not, or why different horses show different clinical manifestations of EHV-1 infection during outbreaks.<sup>9,10,45,60</sup> A genetic strain of EHV-1 with an adenine-to-guanine mutation at the open reading frame 30, causing a mutation in the DNA polymerase, is associated with replicative aggressiveness and a greater potential for causing neurologic disease.<sup>66</sup> The nature and extent of lesions resulting from EHV-1 infection appear to be influenced by the age, gender, reproductive status (including stage of pregnancy), and immune status of the horse; the magnitude of challenge; strain variations; and perhaps the route of infection.<sup>9,45,48</sup> In one carefully monitored outbreak of EHV-1 infection on a stud farm in England, less than 17% of infected horses developed neurologic manifestations of infection, even though almost 60% of the horses on the farm were confirmed to have been infected.<sup>9</sup> Endothelial cell infection and perivascular

cuffing within the CNS appeared to be at least as pronounced in foals that died during this outbreak without showing neurologic signs as in profoundly paretic mares with severe CNS lesions; however, parenchymal neural lesions were minimal in the foals.<sup>9,45</sup> A notable finding during this outbreak was that mares and stallions that developed neurologic signs had considerable antibody responses, whereas the majority of foals did not, despite experiencing a prolonged period of viremia.<sup>9</sup>

The majority of EHV-1 infections that cause neurologic signs probably represent reinfection rather than a new infection.<sup>39,42,80</sup> Infection occurs in horses with significant preexisting serum EHV-1 antibody titers. Affected horses frequently have high titers at the onset of neurologic signs, and those horses that develop the most severe clinical signs are frequently the ones that show the most rapid increase in antibody titer after infection.<sup>9,50,51</sup> In addition, the characteristic vascular lesions in neural tissues of affected horses are typical of type III (Arthus) hypersensitivity reactions, and circulating immune complexes have been demonstrated at the onset of neurologic signs, suggesting that they may result from an immune-complex vasculitis.\* An immune-mediated mechanism is supported further by the difficulty experienced in isolating the virus from neural tissues of affected horses.<sup>45,61,62</sup> In addition, assessment of risk factors during outbreaks of neurologic EHV-1 infection in Southern California in 1984 revealed that horses vaccinated with killed or modified live EHV-1 vaccine within the previous year were significantly (9 to 14 times) more likely to develop neurologic manifestations of infection than were nonvaccinated horses.<sup>64</sup>

The finding of circulating antibodies to the myelin protein P2 in the serum of horses that died from EHV-1 myeloencephalopathy (but not in horses that recovered) has led to the suggestion that an alternate immune-mediated mechanism may play a role in the pathogenesis of neurologic EHV-1.<sup>81</sup> The presence of this antibody, however, may represent a response to leakage of the protein after damage induced by another mechanism.

Despite the foregoing observations, evidence for an immune-mediated pathogenesis for EHV-1 myeloencephalopathy is by no means conclusive. In experimental EHV-1 infections in which the onset of neurologic signs 8 to 9 days after infection correlated with a peak in the level of circulating immune complexes, vasculitis was not present in vessels in which endothelial cells did not support viral replication or in organs such as the kidney that one would expect to trap circulating immune complexes.<sup>72</sup> The finding of greatly depressed platelet counts several days before the onset of clinical signs, presumably the result of consumption in thrombi after endothelial damage, suggests that the neuropathologic changes are initiated before circulating immune complexes peak and that the action of immune complexes may be secondary and localized. Failure to isolate the virus from the CNS may be attributable to high levels of circulating antibody and to the endotheliotropism of the virus.<sup>72</sup>

## ☞ CLINICAL SIGNS

In natural and experimental infections, neurologic signs appear 6 to 10 days after infection by the intranasal route.<sup>†</sup> The onset of neurologic signs may be preceded or accompanied

\*References 9, 50, 51, 54, 58, 62, 74.

†References 26, 35, 45, 50, 51, 72, 73.

\*References 21, 42, 50, 51, 63, 73, 81.

†References 10, 35, 50, 51, 55, 60, 73.

by signs of upper respiratory disease, fever, inappetence, or hindlimb edema within the previous 2 weeks, although in many instances no antecedent signs are notable unless one routinely monitors rectal temperature. However, frequently one finds a herd or stable history of current or recent cases of respiratory tract infection, fever, inappetence, distal limb edema, abortion, neonatal death, foal diarrhea, or neurologic disease, and for one to encounter different signs of EHV-1 infection in different groups of horses on a particular farm is not unusual.<sup>9</sup>

Affected horses are occasionally febrile at the onset of neurologic disease, although most are normothermic and some are hypothermic. Neurologic signs are generally of acute or peracute onset, after which they tend to stabilize rapidly and generally do not progress after the first 1 or 2 days.<sup>39,43,44,52,82</sup> Clinical signs vary depending on the location and severity of lesions, but in most horses, signs reflect predominant involvement of the spinal white matter.<sup>52</sup> Ataxia and paresis of the limbs are the most common signs, with hypotonia of the tail and anus, tail elevation, and urinary incontinence being common but not invariable findings.\* Clinical signs are usually bilaterally symmetrical or only mildly asymmetric, although hemiparesis or sudden onset of unilateral hind- or forelimb lameness progressing to unilateral or more generalized ataxia, paresis, and recumbency have been reported.<sup>52,54,55,74,84</sup> Lesions in peripheral nerves and spinal cord were observed in some of these cases.<sup>54</sup> The hindlimbs generally are affected more severely and earlier in the disease course than the forelimbs. In mildly affected horses, transient ataxia and stiffness of the pelvic limbs or dribbling of urine after overflow from a distended atonic bladder may be the only signs noted.<sup>43,52</sup> One may note conscious proprioceptive deficits in these cases as reluctance to move, clumsiness, toe dragging, knuckling, stumbling, pivoting, and circumduction in one or more limbs on circling, with spasticity evident in some cases.<sup>44,52,85</sup> These signs are often subtle and may go unnoticed. More severely affected horses show profound limb weakness and swaying of the hindquarters, and a small proportion show complete paralysis of affected limbs, manifested as paraplegia and sitting like a dog, complete recumbency, or tetraplegia.<sup>9,21,52,85</sup>

Distention of the urinary bladder is common and may cause signs of colic or dribbling of urine, which frequently results in scalding of the perineum, legs, and other areas.<sup>57</sup> Cystitis is a frequent complication, particularly when repeated catheterization is necessary to relieve bladder distention.<sup>82</sup> Affected stallions and geldings may develop penile flaccidity and paraphimosis or repeated erections, whereas mare may develop vulvar flaccidity.† In addition, stallions may experience reduced libido and swelling of the testes.<sup>9,45</sup> Scrotal edema may accompany hindlimb edema at the onset of neurologic signs in some cases.<sup>9,43-45,58</sup> Sensory deficits are uncommon, but perineal hypalgia or analgesia has been noted, and analgesia of the caudal half of the body was observed in one affected horse.<sup>39,43,52,85</sup> Consistent with predominant involvement of the white matter of the spinal cord, flexor reflexes are normal and perineal reflexes are preserved. In recumbent horses, spinal tendon reflexes can be tested and may be increased. Atrophy is rarely seen, even in the later stages of the disease.<sup>52</sup> Affected horses usually remain alert and have good

appetites, even when recumbent, although some show modest depression and inappetence.<sup>44,83</sup> Severe depression, when it occurs, is more often caused by secondary complications than by brain involvement.<sup>83</sup> Unequivocal signs of brain disease are rare, although infarction of the brainstem may cause depressed sensorium, altered behavior, and cranial nerve damage leading to vestibular signs and to lingual, mandibular, and pharyngeal paresis, which may manifest as dysphagia.<sup>41,59,83,84,86</sup> Strabismus, nystagmus, circling, and head tilt have been observed on occasion.<sup>14,41,52,85</sup>

Affected horses show variable progression of clinical signs. Those horses that are affected mildly frequently stabilize rapidly over a period of hours to a few days as edema and hemorrhage resolve; generally they recover completely over a period of days to several weeks.<sup>9,10,39,44,60</sup> If recumbency occurs, then it generally does so during the first 24 hours, with some horses showing such complete motor paralysis that they are unable to lift their heads.<sup>54</sup> Severely affected horses may show progression of signs during the first few days and may die in coma or convulsion or be euthanatized because of secondary complications.<sup>9</sup>

## ☞ LABORATORY FINDINGS

CSF analysis typically, although by no means always, reveals xanthochromia, an increased protein concentration (100 to 500 mg/dl), and increased AQ (ratio of CSF to serum albumin concentration), reflecting vasculitis and protein leakage into CSF. The white blood cell count in CSF is usually normal (0 to 5 cells/ $\mu$ l) but occasionally is increased.\* Abnormalities in CSF are not present at the onset of clinical signs in some horses, and changes resolve rather quickly; thus the CSF may be normal within 2 weeks of onset of clinical signs.<sup>51,52,82</sup>

The presence of antibodies to EHV-1 in the CSF of affected horses strongly suggests a diagnosis of EHV-1 myeloencephalopathy, although such antibodies are absent in many cases.<sup>14,41,51,52,89</sup> One should take into account the albumin concentration, IgG concentration, and EHV-1 antibody titer in serum and CSF when interpreting positive antibody titers in CSF.<sup>87</sup> Because the AQ usually is elevated in affected horses and the IgG index is normal, the presence of EHV-1 antibodies in CSF reflects leakage of protein across a damaged blood-brain or blood-CSF barrier after vasculitis rather than intrathecal antibody production.<sup>81,87,89</sup> Antibodies therefore are more likely to be present in the CSF of affected horses with concomitantly high serum titers.<sup>51,52,81,87,89</sup> Blood contamination during collection of CSF and other diseases that cause an increase in the permeability of the blood-brain barrier or bleeding into the subarachnoid space may elevate CSF antibody titers falsely if serum titers are also high. Isolation of EHV-1 from the CSF of affected horses would confirm a diagnosis but is rarely successful.<sup>52,57</sup>

Virus isolation and identification of EHV-1 from nasopharyngeal swabs or buffy coat samples strongly supports a diagnosis of EHV-1 myeloencephalopathy in a horse with compatible clinical signs and should be attempted by submission of nasopharyngeal swabs in viral transport medium and an uncoagulated blood sample (citrate or heparinized).† Diagnosis may be achieved more rapidly using real-time PCR

\*References 10, 39, 43, 52, 60, 83.

†References 9, 21, 39, 44, 83, 85.

\*References 50-52, 74, 82, 84, 87, 88.

†References 1, 2, 9, 14, 52, 90.

for identification of EHV DNA from nasopharyngeal swabs or buffy coat samples. The likelihood of isolating EHV-1 during outbreaks of neurologic disease increases by monitoring in-contact horses and collecting nasal swab and buffy coat samples during the prodromal febrile phase before neurologic signs develop.<sup>44</sup> Even so, interpretation of positive results can be confusing because EHV-1 and EHV-4 have been isolated from the respiratory tract of normal horses.<sup>36</sup> Application of new diagnostic methods such as polymerase chain reaction (PCR), *in situ* hybridization, antigen-capture ELISA, and dot immunobinding to nasal swabs or scrapings, buffy coat samples, or pathologic specimens have improved the speed and specificity greatly with which one can diagnose EHV-1 infection.<sup>91-99</sup> Many conventional PCR protocols targeting specific genes of EHV-1 have been published in recent years for molecular detection of EHV-1 in nasopharyngeal swabs or buffy coat samples.<sup>32,94-98</sup> Although considerable progress has been made in developing PCR protocols for clinical use, quality control of nucleic acid amplification techniques remains an ongoing challenge because of lack of protocol standardization between laboratories.<sup>100</sup> Furthermore, the majority of PCR assays targeting genomic EHV-1 DNA are unable to differentiate between a lytic and latent infection. Novel technologies such as real-time PCR that allow quantitation of viral DNA and detection at the level of gene expression likely will feature prominently as molecular diagnostic approaches to EHV-1 infection are refined further in the future.

Serologic testing that demonstrates a fourfold or greater increase in serum antibody titer using serum-neutralizing or complement fixation tests on acute and convalescent samples collected 7 to 21 days apart provides presumptive evidence of infection.\* Many horses with EHV-1 myeloencephalopathy, however, do not show a fourfold rise in serum-neutralizing titer, and some actually show a decline.<sup>57</sup> This may be explained by the finding that when antibody titers rise, they do so rapidly within 6 to 10 days of infection and already may have peaked by the time neurologic signs appear.† Although serologic testing has limitations in confirming a diagnosis of EHV-1 myeloencephalopathy in an individual horse, testing of paired serum samples from in-contact horses is recommended because a significant proportion of affected and unaffected in-contact horses seroconvert, providing indirect evidence that EHV-1 is the causative agent.‡ Interpretation of the results of serologic tests is complicated by the fact that the serum-neutralizing, complement-fixation, and ELISA tests in use at most diagnostic laboratories do not distinguish between antibodies to EHV-1 and EHV-4 because of cross-reaction between these viruses. A specific ELISA test based on the C-terminal portion of glycoprotein G of both viruses has been developed and should prove valuable in the investigation and management of disease outbreaks in the future.<sup>102-104</sup>

## ☞ DIAGNOSIS

The multifocal distribution of lesions results in variability of clinical presentation, which necessitates inclusion of a number of conditions in the differential diagnosis. These conditions

include EPM, cervical stenotic myelopathy, and cervical vertebral instability (wobbler syndrome), cervical vertebral fracture or other CNS trauma, neuritis of the cauda equina, fibrocartilaginous infarction, aberrant parasite migration, degenerative myelopathy, other viral encephalitides (flaviviruses and alphaviruses), rabies, botulism, CNS abscess, and a variety of plant and chemical intoxications.<sup>14,52</sup> Sudden onset and early stabilization of neurologic signs including ataxia, paresis, and urinary incontinence; involvement of multiple horses on the premises; and a recent history of fever (most consistently reported clinical sign before onset of ataxia), abortion, or viral respiratory disease in the affected horse or herd mates is sufficient to make a tentative diagnosis of EHV-1 myeloencephalopathy.<sup>14</sup> Antemortem diagnosis is supported by ruling out other conditions; demonstrating xanthochromia and elevated protein concentration in CSF; identifying EHV-1 in or isolating EHV-1 from the respiratory tract, buffy coat, or CSF; and demonstrating a fourfold increase in antibodies using serum-neutralizing, complement fixation, or ELISA tests performed on acute and convalescent serum samples collected from affected or in-contact horses 7 to 21 days apart.<sup>10,60,105</sup> Antemortem confirmation of a diagnosis of EHV-1 myeloencephalopathy is frequently not possible, however, particularly when an individual horse is affected, because the foregoing tests do not yield consistent results in all cases. Hematologic abnormalities with EHM are inconsistent but may include mild anemia and lymphopenia, followed by increased plasma concentration of fibrinogen.

## ☞ TREATMENT AND PROGNOSIS

Because EHV-1 is a contagious and potentially devastating infection, horses suspected of being affected should be isolated promptly and strictly until EHV-1 is ruled out by confirmation of an alternate diagnosis.<sup>83</sup> No specific treatment is available; thus management of horses with EHV-1 myeloencephalopathy aims toward supportive nursing and nutritional care and reduction of CNS inflammation.<sup>14</sup> One should encourage horses that are not recumbent to remain standing and should protect them from self-inflicted trauma by the provision of good footing, such as a grass paddock, by placement of food and water in an accessible location at a convenient height above ground level, and by other measures, including the use of padded hoods and elimination of obstacles. Patients that become recumbent should be maintained in a sternal position on a thick cushion of dry absorbent bedding and should be rolled frequently (at least every 2 to 4 hours) to reduce the risk of myonecrosis and decubital ulcers. Whenever possible, one should lift and support the horse in the standing position using an appropriately fitting sling.<sup>10</sup> Slings are most beneficial for moderately affected horses that are too weak to rise but are able to maintain a standing position with minimal assistance.

Affected horses usually maintain a good appetite, even when recumbent, although hand feeding may be necessary to encourage some horses to eat. Maintenance of hydration is important, and provision of a laxative diet or the administration of laxatives such as bran mashes, mineral oil, or psyllium may be necessary to reduce intestinal impaction. One usually can meet the caloric and water needs of anorectic patients by feeding gruels of alfalfa-based or similar pelleted feeds in water or balanced electrolyte solution via nasogastric tube. If oral intake is insufficient to meet the daily water needs of 60 to 80

\*References 9, 10, 14, 21, 39, 56, 59, 60, 83, 90.

†References 9, 10, 50, 51, 56, 60, 90, 101.

‡References 9, 10, 14, 56, 57, 59, 60.

ml/kg of body mass per day, then one can maintain hydration by intravenous administration of balanced electrolyte solutions.<sup>52</sup> Partial or total parenteral nutrition can also be used to meet the caloric needs of anorectic, recumbent horses.

If affected horses are unable to stand and posture to urinate or if bladder function is impaired significantly, manual evacuation of the bladder by application of pressure per the rectum may be necessary. If these measures are unsuccessful, then judicious urinary catheterization is indicated and should be performed aseptically with the collection tubing attached to a sterile closed bag to minimize the risk of inducing urinary tract infection.<sup>14,83,85</sup> Cystitis is, however, a frequent complication, particularly in recumbent horses, and can lead to bladder wall necrosis, bladder rupture, and systemic sepsis. Urine scalding can become a major problem, particularly in mares that dribble urine. Prevention involves regular washing of the perineum, tail, and hind legs with water, application of water-repellent ointments, and braiding or wrapping the tail to simplify cleaning.<sup>14</sup> Administration of enemata or manual emptying of the rectum also may be necessary to promote defecation and improve patient comfort.<sup>14</sup>

Because vasculitis, hemorrhage, and edema are prominent early lesions and may have an immune basis, treatment with corticosteroids early in the disease course is recommended by some clinicians, although no objective data are available to document the efficacy of these or other anti-inflammatory drugs.<sup>44,52,83</sup> A short course of treatment with prednisolone acetate (1 to 2 mg/kg/day) or dexamethasone (0.05 to 0.25 mg/kg parenterally twice daily) for 2 to 3 days with decreasing doses over another 1 to 3 days may be beneficial.<sup>14,52,85</sup> Flunixin meglumine (1.1 mg/kg body mass every 12 hours) is indicated to treat CNS vasculitis. DMSO at a dose of 0.5 to 1.0 g/kg administered intravenously as a 10% to 20% solution in normal saline or 5% dextrose once daily for up to 3 days commonly is used to treat horses with suspected CNS trauma or inflammatory disease, such as EHV-1.<sup>11,14</sup> Although the efficacy of DMSO for treating herpesvirus myeloencephalopathy has not been evaluated, its reported ability to inhibit platelet aggregation and scavenge free radicals support its continued use. Because of the high risk of development of cystitis and other secondary bacterial infections, administering broad spectrum antibiotics such as potentiated sulfonamides (trimethoprim-sulfamethoxazole 30 mg/kg body mass orally every 12 hours) or ceftiofur (2.2 mg/kg body mass intramuscularly or intravenously every 12 hours) is advisable, particularly when corticosteroid treatment is used.<sup>10,14,52</sup> One should base the choice of antibiotics for treating established secondary bacterial infections of the urinary tract, respiratory tract, or other areas on the results of culture and susceptibility testing.

Acyclovir, a synthetic purine nucleoside analog with inhibitory activity against several human herpesviruses, has been shown to exert an inhibitory effect on EHV-1 *in vitro*.<sup>106</sup> Apparent efficacy of acyclovir was suggested by a successful treatment outcome in occasional outbreak situations.<sup>60,107</sup> Although these anecdotal reports seemed promising, data describing the pharmacokinetics, bioavailability, and safety of acyclovir in horses do not support claims of efficacy, especially after oral administration. Bioavailability of acyclovir after oral administration to horses is extremely low; in contrast, bioavailability of valacyclovir, a prodrug for acyclovir, is much higher.<sup>108,109</sup> Clearly, additional studies are needed to define the appropriate dose for valacyclovir in horses and to document its efficacy for the treatment of EHV-1 myeloencephalopathy.

Another nucleoside analog, penciclovir, has been shown to have excellent activity against EHV-1 in tissue culture and in a mouse model of EHV-1 infection.<sup>110</sup>

Affected horses that remain standing have a good prognosis for recovery, and improvement generally is apparent within a few days, although a period of several weeks to more than a year may be required before horses with severe deficits show complete recovery.\* In these instances, control of urination frequently returns before gait abnormalities resolve completely.<sup>83</sup> Some horses may be left with permanent residual neurologic deficits, including urinary incontinence and ataxia, that may necessitate euthanasia many months beyond onset of neurologic signs.<sup>10,52,56,57</sup> Horses that become recumbent have a greatly increased likelihood of developing complications such as myonecrosis, urinary tract infection, decubital ulcers, respiratory tract infection, gastrointestinal obstruction and ulceration, injuries, and complications of dehydration and malnutrition. Their prognosis for recovery is therefore poor, particularly if they remain recumbent for more than 24 hours and they are unable to stand after being lifted with a sling.<sup>9,10</sup> One should not elect euthanasia prematurely in valuable horses, however, because reports document horses standing again and recovering completely to race successfully after being recumbent for several days to 3 weeks.<sup>44,54,58</sup> Most mildly affected mares return to breeding soundness in the same season, whereas fertility is likely to be compromised in more severely affected mares that experience urinary retention.<sup>9</sup> Recurrence or exacerbation of neurologic signs in horses that have recovered completely has not been documented, even though the majority likely remain latently infected.<sup>21,34,52,83</sup>

## ⊕ PATHOLOGIC FINDINGS

When horses with suspected EHV-1 myeloencephalopathy die or are euthanized, one should submit the whole carcass or at least the head, spine, spleen, thyroid, and lung for postmortem examination because lesions frequently are not confined to the CNS of horses with EHV-1 myeloencephalopathy.\* Gross pathologic lesions in the CNS frequently are not found, but small (2 to 6 mm) focal areas of hemorrhage distributed randomly throughout the meninges and parenchyma of the brain and spinal cord may be observed.† More diffuse dural hemorrhage is notable in some cases and may extend to spinal nerve roots and the cauda equina.<sup>50,51,62</sup> Small plum-colored areas of degeneration and hemorrhage are sometimes grossly visible in fresh tissue at various levels of the spinal cord (white matter), and malacic foci may be visible macroscopically in the gray and white matter in sliced fixed sections of brain.<sup>50,51,58,59,62</sup>

The gross and histologic lesions in the CNS reflect vasculitis, congestion, and secondary ischemic degeneration of nervous tissue.‡ Although vasculitis is a consistent finding, degeneration of nervous tissue is evident chiefly in those horses with clinical signs of severe neurologic disease.<sup>45,50,51</sup> The vasculitis is often severe and has a widespread, random, multifocal distribution, with the most severe lesions usually in the brainstem and spinal cord. In the brain the meningeal and penetrating or radiating vessels in gray matter are the

\*References 10, 39, 44, 56, 60, 82, 84, 85.

\*References 9, 21, 36, 45, 50, 51, 62.

†References 21, 45, 51, 58, 59, 62.

‡References 45, 50, 51, 58, 59, 62.

major sites of vascular involvement. Thus foci of axonal swelling and malacia develop in the gray and white matter, particularly adjacent to the meningeal surface and in the deep cortex adjacent to the white matter.<sup>50,51,62</sup> In the spinal cord a similar orientation to meningeal vessels results in degeneration of white matter within ovoid, linear, or wedge-shaped foci, affecting predominantly the lateral and the ventral white columns.<sup>51</sup> In some instances, sheaths of nerve roots and nerves and capsules of ganglia also are involved.<sup>45,50,51,52</sup> Trigeminal ganglionitis may be present but usually is not manifest clinically.<sup>54</sup>

Ocular lesions, including uveal vasculitis with perivascular mononuclear cell cuffing in the ciliary body and optic nerve or extensive retinal degeneration, have been observed in foals showing signs of bilateral hypopyon and iritis or severe visual impairment and chorioretinopathy without anterior segment involvement during field and experimental EHV-1 infections.<sup>9,45,51,62,75</sup> In some foals, EHV-1 appears to induce ocular and neural damage in the absence of gross signs of neurologic or visual impairment.<sup>75</sup> During paralytic infections, secondary viral replication occurs in blood vessels of the testis and epididymis in addition to CNS and may be responsible for reported signs of scrotal edema and loss of libido in affected stallions.<sup>9,111</sup>

EHV-1 infrequently is isolated from the CNS of affected horses that show typical lesions.\* Thus one should attempt to isolate the virus from other sites to support the diagnosis. Those sites most likely to yield virus or to contain viral antigen include the turbinates and nasal passages, as well as lymph nodes draining the upper respiratory tract, lung, thyroid, spleen, and endometrium, in addition to the brain.<sup>45,52,101</sup> Immunofluorescent antibody testing of brain and spinal cord sections is considered to be more sensitive than virus isolation, but false-negative results have been observed.<sup>45,52,61</sup> An indirect immunoperoxidase method using orthodox light microscopy was highly sensitive for identifying individual antigen-containing cells in the CNS and other areas of the body, even at sites containing few or no lesions or inclusion bodies and in which virus could not be detected by immunofluorescent antibody testing or virus isolation.<sup>45</sup> Similarly, the PCR technique is more sensitive than virus isolation for detecting viral antigen in nasopharyngeal swabs collected from horses with respiratory tract disease caused by EHV-1 or EHV-4.<sup>94</sup> Both of these techniques—as well as antigen-capture ELISA tests, dot immunobinding, and *in situ* DNA hybridization, which are sensitive and readily differentiate between EHV-1 and EHV-4—show great promise for routine application to samples collected antemortem or at necropsy from affected horses.<sup>45,73,92,95,99</sup>

## ☞ CONTROL AND PREVENTION

Control measures during outbreaks of EHV-1 infection aim at reducing spread by infectious aerosols, direct contact, and fomites, as well as at reducing stress-induced recrudescence of latent EHV-1 infection.<sup>1,2,21</sup> If neurologic signs or other clinical signs suggestive of EHV-1 infection occur, then one should isolate affected animals promptly and completely in a well-ventilated airspace separate from the remainder of the herd. In-contact horses should be isolated in their current location

in small groups for at least 1 month; pregnant mares should be isolated preferably until they foal.<sup>1-3,9,21,44,86</sup> On breeding farms, one should suspend covering.<sup>9</sup> Aborted fetuses and fetal membranes are rich sources of infectious virus; therefore they should be collected and placed in leak-proof containers (e.g., heavy-gauge plastic bags) for submission for diagnostic evaluation or disposal by burning.<sup>1,2</sup> Similarly, bedding and dirt contaminated with fetal fluids should be disposed of or burned, and stalls or other areas occupied by infected horses should be cleaned thoroughly, disinfected with an iodophor or a phenolic product, and left empty for several weeks.<sup>21</sup> Equipment used to handle, groom, feed, water, muck out, or transport affected horses also should be cleaned and disinfected or disposed of properly. Thereafter separate equipment and personnel should be used for affected and unaffected horses, or at least caretakers should handle affected horses last and wear disposable gloves, surgical masks, and protective clothing that can be changed or disinfected between groups.<sup>21</sup> Although control measures are frequently successful in stopping further spread of infection during outbreaks, one should note that transmission of infection before control measures are implemented may result in a secondary waves of disease 1 to 2 weeks later.<sup>9,21,44</sup>

Traffic of horses and human beings on the premises should be minimized, and movement of horses onto and off of the infected premises should be suspended until at least 3 weeks after resolution of acute signs in the last clinical case or until tests show that virus transmission is no longer occurring.<sup>1-3,14,21</sup> Collection of nasal swabs and uncoagulated blood (buffy coat) samples from clinically affected and exposed horses within each group and demonstration of stable or declining antibody titers in serum samples proved to be helpful in determining patterns of exposure and spread and in establishing when virus transmission had ceased in one reported outbreak. Protracted viremia lasting several weeks or months occurs in some horses and extends the period during which movement of horses should be restricted.<sup>9</sup>

If horses must enter the farm, they should be current on EHV-1 vaccination and should be isolated away from the resident population. Although giving booster vaccinations to exposed pregnant mares during outbreaks of abortigenic EHV-1 infection is common practice,<sup>1,2,21</sup> vaccination of exposed horses during outbreaks of EHV-1 myeloencephalopathy has not been investigated and cannot be recommended at this time because of the possibility of an immune-mediated pathogenesis. Administering booster doses of inactivated EHV-1 vaccine to all unexposed horses that have not been vaccinated within the previous month is common practice, however.

Preventive measures should include routine management practices aimed at reducing the chances of introducing and disseminating infection.<sup>3,21,74,113</sup> New arrivals should be isolated for at least 3 weeks before joining the herd, distinct herd groups should be maintained based on the age and use of horses, and care should be taken to minimize or eliminate commingling of resident horses with visiting or transient horses. In particular, pregnant broodmares should be maintained in groups separate from the remaining farm population. In addition, minimizing stress associated with overcrowding and handling procedures is prudent in an attempt to reduce recrudescence of latent EHV-1 infection.<sup>21,34,74,113</sup>

No method is known that reliably prevents the neurologic form of EHV-1 infection. None of the EHV-1 or EHV-4 vaccines currently available carry a claim that they prevent EHV-1

\*References 41, 45, 48, 52, 55, 58, 59, 72, 101, 112.

myeloencephalopathy, and the disease has been observed in horses vaccinated regularly at 3- to 5-month intervals with inactivated or modified live vaccines.<sup>14,52,57,59,60</sup> Repetitive administration of currently available EHV-1 and EHV-4 vaccines appears to induce some immunity to respiratory disease and reduce the incidence of abortion but does not block infection and induction of viremia or eliminate the possibility of clinical disease and establishment of the carrier state.<sup>1,2,21,59,113-118</sup> Although the protection induced by inactivated EHV-1 vaccines is incomplete and of short duration, the vaccine reduces virus excretion in horses that do become infected.<sup>115,118</sup> To maintain appropriate vaccination procedures in an attempt to reduce the incidence of other manifestations of EHV-1 infection and reduce the magnitude of challenge experienced by in-contact horses is logical. This indirectly may help prevent EHV-1 myeloencephalopathy.<sup>52</sup> An attenuated live virus vaccine based on the temperature-sensitive and host range mutant clone 147 of EHV-1 has been evaluated recently. The novelty of this vaccine lies in the fact that a low dose administered intranasally replicated in conventional target species and conferred exceptional efficacy against respiratory disease, virus shedding, viremia, and abortion caused by a severe EHV-1 challenge.<sup>119-121</sup> Intranasal vaccine also claims to protect against less common manifestations of EHV-1 infection such as paresis and jaundice.<sup>8</sup>

## POLYNEURITIS EQUI

William J. Saville

Polyneuritis equi is an uncommon neurologic disease of all equine species that is characterized by tail and anal sphincter paralysis, often accompanied by cranial and peripheral nerve damage.<sup>1-13</sup> Previous reports referred to the disease as *neuritis of the cauda equina* because of the susceptibility of this region, but frequent involvement of the cranial and peripheral nerves led to the term *polyneuritis equi*.<sup>2</sup> Although the disease has been recognized more readily in Europe, where Dexler first reported it in 1897, cases have now been reported in Great Britain, Canada, and the United States.<sup>3,4,6,14</sup> The disease does not appear to have a breed, gender, or age predilection, but the youngest horse affected was 17 months of age.<sup>2,5,6,13-15</sup>

The cause of this disease is unknown. Primary immune reaction and viral inflammatory disease have been suggested, although possibly one may be a consequence of the other.<sup>2</sup> Several infectious agents have been suggested, such as EHV-1, equine adenovirus, and streptococcal and *Campylobacter* spp. bacteria.<sup>10,12,16</sup> The pathologic lesions resemble those of Guillain-Barré syndrome in human beings, and the disease is similar to experimental allergic neuritis in rats.<sup>10,13</sup> Evidence suggests that the immune system is involved because horses with polyneuritis equi have circulating antibodies to P2 myelin protein, which is present in rats with experimental allergic neuritis.<sup>10,17</sup> Inflammatory lesions contain both T and B lymphocytes, suggesting the possibility of an immune-mediated reaction to myelin.<sup>18</sup>

## CLINICAL SIGNS

Although the disease manifests itself in two forms, signs are generally slow and progressive: (1) the acute or early signs include hyperesthesia of the perineal or head regions (or both), and (2) in the chronic form, horses show paralysis of

the tail, anus, rectum, and bladder. Paralysis often is accompanied by fecal and urinary retention, urinary scalding of the pelvic limbs, and penile paralysis in male horses.\*

The pelvic limb signs are often symmetrical, whereas the signs involving the head and cranial nerves are often asymmetrical.<sup>6,13,15</sup> Muscle atrophy in the gluteal region is sometimes present along with mild degrees of ataxia.<sup>2,3,5,6,9</sup> Muscle atrophy associated with cranial nerve involvement may occur in the head region. Damage to peripheral motor nerves may result in gait deficits and abnormal use of thoracic or pelvic limbs.<sup>1,12,13,15</sup>

Although cranial nerve involvement is reported primarily to affect cranial nerves V, VII, and VIII, any of cranial nerves II, III, IV, VI, IX, X, and XII also may be involved.<sup>2,4,5,8,13</sup> As a result of damage to the cranial nerves, horses may have trouble with mastication and swallowing.<sup>12</sup> A head tilt, ear droop, lip droop, and ptosis are common signs.<sup>8,12,13</sup> One report describes a horse with brachial neuritis along with involvement of cranial nerves V, VII, and XII. The horse in that report also exhibited mild ataxia and weakness in all limbs. The horse performed the hopping test poorly on the right thoracic limb, and the horse resented palpation in the right caudal cervical and prescapular region.<sup>2</sup>

Colic caused by fecal retention may be the primary sign when one initially examines horses with polyneuritis equi. Fecal retention leads to an impaction caused by the flaccid anal sphincter, often accompanied by an atonic, distended bladder.<sup>1</sup> If the clinician sees these signs in the acute or hyperesthetic form, then they usually progress to the chronic form of hypalgesia or anesthesia. An area of hyperesthesia may surround the area of anesthesia.<sup>1,2,8</sup>

## DIAGNOSIS

The definitive diagnostic test is a postmortem examination. The peripheral white blood cell count usually reveals a mature neutrophilia with hyperfibrinogenemia, mild to moderate anemia, and an increased total protein—all indications of a chronic inflammatory process.<sup>3,5,13,15</sup> Examination of the CSF may reveal an elevated protein (70 to 300 mg/dl), along with an elevated white blood cell count, which indicates a mononuclear inflammatory reaction, although cytologic examination of CSF may be normal, particularly in the acute stage of the disease.\*

Radiography may be helpful to rule out trauma to the tail-head or cranial nerve involvement, such as a fractured petrous temporal or other bones of the skull.<sup>2,8</sup>

Some horses with clinical signs exhibit circulating serum antibodies to P2 myelin.<sup>10,17</sup> However, the presence of this antibody is only weakly supportive of the diagnosis, because the same antibody has been detected in horses with EHV-1 and equine adenovirus infections.†

Classically, the primary pathologic lesions involve the extradural nerve roots but also may involve the intradural nerve roots.<sup>2,3,5,12,13</sup> The lesions are granulomatous with various degrees of inflammation and infiltration of lymphocytes, eosinophils, macrophages, giant cells, and plasma cells. This inflammation leads to myelin degeneration, subsequent axonal degeneration, and thickening of the epineurium, endoneurium, and perineurium with proliferation, which causes obliteration of the neural architecture by the fibrous tissue.<sup>1,2,9,13</sup> The most

\*References 1-3, 6, 8, 9, 12, 13, 15.

†References 2, 3, 5, 6, 8, 11, 13.

‡References 1, 2, 10, 13, 16, 19.

severe lesions are in the cauda equina, but swelling, edema, and hemorrhage of cranial nerves may occur. The fibrous tissue formation may lead to adhesions between the meninges and the periosteum of the vertebral bodies.<sup>13</sup> Reports describe involvement of the autonomic nervous system, but no changes in clinical signs have been reported (post mortem only).<sup>2,4</sup>

The polyneuritis lesions are similar to those observed with Guillain-Barré syndrome in human beings, experimental allergic neuritis in rats, and coonhound paralysis in dogs.<sup>2,5,11-13</sup> This similarity may indicate a combination of inflammatory and immune-mediated mechanisms in the pathogenesis of polyneuritis equi.

## ☞ DIFFERENTIAL DIAGNOSIS

The most important differential diagnosis is trauma to the sacrococcygeal area of the spinal canal, which can be differentiated by radiography of the area looking for fractures or displacements.<sup>2,6,8</sup> EPM is the second most common disease in the differential diagnosis of polyneuritis equi. The usual signs of EPM include asymmetrical damage in the limbs and brain and brainstem lesions causing cranial nerve deficits with alterations in attitude, whereas the cranial nerve deficits of polyneuritis equi are peripheral, with no change in attitude.<sup>6</sup> This disease may be differentiated from polyneuritis equi by Western blot analysis of the CSF.<sup>20</sup> EPM is discussed in detail elsewhere in this text.

EHV-1 myeloencephalitis may be preceded by an episode of fever, cough, and nasal discharge or one or more abortions on a farm. This condition frequently affects more than one horse on a farm. Herpesvirus has a rapid onset and often results in severe hindlimb weakness and ataxia along with bladder dysfunction. Urinary dribbling sometimes may occur. The ataxia and weakness is usually symmetrical and may result in recumbency. Occasionally, affected horses sit like a dog because of profound pelvic limb weakness. Cranial nerve involvement is not common but may occur between 10% to 15% of affected horses.<sup>21-24</sup>

One should consider verminous myeloencephalitis as a differential diagnosis for polyneuritis equi. The signs vary and depend on the migratory pathway of the parasite. Diffuse or multifocal brain and spinal cord lesions have been reported. The onset is usually sudden with rapid deterioration and death. The incidence of this disease is low, perhaps because of more intense parasite control.<sup>25-27</sup>

One should consider EMND in the differential diagnosis. Horses with motor neuron disease have symmetrical muscle wasting or atrophy and weight loss with significant weakness, sweating, and muscle fasciculations. However, these horses are not ataxic and their unique clinical feature is that they walk better than they stand. This disease is a denervation atrophy of type 1 muscle fibers only and may be diagnosed by a spinal accessory nerve biopsy or sacrodorsalis caudalis muscle biopsy.<sup>28</sup>

## ☞ TREATMENT

The primary therapy is palliative. No treatment for the disease is known. Removing feces from the rectum and evacuating the bladder are usually necessary. If cystitis caused by bladder distention occurs, then systemic antibiotics may be indicated. Some attempts have been made at treating the inflammation with corticosteroids, but the effects have been short lived. The

prognosis is usually poor, but the progression of the disease is slow. Some animals may be maintained for many months.\*

## VIRAL ENCEPHALITIS

*Joseph J. Bertone*

A wide variety of viruses can affect the CNS of horses, resulting in encephalitis or meningoencephalitis. Rabies, caused by a member of the Rhabdoviridae family, and WNV, a member of the Flaviviridae family, are discussed in detail elsewhere in this chapter. This section describes disease resulting from infections with members of the Togaviridae family of viruses (eastern, western, and Venezuelan encephalitis) and CNS infections caused by viruses from miscellaneous viral families.

## ☞ TOGAVIRAL ENCEPHALITIS

Togaviridae are small, lipid- and protein-enveloped RNA viruses. Those that cause disease are insect-borne viruses (arboviruses) of the genus *Alphavirus*. The structure of the viruses and associated clinical presentations are similar among the viruses, but the epizootiology and antigenicity are distinct. In general, birds, rodents, and reptiles act as reservoirs. Mosquitoes often play a role in transmitting the disease among these species. Mosquitoes and, less commonly, other insects feed on sylvatic hosts and subsequently transmit the disease to horses and human beings.

### ALPHAVIRUS ENCEPHALITIDES: EASTERN, WESTERN, AND VENEZUELAN EQUINE ENCEPHALOMYELITIS

EEE, WEE, and Venezuelan (VEE) equine encephalitis viruses are the most frequently isolated alphaviruses from epidemics of encephalitis in horses and human beings in the Western Hemisphere (Table 12-13). The first recorded epidemic of EEE in North America likely occurred in Massachusetts in 1831.<sup>1</sup>

#### CAUSE

The alphaviruses are single-stranded, linear, positive-sense RNA viruses that measure between 60 to 70 nm in diameter. EEE and WEE are specific and discrete togaviral species; North and South American antigenic variants of EEE exist.<sup>2</sup> WEE is a recombinant between an EEE-like virus and a Sindbis-like virus.<sup>3</sup> Two antigenic subtypes of WEE virus exist: (1) WEE and (2) Highlands J viruses. The Highlands J virus causes most infections that occur east of the Mississippi River. The various strains have equivocal differences in antigenic properties and biologic behavior, and extensive geographic overlap occurs.<sup>2</sup> The molecular basis for the antigenic variation between EEE and WEE has been described.<sup>4</sup> VEE virus has six distinct subtypes designated by Roman numerals I through VI. Subtypes IAB, IC, and IE are responsible for large outbreaks of encephalitis in horses in the Western Hemisphere in the past 20 years. The so-called endemic types of VEE virus are considered to be of low pathogenicity for horses under most circumstances.

\*References 2, 4-6, 8, 12, 13, 15.

TABLE 12-13

A Summary of the Major Togaviral Equine Encephalitides*						
Virus	Major Disease Vector	Zoonotic Potential	Amplification from Horses	Disease Spread	Viremia	Equine Mortality
EEE	<i>Aedes</i> spp.	Unlikely	Unlikely	Vector	Low	75%-100%
WEE	<i>Culex tarsalis</i>	Unlikely	Unlikely	Vector ± secretions	Low	20%-50%
VEE	<i>Culex melanconium</i> , <i>Aedes</i> spp. <i>Phosphora</i> spp.	Occurs	Occurs	Vector ± secretions	High	40%-80%

EEE, eastern equine encephalitis virus; WEE, western equine encephalitis virus; VEE, Venezuelan equine encephalitis virus.  
\*The statements made are generalizations, and some degree of variation occurs.

These include ID and IF variants from Central America and Brazil, respectively; type II (Everglades) virus found in Florida; and types II, IV, V, and VI viruses.<sup>5-8</sup>

### EPIZOOTIOLOGY

Encephalitis similar to the viral encephalitides has been reported in the United States for many years with high morbidity and mortality rates.<sup>9-11</sup> Evidence that an eastern and western virus exist and are antigenically distinct was first reported in 1933.<sup>12</sup> Horses immunized with strains of virus isolated from infected horses from the east or west were protected differentially when vaccinated with attenuated virus from one location and exposed to virus from the other.<sup>12-15</sup>

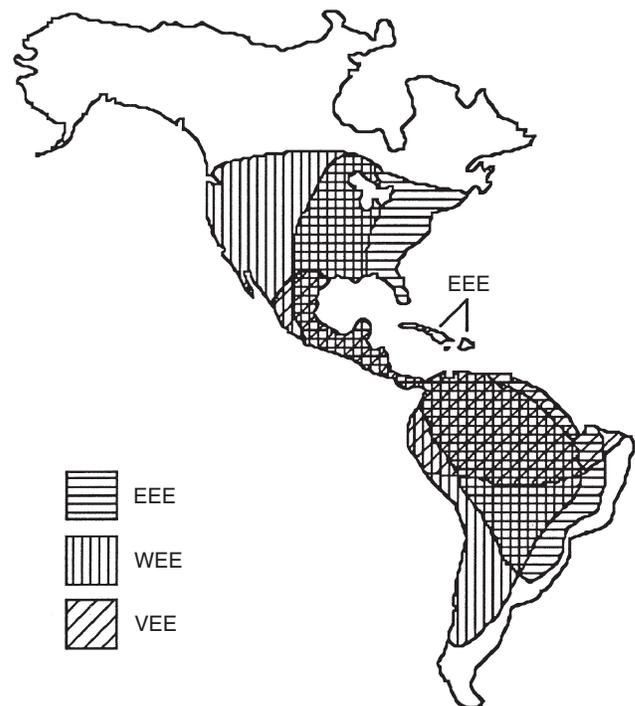

**Distribution** In general, disease associated with EEE, WEE, and VEE is restricted to the Western Hemisphere and ranges from temperate to desert climates. Each virus and incidence of associated equine disease has a characteristic distribution. The range of positive serologic tests for the viruses is often far greater than the range of clinical disease<sup>15-41</sup> (Figure 12-41).

EEE virus is found as far north as eastern Canada, south throughout the Caribbean, and in parts of Central and South America. Disease in the United States is primarily seen in the Southeastern United States but has been detected in all states east of the Mississippi River and some Western states. Outside the Western Hemisphere, EEE has been identified in the Philippines,<sup>42</sup> and some indications point to its presence in Europe.<sup>43</sup>

The WEE virus is recognized in reservoir avian hosts in the western United States; however, clinical disease rarely has been identified there in the last 20 years. Historically large outbreaks of WEE have been described in horses in California and other Western states. The reason for the dramatic decrease in incidence of clinical disease from WEE is largely unexplained to date. Geographic variation in virulence may be an explanation. Equine disease associated with WEE is rare on the Eastern seaboard of the United States but is recognized.<sup>44</sup>

Venezuelan equine encephalitis is a very important human and veterinary pathogen in the Western hemisphere that can cause large outbreaks of disease in human beings and horses over large geographic areas. Outbreaks have occurred in Mexico, Venezuela, and Colombia in recent years. The virus has also been recently isolated in Trinidad, French Guiana, Peru, and Brazil.

**Epidemic** Several requirements must be met for epidemics associated with alphavirus encephalitis to develop. Long lapses can occur between outbreaks if all of these conditions are not met. These prerequisites include adequate and adjacent

**FIGURE 12-41** Predominant distribution of *Alphavirus* spp.–associated equine encephalitis in the Western Hemisphere. This figure represents the disease distribution. Positive serologic results for the diseases are more widespread. EEE, Eastern equine encephalitis virus; WEE, western equine encephalitis virus; VEE, Venezuelan equine encephalitis virus.

numbers of reservoir animals, sufficient quantities of virulent viruses, infected intermediate hosts, insect vectors, and susceptible horse and human populations.<sup>45,46</sup> Prediction of outbreaks has been attempted but without success,<sup>1,38,47</sup> which indicates that other, unknown factors may exist.

**Reservoirs** With minor exceptions, Togaviridae persist by asymptotically infecting wild animals (sylvatic hosts) such as birds, small mammals, and reptiles by unknown mechanisms.<sup>48</sup> The viruses survive during the winter or nonvector season in sylvatic populations.<sup>47,49</sup>

**Vectors** Specificity of the viruses for particular vectors occurs. Vector distribution explains viral distribution to a large degree. The vectors for EEE include *Culiseta melanura* and *Aedes* spp.<sup>15,31,50,51</sup> *C. melanura* for the most part is confined to

freshwater swamps, feeds primarily on swamp birds, and rarely is found in areas of increased horse populations.<sup>15</sup> In general, *C. melanura* serves as the vector for the enzootic cycle, which involves swamp birds. *Aedes* spp. appear to be more important in epizootics and epidemics.

*Culex tarsalis* is the primary vector that maintains WEE virus in an enzootic cycle with passerine birds. *Dermacentor andersoni* ticks,<sup>52,53</sup> *Triatoma sanguisuga* (assassin bug),<sup>54,55</sup> and the cliff swallow bug (*Oeciacus vicarius*) may also be involved as vectors or overwintering reservoirs for WEE.<sup>52,56</sup> Several species of mosquitoes from at least 11 genera have been determined to be naturally infected with epidemic strains of VEE virus, including *Culex melanconium*, and *Mansonia*, *Aedes*, and *Psorophora* spp.<sup>18,19,25,26</sup> Ticks may also be capable of virus transmission.

**Vector Ecology** Vector transmission is the most important way infection spreads for any of the alphavirus encephalitides. WEE and VEE may spread by nasal secretions, but this is less likely.<sup>18,19,55,57</sup> Vectors transmit viral particles between sylvatic hosts when taking a blood meal. If the virus is able to penetrate the gut of the vector, then it may pass through the hemolymph to oral glands, multiply, and subsequently be shed in saliva and other oral secretions. If the blood meal contains adequate numbers of viral particles, then multiplication may not be required for transmission. In most instances and judiciously assumed, the mosquito remains infected for life.<sup>51,58</sup>

**Seasonal Incidence** In most instances the diseases occur during the height of the vector season. In temperate climates the highest number of cases occurs between June and November. In warm climates, where the vector season is longer, the disease problem lasts longer. Some of these attributes have contributed to disease outbreaks in colder climates where the disease has been less usual.<sup>59</sup> We are likely to see more cold-climate outbreaks with the increase in global temperatures.

**Zoonology** Clinical infection in human beings usually involves old or young persons. Signs and morbidity and mortality rates are virus specific.<sup>60</sup> Circulating virus concentrations are usually insufficient for transmission of EEE from infected horses to human beings, mosquitoes, and other animals. Human disease most likely is associated with insect vector contact and often coincides temporally with or is preceded by equine epizootics.<sup>1</sup> In the acute stages of equine disease, a transient, substantial viremia occurs. Therefore if vector density increases, then an acutely infected horse could be a transient amplifier of EEE. Spread from horse to horse is possible.<sup>50</sup> Clinical signs in human beings include acute fulminant encephalitis, headache, altered consciousness, and seizures. The mortality rate in human patients is between 50% to 75%.<sup>60</sup>

Human beings and horses are terminal hosts for WEE. Human cases of WEE occur, but fatality and incomplete recovery are rare. These cases are associated with vector contact. Environmental conditions that decrease exposure to insects decrease the incidence of disease.<sup>61</sup> Increased numbers of animals with clinical equine disease are an indication of heavy sylvatic concentrations of virus and are not a potential source of infection for human beings. Generally, increased numbers of horse cases precede cases in human beings by 2 to 5 weeks.<sup>62</sup> Thus horses are sentinels for human beings in a given area. Clinical signs in human beings include fever, headache, confusion, stupor, and seizures, with a 5% to 15% mortality rate.<sup>60</sup>

Horses with VEE have sufficient circulating viral concentrations that act as amplifiers of disease.<sup>25,63</sup> Ocular and nasal

secretions from infected horses contain high concentrations of VEE.<sup>18,19</sup> Infection via entry through the respiratory tract may occur by direct contact with infected animals. Equine and human survivors of VEE infection and clinical disease may develop chronic relapsing viremias and serve as chronic disease amplifiers.<sup>63</sup> Clinical signs in human beings include fever, headache, myalgia, and pharyngitis. The mortality rate in human beings is 1%.<sup>60</sup>

With any of the alphaviral equine encephalitides, sufficient viral particles for infection may be present in CNS and other tissues, and one should take precautions when performing a necropsy examination on suspect cases. Strict mosquito control and vaccination can prevent human and equine cases, and all equine cases should be reported to state health officials.<sup>1,63</sup> A recent study demonstrated that EEE has poor ability to replicate in lymphoid tissues, whereas VEE does so very efficiently. EEE can therefore avoid IFN- $\alpha$  and IFN- $\beta$  induction in vivo, which may allow EEE to evade the host's innate immune responses and thereby enhance neurovirulence. Inhibition of genome translation restricts EEE infectivity for myeloid but not mesenchymal cells. This factor likely contributes to the observed differences in disease cause and presentation.<sup>64</sup>

**Other Domestic Species** Outbreaks of disease because of EEE have been described in emus, ostriches, and swine, with isolated cases in cattle, sheep, and nondomestic ungulates.<sup>65-68</sup> Pigs may also be affected by VEE.<sup>68</sup> The signs of disease in these species are similar but are milder than disease in horses for the respective viruses. Burros and mules may contract all three diseases, and the disease is as severe as that identified in horses.<sup>69</sup>

## PATHOGENESIS

After viruses are inoculated, they multiply in muscle, enter the lymphatic circulation, and localize in lymph nodes. Viruses replicate in macrophages and neutrophils and subsequently are shed in small numbers. Many of the viral particles are cleared at this time. If clearance mechanisms are successful, then no further clinical signs develop. Neutralizing antibodies still will be produced. Several mechanisms of viral immunologic avoidance exist and include erythrocyte and leukocyte absorption. If viral elimination is not complete, then the remaining viruses infect endothelial cells and concentrate in highly vascular organs such as the liver and spleen. Viral replication in these tissues subsequently is associated with circulating virus. The second viremic period often is associated with early clinical signs of disease. Infection of the CNS occurs within 3 to 5 days.<sup>7,19,70,71</sup>

## CLINICAL SIGNS

Clinical signs are more profound in unvaccinated animals.<sup>62,72</sup> Acute clinical signs of EEE and WEE are nonspecific and include mild fever to severe pyrexia, anorexia, and stiffness. Viremia occurs during this period. A 1- to 3-week incubation period exists after experimental infection with EEE or WEE. The incubation period is often shorter with EEE than WEE. Early signs of the diseases include fever and mild depression. This stage is transient and, presumably, often undetected because of lack of overt clinical signs. The acute signs may last for up to 5 days after they first manifest. Many cases of WEE do not progress beyond this point. With EEE, progression is more common. Once nervous signs develop, the viremia is past, and animals are unlikely to be able to amplify the disease. In progressive cases the fever may rise and fall sporadically. Cerebral signs may develop at any time but often occur a few days after infection. Acute signs often range from propulsive walking,

depression, and somnolence to hyperesthesia, aggression, and excitability. Some horses may become frenzied after any sensory stimulation. Conscious proprioceptive deficits often are evident in the early stages. With progression, signs become less disparate and more consistent between EEE and WEE. The later signs are evidence of the dynamic nature of these conditions and increased severity of cerebral cortical and cranial nerve dysfunction. These signs include head pressing, propulsive walking, blindness, circling, head tilt, and facial and appendicular muscle fasciculations. Paralysis of the pharynx, larynx, and tongue is common. Death often is preceded by recumbency for 1 to 7 days. Comatose animals rarely survive. If animals are to survive, then they show gradual improvement of function over weeks to months.<sup>72-75</sup>

VEE may have similar or different clinical presentations compared with WEE and EEE, which is most likely because of the difference in strain pathogenicity and persistent high titer viremia with VEE.<sup>18,71</sup> The pyrexia in cases of VEE peaks early and remains increased through the course of the disease. In experimental disease, endemic strains are associated with mild fever and leukopenia. Epidemic strains are associated with severe pyrexia and leukopenia.<sup>7,71</sup> Diarrhea, severe depression, recumbency, and death may be prominent before neurologic deficits are evident. Neurologic signs occur at approximately 4 days after infection. Other associated signs include abortion, oral ulceration, pulmonary hemorrhage, and epistaxis.<sup>18,19</sup>

## DIAGNOSIS

The presumptive diagnosis is based on findings at clinical presentation and the presence of associated epidemiologic features. Serologic and necropsy evaluation provide a definitive determination.

**Clinical Immunology and Virology** One usually identifies viral infections by complement fixation, hemagglutination inhibition, and cross-serum neutralization assays. A combination of these techniques increases the likelihood of a positive diagnosis.<sup>76</sup> A fourfold increase in antibody titer in convalescent sera commonly is recommended for diagnosis. However, one possibly may not detect a rise in titer. Viral antibodies are commonly present within 24 hours after the initial viremia, and their presence often precedes clinical encephalitis.<sup>43</sup> The concentration of antibodies increases rapidly and then decreases over 6 months.<sup>77</sup> An initial sample often is taken when encephalitic signs are present, which may be after titers have peaked. Therefore a second sample possibly may have a decreased titer compared with the initial sample. If increased titers exist for hemagglutination inhibition, complement fixation, and neutralizing antibody, then one can make a presumptive diagnosis on a single sample.<sup>76</sup> In the case of suspected VEE, an ELISA can detect viral-specific immunoglobulin M (IgM) antibodies to surface glycoprotein by 3 days after the onset of clinical signs. These antibodies are not produced in response to vaccine. The antibodies disappear by 21 days after infection.<sup>77</sup> The assay for confirming acute VEE infection should be used when one cannot collect convalescent serum samples. Viral cultures are unlikely to be fruitful, except in the case of acute VEE. One may isolate the virus from CSF of horses with acute infections.<sup>19</sup> The usefulness of CSF viral titers in light of a negative viral isolation is questionable. Fluorescent antibody, ELISA, and viral isolation are useful in identifying virus in brain tissue.<sup>78,79</sup>

Colostrals antibodies may interfere with diagnosis in foals. The antibody titers to VEE, WEE, and EEE viruses in the sera

of 2- to 8-day-old foals are similar to those of dams. The serum half-life of maternal antibodies in foals is approximately 20 days.<sup>80</sup>

**Clinical Pathology** The CSF changes associated with togaviral infections are similar to those of other viral encephalitides and include increased cellularity (50-400 mononuclear cells per microliter) and protein concentration (100 to 200 mg/dl).

**Necropsy Findings** For animals that die or are euthanized, one should perform necropsy and gross and histologic examinations with special reference to the CNS. With any of the alphaviral equine encephalitides, sufficient viral particles for infection may be present in CNS and other tissues, and one should take precautions when performing a necropsy examination on suspect cases. The brain and spinal cord often have a normal gross appearance. In some cases vascular congestion and discoloration of the CNS is evident. Histologic findings include nonseptic mononuclear cell and neutrophilic inflammation of the entire brain.<sup>18,81-83</sup> Severe lesions are evident in the cerebral cortex, thalamus, and hypothalamus. Specific lesions include significant perivascular cuffing with mononuclear and neutrophil cell infiltration, gliosis, neuronal degeneration, and mononuclear cell meningeal inflammation. With VEE, liquefactive necrosis and hemorrhage of the cerebral cortex, atrophy of the pancreatic acinar cells, and hyperplasia of the pancreatic duct cells commonly occur.<sup>82</sup> Immunohistochemistry can be diagnostic on necropsy samples.<sup>84,85</sup>

**Differential Diagnosis** The differential diagnosis for EEE, WEE, and VEE should include other conditions associated with diffuse or multifocal neurologic deficits such as other togaviral encephalitides, trauma, hepatoencephalopathy, rabies, leukoencephalomalacia, bacterial meningoencephalitis, EPM, verminous encephalitis, and WNV. Plant and other toxins should also be considered.

## TREATMENT

No known effective, specific treatment of the viral encephalitides exists. Treatment is primarily supportive. NSAIDs (phenylbutazone, 4 mg/kg every 12 hours; flunixin meglumine, 1 mg/kg every 12 to 24 hours) control pyrexia, inflammation, and discomfort. DMSO given at 1 g/kg intravenously in a 20% solution may be useful in controlling inflammation and provides some analgesia and mild sedation. The use of corticosteroids is controversial because beneficial effects are short term and the risk of developing secondary bacterial infections increases. One may control convulsions with pentobarbital, 0.05 to 2.2 mg/kg diazepam administered intravenously, 2 mg/kg phenobarbital given orally, or 0.2 to 1.0 mg/kg phenytoin administered intravenously. If horses develop secondary bacterial infections, then one should use appropriate antibiotic therapy. One should monitor hydration and administer balanced fluid solutions orally or intravenously as needed. Other supportive care should include dietary supplementation and administration of laxatives to minimize the risk of gastrointestinal impaction. If anorexia persists for more than 48 hours, then enteral or parenteral supplementation should be used; one can use commercial formulations. For the short term, pelleted feeds may be put into suspension for oral administration. Protection from self-induced trauma may require protective leg wraps and head protection. If the horse is recumbent, then one should attempt to provide support in a sling, and all animals should be bedded heavily.

## PROGNOSIS

Complete recoveries from the neurologic deficits associated with these viruses are reported, but they are rare.<sup>84</sup> Animals that have recovered from EEE often have residual neurologic deficits that commonly include ataxia, depression, and abnormal behavior. Neurologic sequelae are similar but less common in horses that recover from WEE. For horses that develop neurologic disease, the mortality rate for EEE is between 75% to 100%; for WEE, 20% to 50%; and for VEE, 40% to 80%.<sup>18,43</sup> If horses recover from any of the diseases, then they seem to be protected variably for up to 2 years after infection. One would wisely assume that infection affords no protection.

## PREVENTION

Prevention of alphavirus encephalitis should aim at reducing the concentration of insect vectors and implementing vaccination programs.<sup>35-37,86-90</sup> Most vaccines are killed (formalin inactivated) viruses of chick tissue culture origin. Significant increases in antibody titer occur at 3 days after vaccination.<sup>18,19,89-92</sup> One should vaccinate susceptible horse populations with monovalent, divalent, or trivalent vaccines containing EEE, WEE, or VEE. Administration of trivalent vaccines increases specific antibody production to all viruses. Some cross-protection exists between EEE and WEE and between EEE and VEE, but none exists between WEE and VEE.<sup>80,93,94</sup> If one is to give VEE vaccine, then simultaneous administration of all three vaccines is recommended.<sup>95-97</sup> The response to VEE vaccination alone is poorer in horses previously vaccinated against WEE and EEE.<sup>91,92,96,97</sup> VEE vaccination does not seem to interfere with responses to EEE or WEE vaccination.<sup>98</sup> One should complete annual vaccinations in late spring or several months before the beginning of the encephalitis season. Adequate titers appear to last for 6 to 8 months. In areas in which the mosquito problem is prolonged or continuous, biannual or triannual vaccination is suggested. Vaccination of susceptible horses in the face of an outbreak is recommended. If vaccinated horses develop disease, then the affected individuals are often young or old. Vaccination of mares 1 month before foaling enhances colostral antibody concentrations. Antibody concentrations in foals born to immunized mares appear by 3 hours after colostrum is fed and persist for 6 to 7 months.<sup>80</sup> Vaccination may begin at any age, but if they are vaccinated early, one should revaccinate foals at 6 months and 1 year to ensure adequate protection. Foals respond to vaccination with VEE in utero.<sup>99</sup> A prospective study to determine the serologic response of previously vaccinated horses to revaccination against EEE and WEE identified that horses responded variably to each antigen, and some horses had low or undetectable antibodies 6 months after vaccination. Some horses did not develop increasing titers to EEE or WEE despite recent vaccination. Geometric mean titers peaked 2 weeks after revaccination and were significantly increased from before revaccination.<sup>100</sup>

Owners should use insecticides and repellents when possible and practical, should eliminate standing water, and in endemic areas or during an outbreak should implement environmental insecticide application and should screen stalls. Horses with VEE can be persistently viremic and should be quarantined for 3 weeks after complete recovery. Cases of VEE must be reported to regulatory authorities in the United States. Public health officials may institute other measures of disease control.

## ☪ MISCELLANEOUS VIRAL ENCEPHALITIDES

California encephalitis is a mosquito-borne disease caused by a group of closely related viruses belonging to the *Orthobunyavirus* genus of the Bunyaviridae family. Snowshoe hare and Jamestown Canyon viruses have been isolated in Canada and California. Snowshoe hare virus is the most widely occurring arbovirus in Canada and is maintained in an amplification cycle involving small mammals and mosquitoes primarily of the *Aedes* genus. Seroconversion without clinical disease is widespread.\* One report exists of acute encephalitis with complete recovery in a horse that seroconverted to the snowshoe hare serotype of California encephalitis viruses.<sup>116</sup> Jamestown Canyon virus has been isolated from vesicular lesions in a horse.<sup>117,118</sup>

Main Drain virus, a member of the *Orthobunyavirus* genus of the Bunyaviridae family that is not part of the California encephalitis serogroup, was isolated from the brain of a horse with encephalitis in Sacramento County, California. Signs included incoordination, ataxia, stiffness of the neck, head pressing, dysphagia, fever, and tachycardia. The major vector is *Culicoides variipennis*, which transmits the virus from infected rabbits and rodents.<sup>107</sup> The Cache Valley virus, a member of the *Bunyamwervirus* genus of the Bunyaviridae family, has been isolated from a clinically normal horse; a high seroprevalence exists for this virus among horses in some geographic areas.<sup>115</sup>

St. Louis encephalitis virus is a member of the Flaviviridae family that is associated most commonly with encephalitis in human beings and may rarely be involved in equine disease. Experimental inoculation in horses produces viremia but no clinical signs. Neutralizing antibody is often present. *Culex pipiens* and *C. tarsalis* are the major vectors. Wild birds seem to be the primary reservoir.<sup>29,108-109</sup>

Powassan virus is also a member of the Flaviviridae family and has been associated with nonsuppurative, focal necrotizing meningoencephalitis in horses.<sup>110</sup> Antibodies for Powassan virus commonly are identified in Ontario and the Eastern United States. *Ixodes cookei*, *I. marxi*, and *Dermacentor andersoni* appear to be important vectors, with snowshoe hares and striped skunks as major reservoirs. Zoonoses occur after bites by infected ticks. Approximately 13% of horses sampled across Ontario in 1983 were serologically positive for the virus.<sup>110</sup> Experimental infection with Powassan virus strain M794 in horses was associated with neurologic deficits within 8 days. A nonsuppurative encephalomyelitis, neuronal necrosis, and focal parenchymal necrosis occur. Signs include tremors of the head and neck, ptyalism, myalgia, ataxia, and recumbency. No clinical signs were identified in inoculated rabbits, but widespread encephalitis characterized by lymphoid perivascular cuffing, lymphocytic meningitis, and lymphocytic choroiditis occurred.<sup>45,110</sup>

Experimental infection with Murray Valley virus, a member of the *Flavivirus* genus of the Flaviviridae family, results in transient pyrexia, myalgia, and ataxia. Horses are unlikely to be efficient amplifiers of this virus.<sup>111-113</sup> In Australia, the virus is more commonly a disease of human beings. An epidemic in human beings was associated with significant titers in horses. Some horses with clinical signs, significant titers, and histologic evidence of viral encephalitis were identified.<sup>113,114</sup>

\*References 46, 62, 95, 101-106, 115.

Nipah virus, a member of the *Henipavirus* genus of the Paramyxoviridae family, causes encephalitis in human beings and pigs in Southeast Asia. It is transmitted from bats to pigs, and then spreads horizontally to other pigs and human beings. One anecdotal report exists of dilated meningeal vessels in a horse from which Nipah virus was isolated.<sup>119</sup>

Equine encephalosis virus, a member of the *Orbivirus* genus of the Reoviridae family, is an insect borne virus transmitted by a variety of *Culicoides* spp.<sup>120,121</sup> Horses, donkeys, and zebra in Southern Africa are frequently seropositive. The clinical importance of equine encephalosis virus as a cause of neurologic disease in equids appears to be limited despite the fact that it was originally isolated from a horse with clinical neurologic disease. Clinical signs that have been attributed to equine encephalosis virus include fever, depression, edema of the lips, acute neurologic signs, enteritis, and abortion.<sup>122</sup>

Borna disease virus is a member of the *Bornavirus* genus of the Bornaviridae family, a group of enveloped viruses with a nonsegmented, negative sense, single-stranded RNA genome. It is the cause of a naturally occurring, infectious, usually fatal, progressive meningoencephalitis that affects horses and sheep most commonly.<sup>122</sup> Less often the virus affects other equids, cattle, goats, rabbits, and possibly human beings. The disease is recognized to date in Germany, Switzerland, Liechtenstein, and Austria. Antibody-positive horses are present in the Middle East, Asia, Australia, and the United States. The route of transmission is unclear but may occur through virus shed in body secretions, gaining entrance to a new host through exposed nerve endings in the nasal and pharyngeal mucosa.<sup>123</sup> Borna disease is caused by a virus-induced immunopathologic reaction.<sup>124</sup> Natural infection in horses results in peracute, acute, or subacute meningoencephalitis leading to death in 1 to 4 weeks in 80% of affected animals. Specific neurologic signs are variable but may include slow-motion eating, chewing motions of the mouth, head pressing, somnolence and stupor, hyperexcitability, fearfulness, aggressiveness, hypokinesia, abnormal posture, hyporeflexia, head tilt, neurogenic torticollis, and inability to swallow. Disease is confirmed serologically by detection of specific antibodies.

Other viruses, identified in areas around the world, that have been implicated in equine encephalitis or that are associated with encephalitis in other species and for which significant titers have been identified in horses include the louping ill,<sup>125,126</sup> Maguari,<sup>29,103,127</sup> Aura,<sup>28,127</sup> Una,<sup>28,127,128</sup> Highlands J,<sup>49,129</sup> Semliki forest,<sup>130</sup> and Getah viruses.<sup>131</sup>

## FLAVIVIRUS ENCEPHALITIS

Maureen T. Long

Emergence of new diseases or new outbreaks of previously described diseases are largely the product of globalization and global climate change. This has created an interface of exotic disease and new contacts with people, pests, and animals traveling over unprecedented distances as a result of modern transportation. Before 1999, the U.S. equine practitioner had little familiarity with flaviviruses and horse owners, for the most part, did not even know these diseases existed. After WNV was

first identified in the United States, the widespread outbreak in human beings and horses residing in Middle and Northern latitudes of the North American continent was not predicted.<sup>1-3</sup>

## ETIOLOGY

The family Flaviviridae consists of a pathologically active group of viruses composed of three genera that are found worldwide.<sup>4</sup> The genus *Flavivirus* contains many viruses (approximately 70) that are usually transmitted by either ticks or mosquitoes (some are through direct contact or the vector is unknown) and organized into groups according to cross-neutralization with polyclonal hyperimmune mouse ascites. A quarter of these viruses are of veterinary importance. The other two genera have viruses of veterinary and human importance with the genus *Pestivirus* containing the ubiquitous bovine diarrhea virus (BVD) and *Hepacivirus* containing the human pathogen, hepatitis C virus (HCV). At least half of the members of Flaviviridae are zoonotic.

The members of the Japanese encephalitis (JE) serogroup that are most likely to cause overt disease in horses are JE virus, WNV, and Kunjin virus (KV) (an Australian flavivirus, now considered a variant of WNV).<sup>5</sup> Disease in horses caused by Murray Valley Fever (MVF) is geographically restricted to the South Pacific, and disease in horses is sporadic.<sup>6-8</sup> Other members of this group and those belonging to the other major groups of flaviviruses have been detected serologically in horses with limited reports of clinical disease. The following discussion will emphasize WNV and JE.

All Flaviviridae are positive sense single-stranded RNA viruses measuring approximately 50 nm.<sup>9</sup> The virions are spherical and enveloped with the C protein, making up a nucleocapsid of about 25 nm. Electron microscopy reveals an icosahedral symmetry of the envelope and capsid of these viruses. An approximately 11-kb genome contains a single open reading frame that is translated in its entirety and cleaved into 10 viral proteins by both cell and viral proteases.<sup>10,11</sup> Three structural and seven nonstructural proteins exist; the structural proteins include the capsid (C), premembrane (prM) and membrane (M), and envelop (E) proteins. The nonstructural (NS) proteins, numbered 1 through 5, are cleaved after translation and are required for viral replication and assembly.

The final M protein and the E protein are important for virulence.<sup>12-17</sup> The M protein is formed from a precursor protein (prM protein) that is modified as immature virions are secreted through the Golgi network of the cell. The E protein is only secreted in its native conformation through association with the prM protein. The E protein is the immunodominant viral protein and is important in receptor ligand binding and fusion to host cells.

## EPIDEMIOLOGY

### LIFE CYCLE

Japanese encephalitis serogroup viruses are vector-borne diseases with transmission occurring to avian and mammalian hosts from blood meal-seeking mosquitoes.<sup>18</sup> Virus is either maintained or cycled between vectors, and biological amplification occurs within the vector species. Vertical transmission within vectors must occur for maintenance of virus within a geographic area.<sup>19</sup> The primary nonarthropod reservoir hosts for these viruses (in which the virus is amplified and

This section is adapted from Sellon D and Long MT: Equine Infectious Diseases, St Louis, 2007, WB Saunders.

transmitted to vectors) are birds. Horses and human beings are dead-end hosts and do not amplify the virus in quantities sufficient to infect mosquitoes. In JE, swine are considered important amplifying hosts. Additional modes of transmission have been identified in the recent North American WNV outbreak. Transmission through oral ingestion in both avian and mammalian hosts has been proven, and oral and cloacal shedding has been demonstrated in birds.<sup>20-24</sup> West Nile virus may also be transmitted through contaminated blood transfusion or organ transplantation if donors are viremic.<sup>25-29</sup> Vertical transmission through placenta and milk has been demonstrated in people.<sup>27,30,31</sup>

## RECENT EPIZOOTOLOGY

The largest documented outbreak of equine neurologic disease caused by a flavivirus began in 1999, with WNV encroachment into the United States. WNV was first detected in 1999 in New York City.<sup>32</sup> Since that time, more than 25,000 cases of equine West Nile encephalomyelitis (WNE), with an estimated 30% to 40% case fatality rate have been reported in horses in the United States. Overt clinical disease is still common in most states, with 1338 human cases (43 fatalities) and 218 veterinary cases reported during 2008.

By 2005, WNV had been identified in all of the 48 continental U.S. states.<sup>33</sup> Canadian provinces reporting disease include Quebec, Ontario, Manitoba, Saskatchewan, and Alberta, with New Brunswick and Nova Scotia reporting evidence of WNV-positive birds.<sup>34</sup> Serologic evidence of WNV has been reported in the Latin American countries of the Dominican Republic, Mexico, Guadeloupe, El Salvador, Puerto Rico, Cayman Islands, Jamaica, Belize, and Cuba.<sup>24,35-40</sup> The incidence of equine and human disease appears low for Central and South America and the Caribbean compared with the United States.<sup>41</sup>

JE virus causes between 30,000 to 50,000 human encephalitis cases annually worldwide, with endemic areas including China, the southeast region of the Russian Federation, South and Southeast Asia, and Australia. Exact numbers of horses with clinical JE are difficult to ascertain; however, reports exist of JE isolation from horses in Taiwan, China, Pakistan, and Australia in the literature since the 1980s. Outbreaks in horses have also been reported in India, Nepal, the Philippines, Sri Lanka, and Northern Thailand. Seroconversion of young horses over their first year of exposure in Hong Kong is as high as 63% in some locales.

The spread and yearly incidence of JE serogroup viruses coincides with the availability of vectors and reservoir hosts with transmission potential. Thus outbreaks are seasonal and reflect mosquito activity. *Culex* spp. of mosquitoes are considered the primary mosquito vector for the JE serogroup.<sup>24,42-45</sup> WNV has been detected in approximately 60 species of North American mosquito, but the overall vector efficiency (moderate to high) and wide range of feeding activity of the *Culex* spp. indicates that the North American WNV outbreak is propelled mainly by this genera.<sup>46</sup> In the Northeastern United States, more than half of the WNV-positive mosquito pools are *Cx. pipiens*.<sup>47-51</sup> In the West, populations of the highly efficient *Cx. tarsalis* constitute the majority of positive pools with *Cx. pipiens* the next most commonly found *Culex* spp.<sup>52-54</sup> In the Southeast, *Cx. quinquefasciatus* and *Cx. nigripalpus* have the highest WNV infection rates.<sup>55-59</sup> In the Southwest, epidemics are most commonly associated with

positive mosquito pools of *Cx. quinquefasciatus*, *Cx. tarsalis*, and *Cx. pipiens*.<sup>60-64</sup>

A reservoir host is one in which a pathogen is amplified in vivo so that it can be transmitted to a vector species.<sup>49</sup> A blood meal taken from a mammal containing 10<sup>5</sup> to 10<sup>7</sup> plaque-forming units (PFU) per millimeter (PFU/ml) of WNV results in infection of 30% to 100% of feeding mosquitoes, respectively. Human beings (voluntarily infected with the Egyptian strain of WNV) developed virus titers of 10<sup>3</sup> to 10<sup>5</sup> PFU/ml. In horses, the maximal titer after infection with this strain was similar.<sup>65</sup> Horses and human beings are considered dead-end (nonreservoir) hosts for WNV.

Viral titers capable of transmitting JE are similar to WNV. Swine are a notable reservoir host for JE (with little indication that the same is true for WNV here in the United States). The primary clinical manifestation of JE infection in swine is abortion. Affected litters contain weak pigs (which die soon after birth), dead fresh term fetuses, or mummies. Semen from infected boars contains infectious virus, and the semen has decreased sperm count and motility.

To date, more than 300 species of birds have been reported WNV-positive in the United States with 16 new species identified during the recent 2005 season.<sup>66</sup> High levels of viral amplification occur in many birds species (118), especially Passeriformes (e.g., songbirds) and Charadriiformes (e.g., shorebirds); the house sparrow and the American robin are considered two of the most important amplifying hosts for WNV. Although the crow is one of the most competent vectors, sparrows and robins have a lower mortality and hence longer days of infectious viremia. Strigiformes (owls) and Falconiformes (e.g., falcons) develop a viremia of shorter duration (but sufficient to infect mosquitoes). Psittaciformes (e.g., parrots) and Galliformes (e.g., game birds) develop the lowest viremias. By contrast, Anseriformes (e.g., waterfowl) are considered the most efficient avian reservoirs of JE and are essential for the spread of this virus through avian flyways.

Because transmission of JE serogroup viruses is via vectors, disease because of JE and WNV in horses and human beings is seasonal in temperate regions and year-round in subtropical regions. Intense virus activity in the United States begins in July, with a peak incidence in September and October.<sup>67-70</sup> A drop in ambient temperature with soft frost usually results in a rapid decrease in reporting activity.<sup>71,72</sup>

Older people appear more susceptible to neuroinvasive disease from both JE and WNV. This age bias in reporting appears true, at least for WNV, in horses.<sup>24,73-77</sup> Although men are more frequently affected with neuroinvasive disease, there appears to be no breed or gender predilection in horses. In one study of horses with WNV encephalomyelitis, female horses were 2.9 times more likely to die than male horses with neurologic signs.<sup>78-80</sup>

The remarkably explosive North American outbreak of WNV has introduced new potential hosts for the virus. Seropositive, free-ranging mammals include the big brown bat, little brown bat, eastern chipmunk, eastern gray squirrel, eastern striped skunk, white-tailed deer, and the brown bear.<sup>24,49,66,81</sup> Neurologic disease has been confirmed as WNV in gray squirrels and fox squirrels.<sup>82,83</sup> Alligators can have an extremely high titer of viremia and may be an important reservoir for WNV in the Southeast.<sup>84</sup> Reports exist of both farmed and free-ranging alligators with neurologic signs from which WNV has been isolated. In farm-raised alligators, cloacal shedding of virus has been demonstrated with oral infection likely.

Serologic evidence of natural infection has been demonstrated in domestic dogs and cats.<sup>21</sup> Experimental infection of cats resulted in a mild transient fever in some cats and a short-term viremia high enough to possibly transmit to mosquitoes. Oral transmission to cats has also been documented. New world camelids develop neurologic disease with natural exposure to WNV.<sup>85,86</sup>

## ☞ PATHOGENESIS

Mammalian disease because of infection with the JE serogroup viruses uniformly demonstrates predilection of these viruses for nervous tissues. Neurologic disease in the horse consists of changes in mentation, signs consistent with spinal cord abnormalities, and defects in cranial nerves of the hindbrain.<sup>87-97</sup> The change in behavior is likely the result of viral infection and pathology induced in the neurons of the thalamus, medulla, and pons, with limited viral load in the cerebrum.<sup>89,90,98</sup> Although the thalamus integrates all sensory input to higher centers, lesions within the midbrain and rostral pons may affect the reticular formation, which has an important role in regulation of consciousness.<sup>97,99</sup> The reticular formation projects to the thalamus, which in turn sends diffuse projections to the entire cortex.<sup>97</sup> This formation also travels directly to the base of the forebrain, which is the source of cholinergic stimulation to the entire cerebral cortex. Disturbances of the reticular formation and the midbrain may induce behavioral changes ranging from severe aggression to somnolence and even coma.

WNV-induced motor deficits are multifocal, asymmetrical, and primarily characterized by weakness and ataxia.<sup>89-91,98,100-102</sup> These two clinical signs are likely a reflection of brain and spinal cord disease through direct infection of the spinal cord, interruption of motor tracts in the hindbrain, and loss of fine motor control through infection of the large nuclei of the thalamus and the basal ganglia. Ataxia can be attributable to interruption of general proprioception. Although ataxia is commonly detected and could be profound, many horses have difficulty standing primarily because of profound weakness. These clinical signs are attributable to infection of the gray matter within the midbrain and hindbrain. In some reports there appears to be with increasing severity in spinal cord lesions proceeding caudally.<sup>101</sup> Lower motor neuron disease characterized by weakness would be a common clinical sign associated with these spinal cord lesions.

Involuntary skin and muscle fasciculations, tremors, and hyperesthesia, extremely common in this disease, likely results from loss of fine motor control, which is regulated mainly by the basal ganglia.<sup>103,104</sup> Movement disorders are detected with flavivirus infection in a long-term Parkinson-like syndrome in rats and experimental infection in monkeys.<sup>104</sup> Infection in the pons and medulla oblongata can explain clinical deficits of CN VII, XII, and IX.<sup>105</sup>

In mammalian hosts, the actual virus load in neuronal tissues is low, indicating the possibility of another mechanism for severe neurologic clinical signs. Although cell lysis occurs with viral replication, WNV also induces apoptosis in neurons as demonstrated in cell culture and in vivo.<sup>106</sup> This apoptosis can be induced by the capsid protein through the caspase-9 pathway in the mitochondria. Another mediator of neuronal injury is the host immune response. Although CD8 T cells may be important in long-term protective immune responses, lesions in brains of mice with fatal WNV are predominantly composed of CD8+ T cells.<sup>107,108</sup>

## ☞ CLINICAL FINDINGS

JE and WNV produce similar clinical signs, except that fatal JE infection in horses commonly results in blindness, coma, and death, whereas these signs are relatively limited in WNV horses.<sup>109,110</sup> For both these viruses, evidence exists of widespread subclinical infection in both people and horses. Horses develop clinical signs when infected with the neurally invasive lineage type I WNV, whereas infection with the African lineage type II viruses is universally subclinical in nature.<sup>111,112</sup> Infection with JE virus may result in severe clinical disease in naïve horses, but a great deal of variation is seen in virulence in JE viruses.

When clinically apparent disease occurs, both systemic and neurologic abnormalities are observed in horses with WNV. A mild to moderate increase in rectal temperature (38.6° to 39.4° C), anorexia and depression are the most common initial systemic signs.<sup>87</sup> Abdominal pain is not an uncommon initial presenting complaint.<sup>87,90,113,114</sup> Gait abnormalities, including overt lameness or dragging of a limb before development of an obvious neurologic syndrome, have also been reported. Both spinal cord disease and moderate mental aberrations occur. Onset of neurologic signs is frequently sudden and progressive, and the exact course of disease in any one animal is unpredictable.

The major hallmarks of equine WNV encephalomyelitis are muscle fasciculations and changes in personality. Many horses have periods of hyperexcitability and apprehension, sometimes to the point of aggression. Frequently a quiet horse will become hyperexcitable, and an abnormally aggressive horse will become compliant. Interspersed during periods of hyperexcitability, some horses appear to have abnormalities of sudden sleeplike activity resembling narcolepsy. This can occur to the point of cataplexy, and horses may partially or completely collapse for a short period of time. In some horses a change of mentation is persistent and a state of nonresponsiveness, resembling coma, results.

Fine and coarse fasciculations of the muscles of the face and neck are very common. Fasciculations can be quite severe and involve all four limbs and trunk, affecting normal activities such as walking, eating, and interactions with handlers and other horses. The fasciculations are most notable at the muzzle and eyelids. Eyelid activity during this period is enhanced with light and at times it appears that horses are quite photophobic.

One of the initial signs of motor abnormality is a short, slow, stilted gait described by observers as *lameness* (laminitis being a frequent differential diagnosis at this stage). However, in human patients, bradykinesia or slow, deliberate movement is frequently described, and this may be the equine corollary.<sup>115</sup> Spinal abnormalities are characterized by ataxia and paresis that can be highly asymmetrical or involve only one or two of the front limbs or hindlimbs. This may be of short duration, or horses may become suddenly recumbent and either die or require prolonged treatment. Horses that become recumbent often need aggressive supportive care.

Cranial nerves are frequently abnormal for short periods of time; weakness of the tongue, muzzle deviation, and head tilt are the most common abnormalities reported. Dysphagia has been reported with choke as a sequelae. A cauda equine syndrome consisting of stranguria and rectal impaction is infrequently reported.

Overall, the combination, severity, and duration of clinical signs can be highly variable. After initial signs abate, about 30%

of clinical horses experience a recrudescence in clinical signs within the first 7 to 10 days of apparent recovery. Irrespective of recrudescence, about 30% of affected horses progress to complete paralysis of one or more limbs overall. Most of these horses are euthanized for humane reasons or die spontaneously.

Many horses will improve within 3 to 7 days of displaying clinical signs. If the horse demonstrates significant improvement, then full recovery within 1 to 6 months can be expected in 90% of patients. Residual weakness and ataxia appear are common with long-term loss of the use of one or more limbs infrequently described. Mild to moderate persistent fatigue on exercise has been observed.

## ☞ DIAGNOSIS OF WEST NILE VIRUS

Ancillary diagnostic testing for horses with suspected WNV infection should include CBC, serum biochemistry analysis, and CSF analysis.<sup>116,117</sup> CBC and serum biochemistry profiles of West Nile virus–infected horses are usually normal. Horses may have a mild absolute lymphopenia. Horses can have elevated muscle enzymes secondary to trauma and prolonged periods of recumbency. A frequent finding is hyponatremia, which has also been described in human beings with encephalitis, potentially caused by inappropriate release of antidiuretic hormone.<sup>118,119</sup> CSF cell counts and protein concentration may be elevated. Differential cell counts in CSF of West Nile virus–infected horses are consistently increased, primarily because of increased mononuclear cell populations; in contrast, the most numerous cells in the CSF of horses with EEE are neutrophils, especially during the initial stages of disease.<sup>117</sup>

No pathognomic signs distinguish WNV infection in horses from other CNS diseases and a full diagnostic evaluation should be pursued. Infectious CNS diseases that should be considered as differential diagnoses include alphavirus encephalitis, rabies, EPM, EHV-1, botulism, and verminous meningoencephalomyelitis (e.g., *Halickephalobus gingivalis*, *Setaria* spp., *Strongylus vulgaris*). Noninfectious causes to consider include hypocalcemia, tremorgenic toxicities, hepatoencephalopathy, and leukoencephalomalacia. In alphavirus encephalitis and rabies, signs of cerebral involvement are characterized by behavioral alterations, depression, seizure, and coma. The appearance of seizure and coma is rare in WNV horses. Motor function is frequently abnormal in EEE and WEE. In WNV suspects, circling and propulsive walking may occur, but head pressing is rare. Cranial nerve signs common in EEE and WEE are common in WNV and include head tilt, pharyngeal and laryngeal dysfunction, and paresis of the tongue. Other clinical signs of alphavirus encephalitis that are observed with WNV infection are muscle fasciculations, hyperesthesia, excitability, blindness, somnolence, weakness of the tongue, and progression to recumbency. Differentiation of WNV from rabies is quite problematic, because clinical signs in horses with rabies frequently include ataxia, weakness, or gait abnormalities. Alphaviruses, rabies, *H. gingivalis* infection, hepatoencephalopathy, and leukoencephalomalacia are rapidly progressive with cortical signs. Although periods of somnolence, blindness, and some cranial nerve deficits occur, WNV horses appear to become rapidly recumbent or stabilize over several days. Spinal disease caused by EPM is a more difficult differential diagnosis if horses with WNV are not febrile and do not exhibit excessive muscle fasciculations. Both diseases demonstrate hindbrain disease with diffuse spinal cord abnormalities.

Confirmation of WNV infection with encephalitis in horses begins with assessment of whether or not a horse meets the case definition based on clinical signs, as well as whether or not the horse resides in an area in which WNV has been confirmed in the current calendar year in mosquitoes, birds, human beings, or horses.<sup>100</sup> Serologic testing developed by the National Veterinary Services Laboratory (NVSL) is based on detection of the IgM antibody response that uniformly occurs in acutely infected horses. The preferred test is an IgM capture ELISA (MAC-ELISA).<sup>120</sup> Horses develop a very intense IgM response on exposure to WNV that lasts approximately 6 weeks. This immunologic reaction is much more reliable than in human infection in which a more persistent IgM response is common. Most diagnostic laboratories use the WNV IgM capture ELISA (MAC) for actual confirmation of disease (increases in IgM rarely occur after vaccination). The sensitivity and specificity of this test is 81% and 100%, respectively.

In the nonvaccinated horse, a fourfold change in paired neutralizing antibody titers is confirmatory of a diagnosis of WNV infection. The most common neutralizing antibody test formats are the classic plaque reduction neutralizing antibody response (PRNT) and a more recently developed microwell format.<sup>88,100,120,121</sup> Vaccination induces formation of neutralizing antibody that likely confounds interpretation of the PRNT. Since 2001 reliance on the PRNT for serologic confirmatory diagnosis of WNV in horses has diminished because of widespread vaccination.

Other methods for confirmation of a diagnosis of WNV include postmortem detection of WNV by PCR, culture, and immunohistochemistry in tissues of the CNS. Nested PCR targeting the E protein has demonstrated sensitivity for relatively low viral load in equine tissues.<sup>122,123</sup> Real-time PCR methodology has been used to detect WNV in equine tissues.<sup>123</sup> The E-protein target appears less sensitive; however, the NS5 target has detected WNV nucleic acids in CNS tissues, heart, and intestine of clinically affected horses.

## ☞ DIAGNOSIS OF JAPANESE ENCEPHALITIS

JE should be suspected in horses with compatible clinical signs that reside in an area of virus activity. Diagnostic confirmatory tests include serologic assays such as neutralizing, complement fixation, hemagglutination inhibition, and ELISA tests.<sup>124-126</sup> All single sera testing, including IgM assays, must be interpreted with caution in horses from areas with other endemic flaviviruses. In fatal JE cases, viral isolation, PCR assays, and immunohistochemistry for detection of virus in CNS tissues is confirmatory.

## ☞ PATHOLOGIC FINDINGS

Gross pathologic findings are limited in WNV infection in the horse. The meninges may be congested. Small- to moderate-sized foci of hemorrhagic discoloration may be observed in the brain, spinal cord, or both. These areas occur most commonly in the basal ganglia, rostral colliculus, pons, medulla, and lumbar spinal cord. Edema and softening of tissues are also common findings.

Flaviviruses cause polioencephalomyelitis (inflammation of the gray matter) with lesions that increase in number from the diencephalon through the hindbrain and frequently

increase in severity caudally through the spinal cord.\* By contrast, these lesions are limited in the cortex and cerebellum. The basal ganglia, thalamus, pons, and medulla have the highest numbers of lesions with two to several cell layers of mononuclear perivascular cuffing. Most of the horses that are euthanized with WNV have histological lesions that predominate in the gray matter with inflammatory foci within the midbrain and hindbrain and increasing severity caudally through the spinal cord. Neuronal damage includes chromatolytic neurons and neuronophagia. In long-standing disease, areas of neuronal dropout may exist. In the spinal cord, perivascular cuffing, gliosis, and damaged neurons may be seen. The inflammation associated with the neuropil is confined primarily to the gray matter.

## ☞ THERAPY

No known antiviral medications are marketed that demonstrate reliable activity against flaviviruses, thus treatment of disease is supportive.<sup>87,90,132,133,134</sup> In horses, the survival rate for WNV encephalitis is high compared with other infectious encephalitides. In most cases horses appear to begin recovery between 3 and 5 days after onset of signs. This fact makes it difficult to accurately assess the effect of any pharmacologic intervention when a feature of analysis is resolving clinical disease. Flunixin meglumine (1.1 mg/kg IV q12h) early in the course of the disease appears to decrease the severity of muscle tremors and fasciculations within a few hours of administration.

To date, much of the mortality in WNV horses results from euthanasia of recumbent horses for humane reasons. Recumbent horses are mentally alert and frequently thrash, sustaining many self-inflicted wounds and posing risk to personnel. Therapy of recumbent horses is generally more aggressive and may include dexamethasone sodium (0.05 to 0.1 mg/kg IV every 24 hours) and mannitol (0.25 to 2.0 gm/kg IV every 24 hours). Controversy remains as to whether corticosteroids enhance peripheral and CNS viral load.<sup>135-138</sup> Detomidine hydrochloride (0.02 to 0.04 mg/kg IV or IM) is effective for prolonged tranquilization. Low doses of acepromazine (0.02 mg/kg IV or 0.05 mg/kg IM) provide excellent relief from anxiety in both recumbent and standing horses. Until EPM is ruled out or WNV is confirmed, prophylactic therapy with antiprotozoal medications is recommended for horses in geographic areas where *Sarcocystis neurona* infection is prevalent. Other supportive measures may include oral and intravenous fluids and antibiotics for treatment of infections that frequently occur in recumbent horses (wounds, cellulitis, and pneumonia).

A variety of treatments has been recommended for horses with WNV; however, limited evidence exists to support their efficacy at this time.<sup>1,139-143</sup> The recommendation for interferon alpha (IFN- $\alpha$ ) therapy is based on anecdotal reports in the human and veterinary literature. Limited information regarding efficacy in the horse is available. In a blinded study in which children with encephalitis because of JE were treated with IFN- $\alpha$ , survival was not enhanced. In fact, length of hospitalization was increased in the IFN- $\alpha$  treated group.

Therapy with intravenous WNV-specific immunoglobulin (Ig) has also been recommended. In a blinded placebo-controlled trial with low numbers of animals, the risk for

development of recumbency was less in horses receiving plasma from horses immunized against WNV.<sup>144</sup> However, plasma treatment did not change outcome and severity of WNV disease. In human patients, high-dose glutamate therapy has been suggested to prevent neuronal cell death. Another experimental therapy in mice is administration of  $\beta$ -lactam inhibitors that stimulate GLT1, a chemical that activates glutamate.

## ☞ PREVENTION

Epidemiological, experimental, and anecdotal evidence exists regarding the effectiveness of vaccination against flaviviruses.<sup>145</sup> Initial epidemiologic studies performed in 2000 established a point source for infection of WNV, demonstrating that outbreaks in horses may best be controlled by vaccination.<sup>146-148</sup> This finding was consistent with prior experience with JE, in which vaccines were advocated for horses before the WNV epizootic. Presently, four vaccines are licensed for prevention of WNV viremia in the United States. As of 2005 at least three vaccines are available for vaccination of horses against JE.<sup>149-153</sup> Vaccination before the mosquito season is critical. Manufacturer's labeling instructions must be followed for induction of immunity with initial immunization. All available vaccines are labeled for administration every 12 months after the initial series; however, only the modified live chimera vaccine has published 12-month efficacy data.<sup>154</sup> More frequent vaccination in areas with year-round mosquito seasons is recommended for most vaccines because it is not expected that the initial vaccine series will provide long-term protection, especially with killed virus vaccines with which antibody levels rapidly decrease after 4 to 6 months. Where these viruses are endemic, vaccination schedules should be maintained even when a decrease in the incidence of overt disease exists. This is evidenced by the persistence of reports of JE disease in naïve horses after introduction into endemic areas. Horses that have recovered from clinical disease have long-term immunity and should not require annual boosters.

## ☞ PUBLIC HEALTH CONSIDERATIONS

West Nile virus is considered a zoonotic disease. A bird reservoir maintains the virus in an endemic life cycle in the environment, allowing for transmission by mosquitoes to human beings. Little risk exists of disease by direct contact with an infected horse, except during postmortem examination with inappropriate handling of infected tissues. The ecology of horse pastures and stables with standing water, a high degree of biological debris, and "bridge" vectors that feed on mammalian populations likely increase the risk of exposure in that environment. The same types of management tactics for prevention of disease in horses are important for human beings, except that no vaccine is available. Personal mosquito protection with a DEET-based product is recommended in areas with endemic disease.

The North American epidemic of WNV has demonstrated new modes of transmission including blood-borne and occupational risks. Blood-borne transmission can occur between viremic hosts. In addition, occupational infection has occurred through necropsy of avian hosts. Veterinarians and horse owners should institute personal protection with appropriate clothing, gloves, and eye protection when coming into contact with animal tissues during the arbovirus season.

## RABIES

Carla S. Sommar Dahl

### EPIDEMIOLOGY AND PATHOGENESIS

Rabies is an uncommon disease in equids, but because of its zoonotic potential, one should consider it in the differential diagnosis for horses showing neurologic signs lasting less than 10 days. In the United States during 2006, 547 cases of rabies were reported in domestic animals, with 53 of these being in horses and mules.<sup>1</sup>

The rabies virus is a large, cylindrical, bullet-shaped neurotropic rhabdovirus (genus *Lyssavirus*, family Rhabdoviridae).<sup>2</sup> Rhabdoviruses are enveloped with single-stranded RNA. They are heat-labile and are susceptible to degradation by radiation, strong acids, alkalis, most disinfectants, lipid solvents, and anionic solvents.<sup>2,3</sup> Rabies virus is transmitted by saliva-contaminated wounds. In the horse the most common method of infection is a bite wound from a wild carnivore or insectivorous bat carrying the virus.<sup>4</sup> The most common reservoir hosts in the United States are skunks, raccoons, and the red fox.<sup>2</sup> However, domestic dogs, cats, and other horses may transmit rabies to horses by bite wounds. Furthermore, rabies virus can be transmitted by droplet inhalation, orally, or transplacentally. Droplet transmission has been reported to have occurred in foxes, coyotes, opossums, and raccoons in a bat cave in Texas. In that report the virus was isolated from the air in the cave.<sup>5</sup> Aerosolization of the virus also caused an outbreak of rabies in a laboratory. Transplacental transmission of the virus has occurred in naturally infected cattle and experimentally infected mice and bats.<sup>2</sup>

Rabies virus infects and replicates in myocytes at the inoculation site and may remain undetectable for weeks or months before moving centrally. The virus infects peripheral nerves by traversing neuromuscular and neurotendinous spindles. Progression along the nerve is thought to occur in the tissue spaces of the nerve fasciculus.<sup>5</sup> After progressing centripetally up the peripheral nerve by axoplasmic flow, the virus replicates in spinal and dorsal root ganglia of the corresponding peripheral nerve. Once the virus reaches the CNS, spread occurs rapidly through multiplication in neurons of the brain, spinal cord, sympathetic trunk, and glial cells. Spread of rabies virus also can occur through passive transport within CSF or blood.<sup>2,4</sup> Finally, the virus reaches tissues outside the CNS via centrifugal movement of the virus along nerve axons.<sup>2,3</sup>

The incubation period for rabies varies between 9 days to 1 year in horses. The incubation period can be affected by the virus strain, host species, inoculum size, and proximity of the inoculation site to the CNS.<sup>2,4</sup> Retention of virus in myocytes at the inoculation site may be a mechanism for variation in the incubation period. A shorter incubation period also may be explained by the virus entering peripheral nerves soon after exposure and rapidly migrating centripetally to the CNS without replication in nonneural tissue.<sup>2</sup>

### CLINICAL SIGNS

No signs are pathognomonic for rabies infection in horses. Clinical signs on presentation vary and range from lameness to sudden death.<sup>6-9</sup> Hyperesthesia, ataxia, behavior change,

anorexia, paralysis or paresis, and colic have been reported as initial clinical signs.<sup>6-11</sup> One rarely finds a bite wound, and the horse may or may not be febrile. The site of inoculation and its proximity to the CNS influence what clinical signs one observes.<sup>2,7,8</sup> The neurologic signs exhibited in rabies-infected horses can be classified into three forms, depending on the neuroanatomic location in the CNS infected by the virus. First, in the cerebral or furious form, one may see aggressive behavior, photophobia, hydrophobia, hyperesthesia, straining, muscular tremors, and convulsions.<sup>12</sup> Second, in the brainstem or dumb form, one commonly sees depression, anorexia, head tilt, circling, ataxia, dementia, excess salivation, facial and pharyngeal paralysis, blindness, flaccid tail and anus, urinary incontinence, and self-mutilation.<sup>10,12,13</sup> Finally, in the paralytic or spinal form, one sees progressing ascending paralysis, ataxia, or shifting lameness with hyperesthesia, and self-mutilation of an extremity.<sup>11-14</sup> Most affected animals with the paralytic form become recumbent in 3 to 5 days, with normal eating and drinking often remaining.<sup>13</sup> The neurologic signs may vary as the virus spreads to other portions of the CNS. Thus horses may have clinical signs of two or all forms of rabies. Disease progresses rapidly, and death is usually inevitable regardless of the clinical manifestation. Anti-inflammatory therapy can delay virus progression,<sup>12</sup> but death usually occurs within 5 to 10 days after onset of clinical signs.<sup>9,13</sup>

### DIAGNOSIS

Antemortem diagnosis of rabies is difficult, but one should consider the disease in horses showing rapidly progressing or diffuse neurologic signs. Other diseases that one should consider include hepatoencephalopathy, togaviral encephalitis, protozoal encephalomyelitis, nigropallidal encephalomalacia, botulism, lead poisoning, cauda equina neuritis, meningitis, space-occupying mass, trauma to the brain or spinal cord, and esophageal obstruction.<sup>3,5,13</sup> Clinical laboratory data of body fluids are nonspecific. CSF may be within normal reference range or may show a moderate increase in total protein concentration (60 to 200 mg/dl) and a pleocytosis (5 to 200 mg/dl).<sup>3,5,13</sup> Fluorescent antibody testing of tactile hair follicles of facial skin taken on biopsy or corneal epithelium may help diagnose rabies ante mortem. The fluorescent antibody technique detects the rabies virus antigen in these tissues. Unfortunately, a negative test does not exclude rabies as a differential diagnosis.<sup>9</sup> One can achieve definitive postmortem diagnosis by submitting half the brain in 10% formaldehyde for histologic examination and the other half frozen to a public health diagnostic laboratory for immunofluorescent antibody tests, mouse inoculation, and monoclonal antibody techniques. The whole brain may be shipped unfrozen on ice for further rabies evaluation and testing. One should examine the rest of the carcass only with careful precautions against transmission of the virus, if present, by wearing gloves, caps, and masks until a negative rabies diagnosis is made.

Common histopathologic changes are a mild, nonsuppurative encephalomyelitis; perivascular cuffing by mononuclear cells; gliosis; glial nodules; and neuronal degeneration.<sup>3,13</sup> These lesions occur most commonly in the hippocampus, brainstem, cerebellum, and gray matter of the spinal cord. Large intracytoplasmic eosinophilic inclusions within neurons and ganglion cells, known as *Negri bodies*, are pathognomonic for rabies.<sup>2,3,13</sup> However, in 15% to 30% of confirmed rabies cases, *Negri bodies* are not present in histopathologic sections,

especially if the animal died or was euthanized early in the disease process.<sup>2</sup> The most commonly used and fastest diagnostic test for rabies is the fluorescent antibody test. This technique may identify 98% of infected brain specimens. The mouse inoculation test is the most accurate method for diagnosing rabies virus infection but requires 5 to 6 days to complete. The mouse inoculation test involves the injection of suspect brain or salivary gland tissue homogenates intracerebrally in mice and observation of clinical and neurologic signs or death.<sup>2,3</sup> The monoclonal antibody test has been used most recently for rabies diagnosis in horses. The test can differentiate specific street, fixed, or vaccinal strains of rabies virus by their glycoprotein or nucleocapsid antigens.<sup>2</sup> This is important in postexposure vaccination of human beings and animals when using the specific strain of virus.

## ☞ TREATMENT AND PREVENTION

No specific treatment exists for rabies in horses. Symptomatic treatment and supportive care may help prolong the disease course to complete diagnostics and to rule out other diseases with similar signs. Prolonging the course, however, creates a risk of exposure to handlers and other animals. Therefore one should isolate any animal suspected of having rabies and should handle it as little as possible. Horses that are known to have been exposed to rabies should have all wounds cleaned and lavaged with iodine or quaternary ammonium disinfectant (and rabies antiserum, if available, infiltrated around the bite wound).<sup>3,13</sup> No postexposure protocol exists for unvaccinated or vaccinated horses. However, exposed horses should be quarantined for 6 months and observed for the occurrence of neurologic signs. Unvaccinated horses should not receive postexposure prophylaxis until after the 6 months of quarantine. Currently, the American Association of Equine Practitioners recommends that all horses in the United States be vaccinated against rabies. Available vaccines are inactivated tissue culture–derived products with an adjuvant. Foals from vaccinated mares should be vaccinated no earlier than 6 months of age. The second dose of vaccine should be given 4 to 6 weeks after the first. A third dose should be given at 10 to 12 months of age. The first dose of vaccine should be given to foals from unvaccinated mares at 3 to 4 months of age. A second dose should be given at 10 to 12 months of age. Adult horses should receive annual revaccination. Pregnant mares may be vaccinated annually before breeding or 4 to 6 weeks before foaling.

## EQUINE MOTOR NEURON DISEASE

Yvette S. Nout

Equine motor neuron disease is an acquired neurodegenerative disease of adult horses that has been reported in North and South America, Japan, and Europe.<sup>1-9</sup> Lower motor neuron disease was recognized in 1988 based on histologic changes in skeletal muscle,<sup>10</sup> and EMND was first described in 1990.<sup>1</sup> In the 1990s, EMND was recognized worldwide in an apparently increasing frequency<sup>3,11</sup>; however, recently the number of EMND cases appears to be decreasing.<sup>9</sup> The decrease may be the result of preventive management measures taken for horses at risk of developing the disease.

The disease affects primarily the motor neurons in the spinal cord ventral horn cells and brainstem and leads to characteristic clinical signs, including generalized neuromuscular weakness and neurogenic muscle atrophy.<sup>1,2,5,12</sup> EMND closely resembles human motor neuron disease, which is known as *amyotrophic lateral sclerosis (ALS)* or Lou Gehrig disease.<sup>1,13</sup> However, EMND only affects the lower motor neurons, which is not the case in ALS. A chronic lack of antioxidants is implicated in the pathogenesis of this disease.

## ☞ CLINICAL SIGNS

EMND occurs in adult horses with a mean age of onset of clinical signs of 9 years (range of 2 to 23 years).<sup>14</sup> The risk for EMND increases with age, peaking at around 15 years.<sup>15</sup> Quarter Horses appear at increased risk for developing EMND; however, this may reflect management factors.<sup>2,15</sup> No gender predilection is apparent.

Clinical signs vary depending on the stage or duration of the disease. Currently, a subacute and a chronic form are recognized.<sup>9</sup>

### SUBACUTE FORM

During the early phase of EMND, trembling, muscle fasciculations, base-narrow stance, shifting of weight in the rear limbs, abnormal sweating, excessive recumbency, muscle atrophy, and weight loss despite a normal or even ravenous appetite are the most characteristic clinical signs (Figure 12-42).<sup>1,2,6,8,9</sup> Ataxia is not a clinical sign of EMND. A horse with EMND moves better than it stands.<sup>2,8</sup> Muscle wasting is most noticeable in the quadriceps, triceps, and gluteal areas. In more than 50% of cases, horses may display a lower than normal head carriage with muscle wasting of the cervical musculature (hangdog appearance).<sup>8</sup> Onset of muscle wasting may occur for approximately 1 month before the acute onset of clinical signs.

### CHRONIC FORM

Owners may present horses for poor performance, gait abnormalities (stringhalt-like movement), and failure to gain weight. Trembling and muscle fasciculations are not pronounced in

**FIGURE 12-42** Characteristic appearance of a horse with equine motor neuron disease (EMND), including muscle wasting, sweating, base-narrow stance, low head carriage (hangdog appearance), and tailhead elevation.

the chronic form of EMND. Horses with the chronic form of EMND are often horses that have stabilized from the subacute form; however, some horses develop the chronic form without experiencing the subacute form. Muscle atrophy varies from mild to severe, and some horses may appear emaciated.<sup>1,8,9</sup>

### SUBCLINICAL FORM

Experimental evidence indicates that horses may develop a subclinical form of EMND, which may affect performance and safety.<sup>8,9</sup> In the subacute and chronic forms of EMND, the tailhead often is elevated because of denervation atrophy and fibrotic contracture of the sacrococcygeus dorsalis medialis muscle.<sup>6,8,9</sup> In approximately 30% of cases, ophthalmoscopic examination may reveal a distinctive retinopathy with a mosaic pattern of brown pigment deposition in the fundus. These horses are not necessarily visually impaired.<sup>16,17</sup>

### ⊄ PATHOLOGIC FINDINGS

Gross necropsy findings in EMND include diffuse muscle atrophy and pallor (especially of the intermediate vastus and medial head of the triceps muscles). The CNS and peripheral nerves are grossly normal. Histologically, one may detect non-inflammatory neuronal degeneration and neuronal loss at all levels of the spinal cord, but such loss is most obvious in the cervical and lumbar intumescence. One finds the lesions in the ventral horn cells (lower motor neurons) of the spinal cord gray matter; the nuclei of cranial nerves V, VII, and XII in the brainstem; and the nucleus ambiguus. Secondary axonal degeneration with loss of myelinated fibers because of dysfunction or death of these motor neurons is present in the ventral spinal roots; spinal nerves; cranial nerves V, VII, IX (sometimes), and XII; and peripheral motor nerves.<sup>1,12</sup> Peripheral motor nerve degeneration also may be evident on antemortem muscle biopsy.<sup>18</sup>

Skeletal muscle changes include nonspecific myopathic changes such as excessive fiber size variation, internal nuclei, and cytoarchitectural alterations. Scattered fiber degeneration and necrosis is a consistent finding in EMND. Atrophy of type I and type II muscle fibers occurs in severely affected muscles in EMND and is pathognomonic of denervation atrophy.<sup>1,12,13</sup> EMND predominantly affects type I fibers, in contrast to denervating diseases in other species, and has not been reported in ALS. Motor neurons supplying the type I fibers have a higher oxidative activity and thus may be more susceptible to oxidative injury.<sup>12</sup> Similar to ALS, in which at least 30% of motor axons must be destroyed before clinical evidence of atrophy occurs, in horses with muscle wasting caused by EMND, a mean motor neuron loss of 31% was recorded.<sup>19</sup>

A pigment retinopathy may be visible, as well as deposition of lipopigment in the endothelial capillaries of the spinal cord. These findings have been reported in other animals with vitamin-E deficiency.<sup>16,17</sup> Besides the abnormalities in the neuromuscular system, no other pathologic findings have been found consistently in horses with EMND.

### ⊄ PATHOGENESIS

The clinical signs of neuromuscular weakness result from the generalized denervation muscle atrophy found in horses with EMND. The pathogenesis of the neuron damage and death in EMND is not understood fully but is thought to result from

free radical damage. EMND occurs sporadically and affects horses of all ages and breeds. Therefore infectious agents or environmental toxins are less likely to be a cause of the disease.<sup>2</sup>

A chronic vitamin E deficiency is thought to be the most important factor in the development of EMND based on the fact that affected horses consistently have low plasma vitamin E concentrations and have not had access to pasture or green forages for a prolonged time.<sup>2,11,15,20</sup> Vitamin E concentrations in the CNS, peripheral nerves, muscle, liver, and adipose tissue have been found to be correlated to blood concentrations.<sup>9</sup> Horses generally have been on the same premises for more than 2 years before developing clinical signs.<sup>15</sup> The type I muscle fiber atrophy and the lipopigment deposition in the capillaries of the spinal cord are pathologic findings suggesting an oxidative type of injury as a cause of the neuronal death.<sup>13</sup> The pigment retinopathy found in approximately 30% of cases, and the lipopigment deposition in the vasculature of the spinal cord occurs in other species and is related to a vitamin E deficiency.<sup>8,16</sup>

EDM, another neurodegenerative disease in horses, also is associated with a vitamin E deficiency; however, the CNS lesions in EDM are different from those in EMND. Vitamin E-deficient adult horses have been suggested to develop EMND after a transitory period of triggering events such as exposure to neurotoxins or excessive amounts of pro-oxidants.<sup>2,9</sup> So far a neurotoxin has not been identified. The presence of pro-oxidants such as copper and iron in spinal cord, liver, and plasma has been investigated but has not been confirmed to play a role in the development of EMND.<sup>9,21</sup>

Although EMND is the only naturally occurring model for ALS<sup>13</sup> and oxidative injury is implicated in the cause of both diseases, some important differences exist between the two.<sup>6,12,13</sup> In contrast to EMND, in which the disease process is limited to the lower motor neurons, ALS affects upper and lower motor neurons. Only mild degeneration of the pyramidal tracts is present in horses with EMND, but the pyramidal tracts in horses are less extensive and poorly developed compared with human beings. ALS is familial in approximately 10% of cases, and 20% of patients with familial ALS carry a mutation of the Cu/Zn superoxide dismutase 1 gene.<sup>22</sup> This metalloenzyme is one of the principal oxygen-derived free radical scavengers and protectants against oxidant injury to the nervous system. The mutation of this gene leads to an altered form of the enzyme that is actively toxic to cells.<sup>23</sup> In these patients the quantity of oxidants is increased, whereas in horses with EMND, a lack of antioxidants is the presumed cause of neuronal degeneration and death.<sup>2,24</sup> Mutations in the Cu/Zn superoxide dismutase 1 gene have not been found in EMND.<sup>25</sup> The cause of spontaneously occurring ALS is unknown; however, the similarities between familial ALS and spontaneous ALS suggest a common pathway for neuronal death.<sup>13</sup> The question of why the disease affects motor neurons so selectively has not been answered thus far. Motor neurons are particularly susceptible to oxidative injury by having high energy requirements associated with the maintenance of long axons. The high concentration of polyunsaturated fatty acids in neuronal cell membranes make these cells particularly susceptible to lipid peroxidation.<sup>26</sup> A recent investigation has shown that chronic or episodic deficits in oxygen and glucose, through an altered function of vascular endothelial cell growth factor, result in a failure of the motor neurons to meet their metabolic requirements. This altered

function of vascular endothelial cell growth factor resulted in ALS-like symptoms and neuropathy.<sup>27</sup> If a relationship between superoxide dismutase 1 and altered vascular endothelial cell growth factor function exists, then it remains to be investigated.

## DIAGNOSIS

Clinical signs and a history of other EMND cases in the stable and absence of pasture or green hay may lead to a tentative diagnosis of EMND. Ophthalmoscopic examination may reveal fundic lesions in approximately 30% of cases. Serum enzyme activities of AST and CK are generally mildly to moderately increased. The plasma vitamin E concentration is consistently low (less than 1 µg/ml). CSF analysis has been performed in horses with EMND and demonstrated elevated IgG concentrations in approximately 50% of cases. Intrathecal production of IgG also occurs in ALS; however, in both diseases this is considered a secondary effect of the disease process rather than a cause. The AQ was normal in most horses examined, indicating of normal blood-brain barrier function.<sup>2</sup>

EMG of cervical, facial, triceps, rear limb, and tailhead muscles may be useful in acute cases.<sup>1,28</sup> To eliminate motion artifacts, one can sedate horses or place them under general or caudal epidural anesthesia.<sup>28</sup> However, the electromyographic changes, which include positive sharp waves and fibrillation potentials, may be difficult to evaluate because they are expected in any peripheral nerve disease, myopathy, or myositis.<sup>1,6,28</sup>

In some horses with EMND, the glucose absorption test has been found to be abnormal; however, histopathologic examination of the small intestine has failed to identify lesions. The plasma glucose concentration increases only by 40% after 1 g/kg of 20% glucose administered orally, but relatively normal peak concentrations occur after 0.5 g/kg xylose administration (18-25 mg/dl). An abnormality in intestinal glucose transport has been identified in vitro.<sup>6,8,9</sup> The clinical significance of this finding is unknown.

More invasive diagnostic tests to confirm the tentative antemortem diagnosis of EMND are the examination of muscle and nerve biopsies. A biopsy of the sacrocaudalis dorsalis muscle is easy to obtain in a standing horse, and microscopic examination of this muscle may reveal changes consistent with denervation muscle atrophy and scattered muscle necrosis. This test has a sensitivity of approximately 90%. One should place the muscle biopsy sample on a tongue depressor in 10% formalin to prevent contracture artifact.<sup>18</sup> Examination of a biopsy of the ventral branch of the spinal accessory nerve may be more sensitive in chronic cases. Horses generally need to be anesthetized for one to obtain a biopsy from this nerve. As with muscle biopsies, nerve biopsies must be placed on a tongue depressor and in 10% formalin or another fixative suitable for electron microscopy. An experienced neuropathologist should examine nerve biopsies carefully; samples may reveal only evidence of smaller Bungner's bands (columns of proliferated Schwann cells).<sup>12,29</sup>

The definitive diagnosis is based on postmortem examination of spinal cord, brainstem, nucleus ambiguus, and skeletal muscle. The most important differential diagnoses that one should consider are laminitis, rhabdomyolysis, and colic. Other diseases that may cause similar signs are botulism, EPM, polysaccharide storage myopathy, iliac thrombosis, equine grass sickness (EGS), and lead toxicosis.<sup>8,9,30</sup>

## TREATMENT AND PREVENTION

Currently, no treatment for EMND has been proved efficacious. In acute cases an anti-inflammatory dose of corticosteroids or nonspecific antioxidant treatment with DMSO may be beneficial. The only recommended treatment is based on the idea that this disorder is caused by oxidative injury and on the fact that horses with EMND consistently have low plasma vitamin-E concentrations.

Treatment with vitamin E (5000 to 7000 IU/horse/day) results in an increase of plasma vitamin-E concentrations to 2.0 µg/ml or greater after 4 to 6 weeks.<sup>9</sup> This treatment may be beneficial; however, full recovery is unlikely because neuronal death is irreversible.<sup>6,8,9</sup> Treatment with vitamin E has been associated with improvement of clinical signs; however, no published studies examining the effect of treatment exist at this time. Response to treatment is thought to depend on the number of neurons that are damaged versus those that are dead. Currently, no diagnostic modality exists to examine this in live horses.

One should give vitamin E supplements to horses that have limited or no access to green grass or hay for prolonged periods. The recommended dose for supplementation is 2000 IU/day of dl- $\alpha$ -tocopherol acetate. Not all commercial feeds or supplements contain required amounts of vitamin E for deficient horses. Periodic monitoring of plasma vitamin E concentrations is recommended in horses that are at risk for developing EMND.<sup>8,9</sup>

## PROGNOSIS

The prognosis is poor for return to performance and guarded for life. Although no published investigations exist regarding the survival rate and follow-up of horses with EMND, horses with EMND generally have been shown to follow one of three possible clinical courses.<sup>8,9</sup> Approximately 20% of horses continue to deteriorate, and the severe weakness and excessive recumbency necessitate euthanasia. In approximately 40% of horses, clinical signs appear to stabilize; however, these horses do not regain muscle mass and may develop severe gait abnormalities. Continued clinical abnormalities frequently lead to euthanasia within 1 year of onset of clinical signs. The third group of horses (approximately 40%) show dramatic improvement after treatment with vitamin E, and many may regain a normal muscle mass. These horses may remain stabilized, that is, appear normal, for 1 to 6 years or more; however, many relapse, resulting in euthanasia. In a small number of human beings with ALS, a similar scenario occurs when clinical signs stabilize without progression for years.<sup>13</sup> In horses with EMND, the relapse appears associated with return to exercise and may be caused by exercise-induced premature death of remaining neurons.<sup>8,9</sup>

## TETANUS

Peter R. Morresey

Tetanus is an infectious disease of all domestic animals and human beings. Although tetanus has long been recognized, it is only recently that the nature of the toxins of *Clostridium tetani* and their mechanisms of action have been described.

Tetanus has been recognized since ancient times, including mention in the writings of Hippocrates. Tetanus (from the Greek *tēnanos*, to contract) was first identified as a neurologic disease more than 20 centuries ago by Greek physicians.<sup>1</sup> A causative infectious agent was first hypothesized in the 1860s. Transfer of tetanus by injection of infected material from a human wound into a rabbit was demonstrated in 1884. Inoculation of soil into small mammals caused classical symptoms of tetanus.<sup>2</sup> Reinforcing the transmissible nature of an infectious agent, smears of wounds from infected patients showed a bacillus-like organism under microscopy. Pure culture of the toxigenic organism was obtained in 1889, and it was subsequently shown that animals immunized with modified tetanus toxin generated neutralizing serum antibodies.<sup>2</sup> In 1986 the amino acid sequence of tetanus toxin was revealed,<sup>3</sup> with the mechanism of action elucidated in 1992.<sup>4</sup>

## ☞ BIOLOGY OF CLOSTRIDIUM TETANI

*Clostridium tetani* is a common soil inhabitant found throughout the world. It can be readily isolated from the intestinal tract and feces of a wide range of animals, with fecal surveys in North America, Brazil, and Canada revealing between 30% and 42% positive samples.<sup>2</sup>

*C. tetani* is a strict anaerobe and thus requires anaerobic conditions to grow. Organisms are highly motile by means of flagellae uniformly distributed over the entire bacterial surface allowing them to swarm over a culture plate. Optimal growth occurs at 37° C. Colonies have irregular margins, are flat, translucent, and gray with a matte surface on blood agar. Colonies are 4 to 6 mm in diameter with a narrow zone of clear ( $\beta$ -type) hemolysis. Microscopically, the bacilli often possess terminal endospores giving them a “drumstick” appearance.<sup>2</sup>

In adverse environmental conditions, *C. tetani* produces round terminal spores able to survive in the environment for a prolonged period (years) in the absence of direct sunlight. Spores are resistant to boiling water and many standard disinfection techniques. The vegetative form is susceptible to heat and numerous disinfectants.

## ☞ TOXINS

As is common with all clostridial bacteria, *C. tetani* produces a number of toxins. Two of importance to pathogenesis of disease have been identified.

### TETANOSPASMIN

The classical tetanus toxin (tetanospasmin) is produced in the bacterial cell as a single polypeptide chain of 1315 amino acids,<sup>3</sup> with a molecular mass of approximately 150 kd.<sup>5</sup> The amino acid sequence of tetanus toxin shares marked similarities to the amino acid sequences of botulinum toxins A, B, and E, suggesting that although neurotoxins from *Clostridium tetani* and *C. botulinum* have different clinical effects, they are derived from a common ancestral gene.<sup>3</sup>

After release from the cell, the molecule is cleaved into two polypeptide fragments by proteases produced by the organism—a heavy chain of about 100 kd and a light chain of about 50 kd that remain joined by a disulfide bond.<sup>6</sup> Toxin spreads from the infected site by diffusing into the adjacent tissues and is subsequently transported by the lymphatic system, allowing entrance to the bloodstream.<sup>2</sup> Toxin is also

transported by retrograde movement centrally along the nerve axons.<sup>2</sup> Tetanospasmin is poorly absorbed across mucous membranes, is destroyed by gastric juices, and is unable to cross the placenta as result of its high molecular weight.

Tetanospasmin travels centripetally along the  $\alpha$  motoneurons via membrane associated endoplasmic reticulum.<sup>7</sup> Once at the synaptic cleft, the toxin crosses to affect the presynaptic inhibitory interneurons (Renshaw cells). Tetanospasmin causes blockage of the inhibitory synapses of spinal cord motor neurons by inhibiting neurotransmitter release (glycine and gamma-amino butyric acid [GABA]), thereby inducing the characteristic spastic paralysis.

Three main steps exist at the level of the cell that result in action of this toxin: (1) binding to the neuronal cell membrane, (2) internalization by endocytosis, and (3) the intracellular blockade of neurotransmitter release.<sup>8</sup> Binding to receptors on the nerve endings is the initial step in the paralytic process. Membrane receptors for these toxins consist of membrane gangliosides and a receptor protein. Tetanus neurotoxin acts mainly at CNS synapses.<sup>9</sup>

Once toxin is bound, it is internalized by endocytosis. The light chain, where it displays its zinc-endopeptidase activity specific for protein components of the neuroexocytosis apparatus, is translocated into the cytosol where it can exert its effect.<sup>9,10</sup> This process of internalization makes toxin unavailable to be bound and neutralized by circulating antibodies.

The target of tetanus toxin is vesicle-associated membrane protein (VAMP), also known as *synaptobrevin*, an integral membrane protein of the synaptic vesicles of nerve cell terminals crucial for normal vesicle physiology.<sup>8,11</sup> Synaptobrevin is one of three proteins present in every cell, these being conserved from yeast to human beings. They are essential for a variety of vesicle docking and fusion events.<sup>9</sup> Mutant studies have shown that any alteration in synaptobrevin leads to disturbed vesicle function.<sup>11</sup> Two copies of a nine-residue motif situated in tandem, each with three negatively charged residues, appear to be responsible for toxin specificity.<sup>11</sup> Cleavage of synaptobrevin by proteolytic action of the zinc-dependent endopeptidase of tetanospasmin light chain is the mechanism of toxicity, incapacitating cellular exocytotic machinery and blocking neurotransmitter release.<sup>1</sup>

Recent findings show that both binding and internalization are mediated only by the heavy chain of the toxin, whereas the intracellular blockade of neurotransmitter release involves the light chain alone.<sup>8</sup>

### TETANOLYSIN

Tetanolysin facilitates the spread of infection by increasing the amount of local tissue necrosis. The mechanism of action is to cause permeability changes in liposomes and biologic membranes resulting in cell lysis.<sup>12</sup> Tetanolysin is an oxygen-sensitive hemolysin similar to streptolysin and can affect a variety of cells including erythrocytes, neutrophils, macrophages, fibroblasts, and platelets. Tetanolysin has an affinity for cholesterol and related sterols that inhibit its lytic and lethal actions. The amount of tetanolysin produced by the organism in vivo is unknown.<sup>2</sup>

## ☞ RISK FACTORS FOR DISEASE

Entry of organisms to the animal is usually by inoculation into a deep wound. Complicating diagnosis, the wound that served as the initial site of introduction of *Clostridium tetani*

**FIGURE 12-43** The extended, rigid tail seen in this horse is characteristic of generalized tetanus.

may involve unbroken skin or be healed by the time clinical signs are observed. Other potential sites of entry include lacerations, surgical sites, the umbilicus of the neonatal foal, and the postfoaling reproductive tract. Once traumatized or devitalized tissue has become contaminated with spores, the spores can remain dormant until necrosis of the tissue provides the strict anaerobic environment necessary for germination to the vegetative, toxin-producing form.

## CLINICAL SIGNS AND COURSE OF DISEASE

Tetanus is manifest as hypertonia of the striated muscles, with clonic paroxysmal muscular spasms superimposed. Muscular activity may be increased to the point that rectal temperature becomes markedly elevated. It may be generalized or localized.

Localized tetanus involves muscular rigidity and spasms in the vicinity of the infected wound. With time, this usually progresses to a more generalized tetanus affecting the entire body; however, the initial manifestation of tetanus is most often generalized rather than localized.<sup>2</sup>

**FIGURE 12-44** This horse exhibits enophthalmos, prolapsed nictitators, and rigidity of facial muscles, typical of generalized tetanus.

With generalized tetanus, a characteristic “sawhorse” stance, with an extended, rigid tail, may be present, and the gait is stiff if the horse remains ambulatory (Figure 12-43). Difficulty in standing or laying down is due to extensor muscle rigidity that is exacerbated by external stimuli. As a result of hyperesthesia, painful reflex muscle spasms progressing to generalized tonic contractions with opisthotonus may be the result of even mild stimulation. Progression of the disease makes voluntary movement impossible because of marked extensor rigidity of all four limbs, often leading to recumbency.

Tetanospasmin affects both the sympathetic and parasympathetic nervous systems. Sympathetic hyperactivity associated with adrenergic stimulation may lead to tachycardia, cardiac arrhythmias, and peripheral vasoconstriction. Parasympathetic hyperactivity increases vagal tone that may result in bradyarrhythmias, arterioventricular block, and sinus arrest.

Intracranial signs, when present, are due to the action of tetanospasmin on cranial motor nuclei. Trismus is due to contraction of the masticatory muscles, with sustained facial muscle contracture and lip retraction resulting in risus sardonicus (a sardonic grin). Dorsomedial retraction of the ears and excessive wrinkling of the skin of the forehead can be seen. Prolapse of the nictitating membrane and enophthalmos is due to retraction of the globe by the hypertonic extraocular muscles (Figure 12-44). Miosis, dysphagia, ptyalism, and laryngeal spasm may also occur.

Complications from tetanus include decubital ulcers after periods of recumbency, regurgitation because of dysphagia, dysuria because of a hypertonic urethral sphincter, and constipation with gaseous distention because of a hypertonic anal sphincter and lack of exercise.

Death may result from respiratory failure secondary to the spasm of respiratory muscles or central respiratory arrest from medullary intoxication. Aspiration pneumonia secondary to dysphagia or increased airway secretions may also be fatal. No characteristic necropsy lesions can be ascribed to the tetanus toxins themselves.

Various factors were found to influence survival in one study. Younger horses were significantly less likely to survive than older horses.<sup>13</sup> Dyspnea, dysphagia, and recumbency

were significantly more common in nonsurvivors than survivors and can be considered indicators of a poor prognosis.<sup>13</sup> Of interest, a significant relationship has also been found in dogs between younger age and the development of more severe clinical signs, with more severe disease also decreasing survival.<sup>14</sup>

## DIAGNOSIS

A presumptive diagnosis of tetanus is based on history, clinical signs, and response to treatment. Confirmation is difficult. On physical examination, a recent or healed wound may be found; however, absence of a detectable wound at the time of clinical onset is not uncommon. Devitalization of deep tissue undetectable externally may be the site of toxin production.

Gram staining of samples from the wound is of limited diagnostic value. Sporulated and vegetative forms of *Clostridium tetani* appear similar to other anaerobic bacteria. Furthermore, *C. tetani* may be present as a wound contaminant, with some strains of *C. tetani* nontoxicogenic because they lack the 75-kilobase plasmid containing the toxin gene.<sup>3,15</sup>

Bacteriologic confirmation of tetanus is not often attempted but would be obtained by isolating *C. tetani* from the infected wound. However, isolation of *C. tetani* can be difficult and often fails because of low concentration of organisms present in the wound and strict anaerobic conditions required for culture.

Hematology, serum chemistry, and CSF analysis are usually unremarkable. If a wound or aspiration pneumonia is present, then neutrophilic leukocytosis with a left shift may be observed. Muscle enzymes may be elevated (CK and AST) because of muscle trauma from sustained contracture and prolonged recumbency.

## TREATMENT

The binding of tetanospasmin to the  $\alpha$ -motor neuron is extremely difficult to combat. Recovery is slow and does not occur until new interneuronal synapses develop to replace those that were inactivated by toxin. Therapeutic management of clinical cases of tetanus is centered on five goals discussed following.

### INTERRUPTION OF TOXIN PRODUCTION

Local and parenteral antibiotic therapy is initiated to prevent further production of tetanospasmin by eradication of the vegetative form of *Clostridium tetani* at the site of infection. Penicillin is the drug of choice for eliminating the vegetative form and is recommended to be administered at high dosages. Other antimicrobials that may be effective include the tetracyclines, macrolides (to be avoided in adults), and metronidazole. Metronidazole is indicated for deep and contaminated wounds because it is able to penetrate necrotic tissues without losing efficacy.

### NEUTRALIZING UNBOUND TOXIN

Neutralizing any toxin that is not already bound to the CNS is of primary importance. Tetanus antitoxin (TAT) is produced from the sera of hyperimmunized horses. Once administered to the affected horse, the passively acquired antibodies neutralize unbound toxin both circulating in the blood and present

in the wound. Injection of TAT, both around and proximal to the wound site, has been suggested to be beneficial in neutralizing unbound toxin.

It is vitally important to realize that once the toxin is internalized it can no longer be neutralized by antitoxin. Therefore the disease will likely continue to progress after the administration of TAT.

### CONTROL OF MUSCULAR SPASMS

Sedatives can be used to control muscle spasms and rigidity. Phenothiazines work at the level of the brainstem, depressing descending excitatory input on the lower motor neurons within the spinal cord. Although these medications have been reported to lower the seizure threshold, their effectiveness in the management of clinical cases strongly supports the use of these drugs. Phenothiazines potentiate barbiturates, which are also useful because of their ability to depress the motor areas of the brain and abolish spontaneous spinal cord activity.

Muscle relaxants such as the benzodiazepines, which act as GABA agonists, indirectly antagonize tetanospasmin. Methocarbamol, as a central acting muscle relaxant, would also be considered a rational and useful therapeutic agent.

### SUPPORTIVE CARE

Supportive care is of utmost importance in the successful treatment of tetanus. Patients should be placed in a dark, quiet environment, with minimal stimulation and handling. If recumbent, then deep soft bedding and regular turning (every 4 hours) to minimize decubital ulcers and pulmonary congestion is essential. Urinary catheterization, enemas, and manual rectal evacuation of feces may be required because of hypertonic urethral and anal sphincters and lack of an effective abdominal press. If dysphagic, then an esophagostomy or gastrostomy tube may be required for feeding. Tracheostomy may be required should laryngeal spasm and respiratory obstruction occur. Generalized muscle contraction can result in hyperthermia that must be managed.

### GENERATION OF ACTIVE IMMUNITY TO TETANUS TOXINS

Unfortunately, the concentration of tetanus toxin required to cause overt neurologic disease is insufficient to generate a protective immunologic response. Therefore at the initiation of treatment for tetanus, all horses should be immunized with tetanus toxoid to initiate a protective antibody response. Experimentally, horses were resistant to challenge 8 days after receiving a single dose of toxoid.<sup>16</sup> To ensure optimal antibody production, affected horses should receive a second dose 1 to 2 months later.

## PROGNOSIS

Prognosis depends on the incubation period, duration of onset, severity of clinical signs, and presence of any secondary complications. Therefore a short incubation period, short duration of onset, and rapid progression of signs results in a poor prognosis. When attempting to treat clinical cases, it must be realized that the required supportive care is prolonged, labor intensive, and costly.

## PREVENTION

Where possible, management of contaminated or necrotic wounds should include thorough débridement, large volume flushing, and comprehensive cleansing. After this, rational antibiotic therapy should be instituted. Together these procedures, in conjunction with the following, should greatly minimize the occurrence of tetanus.

### TETANUS TOXOID

Low concentrations of tetanospasmin are capable of inducing clinical signs. As a result, neither exposure to tetanospasmin nor recovery from clinical disease induces the development of immunity. Prophylactic antibody formation and generation of immunity is stimulated by vaccination with tetanus toxoid, derived from inactivation of tetanospasmin with formaldehyde. Significant differences were found in antibody response (IgG titers) between commercially available multivalent vaccines.<sup>17</sup> It was suggested that differences were the result of variations in antigenic mass.

Vaccination with tetanus toxoid markedly reduces the occurrence of clinical disease, with annual vaccination of all horses recommended. However, no vaccination is absolute,<sup>18</sup> with protection being dependent on proper administration and subject to breakdown in the face of overwhelming challenge. Experts recommend that tetanus toxoid be administered to horses with susceptible wounds if longer than 6 months since vaccination.

### TETANUS ANTITOXIN

TAT is produced by hyperimmunization of horses with tetanus toxoid. Administration of 1500 U of antitoxin to unvaccinated horses provides immediate passive protection lasting approximately 3 weeks.<sup>19</sup> Higher doses result in longer duration of protection.

In one study monitoring antitoxin levels as a measure of protection, combined active-passive immunization (tetanus toxoid concurrently with TAT) was effective at providing rapid and prolonged protection for previously unvaccinated horses.<sup>20</sup> Administration in separate, remotely located sites on the horse was recommended.

Subclinical and clinical hepatic disease after TAT administration has been reported.<sup>21-23</sup> Known as *idiopathic acute hepatic disease*, this condition has also been called *Theiler's disease*, serum hepatitis, serum sickness, and postvaccinal hepatitis. Signs vary from hepatic enzyme elevation to hepatic encephalopathy in severe cases. Occurrence of this disease is rare and sporadic, but prognosis is poor in most affected horses.

### FOAL VACCINATION

Tetanus-specific IgG antibodies inhibiting the foal's response to tetanus toxoid are passively transferred via colostrum. High titres of IgGa, IgGb, and IgG(T) subisotypes were detected in postsuckling serum samples collected from foals born to mares that had received booster doses of multicomponent vaccines during the last 2 months of gestation. Because these maternal antibodies exert a significant inhibitory effect on the response of foals to tetanus toxoid, it is recommended that primary immunization of foals born to vaccinated mares should not commence before age 6 months.<sup>24</sup> In addition, antibody

response to vaccination of younger foals was shown to be poor,<sup>19</sup> necessitating multiple doses of toxoid. Vaccination for foals born to unvaccinated mares should begin at a younger age (3 months).

## BOTULISM

Stephen M. Reed

Botulism is a severe neuroparalytic disease caused by toxins produced by *Clostridium botulinum*, a gram-positive, spore-forming, obligate anaerobic bacterium.<sup>1-5</sup> The bacteria are distributed widely in nature and can be found in soil, agricultural products, and marine environments. Organisms produce several types of antigenically distinct toxins designated as A, B, C1, C2, D, E, F, and G. Bacteria-producing toxin types A, B, E, F, and G are found in the environment, whereas types C and D are found within the intestinal tract of animals and birds.<sup>3,5,6</sup> Human disease is caused by types A, B, E, and rarely F.<sup>1</sup> The molecular weight of botulinum toxins is approximately 150 kd.<sup>3</sup>

In general, type B botulinum spores are most frequently isolated from the soil of the Northeastern and Appalachian regions of the United States. As a result, type B botulism is most often seen in the Mid-Atlantic states and Kentucky. In contrast, *C. botulinum* type C is most common in Florida, and type A occurs predominantly in the Western United States. Most reported cases (>85%) of botulism in horses in the United States result from type B botulism.<sup>2,3,5,6,8-11</sup> Less frequently, cases of type C and A botulism have been recognized. Type D botulism in horses has been suspected in the United States, but no cases have been confirmed at this time.

Botulinum toxins act presynaptically at the peripheral cholinergic neuromuscular junction. The toxin first binds to polysialogangliosides on the nerve terminal and is then internalized into the nerve terminus via a specific receptor.<sup>7</sup> The toxin then binds to SNARE (soluble N-ethylmaleimide-sensitive factor attachment *protein* receptor) proteins, preventing fusion of synaptic vesicles with the plasma membrane at the neuromuscular junction.<sup>7</sup> By attacking the SNARE proteins, the toxin prevents the synaptic vesicle from releasing acetylcholine, thus resulting in flaccid paralysis. Once the toxin is bound, improvement in clinical signs is achieved only by the regeneration of new motor end plates, explaining the delay of 4 to 10 days before noticeable clinical improvement even after treatment with antitoxin.

Clinical botulism in horses may occur by any of three mechanisms. Forage poisoning typically occurs in adult horses after ingestion of preformed toxin in feed material that has been contaminated by bacteria. Contaminated feed material may be spoiled grain, haylage, silage, or hay. In most cases, feed material contains decaying vegetable matter with bacterial proliferation and toxin production; however, occasionally feed is contaminated with decomposing animal carcasses.<sup>5</sup> In horses that had disease resulting from type C toxin, the cause was the ingestion of decomposing tissue of animals that contained the bacteria within the lumen of the intestinal tract.<sup>8</sup> A report describes type C1 and C2 toxins resulting in signs of neurotoxicity in one horse.<sup>8,9</sup> The same feed given to horses and cattle has been shown to result in disease in the horses, although not affecting the cattle, suggesting a species

difference in susceptibility to these toxins.<sup>6,8</sup> Whenever more than one horse on a premise demonstrates clinical signs compatible with botulism, quick analysis of the entire ration and the feeding methodology to determine if contamination has occurred is recommended. This aggressive approach may prevent additional horses or other animals on the farm from becoming infected. Beginning the investigation with the feed, especially ensilage, is always best, because this is the most common source of toxin. Conditions may be optimal for proliferation of botulism spores and toxin production in improperly prepared hay or hay stored in plastic bags.<sup>8</sup>

Wound botulism occurs when wounds become contaminated with *C. botulinum*, producing toxin *in vivo*.<sup>2</sup> Published reports have described this type of infection after castration, an injection abscess, an infected umbilicus, and other contaminated wounds.<sup>2,4,5,10</sup> This problem is unique to horses, although a few cases have been described in other species (e.g., in human beings after sharing of needles during illicit drug use).

In foals a syndrome referred to as *toxicoinfectious botulism*, or *shaker foal syndrome*, occurs.<sup>5,6,11</sup> The disease appears to be a sporadic condition affecting foals from a few days to several months of life<sup>10</sup> and most commonly is associated with type B toxin. A high percentage (94%) of soil samples collected from farms that previously have had affected foals contained type B neurotoxin gene.<sup>12</sup> The foals on these farms are suspected to have ingested contaminated soils, and this may have led to the proliferation of spores within the intestinal tract, toxin production and absorption from the intestinal tract, and disease. A similar condition has been described in human infants fed honey or other food contaminated with botulism spores. In adult horses the intestinal flora appears to have a protective effect against the proliferation and absorption of spores and toxin.

## CLINICAL SIGNS

The clinical signs of botulism in horses are similar, regardless of the source of contamination or the type of toxin.<sup>5,6,10,11</sup> The time of onset of clinical signs after ingestion of contaminated feed may vary from as short as 12 hours to as long as several days, but it usually occurs within 24 hours of exposure.<sup>1</sup> The incubation period may be associated with inoculum size, which suggests that the shorter the incubation, the more severe the disease. The disease usually affects motor nerves with high efferent traffic, resulting in weakness, dysphagia, and poor muscle tone. One can detect the lack of normal muscle clinically by evaluating eyelid tone, which often is weak. Affected horses appear to maintain coordination and therefore appear weak but not ataxic. Early in some cases the owners will note prolongation of the time the horse takes to eat its grain, or they will note abdominal discomfort and colic. The time to ingest a small quantity (usually a cup) of grain can be useful as a predictor of whether the horse has botulism. Some horses may have colic, decreased salivation, and occasionally urinary retention resulting from involvement of the cholinergic autonomic nervous system.

Over time affected horses demonstrate muscle fasciculations, often first in the triceps region, that eventually progress to the entire body and result in recumbency. At first the horse appears to gain strength after lying down for a short time and may return to standing spontaneously or with coaxing. Eventually the horse is unable to rise. Clinical evaluation

should include careful examination of the tongue, eyelid and tail tone, and the pupillary light response, which appears sluggish. One will note ptosis of the eyelids. In horses affected for a longer time, an abnormal pattern of respiration may be noted. Death often results from respiratory failure.<sup>5,6,9</sup>

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis for horses affected with botulism can be any cause of weakness and dysphagia in horses and should include protozoal myeloencephalitis; EMND; EHV-1 myeloencephalopathy; WNV; rabies; several toxins such as lead, yew, and yellow star thistle; low blood calcium; and hyperkalemic periodic paralysis.<sup>5,6,11</sup> One also should consider less common clinical diseases such as tick paralysis, vascular accident, or even unusual examples of exercise intolerance.

The diagnosis of botulism is difficult and frequently is based on compatible clinical signs of acute onset of flaccid paralysis, weak or poor eyelid tone, poor tail tone, slow or difficult eating, and dysphagia, as well as a compatible history of possible exposure to toxin. To confirm the diagnosis, one must detect the toxin in feed, serum, gastrointestinal contents, feces, or debris collected from a wound.<sup>4,5,11-14</sup> The toxin is stable in frozen tissues or plasma and can be stored at  $-20^{\circ}\text{C}$  for several weeks. The presence of botulism spores in intestinal contents or feed or the presence of an antibody response to *C. botulinum* in a recovered patient are also useful to confirm the diagnosis of botulism in horses.

Methods for detecting botulinum toxin include mouse bioassay, ELISA, PCR test, and use of an optical-based biosensor.<sup>4,9,12-14</sup> The mouse bioassay is sensitive but requires several days to complete and uses many mice. If serum has been collected from a horse in the acute stage of infection, then this assay is most accurate. One of the problems associated with this test in serum of horses is that because these animals are so sensitive to botulinum toxin, clinical signs may appear before the toxin reaches threshold levels required for detection. One must add specific antiserum to the test to detect the exact toxin type. Other tests are available, although these are less sensitive than mouse inoculation. The ELISA may be less specific because of cross-reactivity with other clostridial toxins, but it does have a turnaround time of 24 hours. The PCR test was used to identify an outbreak in Australia caused by type B botulism.<sup>12</sup> The fastest but least sensitive is the optical fiber-based biosensor.<sup>13</sup> The detection of botulism spores from the feces of infected horses has been useful in some outbreaks.<sup>5,9</sup> Compared with normal horses, the detection of spores in the feces is a rare occurrence (16 out of 507 samples). The use of ELISA for the detection of antibody in the serum of horses has been helpful to detect type C and D toxin in horses and cattle.<sup>5</sup>

EMG of horses with botulism will often identify a decremental response after repetitive stimulation. Although this test has been helpful in human beings, it is rarely helpful in horses.

## TREATMENT

Treatment of horses with botulism is expensive, time consuming, and often unrewarding. The first therapeutic objective is prompt administration of specific or multivalent antitoxin to bind circulating toxin. Additional therapy includes appropriate nursing care, tube feeding, sedation to reduce muscle activity,

antimicrobial agents, and laxatives. In severely affected foals or adults with respiratory failure, mechanical ventilation is indicated.<sup>2,5,6,9,11</sup>

Prognosis for horses with untreated botulism is poor; however, for horses that remain standing and that have been given antitoxin, the survival may approach 70%.<sup>4</sup> The shorter the time is that the horse is recumbent and the more rapidly it regains the ability to swallow, the better is the prognosis. In horses that do survive, recovery is complete but it can take months for the horse to regain full strength. Type B botulism is preventable by vaccination using type B toxoid, which was initially developed to prevent disease in newborn foals. The recommended vaccination schedule includes an initial three doses at 1-month intervals followed by an annual booster. For pregnant mares it is best to administer the annual booster 4 to 6 weeks before foaling.<sup>5,6,11</sup> Additional preventative measures involve good husbandry and proper processing and storage of feed material.

## EQUINE GRASS SICKNESS (EQUINE DYSAUTONOMIA)

Yvette S. Nout

Equine grass sickness is an acquired degenerative polyneuropathy that predominantly affects the neurons of the autonomic and enteric nervous system. The disease was recognized first in Scotland in 1909.<sup>1</sup> Since then it has been reported in other parts of England, continental Europe, and Australia.<sup>2,3</sup> A clinically and histopathologically similar disease, *mal seco*, occurs in Argentina, southern Chile, and the Falkland Islands.<sup>4</sup> So far the disease has not been recognized in North America.

The disease affects postganglionic parasympathetic and sympathetic neurons and is characterized as a dysautonomia. Clinical signs vary, and the severity of EGS is suggested to be related to the extent of neuronal damage. The disease occurs sporadically and is often fatal. Although EGS has been studied extensively, the cause of the disease remains unknown.

## CLINICAL SIGNS

EGS has been reported in other equids such as the Przewalski's Horse, zebra, donkey, and pony, but it occurs primarily in young, mature horses that have access to pasture. Horses with EGS are generally between 2 and 12 years of age, and horses between the ages of 3 and 5 years are at greatest risk for developing the disease. No breed or gender predilection to the disease is apparent.<sup>3</sup>

Acute, subacute, and chronic forms of EGS are recognized, of which clinical signs overlap from one form to the other.<sup>5,6</sup> Most horses are depressed and dysphagic. The dysphagia is caused by cranial nerve involvement and is recognized by drooling of saliva, feed material in the nares, impacted feed material in the buccal pouches, and difficulty drinking.

## ACUTE FORM

Clinical signs are related to acute onset of gastrointestinal ileus. The course of disease is generally less than 48 hours. Signs of abdominal pain may be severe and are caused by gastric and small intestinal distention. Affected horses are hypovolemic,

and the reduced circulating volume may cause death from cardiac failure. Other clinical signs are generalized or patchy sweating, fine muscular fasciculations, pyrexia, severe dysphagia, and bilateral ptosis. Examination per rectum reveals small intestinal distention and often a mild secondary impaction of the large colon. One can obtain a large quantity of reflux after nasogastric intubation.

## SUBACUTE FORM

The course of disease is 3 to 7 days, and clinical signs are less severe than in acute EGS. Horses with subacute EGS do not develop gastric or small intestinal distention but develop large colon impactions. These horses have a characteristic "tucked up" stance. Clinical signs include intermittent colic and patchy sweating. These horses often have rhinitis sicca.

## CHRONIC FORM

The course of the disease is weeks to months. Cachexia is the most prominent clinical abnormality in horses with chronic EGS. The entire gastrointestinal tract is empty in these horses, and they usually have rhinitis sicca characterized by accumulation of mucopurulent material in the nasal passages. Other clinical signs in animals with chronic EGS are sweating, muscle tremors, gait abnormalities (short strided), leaning against walls, base-narrow stance, snoring, pica, and penile prolapse. In a later stage, one may observe coat abnormalities such as areas of piloerection, growth of a long coat, and pallor of the coat.

## PATHOLOGIC FINDINGS

Gross necropsy findings in acute EGS are consistent with gastrointestinal ileus. A large fluid-filled stomach and distended small intestine are present. Secondary impacted ingesta is often present in the large colon and cecum. Splenomegaly and erosions of the esophageal mucosa are other findings in acute EGS. Gross necropsy findings in subacute EGS are less severe and include colonic impaction.<sup>2,5</sup> One may find inspissated mucus in the lumen of the small colon and rectum and evidence of intraluminal hemorrhage such as inspissated blood or black feces. In horses with subacute and chronic EGS, one may find rhinitis sicca.

Neuronal lesions are most severe in the autonomic ganglia (cranial cervical, stellate, celiacomesenteric) and enteric nerves. One finds less severe lesions in some brainstem nuclei and parts of the spinal cord.<sup>2,5-7</sup> Changes detected in affected neurons are degenerative and include chromatolysis, loss of Nissl's substance, loss of the nucleus, spheroid formation, neuronal swelling, and an increase in the number of lysosomes and mitochondria.<sup>2,5,6</sup> Loss of a recognizable Golgi apparatus appears to be an early neuropathologic event in EGS.<sup>5</sup>

A recent study has demonstrated a reduction of neuropeptide expression in nasal mucosal innervation in horses with EGS.<sup>8</sup> This is suggested to underlie the presentation of rhinitis sicca seen in this disorder.

Similarly to other neurodegenerative diseases, one finds a specific anatomic distribution of neuropathologic conditions in EGS, which supports the hypothesis of a common factor sensitizing the neurons to specific insults. As in EGS, multiple system involvement is a common feature in human neurodegenerative disorders. The central pathologic condition in EGS

appears to be specific and repeatable, consistent with findings in primary dysautonomias in other species. However, in EGS, one does not see the increasing severity of pathologic findings and severity of clinical signs with increased duration of disease consistently as is seen in classical neurodegenerative diseases. Moreover, the decrease in severity of pathologic conditions of the brain with increased duration of disease may suggest a healing process from the initial insult. The association between central neuronal pathologic findings and severity of clinical disease is unclear. In one study, increased neuronal pathologic findings were observed in milder clinical cases (chronic EGS),<sup>7</sup> which contrasts to another study that demonstrated increased neuronal pathologic findings in acute cases of EGS.<sup>9</sup>

## ∞ PATHOGENESIS

Clinical signs are related to the damage of the autonomic nervous system. The most severe lesions are found in the myenteric and submucosal plexuses of the ileum and less severe changes occur in the celiacomesenteric ganglion. The altered autonomic activity results in cessation or decrease of intestinal peristalsis and subsequently leads to the development of ileus and colonic impaction. The dysphagia in most cases of EGS is caused by cranial nerve or brainstem involvement.<sup>5</sup> Based on epidemiologic and pathologic findings in horses with EGS, an unidentified neurotoxin is implicated as the causative agent of the disease; however, because of the complexity of the disease, multiple factors are suspected to be involved in the pathogenesis of EGS.<sup>2,3,5</sup>

Multiple experimental studies have failed to identify the causative agent or agents of EGS. Risk factors for developing the disease have been identified, however. Young horses between 3 and 5 years of age are at greatest risk for developing EGS.<sup>3</sup> Older horses have been suggested to be resistant to EGS, perhaps after nonfatal exposure to the causative agent. Moreover, horses that had been in contact with cases of EGS were 10 times less likely to develop the disease.<sup>10</sup> Similarly, transfer of maternal antibodies against this causative agent may explain the fact that EGS has not been reported in horses younger than 6 months. Horses that are kept solely at pasture are at increased risk of developing EGS; however, the disease has been reported in stabled horses and in horses that had no access to grass at all. The type of pasture or the type of supplementary feeds do not appear to be associated with the development of EGS. Horses that have been on the premises for less than 2 months and horses that have been moved recently to a different pasture are at increased risk of developing EGS. Horses are more likely to be affected with EGS when they are housed on premises that have experienced the disease previously. Although cases of EGS can occur throughout the year, the incidence of EGS consistently has been found to be greatest during the spring months, particularly if a period of warm weather is followed by a period of wet weather.

Paravertebral ganglionic damage exceeds and occurs earlier than prevertebral ganglionic damage. The putative neurotoxin is suggested to be ingested and initiates damage in the enteric plexuses, which leads to immediate functional deficits seen in the acute form of EGS.<sup>5</sup> Functional lesions precede structural lesions caused by secondary retrograde axonal degeneration. In chronic EGS, less initial enteric nerve damage occurs, and subsequently fewer secondary prevertebral ganglionic lesions occur. Consequently, the body has more time to develop functional and structural compensatory mechanisms. The less

severe damage to the celiacomesenteric ganglion compared with the damage in the paravertebral ganglia is suggested to be caused by hematogenous spread of an ingested neurotoxin.

Currently, toxicoinfection with *Clostridium botulinum* type C is being investigated as a cause of the disease.<sup>11-13</sup> This organism grows and produces toxin in the gastrointestinal tract. The role of this organism in the cause of EGS is supported by the fact that type C botulinum neurotoxin has been detected in the gastrointestinal tract of 67% of horses with acute and 74% of horses with chronic EGS compared with 10% of control horses.<sup>14</sup> Moreover, horses with EGS were found to have lower IgG concentrations to the surface antigens of *C. botulinum* type C and to type C botulinum neurotoxin. An association between antibody concentration and form of EGS was not demonstrated, but horses that had been exposed to other horses with EGS or that had been grazing on pasture where the disease had occurred previously had significantly higher antibody concentrations to these antigens.<sup>11</sup> These findings may indicate the development of a protective immune response against the putative neurotoxin. More recently it has been demonstrated that fresh grass may contain botulinum neurotoxin, and this supports the hypothesis that EGS may be a form of soil-borne botulism in horses.<sup>12</sup> The suggestion is that natural-occurring biofilms may protect bacteria and improve their chance of survival; however, further research in the areas of cause, pathogenesis, treatment, and prevention of EGS is necessary.

The sulfur amino acid depletion in horses with EGS has been suggested to contribute to the pathogenesis of this disease through the increase of oxidative neuronal death; however, this has not been proven.<sup>15</sup> A further study found no evidence of systemic macromolecular oxidative damage in horses with EGS.<sup>16</sup> Mycotoxin toxicity also has been implicated as a cause for EGS,<sup>13</sup> and low sulfur amino acid concentrations may enhance the toxicity of mycotoxins.

## ∞ DIAGNOSIS

No noninvasive definitive test exists to obtain an antemortem diagnosis of EGS. Serum biochemical and hematologic examinations do not reveal specific changes in horses with EGS. Plasma amino acid analysis in horses with acute EGS demonstrated a significant increase in plasma taurine concentration and a significant decrease in plasma cysteine, arginine, citrulline, histidine, isoleucine, leucine, methionine, threonine, tyrosine, and valine concentrations. In horses with subacute and chronic EGS, these changes were less significant (and the plasma amino acid profile normalized). Although one cannot use the amino acid analysis as a definitive test for EGS because of overlap in individual amino acid concentrations for control horses, horses with EGS, and horses grazed with EGS-affected horses, the test may have value as an additional diagnostic aid, because adequate plasma cysteine concentrations (>17 μmol/L) may exclude EGS.<sup>15</sup> Most horses with EGS and healthy co-grazed horses had significantly decreased plasma sulfur amino acid (cysteine and methionine) concentrations compared with healthy control animals.

When watching a horse eat, one may notice signs of abnormal esophageal function such as esophageal spasm and reverse peristalsis. Contrast radiography and endoscopy of the esophagus may reveal abnormalities such as megaesophagus and esophageal erosions.<sup>6</sup>

Examination of an ileal biopsy, collected via laparotomy, is the only method to confirm EGS ante mortem.<sup>17,18</sup> Neuronal

degeneration is present in the enteric plexuses from the esophagus to the rectum, but the most severe changes are present in the terminal ileum. Examination of a rectal mucosal biopsy is specific but not sensitive for EGS.

The most important differential diagnoses for acute EGS are a small intestinal strangulating lesion and duodenitis-proximal jejunitis. Clinical signs and neuronal lesions in chronic EMND and chronic EGS may be similar, and these similarities have led to the speculation that these two diseases are related.<sup>19</sup> Further examination, however, reveals important differences such as the fact that EMND occurs in older horses that have not had access to pasture, and EGS occurs in young horses with access to pasture. EGS sometimes occurs along with EMND.<sup>2,19</sup>

## ☞ TREATMENT AND PREVENTION

No effective cure exists for EGS. Horses with acute EGS may respond initially to gastric decompression and intravenous fluid therapy. Management of horses with chronic EGS includes nursing care and the use of the prokinetic drug cisapride and the appetite stimulant diazepam.<sup>6</sup>

## ☞ PROGNOSIS

EGS is usually fatal. The case fatality rate for acute and subacute cases is 100%. If horses with acute EGS are not euthanized within 48 hours, then they die from circulatory failure or gastric rupture. Horses with subacute grass sickness usually are euthanized within 7 days.<sup>7</sup> Horses with chronic EGS often are euthanized because of weakness and emaciation; however, when given appropriate care at a referral hospital, approximately 50% of horses may survive.<sup>6</sup> Survivors may return to work, but some display residual abnormalities such as mild dysphagia, sweating, and coat changes.

### LYME DISEASE IN HORSES

Stephen M. Reed, Ramiro E. Toribio

Lyme disease is the most common vector-borne infectious disease in human beings in the United States. Initially recognized in the mid-1970s in Lyme, Connecticut, as the cause of unexplained rheumatoid arthritis in children, the causative agent of Lyme disease was discovered to be a spirochete, *Borrelia burgdorferi* (*sensu lato*). In addition to human beings, Lyme disease affects domestic animals such as dogs, cats, cattle, and horses.<sup>1-7</sup>

Human beings and animals acquire Lyme disease by transmission of *B. burgdorferi* through the bite of infected hard ticks (*Ixodes* spp.). In the Eastern and Midwestern United States the vector is the blacklegged tick or deer tick, *Ixodes scapularis* (formerly *I. dammini*), whereas in the Western United States the vector is the western blacklegged tick, *I. pacificus*. In Europe the sheep tick, *I. ricinus* is the vector of Lyme borreliosis.

Not all ticks are infected with the spirochete, and infection varies by tick species and geographic region. These ticks have a 2-year, three-stage life cycle and feed once during each stage.<sup>8,9</sup> The larvae hatch in the spring and summer and are usually non-infective because transovarial transmission is rare.<sup>10</sup> The tick may become infected at any stage of the life cycle by feeding on small

mammalian hosts, typically the white-footed mouse (*Peromyscus leucopus*), which is a natural host for the spirochete. The nymphal stage emerges the next spring and is most likely to transmit the disease because it is small, difficult to see, and engorges faster; engorgement is necessary to transmit *B. burgdorferi*. The white-tailed deer (*Odocoileus virginianus*) is the host for adult ticks. The life cycle of *I. ricinus* in Europe involves birds and mammals because immature stages feed on birds and reptiles. Nymphal *I. scapularis* are the main vectors of *B. burgdorferi* in human beings. These ticks are more active from May to July. Once the tick has engorged, *B. burgdorferi* is transmitted to the host via lymphatics or blood. Although larval and nymph stages are responsible for *B. burgdorferi* transmission to other mammals, the stage responsible for transmitting Lyme disease in horses is unknown.

## ☞ EPIDEMIOLOGY

In endemic areas of the Northeast and Midwestern United States, approximately 20% of nymphal stages and 30% to 40% of adult stages of *Ixodes scapularis* are infected with *Borrelia burgdorferi*. In contrast, *I. pacificus* often feeds on lizards that are poor reservoirs for *B. burgdorferi*, and only 1% to 3% of these ticks, including the nymphal stages, are infected with the spirochete.<sup>10</sup> This difference in the number of infected ticks may explain the difference in the prevalence of Lyme borreliosis between the Eastern and Western United States. Equine seroprevalence is high in the Northeastern United States, but limited information is available for other parts of the country.<sup>2,6</sup> In Europe, clinical cases and equine serologic surveys have documented Lyme borreliosis as a cause of equine disease in Poland, Germany, Scandinavia, and England.<sup>5,11,12</sup>

The apparent increasing incidence of disease in human beings and animals may result from an increased deer population, increased number of ixodid ticks, expansion of human and horse populations into previously rural woodland areas, or increased recognition of the disease manifestations.

The disease has a seasonal prevalence and is most common in spring, summer, and fall, with a peak incidence in June and July. In some climates such as California, ticks may be active throughout the year. The organism is maintained in a complex life cycle of small wild mammals and immature stages of the blacklegged tick. Larval and nymphal stages of the tick acquire the infection when they feed on infected mice. The white-tailed deer (*Odocoileus virginianus*) is not a reservoir for Lyme disease but rather the host for the adult stages of the tick. This is relevant to tick and Lyme disease control programs, because regional reductions in the number of *I. scapularis* has only been possible when the deer population has been decreased.<sup>8</sup>

## ☞ CLINICAL SIGNS

Clinical signs associated with *Borrelia burgdorferi* in horses, as in human beings, are often nonspecific and involve multiple body systems. In human beings, clinical signs frequently include annular rash, erythema migrans, myalgia, aseptic meningitis, arthritis, and seventh cranial nerve palsy.<sup>10</sup> The disease usually begins as a skin rash and often progresses to involve joints and the nervous and cardiac systems but may involve other body systems as well. In human beings the skin rash may be slowly progressive and sometimes may take up to 1 month before becoming apparent.

In horses, reported clinical signs of Lyme borreliosis include chronic weight loss, sporadic lameness, laminitis,

low-grade fever, swollen joints, muscle tenderness, anterior uveitis, encephalitis, and abortion.<sup>3,4,13</sup> Some horses may demonstrate clinical illness and depression and may go off feed in a short time. The bacteria may enter the CNS within a short time after exposure. Chronic arthritis may develop as a result of autoimmune mechanisms, although this is not fully understood. *Ixodid* spp. ticks are often co-infected with *Borrelia burgdorferi* and *Anaplasma phagocytophila*; however, dual infections remain to be documented in the horse. An important consideration is that limb swelling and response to tetracycline treatment, indicating Lyme borreliosis could be the result of *A. phagocytophila* infection.

## DIAGNOSIS

The diagnosis of Lyme disease is often difficult. History of tick exposure or living in a Lyme disease endemic area is helpful; when combined with the identification of clinical signs and the elimination of other diseases, this information allows the clinician to make a presumptive diagnosis. Examination of blood work for other diseases may be more beneficial than a positive blood test for Lyme, although one should complete such a test as well. In human beings an early increase in serum IgM often occurs. Response to therapy also helps to support a presumptive diagnosis of Lyme disease. Diagnosis of Lyme disease in horses is difficult,<sup>14</sup> and in many cases one bases a presumptive diagnosis on history, clinical signs, and response to antibiotic therapy in an animal with probable cause to be infected (i.e., possible exposure). In human beings the skin lesions are obvious. Blood tests are of limited value; however, ELISA, kinetic ELISA, Western blot testing, and PCR on blood samples and synovial fluid from suspect animals have been evaluated.<sup>2,5-7,14,15</sup> One may test samples of joint fluid, CSF, and tissues from affected patients for presence of organisms. Several pathologic conditions should be considered in the differential diagnosis of equine borreliosis, including *Anaplasma phagocytophila* infection, chronic diseases, vasculitis, and immune-mediated arthritis if limb or periarticular swelling are present, as well as causes of neurologic disease.

## PATHOGENESIS

*Borrelia burgdorferi* organisms are capable of nonspecifically activating monocytes, macrophages, and synovial lining cells, as well as natural killer cells, B cells, and complement, leading to production of host proinflammatory mediators. These proinflammatory mediators seem to localize in joints, leading to chronic arthritis and lameness. *B. burgdorferi* has developed strategies to interact with the mammalian host, including adhesion to host cells and components of the extracellular matrix such as fibronectin,  $\beta_3$  integrins, and glycosaminoglycans. The current thinking in the development of arthritis is that outer-surface proteins (Osps) of *B. burgdorferi* trigger an autoimmune reaction because antibodies to OspA and OspB have been detected in 50% to 80% of human patients with arthritis.<sup>16,17</sup> Natural killer cells also play a central role in joint inflammation by producing excessive amounts of TNF- $\alpha$  and IL-8.<sup>16</sup>

## TREATMENT AND PREVENTION

Many horses are treated annually for a presumptive diagnosis of Lyme disease. Recommended treatment includes oxytetracycline (6.6 mg/kg IV every 24 hours) or doxycycline (10 mg/kg

PO every 12 hours).<sup>18</sup> Treatment can be started with tetracycline for 1 week followed with doxycycline for 3 to 4 weeks. Ceftiofur (2.2 to 4.4 mg/kg IV every 12 hours) has also been evaluated.<sup>18</sup> In animals infected with *B. burgdorferi*, a rapid clinical response (2 to 4 days) is expected with tetracyclines. In some horses the clinical signs may show an initial worsening as a response to toxins released after death of the organisms. Currently, no licensed vaccine is available to prevent Lyme disease in horses, although vaccines are available for dogs and human beings. A recombinant OspA vaccine was evaluated in horses with promising results.<sup>19</sup>

Aids to prevention include daily grooming with removal of ticks, along with the use of tick repellents that contain permethrin. One should apply tick repellents to the head, neck, legs, abdomen, and under the tail. Keeping pastures mowed and removing brush and woodpiles makes the environment less hospitable for rodents, which in turn decreases the tick population. Regional programs to control Lyme disease are based on reducing the deer population.

## HEAD SHAKING

Robert H. Mealey

## CLINICAL SIGNS

Head shaking is a widely recognized disorder characterized by persistent or intermittent, spontaneous, and frequently repetitive vertical, horizontal, or rotary movements of the head and neck.<sup>1</sup> The affected horse shakes, jerks, or flicks its head uncontrollably in the absence of obvious physical stimuli, and the condition can be severe enough to render the horse unusable and dangerous.<sup>2-5</sup> Head shaking often is accompanied by snorting and sneezing, and many horses rub their noses on stationary objects or on the ground while moving. In addition to shaking the head up and down, flipping the upper lip, or shaking the head side to side, horses also may act as if a bee has flown up the nostril or may strike at the face with the forelimbs.<sup>2,6,7</sup> Head-shaking horses also may exhibit avoidance behavior, with low head carriage, corner seeking, and nostril clamping.<sup>1,8</sup> To characterize the severity of clinical signs, a grading system of 1 to 5 has been described, with grade 1 being a rideable horse with intermittent and mild signs (facial muscle twitching) and grade 5 being an unrideable, uncontrollable, dangerous horse with bizarre behavior patterns.<sup>1</sup> Clinical signs are usually worse during exercise; however, head shaking can affect horses at rest.<sup>1-5,7</sup> Mean age of onset is typically 7 to 9 years, and Thoroughbreds and geldings appear to be over-represented in some studies.<sup>2,3,6</sup> Head shaking can be seasonal or nonseasonal. Early literature suggested an increased incidence of head shaking during the warmer months of the year,<sup>5</sup> and a later study indicated that the peak periods of onset were spring and early summer.<sup>3</sup> Recent studies have found that 64%<sup>6</sup> and 59%<sup>2</sup> of head-shaking horses are affected seasonally, with the majority developing signs in the spring or early summer.

## PATHOGENESIS

Early work suggested 58 possible causes for head shaking, including two that have received considerable attention recently: (1) photophobia and (2) trigeminal neuralgia.<sup>9</sup> Other

reported and suggested causes include behavioral resentment to rider-induced head and neck flexion, exercise-induced hypoxia, ear mites, cranial nerve dysfunction, otitis media or otitis interna, cervical injury, ocular disease, guttural pouch mycosis, dental periapical osteitis, vasomotor rhinitis, allergic rhinitis, *Trombicula autumnalis* (harvest mite) larval infestation, maxillary osteoma, and EPM.<sup>3,4,9-14</sup> A study of 100 head-shaking horses revealed a potential specific cause in only 11 horses, and elimination of the abnormality resulted in resolution of the head shaking in only two of them.<sup>3</sup> Idiopathic head shaking has been used to describe the majority of cases in which no specific underlying cause is found, and necropsy results in these horses reveal no lesions.

The clinical signs exhibited by most head-shaking horses now generally are thought to result from sharp, electric-like, burning pain involving the trigeminal nerve.<sup>1,2</sup> Trigeminal nerve involvement is supported by the observations that some horses improve after blocking the infraorbital nerve (part of the maxillary branch),<sup>15,16</sup> and that most horses improve after blocking the posterior ethmoidal nerve (part of the ophthalmic branch).<sup>1</sup> Horses that head shake in response to light stimulation have been described as *photic head shakers*.<sup>8</sup> Most of these horses are affected seasonally (spring and summer), improve at night or when brought indoors, and improve when blindfolded or when gray lenses are placed over their eyes. Photic head shaking is hypothesized to be caused by optic-trigeminal summation (stimulation of the optic nerve that results in referred sensation to parts of the nose innervated by the trigeminal nerve), a mechanism similar to that proposed for photic sneezing in human beings.<sup>2,8</sup> Many features of head shaking in the horse are similar to trigeminal neuralgia in human beings—a severe chronic pain syndrome characterized by dramatic, brief stabbing or electric shocklike pain paroxysms felt in one or more divisions of the trigeminal distribution, spontaneously or on gentle tactile stimulation of a trigger point on the face or oral cavity. The disease is associated with microvascular compression and pathologic changes in the trigeminal root and trigeminal ganglion.<sup>17</sup> The basic underlying cause of head shaking in the horse may be trigeminal neuralgia,<sup>1</sup> and recent work suggests a degenerative disorder of the brainstem nucleus of the trigeminal nerve (D.C. Knottenbelt, personal communication). The trigeminal nerve is postulated to be hypersensitive and to fire in response to a variety of trigger factors including wind, airway turbulence, increased blood flow, pollen, dust, warmth, cold, insects, allergies, or other irritations. These trigger factors appear to act intranasally in many horses but could act in any trigeminal sensory region.<sup>1</sup>

## DIAGNOSIS AND TREATMENT

One should perform a complete physical examination, including neurologic, dental, ophthalmic, and otoscopic examinations to rule out potential underlying causes. Other diagnostics could include endoscopy of the nasal passages, pharynx, and guttural pouches; radiography of the skull and cervical spine; CBC; and serum biochemistry profile. These examinations reveal no abnormalities in most cases. A recent survey suggests that one should consider idiopathic head shaking if two of the following three clinical signs are present: (1) vertical flipping of the head, (2) acting as if an insect has flown up the nostril, or (3) rubbing the muzzle on objects.<sup>2</sup> For photic head-shaking horses, clinical signs should improve after blindfolding or after placement of a mask shielding the eyes from the sun.

Cyproheptadine, an antihistamine (histamine<sub>1</sub>) and serotonin antagonist with anticholinergic effects, has been used (0.3 mg/kg orally b.i.d.) to treat head-shaking horses, resulting in improvement in 5 of 7 horses in one study<sup>8</sup> and 43 of 61 horses in another.<sup>2</sup> Horses that respond do so within 1 week, and some may respond within 24 hours. Although the mechanism for efficacy of cyproheptadine in these cases is unknown, blocking of serotonin-mediated pain sensation could be involved.<sup>8</sup> Other investigators have found cyproheptadine alone to be ineffective, but the addition of carbamazepine (4 to 8 mg/kg PO q6-8h) resulted in 80% to 100% improvement in seven of nine cases, with horses responding within 3 to 4 days.<sup>1</sup> Carbamazepine is a sodium channel-blocking antiepileptic drug and is the drug of choice for treating trigeminal neuralgia in human beings.<sup>18</sup> Carbamazepine alone was reported to be effective in head shaking horses, but results were unpredictable.<sup>1</sup> The elimination half-life of carbamazepine in the horse is less than 2 hours, making sustaining therapeutic concentrations difficult; the drug is therefore of more benefit diagnostically than therapeutically in head-shaking horses (D.C. Knottenbelt, personal communication). Other medications and therapies including NSAIDs, corticosteroids, antihistamines, acupuncture, chiropractic manipulation, homeopathy, and feed supplements are generally ineffective in most horses.<sup>2,19</sup>

Diagnostic blockade of trigeminal nerve branches can be useful for identifying trigger points in head-shaking horses. Blockade of the infraorbital nerve may improve some horses and might identify candidates for infraorbital neurectomy.<sup>15,16</sup> However, results of infraorbital blockade and infraorbital neurectomy do not correlate, and because of neuroma formation, self-trauma, and low success rate, infraorbital neurectomy is not a recommended procedure.<sup>15</sup> A high percentage of horses improve after blockade of the posterior ethmoidal nerve, and sclerosis of this nerve results in temporary improvement in some horses.<sup>1</sup>

Therapies aimed at decreasing the response to trigger factors can be effective and include tinted contact lenses; face masks or hoods that block sunlight, wind, insects, and dust, with mesh or dark eye cups; and nose nets.<sup>1,2,8,19,20</sup> A recent owner survey found that nose nets that cover the nostrils with mesh and include a drawstring or elastic band that applies pressure to the upper lip resulted in some improvement in 70% of head-shaking horses, and that 70% or more improvement occurred in about 30% of the horses.<sup>20</sup> Finally, permanent tracheostomy is effective in some horses,<sup>1,4</sup> presumably because airflow then bypasses the nasal cavity where the majority of trigger factors are thought to act.<sup>1</sup>

## VERMINOUS ENCEPHALOMYELITIS

Eduard Jose-Cunilleras

Aberrant migration of helminth and fly larvae through the CNS of horses and donkeys is a rare but important cause of severe neurologic disease. Parasites that have been reported to affect the brain and spinal cord of equids include rhabditid nematodes (*Halicephalobus* [*Micronema*] *deletrix* [syn. *H. gingivalis*]), strongyloid nematodes (*Strongylus vulgaris*, *S. equinus*, and *Angiostrongylus cantonensis*), protostrongyloid nematodes (*Parelaphostrongylus tenuis*), spiruroid nematodes (*Draschia*

*megastoma*), filarid nematodes (*Setaria digitata* and other *Setaria* spp.), and warble fly larvae (*Hypoderma* spp.).

Antemortem diagnosis is often impossible; however, a high index of suspicion may be warranted for certain clinical signs (acute onset or rapidly progressive asymmetric, focal, or multifocal brain or spinal cord signs) and changes in CSF analysis, in which case the treatment regimen should include specific antiparasitic drugs (e.g., fenbendazole) in addition to the more routinely used symptomatic and anti-inflammatory treatments (e.g., NSAIDs, DMSO, corticosteroids, antiprotozoal drugs).

## ☞ CAUSES

### HALICEPHALOBUS (MICRONEMA) DELETRIX (HALICEPHALOBUS GINGIVALIS)

*Halicephalobus deletrix* is synonymous with *H. gingivalis*, the latter being the most recent terminology.<sup>1</sup> The parasite was referred to as *Micronema deletrix* until 1970s and 1980s with use of the new nomenclature beginning in 1990.

The life cycle of *Halicephalobus* spp. nematodes is unknown. This small roundworm generally is considered a saprophytic organism that occasionally acts as a facultative parasite in horses and human beings. The likely route of entry is through nasal and oral mucosa, followed by possible hematogenous spread to organs with high vascularization such as the brain, spinal cord, and kidneys. *H. deletrix* recently has been shown to be transmitted from a mare to her foal because of mammary infestation.<sup>2</sup>

Organs affected by migration of *Halicephalobus* spp. include the brain, spinal cord, nasal and oral cavities, pituitary gland, and kidneys and less commonly the lymph nodes, heart, lungs, stomach, liver, and bones.<sup>3,4</sup> Organisms affecting the CNS have been reported to have a predilection for the basilar, pituitary region of the brainstem.<sup>5</sup> Characteristic histopathologic lesions in the CNS include malacia, granulomatous and lymphohistiocytic inflammatory infiltration, meningitis, and vasculitis in addition to identification of the nematodes. Other clinical signs include oral and nasal granulomata, renal involvement (*H. deletrix* is visible in the urine), granulomatous osteomyelitis,<sup>6</sup> and granulomatous chorioretinitis.<sup>7</sup>

Most of the cases of *Halicephalobus* encephalomyelitis in adult horses reported in the literature during the last 30 years describe simultaneous renal granulomatous lesions encapsulating the nematodes (Table 12-14). Granulomata within or adjacent to the renal parenchyma were observed on postmortem examination in 13 of 16 horses with neurologic disease; of the other three horses, in one case lesions were confined to the sacral spinal cord and cauda equine, and in another case only the skull and brain were examined at postmortem examination. In contrast, all three cases reported to date in foals showed no renal involvement but did show pulmonary granulomata.<sup>2,5</sup>

### STRONGYLUS VULGARIS, STRONGYLUS EQUINUS, AND ANGIOSTRONGYLUS CANTONENSIS

Aberrant strongyle larval migration is a much less common cause of neurologic signs because of routine broad spectrum antiparasitic treatment with ivermectin and moxidectin. The

pathogenic mechanisms described for strongyle encephalomyelitis include aberrantly migrating fourth- and fifth-stage larvae in the intima of the aorta or left ventricle, which causes endothelial damage, stimulates the clotting cascade, and results in formation of a thrombus that often contains the parasitic larva.<sup>21</sup> Lesions are generally asymmetrical because of random migration in the brain, although migration along the spinal cord has been reported in a donkey.<sup>22</sup>

### PARELAPHOSTRONGYLUS TENUIS

The meningeal worm *Parelaphostrongylus tenuis* causes neurologic disease in cervids, ovids, bovids, and camelids. Recently, there have been multiple reports of similar disease in horses ranging in age between 6 months to 9 years.<sup>28-30</sup> Affected horses have a history of sudden onset of scoliosis with no history or evidence of trauma.

### DRASCHIA MEGASTOMA

Adult *Draschia megastoma* worms are found in the stomach of equids where they cause mucosal granulomatous masses and mild chronic gastritis. The life cycle of *Draschia* is indirect because the organism uses flies as the intermediate host. Eggs and larvae are released into the gastric lumen, and the first larval stage passes in the feces and is ingested by fly larvae of the genus *Musca* in which *Draschia* spp. organisms develop to infective larvae. Finally, horses become infected when the third larval stage is deposited on the host by adult flies. Infective larvae that are ingested and reach the stomach develop into adults and complete the life cycle. Larvae deposited in damaged skin result in local inflammation and development of extensive granulation tissue, which is the typical lesion of cutaneous habronemiasis.

Stray *D. megastoma* larvae may be found anywhere throughout the body, and a case has been reported of *D. megastoma* migration in the brainstem of a horse in Southern United States, resulting in asymmetrical brainstem disease.<sup>23</sup>

### SETARIA SPECIES

Infestation with the filarial nematode *Setaria* is common in the abdominal cavity of ungulates where the organism does not cause significant clinical effects. *S. labiatopapillosa* is found in cattle, and *S. equina* is found in horses. Microfilariae gain access to peripheral circulation and then are transmitted to other potential hosts via mosquitoes. In a postmortem examination study of 305 horses in Japan, *S. equina* was recovered from 66 of those horses (≈22%).

The cattle parasite *S. digitata* occurs only in Asia, and infestation in unnatural hosts (horses, sheep, goats, camel, and human beings) has been associated with cerebrospinal nematodiasis. This condition can be enzootic in India, Burma, and Sri Lanka, is called *Kumri* (weak back), and has a seasonal occurrence, usually during the fly season (late summer and fall).<sup>31</sup>

Two cases of aberrant *S. digitata* CNS migration have been reported in Japanese racehorses, and one case of *Setaria* spp. larval migration in the brainstem and cervical spinal cord has been reported in a 12-year-old Quarter Horse mare in the Midwestern United States.<sup>20,32</sup>

TABLE 12-14

**Signalment, Organism Identified, Clinical Signs, and Organs Affected in Cases of Verminous Encephalomyelitis**

## ANGIOSTRONGYLUS CANTONENSIS

Adult parasites are found in the right ventricle and pulmonary artery of rats. The pulmonary circulation carries eggs released by adult worms to the alveoli, where the first larval stage develops and migrates up the trachea, is swallowed, and passes in feces. Snails and slugs are intermediate hosts, and ingestion of the snail results in ingestion of the infective larvae that migrate through CNS, and finally, the larvae reach the heart via the circulation.

Aberrant CNS migration of *Angiostrongylus cantonensis* larvae has been reported in two foals with tetraparesis in Australia,<sup>24</sup> and aberrant migration is a recognized cause of eosinophilic meningoencephalitis in human beings and dogs.<sup>33</sup>

## HYPODERMA SPECIES

Cattle are normal hosts of *Hypoderma* spp., but horses are accidental hosts of warble fly larvae. In cattle, *Hypoderma* larvae penetrate the skin after hatching from eggs attached to hair in the rump and lower legs. These larvae migrate through connective tissues to reach the esophagus, in the case of *H. lineatum*, or to the vertebral canal around epidural fat, in the case of *H. bovis*. Finally, the larvae migrate back to the skin over the back where they create a breathing hole. Cutaneous myiasis is uncommon in horses, and warble fly larvae occasionally may migrate aberrantly into the brain. Tissue damage causing necrosis and hemorrhage is extensive because of the big size of the instars.<sup>25</sup> Instars can enter through large natural foramina such as the foramen magnum, optic foramen, and occasionally intervertebral foramina.

## CLINICAL SIGNS

Severity and duration of clinical signs vary from mild, transient, and insidious to severe and fatal. In some cases, clinical signs progress over 2 to 4 months, with periods of improvement or stabilization.<sup>4,8,23</sup> Variability of clinical signs depends on the number of parasites (thromboembolic shower of *Strongylus vulgaris*), on the size of the migrating organism (*Hypoderma* spp. larvae are large and cause severe necrosis and hemorrhage as they migrate in the CNS parenchyma), and neuroanatomic localization of the lesions. Horses suffering from larval migrations in the brain (*S. vulgaris*, *Halicephalobus deletrix*, *Draschia megastoma*, and *Hypoderma* spp.) may display head tilt, circling, recumbency, blindness, hyperesthesia, stiff neck, ataxia, head pressing, recumbency, seizures, and coma. In those cases in which larvae cause lesions in the spinal cord (*S. vulgaris*, *H. deletrix*, *Setaria* spp., *Angiostrongylus cantonensis*), clinical signs may include focal or multifocal asymmetrical ataxia, weakness, dog-sitting posture caused by paraparesis, increased patellar reflexes, atonic bladder, poor tail tone, and poor rectal tone with impaction of feces (see Table 12-13). Recently, a case of cauda equine neuritis has been reported that was caused by *H. gingivalis* migration in the sacral spinal cord and cauda equina nerves.<sup>15</sup>

Clinical signs of *Parelaphostrongylus tenuis* infection are quite characteristic and include acute onset of scoliosis (observed in 90% of reported cases), with progressive gait deficits. Scoliosis is most common in the cervical area.<sup>28-30</sup> The affected area of the vertebral column is usually C shaped, with flaccid muscles and decreased cutaneous sensation on the

convex side of the curve. Tetraparesis and ataxia is mild to moderate and predominantly ipsilateral to the convex side of the curve. If bilateral gait deficits are observed, then they are worse on the convex side. The proposed pathogenesis for clinical signs involves unilateral weakness of the paraspinal epaxial muscles on the convex side of the curve.<sup>30</sup> A linear lesion that extends for several segments, most likely in the dorsal gray column, is most likely to cause the observed signs.

## DIFFERENTIAL DIAGNOSIS

One should consider verminous encephalomyelitis in all cases of acute or progressive asymmetrical disease of the spinal cord, cerebrum, cerebellum, or brainstem. If brain involvement is evident without other localizing signs, then the differential diagnosis list may include equine togaviral encephalomyelitis, rabies, equine protozoal myelitis (EPM), trauma, cerebral abscess or basilar epidural empyema, bacterial meningitis, hepatic encephalopathy, neoplasia, and leukoencephalomalacia. If the neurologic signs are limited to spinal cord involvement, then other diseases to include in the differential diagnosis list may be cervical stenotic myelopathy, EPM, EHV-1 myeloencephalopathy, trauma, WNV meningoencephalitis, EDM, trauma, spinal osteomyelitis or discospondylitis, vertebral fracture, and neoplasia. If the only signs present are related to cauda equina syndrome, then other conditions to consider are polyneuritis equi, sacral or coccygeal fracture, EPM, EHV-1 myeloencephalopathy, sorghum or Sudan grass toxicity, epidural abscess from tail blocking, and neoplasia.

Initial diagnostics should include CBC, serum chemistry profile, urinalysis, and CSF collection for cytologic evaluation. In addition, serologic examination and viral isolation and CSF Western blot for EPM may help eliminate several more common viral and protozoal myeloencephalitis. Radiographs of the cervical or lumbosacral spine and myelography may be required to rule out more common causes of spinal cord disease (cervical stenotic myelopathy, trauma, fractures). Although only routinely available at referral hospitals, advanced imaging techniques (e.g., computerized axial tomography, MRI) may be useful in diagnosing parasitic encephalomyelitis or other conditions with similar clinical signs.

CSF analysis in cases of parasitic encephalomyelitis can be normal; however, CSF changes are common and include xanthochromia, increased protein, and neutrophilic and mononuclear pleocytosis, but eosinophils rarely occur (Table 12-15). Only in a case of *Angiostrongylus cantonensis* were eosinophils the predominant cell type on CSF cytologic examination. In addition, *Halicephalobus deletrix* eggs are visible on microscopic examination of a CSF sample subjected to cytocentrifugation.<sup>5</sup> Similarly, *H. deletrix* larvae may be visible on microscopic examination of urine sediment or semen in cases of renal and testicular involvement.<sup>4</sup> Analysis of CSF obtained from horses with *Parelaphostrongylus tenuis* neurologic disease has been within normal limits.<sup>30</sup>

Antemortem diagnosis may be possible in those cases in which renal or bony involvement is detected and nematodes are identified in biopsies of the affected tissues.<sup>6</sup> As described previously, renal involvement with granulomatous lesions encapsulating *Halicephalobus deletrix* worms is observed in most cases of *H. deletrix* encephalomyelitis. Therefore transabdominal renal ultrasound examination and ultrasound-guided biopsy (in those cases with renal lesions present), as well as microscopic examination of urine sediment, may prove useful

CSF, cerebrospinal fluid; PMN, polymorphonuclear neutrophil leukocytes; N, neutrophils; L, small lymphocytes; M, large mononuclear cells; E, eosinophils; B, basophils.

in cases of acute onset progressive asymmetrical neurologic disease, especially if one suspects cerebrospinal nematodiasis caused by *H. deletrix*.

Additionally, a PCR-based diagnostic test has been developed for confirmation of *Setaria* encephalomyelitis in goats, sheep, and horses.<sup>34</sup> This test is based on specific amplification of *Setaria* spp. filarial DNA from a blood sample from the host.

## ☞ PATHOLOGIC FINDINGS

The gross and histopathologic lesions depend on the parasite involved. Thorough postmortem examination with sectioning and histopathologic examination of all areas of the CNS relevant to the antemortem clinical signs are important to identify migrating parasites. *Strongylus vulgaris* and *Hypoderma* spp. larvae are easy to see, but other nematodes are only visible on microscopic examination. Some reports describe how one may recover and examine whole, fixed nematodes for distinctive morphologic features by centrifugation of formalin solution in which the brain had been fixed.<sup>9,18</sup> Gross examination of other tissues for evidence of *S. vulgaris* thrombi or presence of *Halicephalobus deletrix* granulomatous lesions may help establish a postmortem diagnosis.

On histopathologic examination, one generally sees extensive tissue necrosis with mixed inflammatory response. *H. deletrix* migration in the CNS typically results in histiolympocytic

infiltrates, malacia, glial proliferation, and perivascular lymphocytic cuffing. Migrations of warble fly and *S. vulgaris* larvae result in severe hemorrhage, large malacic tracts, and edema caused by their relative larger size.

## ☞ TREATMENT

Treatment of verminous encephalomyelitis in horses is often unrewarding. None of the cases reported in the literature have responded favorably to anti-inflammatory drugs and antihelmintics. Only in one case of *Halicephalobus deletrix* granuloma limited to the prepuce, therapy with ivermectin and diethylcarbazine was successful.<sup>35</sup> However, numerous cases of cerebrospinal nematodiasis likely respond favorably to anti-inflammatory drugs and antihelmintics, but one never reaches a definitive diagnosis because diagnosis requires a postmortem examination.

Therapeutic recommendations depend on the severity, progression, and localization of neurologic signs, as well as on consideration of possible contraindications (e.g., if one suspects bacterial or viral cause, then one should avoid using corticosteroids). In cases of acute neurologic disease use of the following anti-inflammatory drugs may be warranted: NSAIDs such as phenylbutazone (2.2 mg/kg b.i.d.), flunixin meglumine (1 mg/kg b.i.d.), or ketoprofen (2 mg/kg b.i.d.); intravenously administered DMSO (1 g/kg as a 10% solution once daily for 3 to 5 days); and corticosteroids

(dexamethasone at 0.1 to 0.25 mg/kg once daily or prednisolone at 0.2 to 4.4 mg/kg once daily). If cerebral signs are observed, then one may administer mannitol (0.25 to 2 g/kg as a 20% solution once daily), or hypertonic saline may be warranted in an attempt to minimize cerebral edema. In countries in which EPM is known to occur, antiprotozoal treatment is recommended.

Specific antiparasitics suggested for treating verminous encephalomyelitis include benzimidazole compounds (oxfendazole, thiabendazole, fenbendazole, and mebendazole), diethylcarbamazine and ivermectin for the treatment of nematodes, and organophosphates (trichlorfon and dichlorvos) for the treatment of warble fly larvae. Although ivermectin is effective against most equine parasites, it may not be the best choice because of its delayed method of killing, which may take as long as 10 to 14 days. Some authors have suggested administration of fenbendazole at 50 mg/kg by mouth once daily for 3 days<sup>36,37</sup>; however, specific data on the efficacy of antihelmintics in treating nematode or warble fly larvae migration through the CNS are not available.

## MISCELLANEOUS NEUROLOGIC DISORDERS

*Debra C. Sellon*

In addition to the numerous neurologic problems discussed in detail earlier in this chapter, horses can develop a wide variety of acute or chronic neurologic disorders with clinical signs related to brain, spinal cord, or peripheral nerve dysfunction. Clinical signs can occur because of primary disease or dysfunction of the CNS or secondary to a variety of metabolic disorders or disorders of other body systems. This section will mention the most important of the miscellaneous CNS disorders and refer the reader to relevant chapters for more detailed information.

## NEUROLOGIC NEOPLASIA

Many types of neoplastic lesions have been identified in the brain and spinal cord of horses. A comprehensive review of the clinical and pathologic aspects of equine CNS neoplasia, however, is lacking in the peer-reviewed veterinary literature. Available case reports and summaries of pathologic studies suggest that CNS neoplasia is quite uncommon in horses. In one Australian survey of 450 horses with neurologic disease, the prevalence of neurologic disease secondary to neoplasia was less than 2%.<sup>1</sup> This percentage is likely to be much lower in horses in the United States because of the much higher incidence of encephalitic disorders and EPM.

Tumors of the nervous system can be classified on the basis of their cellular origin as tumors of nerve cells, neuroepithelium, glia, peripheral nerves and nerve sheaths, mesodermal structures, and endocrine organs. Neoplasms of nerve cell origin appear to be extremely uncommon in horses with only a few reports of ganglioneuromas, complex tumors arising in peripheral ganglia and composed of well-differentiated neurons, nerve processes, Schwann cells, and glial cells.<sup>2,3</sup> These tumors may cause intestinal obstruction and signs of colic in affected horses.

Tumors of neuroepithelial origin in horses include ependymoma, choroid plexus papilloma, neuroepithelial tumor of the optic nerve, malignant medulloepithelioma, ocular medulloepithelioma, and pineoblastoma.<sup>4-19</sup> Glial cell tumors include optic disc astrocytoma, retinoblastoma, and microglioma.<sup>13,19,20</sup> Neoplasms of peripheral nerves and nerve sheaths appear to be more common than CNS neoplasia and include neurofibromas and neurofibrosarcomas.<sup>21-26</sup> The most common sites for neurofibromas are in the cutaneous tissues of the pectoral region, abdomen, neck, and face but gastrointestinal tract lesions have also been described.<sup>21</sup> There are also reports of intracranial and mediastinal schwannomas in horses.<sup>27,28</sup>

The most common mesodermal neoplasm in horses appears to be meningioma.<sup>5,18,29</sup> Neoplastic reticulosis, lipoma in the mesencephalic aqueduct, angioma in the cervical spinal cord, primary meningeal lymphoma, and melanoblastoma of the cerebellar meninges have also been described.<sup>30-32</sup>

Older texts often refer to pituitary pars intermedia dysfunction (PPID) of older horses as a neoplastic lesion. This disorder is most likely a manifestation of oxidative damage to dopamine-producing neurons in the central nervous system with subsequent dysregulation of hormone production within the pars intermedia of the pituitary gland. PPID is discussed in detail in the Endocrinology chapter of this text.

Cholesterol granulomas (cholesteatomas, cholesterinic granulomas) are likewise not neoplastic lesions, though they may have been described as such in the past.<sup>33-41</sup> These lesions are found in the choroid plexus of up to 20% of older horses.<sup>42</sup> Although more common in the choroid plexus of the fourth ventricle, lesions in the lateral ventricles may be more likely to result in clinical signs. Lesions may represent a chronic granulomatous reaction to deposition of cholesterol crystals associated with chronic choroid plexus leakage. Grossly the granulomas are circumscribed, firm, granular, and yellow-brown with a glistening cut surface. They are most often recognized as incidental findings at necropsy of horses without noticeable clinical signs. If they are large enough, however, they might cause CNS signs as a result of direct pressure on cerebral tissues or obstructive hydrocephalus. In affected horses, reported clinical signs have included altered behavior, depression, somnolence, seizures, ataxia, weakness, and coma. CSF from affected horses may have an elevated protein and appear xanthochromic.<sup>33-35</sup>

Secondary neoplastic conditions affecting the CNS may penetrate the cranial vault or vertebrae, extend through osseous foramina, or metastasize via the vascular system. Clinical signs vary depending on the type, site, and extent of the lesion. Lymphosarcoma is probably the most common secondary neoplasm of the CNS in horses.<sup>32,43-48</sup> Lesions may cause forebrain signs if present in the cranial vault or ataxia and paresis if causing compression of the spinal cord.

Melanoma of the spinal cord, meninges, and brain may occur with metastasis of primary cutaneous lesions.<sup>49-51</sup> Alternatively, clinical signs may represent spread from affected sublumbar lymph nodes.<sup>32,52</sup> Melanoma of the CNS is most common in gray horses.

Hemangiosarcoma and undifferentiated sarcoma have been reported to affect the CNS of horses<sup>32,53-55</sup> There are numerous descriptions of adenocarcinomas and carcinomas (including squamous cell carcinoma) affecting the CNS of horses by direct spread from a primary site in the head or by metastasis from a distant site.<sup>32,56-62</sup> Tumors of the bone or bone marrow may involve the skull or vertebrae resulting in compression of the brain or spinal cord, respectively.<sup>32,63-65</sup>

Malformation tumors, including epidermoids, dermoids, teratomas, and teratoids, may also affect the CNS.<sup>32</sup> They are often incidental findings at necropsy but may occasionally be clinically significant.

Supportive evidence for the presence of CNS neoplasia can be obtained with advanced imaging (i.e., computed tomography, magnetic resonance imaging) of the brain or spinal cord in select equine patients. Definitive diagnosis of primary CNS neoplasia in horses requires cytologic or histopathologic identification of neoplastic cells or tissues. This diagnosis necessitates biopsy, cytologic evaluation of an aspirate from a suspect lesion, or identification of neoplastic cells in cerebrospinal fluid (CSF). Analysis of CSF is rarely diagnostic of neoplasia in horses because of the rarity of the presence of neoplastic cells in the fluid. Given the practical difficulties inherent in obtaining biopsy samples from the brain or spinal cord, definitive diagnosis of primary CNS neoplasia in horses rarely occurs antemortem. Definitive diagnosis is more likely in horses with secondary CNS neoplasia in which a diagnosis is made by biopsy or cytologic evaluation of primary lesions identified external to the CNS.

## ☞ TOXIC DISORDERS

A wide variety of toxic substances can affect the CNS of horses. Most of these are discussed in detail in the Toxicology chapter of this text. Three toxic neurologic conditions merit mention in this chapter because of their common occurrence in some geographic areas and their distinctive clinical appearance as demonstrated in the referenced video segments on the DVD accompanying this text.

### LEUKOENCEPHALOMALACIA

Equine leukoencephalomalacia is a seasonal disorder of horses, ponies, donkeys, and mules, occurring most commonly in late fall through early spring. Most outbreaks are associated with a dry growing period followed by a wet period. The disorder is caused by ingestion of the mycotoxin fumonisin B1, a metabolite of *Fusarium moniliforme*.<sup>66-88</sup> Two clinical syndromes are associated with fumonisin B1 intoxication. The more common is a neurologic syndrome characterized initially by incoordination, aimless walking, intermittent anorexia, lethargy, depression, blindness, and head pressing. These signs may be followed by hyperexcitability, belligerence, extreme agitation, profuse sweating, and delirium. Recumbency and clonic-tetanic seizures may occur before death. Less commonly, horses develop a hepatotoxic syndrome with swelling of the lips and nose, somnolence, severe icterus and petechiation of mucous membranes, abdominal breathing, and cyanosis. Gross lesions include liquefactive necrosis and degeneration of the cerebral hemispheres; changes may also occur in the brainstem, cerebellum, and spinal cord.

### NIGROPALLIDAL ENCEPHALOMALACIA

Yellow star thistle and Russian knapweed grow over much of the western United States in nonirrigated pastures during dry seasons of summer and fall. Ingestion of these plants result in unilateral or more commonly bilateral softening and necrosis in areas of the globus pallidus and substantia nigra.<sup>89-98</sup> Lesions are often sharply defined and may be cavitory. Although the plants are generally considered unpalatable by most horses, some horses may develop a craving for the plants and selectively

seek them out. The exact toxic principle in these plants has not been determined. Affected horses demonstrate variable degrees of impairment of eating and drinking with lack of coordination of movements of prehension, mastication, and deglutition. Most horses appear to be able to swallow if food or water is placed in the posterior pharynx. Severely affected horses might attempt to drink by immersing their muzzle deeply into the water in an apparent attempt to force water into the posterior pharynx. Hypertonicity of facial muscles is common with the horse often holding the mouth partially open with the lips retracted. The tongue may protrude from the mouth and many horses display constant chewing movements.

## FLUPHENAZINE TOXICITY

Fluphenazine administration to horses may result in characteristic clinical signs of toxicity.<sup>99-103</sup> Fluphenazine is a highly potent phenothiazine neuroleptic that is widely used in human medicine for a variety of psychological disturbances. In horses, fluphenazine decanoate has been used to provide a persistent sedative effect. It binds avidly to dopamine D<sub>2</sub> receptors in the brain. The very slow dissociation of fluphenazine from these receptors is associated with a greater risk of adverse extrapyramidal signs than is observed with newer atypical antipsychotic medications.<sup>99</sup> Its administration to some horses can result in severe extrapyramidal effects and Parkinsonism with clinical signs including agitation, profuse sweating, hypermetria, aimless circling, intense pawing and striking with the thoracic limbs, and rhythmic swinging of the head and neck alternating with periods of severe stupor. There are no published reports of the pharmacokinetics of fluphenazine in horses. A long-acting depot formulation for IM administration is available and appears to be most commonly used. One published report suggests a dosage of 0.05 to 0.08 mg/kg IM every 2 weeks with a warning to beware of idiosyncratic reactions.<sup>104</sup> Horses have exhibited signs of extrapyramidal effects of fluphenazine decanoate after receiving doses as low as 40 mg IM.<sup>99</sup> Given that recommended doses for adult humans range between 25 to 50 mg, it is reasonable to assume that at least some horses are much more susceptible than humans to the adverse effects of fluphenazine decanoate. The severity of clinical signs observed in some affected horses is sufficient to pose considerable safety risks for veterinarians and handlers treating these horses. This author is aware of at least one horse that was euthanized because of the extreme danger of clinical signs after administration of fluphenazine; other authors have indicated similar adverse outcomes.<sup>99</sup> Treatment consists of discontinuation of drug administration and enhancing cholinergic function by administering anticholinergic medications. Diphenhydramine chloride results in significant improvement in some, but not all, affected horses.<sup>99,101</sup> Benztropine mesylate (0.018 mg/kg IV every 8 hours) has also been helpful for treatment of some affected horses.<sup>99</sup> Other horses apparently benefited from sodium pentobarbital (2 mg/kg IV followed by a constant rate infusion at 2.5 mg/kg/h) in an attempt to control maniacal behavior without inducing recumbency or anesthesia.<sup>99</sup>

## ☞ METABOLIC DISORDERS

A wide variety of metabolic disorders can cause clinical signs indicative of central nervous system dysfunction. These signs include hepatic dysfunction, hypoglycemia, hypoxemia and ischemia, and severe abnormalities in plasma electrolyte concentrations.

## HEPATOENCEPHALOPATHY

An excellent review of the etiology, pathogenesis, clinical signs, diagnosis, and treatment of liver disease is included elsewhere in this text. A normally functioning liver is necessary to maintain normal brain neuron and astrocyte function. With acute liver disease hepatoencephalopathy is most often a result of astrocyte swelling, acute cytotoxic cerebral edema and intracranial hypertension. In chronic hepatic disease astrocytes are swollen but also show evidence of Alzheimer type II changes. Horses with hepatoencephalopathy show signs of cerebral cortex dysfunction. The earliest recognizable clinical signs in horses are often depression, lethargy, mild ataxia, and various forms of inappropriate behavior. These signs can progress to head pressing, circling, somnolence, and diminished responsiveness to external stimuli. Eventually affected horses become recumbent and comatose. Seizures may occasionally be observed but they are not common. The type and severity of clinical signs do not correlate with type or reversibility of the underlying hepatic disease.

## HYPOGLYCEMIA, HYPOXEMIA, AND ISCHEMIA

Severe hypoglycemia is not common in adult horses but is common in neonates, often as a complication of sepsis, prematurity, hypoxic ischemic encephalopathy, or hypothermia. When hypoglycemia does occur it may result in weakness, depression, ataxia, and eventually loss of consciousness. Seizure activity is not common in adult horses but may occasionally be observed in affected foals. Iatrogenic hypoglycemia can occur in horses treated with insulin or with abrupt cessation of intravenous glucose therapy. Clinical signs are rapidly reversed with intravenous administration of glucose-containing solutions. Guidelines for intravenous glucose therapy are included in the chapter on foal diseases elsewhere in this text (Chapter 21).

Because of the brain's high and continuous demand for oxygen, the CNS is extremely susceptible to hypoxic or ischemic damage. This is most apparent in the neonate with hypoxic ischemic encephalopathy, discussed in detail in the chapter on foal diseases. As nervous tissue switches to anaerobic glycolysis to meet its energy needs brain glucose is depleted and localized lactic acidosis occurs. Neurons swell and cytotoxic edema exacerbates ischemia. The end result is irreversible cell damage and neuronal death. Clinical signs depend on what areas of the brain are affected. Localized hypoxia may occur with thromboembolic disorders or intracarotid injections. Deprivation of oxygen to the entire CNS results in more dramatic clinical signs of impaired cerebral function ultimately leading to seizures, coma, and death. This type of generalized severe tissue hypoxia may result from decreased inspired oxygen, ventilation/perfusion abnormalities, right to left shunting of blood, impairment of gas diffusion within the lungs, hypoventilation, severe anemia, impaired oxygen utilization by tissues, or profound hypotension secondary to sepsis, hemorrhage, anaphylaxis, or cardiac failure. These disorders are discussed in detail in the appropriate chapters elsewhere in this text.

## ELECTROLYTE ABNORMALITIES

Severe hyponatremia or hypernatremia can result in CNS dysfunction. Hyponatremia most often results from water intoxication because of excessive IV or oral administration

or consumption of hypotonic solutions. A common clinical scenario resulting in hyponatremia is oral consumption of large quantities of water by a patient with a disorder that results in significant concurrent electrolyte loss (e.g., diarrhea, excessive sweating, polyuric renal failure). Clinical signs are most common in horses with a serum sodium concentration of <110 mEq/L. Profound hypernatremia may result in clinical signs of spasticity, myoclonus, and depression. Therapy of foals affected with profound hyponatremia or hypernatremia is discussed in the chapter on foal disorders.
