The principal routes for magnesium excretion are (1) the gastrointestinal tract, (2) the kidneys, and (3) the mammary gland during lactation. In addition, magnesium can be lost in sweat and the developing fetus.

The kidneys play a major role in regulating magnesium balance and serum magnesium concentrations by controlling tubular reabsorption, mainly in the thick ascending limb of the loop of Henle (TAL).<sup>1,12,23-25</sup> Renal excretion of magnesium is tightly matched to gastrointestinal magnesium absorption; magnesium absorbed in excess is excreted by the kidneys. The tubular reabsorption rate is regulated by dietary availability of magnesium, serum Ca<sup>2+</sup> and Mg<sup>2+</sup> concentrations, certain hormones, and urinary Ca<sup>2+</sup> excretion.<sup>1,12,23,24</sup>

Ionized and anion-bound magnesium (ultrafilterable magnesium) is filtered by the glomerulus, whereas protein bound magnesium is not. Approximately 70% of the blood Mg<sup>2+</sup> is filtered by the glomeruli, with 70% to 90% being reabsorbed in different segments of the nephron.<sup>12,24</sup> Around 10% to 20% of the filtered magnesium is reabsorbed in the PCT, 50% to 70% is reabsorbed in the TAL, and the remaining 5% to 10% is reabsorbed in the DCT.<sup>1</sup> The DCT seems to be the site determining the final urinary excretion of Mg<sup>2+</sup>.<sup>12,15</sup> Renal reabsorption of magnesium is paracellular and transcellular. Paracellular (passive, concentration dependent) reabsorption occurs in the PCT, whereas transcellular (active) reabsorption occurs in the DCT. Magnesium reabsorption in the TAL occurs by a voltage-dependent paracellular mechanism.<sup>12</sup>

The mammary gland actively secretes magnesium into milk. The output of magnesium into milk is 3 to 6 mg/kg/body weight/day and the magnesium requirements in lactating mares are 15 to 30 mg/kg.<sup>4</sup> In mare's milk, magnesium concentration is elevated during the first week of lactation (120-300 mg/L), then decreases and remains steady for 2 to 3 months (50 to 70 mg/L).<sup>26,27</sup> High-milk-producing mares are more likely to develop hypomagnesemia. Magnesium can also be lost in the sweat.<sup>28</sup>

## MAGNESIUM HOMEOSTASIS

No precise homeostatic system exists for Mg<sup>2+</sup>, and its extracellular concentrations depend on gastrointestinal absorption, renal excretion, and bone exchange.<sup>1,2</sup> However, hormonal and nonhormonal factors influence magnesium absorption,

excretion, and extracellular concentrations.<sup>1,2</sup> Hormones that increase renal reabsorption of Mg<sup>2+</sup> include PTH, PTHrP, ADH (vasopressin), insulin,  $\beta$ -adrenergic agonists, and aldosterone.<sup>1,23,29-33</sup> Activation of the calcium-sensing receptor in the TAL by hypercalcemia in various species, including the horse, increases the urinary excretion of Ca<sup>2+</sup> and Mg<sup>2+</sup>.<sup>12,34</sup> Impaired Mg<sup>2+</sup> reabsorption occurs with osmotic diuresis (volume expansion, hyperglycemia), loop diuretics, hypercalcemia, hypercalcemia, hypermagnesemia, hypokalemia, hypophosphatemia, tubular acidosis, metabolic acidosis, and various toxicities (aminoglycosides, amphotericin B).<sup>23,34-36</sup> Furosemide and hypercalcemia in healthy horses decrease serum tMg and Mg<sup>2+</sup> concentrations.<sup>12,35</sup> Of interest, both hypercalcemia and loop diuretics act by the same mechanism (inhibition of the Na<sup>+</sup>/K<sup>+</sup>/2Cl<sup>-</sup> co-transporter) in the TAL.<sup>12,34</sup> PTH indirectly increases Mg<sup>2+</sup> release from bone during bone resorption.

## ☪ MAGNESIUM AND EQUINE DISEASE

Although extensive data exists on the role of magnesium in inflammation and disease, information is limited in the horse. Magnesium plays essential roles in inflammation, protection against free radical injury, and neurotoxicity.<sup>37,38</sup> Hypomagnesemia has been associated with increased cytokine production and systemic inflammation.<sup>37,38</sup> A similar process is likely to occur in critically ill horses and foals where the same cytokines are elevated.<sup>9,14,39,40</sup> Horses and foals with gastrointestinal disease often have endotoxemia and hypomagnesemia,<sup>9,14,40-42</sup> and the induction of experimental endotoxemia in healthy horses decreases tMg and Mg<sup>2+</sup>—supporting a role for magnesium in equine disease.<sup>9</sup>

One study in horses that had colic surgery found that serum tMg and Mg<sup>2+</sup> concentrations were below the reference range in 17% and 54% of animals, respectively.<sup>43</sup> The same study found that nonsurvivor horses had significantly lower preoperative serum Mg<sup>2+</sup> concentrations. Toribio et al.<sup>14</sup> found that 78% (50 of 64) of horses with severe gastrointestinal disease had ionized hypomagnesemia. In another study of hospitalized horses, 48.7% (401 of 823) of animals were hypomagnesemic; however, no association with mortality or length of hospitalization was found.<sup>44</sup> Although a clear association between hypomagnesemia, severity of disease, and mortality has been demonstrated in other species; minimal information exists in the horse.<sup>9,14,43,44</sup> Hurcombe et al.<sup>42</sup> did not find an association between serum Mg<sup>2+</sup> concentrations and mortality in critically ill septic foals, although 15% of foals were hypomagnesemic.

Contrary to other species,<sup>45</sup> an association between IR and magnesium deficiency has not been shown in the horse. Mg<sup>2+</sup> is important for insulin receptor signal transduction and glucose metabolism, and insulin increases intracellular Mg<sup>2+</sup> transport.<sup>45</sup> Thus IR may lead to renal Mg<sup>2+</sup> wasting from increased tubular flow (hyperglycemia) and decreased Mg<sup>2+</sup> reabsorption.<sup>45</sup> Subsequently, magnesium depletion worsens IR to create a vicious cycle.

## MAGNESIUM AND HYPOCALCEMIA

An association between hypomagnesemia and hypocalcemia has been demonstrated in lactating mares, transported horses, and in horses with intestinal strangulation, ileus, enterocolitis, endotoxemia, SDF, and blister beetle poisoning.<sup>9,14,43,46,47</sup> Patients with hypocalcemia and hypomagnesemia often do

not respond to calcium therapy until normomagnesemia is restored.<sup>48</sup> The mechanisms by which hypomagnesemia results in hypocalcemia are unclear; however, hypomagnesemia can impair PTH synthesis and secretion and induce target organ resistance to PTH.<sup>49</sup> This results in decreased renal reabsorption of  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  (waste), decreased bone resorption, and decreased renal synthesis of 1,25-dihydroxyvitamin  $\text{D}_3$ . Therefore hypocalcemia associated with magnesium deficiency may be attributed to a lack of PTH secretion (parathyroid gland dysfunction) associated with target organ refractoriness.

## MAGNESIUM AND OTHER ELECTROLYTES

Magnesium is a co-factor for the  $\text{Na}^+/\text{K}^+$ -ATPase that maintains the cell membrane potential. Hypomagnesemia leads to loss of intracellular  $\text{K}^+$ , intracellular  $\text{Na}^+$  accumulation, lowering of the resting membrane potential, which causes hyperexcitability, seizures, arrhythmias, muscle weakness, muscle fasciculations, SDF, and cardiac arrhythmias. The link between hypomagnesemia and equine electrolytes remains unclear; however, the author and colleagues have found that hypomagnesemia in sick horses is often associated with hypokalemia, in particular in foals and ponies receiving parenteral nutrition (personal communication, Toribio RE, 2008). Of interest, hypophosphatemia is a frequent finding in these animals.

## MAGNESIUM AND BRAIN INJURY

$\text{Mg}^{2+}$  is an essential regulator of neuroexcitability by blocking signal transmission via inhibition of  $\text{Ca}^{2+}$ -dependent, presynaptic excitation-secretion coupling.<sup>16,50</sup> Magnesium depletion contributes to tetany by increasing the release of acetylcholine at the neuromuscular junctions and delaying its degradation by acetylcholinesterase.<sup>16,50</sup> Although  $\text{Mg}^{2+}$  infusions are currently used in human beings with brain and spinal injury, the benefit of this treatment remains unclear.<sup>51</sup> The rationale for this treatment is that  $\text{Mg}^{2+}$  decreases free radical injury, modulates N-methyl-D-aspartate (NMDA) receptors, and antagonizes the cytotoxic effects of intracellular calcium. NMDA receptors' activation by glutamate allows intracellular  $\text{Ca}^{2+}$  influx that results in neuronal excitability and death; this process is blocked by cations such as  $\text{Zn}^{2+}$  and  $\text{Mg}^{2+}$ .<sup>52,53</sup> In addition, by blocking  $\text{Ca}^{2+}$  channels in vascular smooth muscle,  $\text{Mg}^{2+}$  prevents  $\text{Ca}^{2+}$  entry, resulting in vasodilation.<sup>54</sup> Under the same premise,  $\text{Mg}^{2+}$  has also been used to treat foals with hypoxic ischemic encephalopathy and horses with brain injury<sup>55,56</sup>; however, controlled studies on the benefits of  $\text{Mg}^{2+}$  therapy to equine adults or neonates are lacking. The clinical scenario appears to be different under experimental conditions of brain injury, where several studies have shown that  $\text{MgSO}_4$  improves outcome.<sup>57,58</sup>

## CLINICAL SIGNS OF MAGNESIUM DEFICIENCY

Hypomagnesemia results from reduced magnesium intake (poor nutrition, low-magnesium diets), reduced absorption (chronic diarrhea, malabsorption, intestinal resection), redistribution (third-space and intracellular sequestration), and increased losses (renal tubular disorders, gentamicin, furosemide, hypercalcemia, gestation, lactation, and heavy exercise).

Magnesium depletion is associated with muscle weakness, tremors, seizures, hypokalemia, hypocalcemia, cardiac arrhythmias (ventricular arrhythmias, supraventricular tachycardia, atrial fibrillation), ileus, and SDF (thumps). Electrocardiographic

changes from hypomagnesemia include prolonged P-R interval, widening of the QRS complex, depression of the ST segment, and tall T waves.<sup>59</sup> Hypocalcemic tetany has been reported in adult horses and ponies,<sup>47,60</sup> as well as in foals fed magnesium-deficient diets.<sup>61</sup> Affected foals exhibited nervousness, muscular tremors, ataxia, profuse sweating, hyperpnea, collapse, and convulsions.<sup>61</sup> On autopsy, all foals had severe mineralization of the elastic fibers of the aorta and pulmonary artery.<sup>21,61</sup> In one study of colic patients, nonsurviving horses had significantly lower preoperative serum  $\text{Mg}^{2+}$  concentrations.<sup>43</sup>

## DIAGNOSIS OF HYPOMAGNESEMIA

The easiest way to assess the magnesium status of horses is by determining serum tMg and  $\text{Mg}^{2+}$  concentrations. Serum  $\text{Mg}^{2+}$  is more reliable because it is the active form of magnesium and is minimally affected by protein concentrations. In animals with respiratory or metabolic alkalosis (observed after prolonged exercise, proximal enteritis) serum  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  concentrations may be low from increased protein binding. Methods to assess total body magnesium status include 24-hour urinary magnesium excretion, percent of magnesium retention after parenteral magnesium loading, and RBC magnesium content. Of these, the 24-hour urinary excretion and the retention tests have been validated in horses.<sup>8</sup>

To assess renal excretion of magnesium, urine is collected over 24 hours (mg/kg/day). Urinary excretion of magnesium is useful to assess dietary intake. Magnesium excretion is low when dietary intake is decreased.<sup>8</sup> The fractional clearance of magnesium (FMg) can be determined by expressing the renal magnesium clearance relative to the creatinine clearance.<sup>8,9,12</sup> FMg in healthy horses ranges between 15% to 35%,<sup>8,9,12</sup> and values less than 6% indicate inadequate dietary magnesium intake.<sup>8</sup> Muscle magnesium content has been used to estimate total body stores in foals and horses.<sup>8,62</sup> One study evaluated magnesium muscle content and intracellular  $\text{Mg}^{2+}$  concentrations in horses fed a magnesium-deficient diet, with no differences found in muscle magnesium content compared with control horses; however, intracellular  $\text{Mg}^{2+}$  concentrations were lower in magnesium-deficient horses.<sup>8</sup>

The magnesium retention test to assess total body status has been evaluated in horses receiving magnesium-deficient diets.<sup>8</sup>  $\text{MgSO}_4$  was given at a dose of 10 mg/kg/IV of elemental magnesium (100 mg/kg of  $\text{MgSO}_4$ ).  $\text{MgSO}_4$  (50% solution) was diluted to 10% before administration. The percent retention (%Ret) was calculated as follows<sup>8</sup>:

$$\% \text{Ret} = (1 - [\text{magnesium excretion in 24 hours}] / [\text{magnesium infused}]) \times 100$$

In this study the 24-hour magnesium excretion was a more sensitive indicator of reduced magnesium intake than the magnesium retention test, and the spot FMg reflected the 24-hour excretion of magnesium.<sup>8</sup> Thus the FMg can be used as a simpler way to assess magnesium status.

## TREATMENT OF HYPOMAGNESEMIA

Mg for oral administration is available as  $\text{MgO}$ ,  $\text{MgCO}_3$ , and  $\text{MgSO}_4$  (Epsom salt).  $\text{MgSO}_4$  and  $\text{MgCl}_2$  are available for IV administration. The type of salt and the route of administration are important when supplementing magnesium. For  $\text{MgSO}_4$  (9.7%  $\text{Mg}^{2+}$ ), a dose of 100 mg/kg will provide 9.7 mg/kg of

elemental magnesium, whereas for  $MgCl_2$  (25.5%) a dose of 100 mg/kg will provide 25.5 mg/kg of elemental magnesium. This is critical because overdosing can be fatal. Likewise, excessive oral (nasogastric) supplementation with  $MgSO_4$  can be laxative and induce depression. Recommended dose rates for  $MgSO_4$  in adult horses are 25 to 150 mg/kg/IV/day diluted in 0.9% NaCl, dextrose or polyionic isotonic solutions. Constant-rate infusion (CRI) of  $MgSO_4$  at 100 to 150 mg/kg/day should meet the daily requirements of foals and adult horses (2-6 mg/kg/min/IV).  $MgSO_4$  is used to treat ventricular arrhythmias, in particular quinidine intoxication (torsades de pointes), and should be considered in horses with refractory ileus and SDF. Doses of 50 to 100 mg/kg over 30 minutes are considered safe. This is equivalent to 25 to 50 g of  $MgSO_4$  for an adult horse. In foals with ischemic encephalopathy, an initial  $MgSO_4$  dose of 50 mg/kg in the first hour, followed by a CRI of 25 mg/kg/hr has been suggested.<sup>55</sup> This regimen can be continued for several days, adjusting the dose based on serum  $Mg^{2+}$  concentrations.<sup>55</sup>

Oral supplementation with  $MgO$ ,  $MgCO_3$ , or  $MgSO_4$  should be considered in animals with chronic hypomagnesemia, malabsorption, renal disease, and exercise-associated hypomagnesemia. Recommended doses are 30 to 50 mg/kg/day for  $MgO$ , 60 to 80 mg/kg/day for  $MgCO_3$ , or 80 to 100 mg/kg/day for  $MgSO_4$ . These doses are safe for horses, in particular when compared with the cathartic doses of  $MgSO_4$  (0.5-1.0 g/kg).

## ☞ HYPERMAGNESEMIA

Hypermagnesemia is rarely documented in horses and in general is iatrogenic from magnesium overdose, associated with renal failure, or in animals with extensive cellular damage (myonecrosis, cancer, hemolysis, severe sepsis). The presence of hyperkalemia and hyperphosphatemia is another indicator of cellular damage. Hypermagnesemia has been reported in horses treated with Epsom salt and diocetyl sodium sulfosuccinate for large colon impaction.<sup>63</sup> Clinical signs in these horses included sweating, hyperexcitability, muscle tremors, recumbency, flaccid paralysis, tachycardia, and tachypnea. Treatment of hypermagnesemia includes 0.9% NaCl, furosemide, and parenteral calcium administration. Sodium sulfate is considered a safer and more efficacious treatment for large colon impaction than  $MgSO_4$ .

## ANHIDROSIS

Ramiro E. Toribio

Equine anhidrosis (dry coat) is defined as the inability of horses to sweat in response to appropriate stimulation. Anhidrosis is frequent in the tropics, as well as in areas with high temperatures and humidity, including the Southern United States. It is believed that anhidrosis results from a lack of adaptation to local conditions, in particular of horses from temperate climates; however, this does not appear to be the case because native horses in Southern states are as susceptible to anhidrosis as imported horses.<sup>1-3</sup> The prevalence of anhidrosis in the United States is unknown, although it has been estimated to range from 6% to 20% in Southern states.<sup>1-4</sup> Anhidrosis does not seem to be associated with exercise as previously suggested but rather to environmental conditions.<sup>2</sup> There is no association with sex or breed.<sup>1-3</sup> One study in Thoroughbred horses

in central Florida found a prevalence of 6.1%, with horses in training and nonpregnant broodmares having the highest prevalence, but the disease was infrequent in young horses.<sup>1</sup> The role of genetics is unclear; however, based on experience the author believes that a genetic component exists in some animals. The influence of diet is controversial, with some authors claiming that anhidrosis is associated with high-protein diets and insufficient electrolyte intake.

## ☞ PHYSIOLOGY

Similar to humans, sweating in the horse is the primary mechanism for heat loss, followed by respiratory evaporation. The efficiency of these thermoregulatory mechanisms is compromised by diseases, as well as environmental conditions. The equine sweat glands (400-1128/cm<sup>2</sup>) are apocrine, associated with the hair follicle (epitrichial), and consist of a secretory portion and a serpentine duct that opens into the follicular canal.<sup>5-7</sup> An important feature of the equine sweat glands compared with other species is their rich capillary network.<sup>6</sup> Sweating in horses is controlled by endocrine and neural mechanisms. Endocrine mechanisms consist of  $\beta$ -adrenergic stimulation by systemic catecholamines, whereas nervous mechanisms consist of sympathetic  $\beta$ -adrenergic innervation.<sup>8</sup> Evidence indicates that in equidae the sympathetic neural control of sweating is indirect by controlling the local vascular beds, whereas the humoral control is direct to the glands.<sup>6</sup> This is evident in horses with Horner's syndrome in which sympathetic  $\alpha$ -adrenergic denervation results in regional sweating that is believed to result from vasodilation.<sup>9</sup> Neural control appears to be more important in the horse. The equine sweat glands are primarily controlled by  $\beta_2$ -adrenergic receptors.<sup>4,6,7,10</sup> The role of cholinergic, purinergic, and nitric oxide stimulation on equine sweating is unclear.<sup>6,11,12</sup>

## ☞ PATHOPHYSIOLOGY

Even though a clear understanding of the pathogenesis of equine anhidrosis is lacking, proposed mechanisms include lack of  $\beta_2$ -adrenergic stimulation ( $\beta_2$ -adrenoreceptor agonist deficiency) or lack of sweat gland response to  $\beta_2$ -adrenergic stimulation (refractoriness).<sup>2</sup> With regard to neural control of sweating, it has been proposed that hypothalamic dysfunction from severe hyperthermia may be involved<sup>4</sup>; however, no evidence exists to substantiate this hypothesis. It seems that the pathogenesis of anhidrosis results from a combination of lack of neural and endocrine stimulation. Horses with skin denervation can sweat, although their response to thermal stimulation is impaired.<sup>13,14</sup> One study found that sweat gland innervation in horses with anhidrosis was normal,<sup>15</sup> making denervation unlikely in the pathogenesis of anhidrosis.<sup>4,13</sup>

With regard to the role of the adrenal medulla in the pathogenesis of equine anhidrosis, some studies have shown that medullary dysfunction is improbable in the development of this disease.<sup>4,13,14,16</sup> Likewise, vascular dysfunction to the sweat glands seems unlikely. Instead it has been proposed that abnormal dermal vascular perfusion could be relevant to anhidrosis.<sup>6,11</sup>

The fact that epinephrine concentrations in anhidrotic horses are normal or elevated<sup>17</sup> but the sweat glands have a decreased response to adrenergic stimulation suggests receptor downregulation.<sup>16</sup> Downregulation of  $\beta_2$ -adrenoreceptors have been demonstrated in anhidrotic horses.<sup>18</sup> It appears that this downregulation is the result of excessive or prolonged

exposure to catecholamines. The presence of sweat gland atrophy, cell flattening, and ductal obstruction on histologic examination does not imply that these changes are the cause but rather the consequence of this disease.<sup>11,19,20</sup> No evidence indicates that inflammation or immune-mediated processes are central to the pathogenesis of anhidrosis. The low expression of the water channel aquaporin-5 in anhidrotic horses may be of clinical relevance to anhidrosis but does not imply that is the cause.<sup>19</sup>

The role of THs in the pathogenesis of anhidrosis is unclear. It is believed by some that anhidrosis is caused by hypothyroidism; however, no data indicate that this is the case. The fact that some horses may show improvement with L-thyroxine or iodinated casein supplementation indicates that THs may enhance adrenoreceptor sensitivity, as documented in other species.<sup>21</sup> It has been claimed that abnormal electrolyte concentrations are part of the pathogenesis of anhidrosis; however, in controlled studies no differences have been found between anhidrotic and healthy horses.<sup>1</sup>

## CLINICAL SIGNS

Typical clinical signs include depression, poor performance, tachypnea, hyperthermia (in particular after exercise), lack or decreased sweating, alopecia, and dry coat. Initial signs are non-specific and related to poor performance and respiratory problems. Early recognition of anhidrosis is important, in particular in hot climates where a delay in core temperature cooling can lead to heat stroke. In addition, anhidrosis represents a major stress to the animal, which can predispose to other diseases.

## DIAGNOSIS

In general the diagnosis of anhidrosis is based on clinical signs. The first specific method developed for the diagnosis of anhidrosis was the intradermal injection of epinephrine.<sup>22</sup> Horses with anhidrosis will have a delayed or lack of sweat response to this test. However, because epinephrine is not specific to  $\beta_2$ -receptors,  $\alpha$ -adrenergic effects may mask the response of the sweat glands. Subsequently, tests based on  $\beta_2$ -receptor agonists (salbutamol, terbutaline) have been developed.<sup>23,24</sup> These methods are semiquantitative. Saline solution and serial dilutions of salbutamol or terbutaline ( $10^{-3}$  to  $10^{-8}$  wt/vol) are injected intradermally over the side of the neck.<sup>23,24</sup> Sweating is evident by 10 minutes, but the final response is evaluated at 20 to 30 minutes. In the terbutaline test, 0.1-ml intradermal injections of terbutaline sulfate (diluted in 0.9% NaCl) in tenfold dilutions (0, 0.001, 0.01, 0.1, 1, 10, 100, 1000 mg/L) are injected intradermally with a 25-gauge needle at 5 cm apart.<sup>23,24</sup> Horses with anhidrosis have minimal or no response to any of the dilutions,<sup>4,23,24</sup> whereas normal horses have a sweat response to most dilutions.

Differential diagnoses are limited to the respiratory tract because most anhidrotic horses have tachypnea and an exaggerated respiratory response (tachypnea) after exercise. In addition, body temperature in these horses remains elevated for longer periods of time than healthy animals.

## TREATMENT, PREVENTION, AND PROGNOSIS

No specific treatment exists for equine anhidrosis. Keeping these horses in a cool environment and reducing physical activity is central to the palliative treatment of anhidrosis.

Measures that reduce environmental temperature or increase heat loss include shades, fans, air-conditioning, misting, and water cooling. Because many afflicted horses are used for various performance activities, unfortunately some of the management measures may not be practical or are not implemented. In hot weather, working these horses in the coolest part of the day is recommended. In severe cases, moving these animals to cooler climates should be considered. Dietary modifications and supplementation of minerals may help. The use of salts and electrolytes (KCl,  $\text{NaHCO}_3$ ) may have some benefit, although they have not been critically evaluated. Dietary supplements containing ascorbic acid, L-tyrosine (catecholamine precursor), cobalt, vitamin E, and water-soluble vitamins have been claimed to improve clinical signs. Methyl-DOPA (3-4 g) to decrease central sympathetic activity has also been used, but information on the success of this treatment is lacking. It has been reported that daily oral administration of iodinated casein (10-15 g/day) or sodium levothyroxine (0.5 to 3.0 mg/lb; 1-6 mg/100 kg) may improve clinical signs.<sup>4,11</sup> Because information in other species indicates that THs enhance  $\beta_2$ -adrenoreceptor sensitivity,<sup>21</sup> these supplements should be considered, keeping in mind potential complications (iatrogenic hyperthyroidism, weight loss).

The use of  $\beta_2$ -receptor agonists is controversial because available information indicates that  $\beta_2$ -receptor downregulation is the result of excessive adrenergic stimulation. However, some clinicians report that the use of clenbuterol in horses with mild anhidrosis or hypohidrosis when environmental temperature and humidity are elevated could ameliorate the severity of clinical signs.

No evidence indicates that anhidrosis is an immune-mediated process; however, glucocorticoids have been proposed in the treatment of this condition. Another combination that has been suggested is glucocorticoids with clenbuterol, with the idea that  $\beta_2$ -receptor agonists may potentiate the anti-inflammatory effects of corticoids. The rationale for this strategy is that glucocorticoids may enhance the  $\beta_2$ -adrenoreceptors' response to agonists. Again, this approach remains unclear because excessive adrenergic stimulation seems to be part of the pathogenesis of anhidrosis. It is also important to avoid the use sedatives that may stimulate sweating in the horse ( $\alpha_2$ -receptor agonists). The prognosis for horses with anhidrosis is guarded and dictated by the severity of this condition, response to therapy, and implementation of palliative measures.

# DISORDERS OF FOALS

## CHAPTER 21

*Pamela A. Wilkins*

### NEONATAL AND PERINATAL DISEASES

*Pamela A. Wilkins*

Before the 1980s intensive management of the compromised neonate was unusual and little was known regarding many of the problems of this special patient population. Although some specific conditions had been described by astute clinician-researchers, most notably the “dummy” foal syndrome<sup>1</sup> and respiratory distress syndrome caused by primary surfactant deficiency,<sup>2</sup> little information regarding the diagnosis and management of conditions of the foal during the neonatal period was available, although at least one active group was investigating fetal and neonatal physiology of the horse in Great Britain.<sup>1-14</sup> When treatment of compromised foals was undertaken, the approach usually resembled treating them as small adults, with little consideration given to the different physiology of the equine neonate. The advent of improved management of reproductive efficiency in mares led naturally to an increased interest in preservation of the conceptus to parturition and the foal thereafter. Interested clinicians, drawing on lessons from human perinatology and neonatology and sometimes collaborating with their counterparts in the human field, pioneered investigations of these small patients and created the fields of equine perinatology and equine neonatal intensive care.<sup>1-19</sup> Because of the foresight and energy of these early investigators, the field of veterinary perinatology-neonatology exploded in the 1980s, leading to the creation of equine neonatal intensive care units throughout the United States and the world. From these units information about the normal and abnormal physiology of foals, the medical conditions affecting them, and methods for treatment and management of these problems has been developed through observational, retrospective, and prospective studies. This veritable explosion of information over the last 20 years has greatly improved the ability of all practitioners to provide appropriate care for these patients, whether in the field or at an equine neonatal intensive care unit. The ability not only to save the lives of these patients but also to treat them in such a manner as to allow them to fulfill their purposes, whether as pleasure animals or racing athletes, has improved almost exponentially from those early days.<sup>20-23</sup> This section aims to

provide the clinician with current information about the management of these patients, with the recognition that much still remains unknown and that advances will continue to be made in this dynamic field. The reader is cautioned that much of this chapter is flavored by the experiences of the authors and that variation in the approach to and treatment of specific problems exists among neonatal intensive care units (NICUs) and among clinicians in the same NICU; moreover, each year results in change. In some cases information that is presented has been gleaned from human NICU studies, essentially using the critically ill infant as the experimental model.

Many of the problems of the newborn foal have their genesis in utero. Identification of high-risk pregnancies is an important component of prenatal care of the foal, and some of the most commonly encountered problems of the dam that result in abnormal foals include previous or concurrent disease, poor reproductive history, poor perineal or pelvic conformation, poor general health, poor nutritional condition, prolonged transport, history of previous abnormal foals, placental abnormalities, and twins.<sup>24</sup>

Some of the more common causes of abortion can result in the birth of severely compromised foals of variable gestation lengths (Box 21-1). These include infectious causes such as equine herpesvirus (EHV) types 1 (most commonly) and 4 (rarely), equine infectious anemia, equine arteritis virus, bacterial and fungal placentitis, leptospirosis, equine ehrlichiosis, and septicemia-endotoxemia.<sup>25-27</sup> Noninfectious causes of abortion include twinning and noninfectious placental abnormalities such as extensive endometrial fibrosis, body pregnancy, and abnormal length (long or short) of the umbilical cord.<sup>24,28</sup>

To the equine neonatologist opportunities for intervention may appear limited, and in the case of many of the aforementioned causes of fetal loss, this is true. However, much can be done in the attempt to preserve the pregnancy and in effect treat the fetus. When confronted with a threatened pregnancy, the veterinarian has various ways of evaluating the fetus and its environment and may use many potential therapies.

### ☪ PREPARTUM EVALUATION OF THE FETUS AND PLACENTA

Once a pregnancy has been established as high risk, the fetus should be evaluated for viability. Evaluation should include as thorough an evaluation as possible of the reproductive tract,

## BOX 21-1

**CONDITIONS ASSOCIATED WITH HIGH-RISK PREGNANCY****Maternal Conditions**

Colic-endotoxemia  
 Abdominal hernia  
 Pelvic anatomic abnormalities  
 Malnutrition  
 Any debilitating disease  
 Uterine torsion  
 Uterine abnormalities  
 Mare reproductive loss syndrome  
 Hyperlipemia

Placentitis  
 Twins  
 Hydrops  
 Prolonged gestation  
 Fetal abnormalities  
 Dystocia  
 Fescue toxicosis  
 Umbilical abnormalities  
 Congenital deformity

placenta, and fetal fluids. The details of this examination are described in Chapter 18. Parturition disorders in the mare usually are readily recognizable, but disorders of the fetus and placenta can be more subtle and difficult to determine. The first step is to take a thorough history of the mare. Of particular interest is any history of previous abnormal foals, but the history taking should include questions regarding transportation; establishment of an accurate breeding date (sometimes more difficult than one would suspect); pertinent medical history, including any diagnostic testing performed for this pregnancy, such as culture, endometrial biopsy, and cytologic results; and any rectal and ultrasound examination results. Additionally, the clinician should obtain information regarding the possible ingestion of endophyte-infected fescue or exposure to potential infectious causes of abortion.<sup>29,30</sup> A complete vaccination and deworming history is requisite, as is a complete history of any medications and supplements administered during pregnancy.

After obtaining a history, the clinician performs a rectal examination, including palpation of the cervix, uterus, fetus, and all palpable abdominal contents. Any abnormalities should be noted. The cervix should be tight throughout gestation; the late-gestation uterus will be large and distended with fluid and usually pulled cranial in the abdomen. Palpation of the fetus frequently results in some fetal movement; however, lack of movement should be interpreted with caution insofar as some normal fetuses do not respond. Ultrasonographic evaluation of the uterus and conceptus by way of the rectum can provide valuable information, particularly regarding placental thickness if placentitis

is a concern. The clinician may evaluate fetal fluids and estimate fetal size on the basis of the size of the eye later in gestation.<sup>31</sup> In some hospitals the practitioners choose not to perform vaginal or speculum examinations because of an association between these examinations and the subsequent development of placentitis. Unless placentitis is recognized with ultrasonographic evaluation by way of the rectum and culture is desirable, these types of examinations generally are not necessary.

After rectal examination a transabdominal ultrasonographic evaluation of the uterus and conceptus is performed.<sup>28</sup> The neonatologist can generate a biophysical profile of the fetus on the basis of this examination in the late-term fetus and readily determine viability.<sup>32,33</sup> It is also possible to determine the presence or absence of twins in the late pregnant mare in this manner. The sonogram is performed through the acoustic window from the udder to the xiphoid ventrally and laterally to the skin folds of the flank. Imaging of the fetus usually requires a low-frequency (3.5-MHz) probe, whereas examination of the placenta and endometrium requires a higher-frequency (7.5-MHz) probe. A complete description of this examination is beyond the scope of this chapter, but several complete descriptions of the technique and normal values for specific gestation lengths can be found by consulting the relevant veterinary literature.<sup>33</sup> The utility of this examination lies in its repeatability and low risk to the dam and fetus. Sequential examinations over time allow the clinician to follow the pregnancy and identify changes as they occur.

A companion to transabdominal ultrasonography is evaluation of the fetal electrocardiogram (ECG). Fetal ECGs can be measured continuously using telemetry or obtained through more conventional techniques several times throughout the day.<sup>24,28,34</sup> The operator places electrodes on the mare's skin in locations aimed at maximizing the magnitude of the fetal ECG. Because the fetus frequently changes position, multiple sites may be needed in any 24-hour period. To begin, one places an electrode dorsally in the area of the sacral prominence, with two electrodes placed bilaterally in a transverse plane in the region of the flank. The fetal ECG maximal amplitude is low, usually 0.05 to 0.1 mV, and can be lost in artifact or background noise, so it is often necessary to move electrodes to new positions to maximize the appearance of the fetal ECG. The normal fetal heart rate during the last months of gestation ranges between 65 to 115 beats/min, a fairly wide distribution. The range of heart rate of an individual fetus can be narrow, however. Bradycardia in the fetus is an adaptation to in utero stress, most commonly thought to be hypoxia. By slowing the heart rate, the fetus prolongs exposure of fetal blood to maternal blood, increasing the time for equilibration of dissolved gas across the placenta and improving the oxygen content of the fetal blood. The fetus also has altered the distribution of its cardiac output in response to hypoxia, centralizing blood distribution.<sup>35,36</sup> Tachycardia in the fetus can be associated with fetal movement, and brief periods of tachycardia should occur in the fetus in any 24-hour period. Persistent tachycardia is a sign of fetal distress and represents more severe fetal compromise than bradycardia. The author has recognized dysrhythmias in the challenged fetus, most commonly as atrial fibrillation but also as apparent runs of ventricular tachycardia.

The ability to monitor the fetus in a high-risk pregnancy inevitably has led to questions of whether, how, and when

to intervene. Most equine neonatologists would agree that removal of the fetus from the uterus before it is ready for birth is not desirable. One of the difficulties in determining fetal preparedness for birth is that prediction of parturition is difficult in these mares. Many of the parameters used in normal mares are unreliable in the high-risk pregnant mare. One must have an accurate history of any previous gestation length in terms of days for the mare in question to allow a more accurate estimate of her usual gestational length. Evaluation of the usual mammary gland parameters, including size, the presence of “wax,” and alteration of electrolyte concentrations, is not generally predictive in the high-risk mare; in the author’s experience many of these mares have changes predictive of parturition for weeks before actual parturition.<sup>37,38</sup> This circumstance may be related to the observation that many high-risk pregnant mares, particularly those with placentitis, are presented for a primary complaint of early onset lactation. Although pulmonary system maturity in human beings can be assessed with some degree of accuracy using measurement of lecithin-sphingomyelin ratios, this measurement—along with sphingomyelin, cortisol, and creatinine concentrations in the amniotic fluid—has proved to be of no benefit in the horse.<sup>39-41</sup> Amniocentesis carries a high risk of abortion in the horse, even with ultrasound guidance, and is not a clinically useful technique at this time.<sup>41</sup> Currently, no clear-cut guidelines are available indicating the best time to intervene, but the presence of persistent fetal tachycardia or prolonged absence of fetal movements, including breathing movements, as determined by transabdominal ultrasound evaluation, should initiate discussion regarding the appropriateness of induction of parturition or elective cesarean section. The goal of induction or cesarean section is to remove a pregnancy that is threatening the survival of the dam, with no thought to fetal survival, or to remove the fetus from a threatening environment to improve its likelihood to survive. Preterm induction is ill advised if fetal survival is desirable because of the limited ability to treat severely immature neonates. Timing of intervention in these circumstances remains an art, not a science.

The approach to management of the high-risk pregnancy is dictated to some degree by the exact cause for concern, but for many mares therapy is similar. Many high-risk mares have placentitis, primarily caused by ascending bacterial or fungal infections originating in the region of the cervix. These infections can cause in utero sepsis or compromise the fetus by local elucidation of inflammatory mediators or altered placental function.<sup>42,43</sup> Premature udder development and vaginal discharge are common clinical signs. Treatment consists of administration of broad-spectrum antimicrobial agents and nonsteroidal anti-inflammatory drugs (Table 21-1). In some clinics trimethoprim-sulfonamide drugs have been the antimicrobial of choice because of unpublished studies that demonstrated an increased concentration of these agents in the fetal fluids compared with penicillin and gentamicin. However, if culture and sensitivity results are available, directed therapy should be instituted. Nonsteroidal anti-inflammatory agents such as flunixin meglumine are useful to combat alterations in prostaglandin balance that may be associated with infection and inflammation. Although the efficacy of these agents is best when administered before the development of clinical signs, to date no detrimental effects have been reported in the fetus or dam when chronically used at low doses in well-hydrated patients. Tocolytic agents and agents that promote

TABLE 21-1

Drugs Used to Treat High-Risk Pregnancy		
Drug	Dose/Frequency/ Route	Reason
Trimethoprim-sulfonamide	25 mg/b.i.d.; PO	Antimicrobial
Flunixin meglumine	0.25 mg/kg t.i.d.; PO or IV	Anti-inflammatory
Altrenogest	0.44 mg/kg s.i.d.; PO	Tocolytic
Isoxuprine	0.4-0.6 mg/kg b.i.d.; IM* or PO	Tocolytic
Clenbuterol	0.8 µg/kg as needed PO*	Tocolytic
Vitamin E	6000-10,000 IU s.i.d.; PO	Antioxidant

*b.i.d.*, Twice daily; *t.i.d.*, three times daily; *PO*, per os (by mouth); *IV*, intravenous; *s.i.d.*, once daily; *IM*, intramuscular  
\*Intravenous form currently not available in the United States.

uterine quiescence include altrenogest, isoxuprine, and clenbuterol.<sup>44-48</sup> Usually, altrenogest is administered, although its need in late gestation has been challenged. The efficacy of isoxuprine as a tocolytic in the horse is unproven, and the bioavailability of orally administered isoxuprine appears to be highly variable.<sup>48</sup> The long-term use of clenbuterol is inadvisable because of receptor population changes associated with chronic use and its unknown effects on the fetus at this time. Clenbuterol may be indicated during management of dystocia in preparation for assisted delivery or cesarean section.<sup>46</sup> The intravenous form of clenbuterol currently is not available in the United States.

Three additional strategies can be used in managing mares with high-risk pregnancies. In mares with evidence of placental dysfunction, with or without signs of fetal distress, the author provides intranasal oxygen supplementation in the hope of improving oxygen delivery to the fetus. Intranasal oxygen insufflation of 10 to 15 L/min to the mare significantly increases partial pressure of oxygen (Pao<sub>2</sub>) and percent oxygen saturation of hemoglobin.<sup>49,50</sup> Because of the horse’s placental vessel arrangement, improvement of these two arterial blood gas parameters should result in improved oxygen delivery to the fetus. Blood gas transport is largely independent of diffusion distance in the equine placenta, particularly in late gestation, and depends more on blood flow. Information from other species cannot be extrapolated to the equine placenta because of its diffuse epitheliochorial nature and the arrangement of the maternal and fetal blood vessels within the microcotyledons.<sup>51,52</sup> Umbilical venous pO<sub>2</sub> is 50 to 54 mm Hg in the horse fetus, compared with 30 to 34 mm Hg in the sheep, whereas the maternal uterine vein to umbilical vein pO<sub>2</sub> difference is near 0. Also unlike the sheep, the umbilical venous pO<sub>2</sub> values decrease 5 to 10 mm Hg in response to maternal hypoxemia and increase in response to maternal hyperoxia.<sup>53-55</sup>

Vitamin E (tocopherol) is administered orally to some high-risk mares as an antioxidant. Administration of large doses of vitamin E before traumatic brain injury improves neurologic

outcome in experimental models and has been examined as possible prophylaxis for human neonatal encephalopathy.<sup>56-58</sup> Extrapolation of that information to the compromised equine fetus suggests that increased antioxidant concentrations in the fetus may mitigate some of the consequences of uterine and birth hypoxia, but no evidence is available to date demonstrating that protection occurs or that vitamin E accumulates in the fetus in response to supplementation of the mare. Finally, many high-risk mares are anorectic or restricted from feed because of their medical condition. These mares are at particularly great risk for fetal loss because of their lack of feed intake, which alters prostaglandin metabolism.<sup>59</sup> Therefore the clinician should administer 2.5% to 5% dextrose in 0.45% saline or water (5% dextrose) intravenously at maintenance fluid rates to these patients.

Perhaps the most important aspect of managing mares with high-risk pregnancies is frequent observation and development of a plan. These mares should be observed at least hourly for evidence of early-stage labor and should be under constant video surveillance if possible. Depending on the primary problem, the team managing the mare should develop a plan for handling the parturition once labor begins and for fetal resuscitation after delivery. Any equipment that may be needed should be readily available stallside, and a call sheet listing contact numbers for all involved should be posted on or near the stall. The plan should include a description of how a complicated dystocia would be handled, should it occur, with permission for general anesthesia and cesarean section obtained before the event so that time is not wasted. An important question to be posed to the owner at the outset is whether the mare or the foal is more important; this answer may dictate the direction of the decision tree once labor begins.<sup>60,61</sup>

## EVALUATION OF THE NEWBORN FOAL

Bonnie Barr

Early recognition of abnormalities is of utmost importance for the successful management of critically ill foals. To recognize the abnormal, the normal must be known. Immediately after birth, several important physiologic and behavioral changes occur. Chief among these changes are the adaptation of the cardiovascular and respiratory systems to extrauterine life; thus persistent increases or decreases in heart or respiratory rates should alert the clinician to existing or impending problems. The normal transition of the respiratory tract involves opening closed alveoli and absorption of fluid from the airway, accomplished by a combination of breathing efforts, expiration against a closed glottis ("grunting"), and a change in sodium flux across the respiratory membrane from net secretion to net absorption.<sup>1-5</sup> The transition from fetal to neonatal circulatory patterns requires resolution of the pulmonary hypertension present in the fetus, normally shunting blood flow through the lower resistance ductus arteriosus in the fetal state, in order to direct cardiac output to the pulmonary vasculature for participation in gas exchange. This change is achieved by opening alveoli; decreasing airway resistance and providing radial support for pulmonary vessels; achieving functional closure of the ductus arteriosus; and increasing

the oxygen tension in the lung, reversing pulmonary vasoconstriction mediated by hypoxia.<sup>6,7</sup> Pulmonary tree vasodilators (prostacyclin, nitric oxide [NO]) and vasoconstrictors (endothelin-1, leukotrienes) play apparently well-coordinated, but as yet not fully elucidated, roles. In the normal newborn this change is smooth and rapid. These critical events are undermined by factors such as inadequate lung development, surfactant deficiency (primary or secondary), viral or bacterial infection, placental abnormalities, in utero hypoxia, and meconium aspiration.

Spontaneous breathing should begin in the neonate within 1 minute of birth; many foals will attempt to breathe as their thorax clears the pelvic canal.<sup>8,9</sup> First breaths are normally triggered by the combination of removal of placental humoral inhibitory factor, cooling of the neonate, tactile stimulation, the catecholamine surge's induction of substances important for breathing (e.g., substance P) and increasing carbon dioxide. Apnea at birth can be caused by asphyxia, central nervous system (CNS) depression from maternal drugs, CNS injury, septicemia, anemia, primary muscular or neurologic disease, and obstructing congenital malformations or other mechanical obstruction of the airway. During the first hour of life, the respiratory rate of a healthy foal can be as high as 80 breaths per minute but should decrease to 30 to 40 breaths per minute within a few hours. Similarly, the heart rate of a healthy newborn foal will have a regular rhythm and be at least 60 beats per minute at the first minute.<sup>8,9</sup> By the time the foal is 1 day of age, the heart rate should range between 70 to 100 beats per minute. Persistent bradycardia can be caused by hypoxic damage, acid-base derangements, and sepsis and is an indication for rapid intervention. A continuous murmur can usually be auscultated over the left side of the heart, although its loudness may vary with position. This murmur is thought to be associated with some shunting through the ductus arteriosus. Variable systolic murmurs, thought to be flow murmurs, may be auscultated during the first week of life.<sup>10</sup> Murmurs that persist beyond the first week of life in an otherwise healthy foal should be more thoroughly investigated, as should any murmur associated with persistent hypoxia. Sinus arrhythmias can be noted relatively frequently during the immediate postpartum period. Various other arrhythmias (e.g., ventricular premature complexes, ventricular tachycardia, supraventricular tachycardia) occasionally can be observed in normal foals; however, all arrhythmias should disappear within 15 minutes post partum.<sup>11</sup> Physiologic changes associated with the adaptive period are probably the main factors contributing to these arrhythmias. The clinical significance of any unusual or abnormal arrhythmias should take into consideration clinical, metabolic, and homodynamic findings of the neonate.

Auscultation of the thorax shortly after birth will reveal a cacophony of sounds as airways are opened and fluid is cleared. End-expiratory crackles are consistently heard in the dependent lung during and after lateral recumbency. Changes in respiratory rate, effort, or breathing pattern are more appreciable than auscultable changes in neonates with respiratory disease. Premature and dysmature foals or foals subjected to peripartum hypoxia can demonstrate abnormal breathing patterns, especially when sleeping. Any sudden change in respiratory parameters should be investigated immediately because it may indicate deterioration in the foal's condition. It is not unusual for a normal newborn foal to appear slightly cyanotic during this initial adaptation period, but this should resolve within minutes of birth. The equine fetus, like all fetuses,

exists in a moderately hypoxic environment, but the equine fetus has a greater partial pressure of oxygen, approximately 50 mm Hg.<sup>12</sup> Because the fetus is well adapted to low oxygen tensions, cyanosis is rarely present in newborn foals once adaptation occurs, even those with low oxygen tensions. Although in many species the fetal blood oxygen affinity is greater than the maternal blood, in the equine fetus the O<sub>2</sub> affinity of its hemoglobin is only approximately 2 mm Hg greater than the maternal blood as a result of lower levels of 2,3 diphosphoglycerate (DPG) compared with other species.<sup>13</sup> The result is enhanced oxygen unloading in the equine fetus compared with others. DPG concentration increases after birth in the foal and reaches mature levels by 3 to 5 days of age. The major blood adaptation of the equine fetus to chronic hypoxia is an increase in PCV of up to 20%, increasing the oxygen content of the blood as compensation for decreased O<sub>2</sub> delivery at the placenta.<sup>14</sup> A higher than expected packed cell volume (PCV) in any newborn foal should alert the clinician to possible sequelae from chronic hypoxia. The presence of significant cyanosis that persists should prompt the clinician to thoroughly evaluate the foal for cardiac anomalies resulting in significant right to left shunting or separated circulations, such as transposition of the great vessels.

Within several minutes after birth, the mucous membranes should be moist and pink. The persistence of an abnormal color of the mucous membranes such as jaundice, cyanosis, injection, ulcerations, and petechial hemorrhages indicates problems to come. Jaundice can accompany a variety of neonatal diseases, such as neonatal isoerythrolysis, sepsis, and meconium retention. Other indications of sepsis include injection and petechial hemorrhages on the mucous membranes; petechiation of the pinnae of the ears, sclera, and vulva; depression; and, in an extreme case, recumbency. Peripheral pulses should be strong and can be detected at the facial artery, brachial artery, on the inside of the elbow joint, and at the great metatarsal artery. Distal extremities should be warm. Cold extremities result when blood is redirected away from them to other tissue, which most often occurs with sepsis. In this case the peripheral pulses may initially be strong and bounding, but as sepsis progresses, the pulses become weak.

The body temperature of the foal at birth is similar to the dam's temperature. Immediately after birth the healthy full-term neonate can effectively thermoregulate despite heat loss associated with wet hair coat and adverse environmental temperatures. Mechanisms of heat production in the healthy newborn foal include shivering, nonshivering thermogenesis, neuroendocrine stimulation, and behavioral processes.<sup>15</sup> Newborn foals shiver within a few minutes of birth and continue to shiver for several hours when exposed to low environmental temperatures. Thyroid hormones and catecholamines stimulate the onset of nonshivering thermogenesis, which involves the oxidation of brown adipose tissue to release energy as heat.<sup>15</sup> Behavioral thermoregulation involves the ability of the animal to modify its behavior to conserve or produce heat. Healthy foals maintain sternal recumbency to minimize heat loss but at the same time will increase heat production by physical activity, such as attempting to stand. A healthy foal should be nursing 1 to 2 hours after birth, thus relying on colostrum fat, colostrum glucose, and milk to provide sufficient energy to support metabolism such that fat stores are not seriously depleted. Premature foals are not able to maintain a steady rectal temperature because of inadequate heat production resulting from poor energy intake, diminished endogenous energy

stores, lack of nonshivering thermogenesis associated with a lack of brown fat, and immaturity of the neuroendocrine system. Foals that suffer from a hypoxic insult, are septic, or are being treated with certain medications (e.g., phenobarbital) must be monitored and managed appropriately because they are unable to thermoregulate properly. In infants sedatives such as benzodiazepine affect the ability to thermoregulate; therefore sedation and general anesthesia used on the mare to correct a dystocia can have an impact on the newborn foal's ability to thermoregulate.

The abdomen should be visually examined and palpated for abnormalities. Congenital scrotal hernias are noted shortly after birth, are usually unilateral, and are easily reduced when the foal is rolled onto its back. Intestinal strangulation is rare with scrotal hernias, and resolution of the hernia usually occurs spontaneously in 3 to 6 months. Inguinal hernias are evident 4 to 48 hours after birth and cause intermittent colic, depression, severe scrotal and preputial swelling, and edema, with skin excoriation and splitting caused by abrasion against the inside of the thigh. Inguinal hernias are classified as either indirect or direct, as described in the human literature. In indirect herniation the herniated intestine is situated inside the vaginal tunic and occupies the same space as the testis.<sup>16</sup> Most indirect hernias are easily reduced and often resolve spontaneously as the foal ages and grows. In direct herniation the intestine herniates through a rent in the peritoneum and transverse fascia (and/or parietal vaginal tunic and scrotal fascia) and comes to lie subcutaneously (i.e., outside the common vaginal tunic, in the inguinal-scrotal region).<sup>16</sup> Surgical intervention is often necessary for direct herniation because of the risk of incarceration of bowel. The exact cause is unknown, but it seems probable that inguinal hernias are a result of an increased intra-abdominal pressure during birth in which the intestinal loops may be forced through the vaginal ring into the vaginal cavity. Tearing of the parietal vaginal tunic could be caused by the limited space in the vaginal cavity. Umbilical hernias are a common defect in neonates and may result from congenital malformations of the umbilical region; infection; traumatic parturition; or opening of the umbilicus caused by straining, which results in increased intra-abdominal pressure. Occasionally, the umbilical defect may be so large that small intestine will eviscerate into the hernia sac. Small umbilical hernias resolve spontaneously, whereas larger hernias may require surgery to correct the defect. Auscultation of the abdomen provides an assessment of gastrointestinal motility and should be performed from the paralumbar fossa to the ventral abdomen, on both the right and left sides. Decreases in motility suggest ileus, which may be due to inflammatory, ischemic, or obstructive lesions. Increased motility occurs during the early stages of enteritis or intestinal obstruction.

The development of the gastrointestinal tract appears to be mostly complete in the neonate. The presence and distribution of the interstitial cells of Cajal (ICC), which generate pacemaker activity, are complete in the small intestine at birth; however, the development in the large intestine and distal colon continues after birth.<sup>17</sup> This immaturity of the ICC at birth may contribute to retention of meconium in the distal colon and rectum in some neonatal foals. Other possible causes of meconium impaction include prematurity, sepsis, and asphyxia, or it can be secondary to prolonged recumbency, dehydration, or medications. Meconium, an accumulation of swallowed allantoic fluid, gastrointestinal secretions, and cellular debris, is generally black to brown and

of firm to pasty consistency. Once meconium is passed, feces change to a lighter brown color and become softer. Evaluation of the quantity and quality of meconium is an important part of the physical examination, and the amount passed varies from foal to foal. Passage of meconium in utero is an indication of fetal distress during late gestation or parturition and should prompt a detailed assessment of the neonate. Aspiration of meconium results in severe pneumonia because of the caustic effect of the meconium on the respiratory epithelium.

Examination of the urogenital system includes evaluation of the external genitalia and the umbilicus. Many male foals have a persistent penile frenulum at birth, which resolves within a few days. When the cord is allowed to break naturally at birth, the umbilical vein and the urachus break at the navel stump and the umbilical arteries retract into their connective tissue sheath within the abdomen, closer to the bladder apex. Once the umbilical stump dries, it should remain dry. A moist stump or observation of urination from the umbilicus indicates a patent urachus, which is commonly found in foals that are recumbent for any reason. The neonate should be observed for the onset, frequency, and quantity of urine output. The mean time for first urination in the colt is 5.97 hours, and in the filly it is 10.77 hours; however, these times vary widely.<sup>18</sup> Evidence of urogenital disease includes depression, straining to urinate, pigmenturia, and decreased urine output (oliguria). When clinical signs of urinary tract disease exist, the foal's urine production should be monitored carefully and serum chemistries evaluated for azotemia and electrolyte disturbances, and a transabdominal ultrasound should be performed so that the clinician can examine the urogenital structures. The full-term neonatal foal has a glomerular filtration rate and effective renal plasma flow comparable with that of the adult.<sup>18</sup> The status of the premature foal's renal function has not been determined.

The musculoskeletal system should be closely evaluated for malformations or injuries secondary to the explosive nature of the equine birth. Congenital anomalies of the limbs include polydactyly, adactyly, defects in the hoof wall, and contractural deformities. Other congenital anomalies include brachygnathism, wry nose, cleft palate, torticollis, and scoliosis. Laxity in the neonate often manifests as weakness of the flexor tendons because of dysmaturity or prematurity, although full-term foals may exhibit a mild degree of fetlock laxity. In most foals the laxity will spontaneously resolve after a few days, but occasionally corrective trimming and shoeing are required. When the foal is malpositioned, injuries such as rib fractures and ruptures of the gastrocnemius muscle may occur. Rib fractures are common and occur even in apparently normal births. Rib fractures usually occur a few centimeters above the costochondral junction, with multiple fractures (4 to 12) commonly occurring in a straight line. Neonates with fractured ribs have soft tissue swelling over the fracture site, crepitus, and pain on palpation and occasionally respiratory distress resulting from pneumothorax or hemothorax. Rupture of the gastrocnemius muscle occurs during delivery if the hock is flexed and the stifle is forced into extension (i.e., the foal is "dog sitting").<sup>19</sup> This results in hyperflexion of the hock caused by tearing of the gastrocnemius muscle at the level of the femur. Most of the time these foals respond well to conservative management.

The righting reflex is present as the foal exits the birth canal, as is the withdrawal reflex. Cranial nerve responses are intact at birth, but the menace response may take as long as

2 weeks to fully develop. Lack of menace should not be considered diagnostic of visual deficits in the newborn foal. Within 1 hour of birth, the normal foal will demonstrate auditory orientation with unilateral pinna control. The normal pupillary angle is ventromedial in the newborn foal; this angle gradually becomes dorsomedial over the first month of life. Foals should begin attempting to stand shortly after birth and should be able to stand on their own within 2 hours of birth.<sup>20</sup> The normal newborn foal will have a suck reflex shortly after birth and should be searching for an udder even before it stands. A normal foal is expected to suck from the dam unaided by 3 hours post partum; many foals will suck well before this time.

The gait of the newborn foal is hypermetric, and the stance is base wide.<sup>21</sup> Extreme hypermetria of the forelimbs, usually bilateral but occasionally unilateral, has been observed in some foals and is associated with perinatal hypoxic-ischemic insults, but this gait abnormality usually resolves without specific therapy with a few days. Spinal reflexes tend to be exaggerated, while the crossed extensor reflex may not be fully present until 3 weeks of age.<sup>22</sup> Foals exhibit an exaggerated response to external stimuli (e.g., noise, sudden visual changes, touch) for the first few weeks of life. Foals are not strongly bonded to their mothers for the first few weeks of life and will follow any large moving object, including other horses and people. Until they are several months of age, orphan foals will bond with surrogate mothers; their primary motivation appears to be appetite. Conversely, mares strongly bond with their foals shortly after parturition: The process begins once the chorioallantois is ruptured, and is driven more by olfaction and taste rather than by vision or hearing. Interference with this process, by medical intervention or excessive owner manipulation of the foal, can disrupt normal bonding and cause the dam to reject the foal.<sup>23</sup>

## NEONATAL RESUSCITATION

*Pamela A. Wilkins*

Most newborn foals make the transition to extrauterine life easily. However, for those in difficulty, immediate recognition of the condition and institution of appropriate resuscitation is of utmost importance. A modified Apgar scoring system has been developed as a guide for initiating resuscitation and assessing the probable level of fetal compromise (Table 21-2).<sup>1</sup> One also must at least perform a cursory physical examination before initiating resuscitation in case there are serious problems (e.g., limb contracture, microphthalmia, hydrocephalus) that would make resuscitation a less humane choice.

The initial assessment begins during presentation of the fetus. Although the following applies primarily to attending the birth of a foal from a high-risk pregnancy, quiet and rapid evaluation can be performed during any attended birth. The goal in a normal birth with a normal foal is to disturb the bonding process as little as possible. This goal also applies to high-risk parturitions, but some disruption of normal bonding is inevitable. The lead clinician should control tightly the number of persons attending, and the degree of activity surrounding, the birth.

One should evaluate the strength and rate of any palpable peripheral pulse and should evaluate the apical pulse as

TABLE 21-2

Apgar Score in the Foal			
Parameter	ASSIGNED VALUE		
	0	1	2
Heart/pulse rate	Undetectable	<60 beats/min irregular	>60 beats/min regular
Respiratory rate/pattern	Undetectable	Slow, irregular	40-60 beats/min regular
Muscle tone	Limp/absent	Lateral, some tone	Sternal
Nasal mucosal stimulation	Unresponsive	Grimace, mild rejection	Cough or sneeze

From Mansmann RA, McAllister ES, Pratt PW, editors: *Equine medicine and surgery*, ed 3, vol 1, Santa Barbara, Calif, 1982, American Veterinary Publications.  
One should determine the score at 1 and 5 minutes after birth. Scores of 7 to 8 generally indicate a normal foal; 4 to 6, mild to moderate asphyxia; and 0 to 3, severe asphyxia. A score of 4 to 6 should prompt stimulation, intranasal oxygen, or mechanical ventilation. For a score of 0 to 3, one should begin cardiopulmonary resuscitation.

soon as the chest clears the birth canal. Bradycardia (pulse <40 beats/min) is expected during forceful contractions, and the pulse rate should increase rapidly once the chest clears the birth canal. Persistent bradycardia is an indication for rapid intervention.

The fetus is normally hypoxemic compared with the newborn foal, and this hypoxemia is largely responsible for the maintenance of fetal circulation by generation of pulmonary hypertension. The fetus responds to conditions producing more severe in utero hypoxia by strengthening the fetal circulatory pattern, and the neonate responds to hypoxia by reverting to the fetal circulatory pattern.<sup>2</sup> During a normal parturition mild asphyxia occurs and results in fetal responses that pave the way for a successful transition to extrauterine life. If more than mild transient asphyxia occurs, the fetus is stimulated to breathe in utero; this is known as *primary asphyxia*.<sup>3</sup> If the initial breathing effort resulting from primary asphyxia does not correct the asphyxia, a second gasping period occurs in several minutes, known as the *secondary asphyxia response*. If no improvement in asphyxia occurs during this period, the foal enters secondary apnea, a state that cannot be reversed except by resuscitation.

Therefore the first priority of neonatal resuscitation is establishing an airway and breathing pattern. The clinician should assume that foals not spontaneously breathing are in secondary apnea and should clear the airway of membranes as soon as the nose is presented. If meconium staining is present, the airway should be suctioned before delivery of the foal is complete and before the foal breathes spontaneously. One should continue to suction the trachea if aspiration of the nasopharynx is productive. Overzealous suctioning worsens bradycardia as it worsens hypoxia. Suctioning should be stopped once the foal begins breathing spontaneously because hypoxia will worsen with continued suction. If the foal does not breathe

or move spontaneously within seconds of birth, one should begin tactile stimulation. If tactile stimulation fails to result in spontaneous breathing, the foal should immediately be intubated and manually ventilated using an Ambu bag or equivalent. Mouth-to-nose ventilation can be used if nasotracheal tubes and an Ambu bag are not available. The goal of this therapy is to reverse fetal circulation, and hyperventilation with 100% oxygen is the best choice for this purpose. However, recent evidence suggests that no clinical disadvantages are apparent when room air is used for ventilation of asphyxiated human neonates rather than 100% oxygen.<sup>4,5</sup> Human infants resuscitated with room air recovered more quickly than those resuscitated with 100% oxygen in one study, as assessed by Apgar scores, time to the first cry, and the sustained pattern of breathing.<sup>6</sup> In addition, neonates resuscitated with 100% oxygen exhibited biochemical findings reflecting prolonged oxidative stress, present even after 4 weeks of postnatal life, which did not appear in the group resuscitated with room air. Thus the current accepted recommendations for using 100% oxygen in the resuscitation of asphyxiated neonates require further discussion and investigation.<sup>7,8</sup> Almost 90% of foals that need resuscitation respond to hyperventilation alone and require no additional therapy. One can initiate nasotracheal intubation while the foal is in the birth canal if the foal will not be delivered rapidly, such as with a difficult dystocia. This technique is "blind" and requires some practice but may be beneficial and lifesaving. Once spontaneous breathing is present, humidified oxygen should be administered by way of nasal insufflation at 8 to 10 L/min.

Cardiovascular support in the form of chest compression should be initiated if the foal remains bradycardic despite ventilation and a nonperfusing rhythm is present. The clinician should make sure that the foal is on a hard surface in right lateral recumbency with the topline against a wall or other support. Approximately 5% of foals are born with fractured ribs, and an assessment for the presence of rib fractures is in order before initiating chest compressions.<sup>9</sup> Palpation of the ribs identifies many of these fractures, which usually are multiple and consecutive on one side of the thorax and located in a relatively straight line along the part of the rib with the greatest curvature dorsal to the costochondral junction. Auscultation over the ribs during breathing results in a recognizable click, identifying rib fractures that may have escaped detection by palpation. Ultrasonography is the diagnostic modality of choice when evaluating for the presence or absence of rib fractures in foals.<sup>10</sup> Unfortunately, ribs 3 to 5 frequently are involved, and their location over the heart can make chest compression a potentially fatal exercise.<sup>11</sup>

Drug therapy should be initiated if a nonperfusing rhythm persists for more than 30 to 60 seconds in the face of chest compression. Epinephrine is the first drug of choice (Table 21-3). Practitioners pose various arguments regarding the best dose and the best frequency of administration for resuscitation. However, most of the data are derived from human cardiac arrest studies and are not strictly applicable to the equine neonate because the genesis of the cardiovascular failure is different.<sup>12,13</sup> Vasopressin is gaining attention as a cardiovascular resuscitation drug, and although the author has used this drug in resuscitation and as a pressor, experience is limited at this time and large doses of vasopressin may compromise gastrointestinal perfusion, according to some accounts.<sup>14-16</sup> The author does not use atropine in bradycardic newborn foals because the bradycardia usually is caused by hypoxia, and if

TABLE 21-3

Resuscitation Drugs Used for Cardiopulmonary Resuscitation of Foals*						
Drug	How Supplied	Per Kg	ml/Kg	DOSE		
				ml/30 Kg	ml/40 Kg	ml/50 Kg
Epinephrine (low dose)	1 mg/ml (1:1000)	0.01-0.02 mg	0.01-0.02	0.3-0.6 3-5 minutes	0.4-0.8	0.5-1
Epinephrine (high dose)	1 mg/ml (1:1000)	0.1-0.2 mg	0.1-0.2	3-6 3-5 minutes	4-8	5-10
Lidocaine	2% (20 mg/ml)	1.5 mg	0.075	2.25 Every 5 minutes for a maximum of 3 mg/kg	3	3.75
Bretylium	50 mg/ml	5-10 mg (30-35 mg/kg maximum dose)	0.1-0.2	3-6 10 minutes	4-8	5-10

\*Epinephrine is the most commonly used of the drugs.

the hypoxia is not corrected, atropine can increase myocardial oxygen debt.<sup>17</sup> The author also does not use doxapram in initial resuscitation because it does not reverse secondary apnea, the most common apnea in newborns. However, recent evidence suggests that doxapram may prove very useful for the treatment of persistent centrally mediated hypoventilation and deserves further study.<sup>18,19</sup>

Because birthing areas are generally cold, the foal should be dried and placed on dry bedding once resuscitation is complete. The fetus has some homeothermic mechanisms, but its size in relation to its mother and its position within her body means that it is in effect a poikilotherm. The body temperature of the foal generally reflects that of its environment, namely its dam, although the human fetal temperature directly measured at cesarean section, induction of labor, or during labor is approximately 0.5° C higher than the dam's.<sup>20-22</sup> Adaptation from poikilothermy to homeothermy normally takes place rapidly after birth. The fetus is capable of nonshivering thermogenesis, primarily through the oxidation of brown fat reserves, but this type of thermogenesis is inhibited in utero, probably by placental prostaglandin E<sub>2</sub> and adenosine.<sup>22,23</sup> Immediately after birth the foal must adapt to independent thermoregulation. Local physical factors, including ambient temperature and humidity, act to induce cold stress, and the newborn must produce heat by metabolic activity. In response to the catecholamine surge associated with birth, uncoupling of oxidative phosphorylation occurs within mitochondria, releasing energy as heat. This nonshivering thermogenesis is impaired in newborns undergoing hypoxia or asphyxiation and in those that are ill at birth. Infants born to mothers sedated with benzodiazepines are affected similarly, a consideration in the choice of sedative and preanesthetic medications in mares suffering dystocia or undergoing cesarean section.<sup>24-26</sup> Heat losses by convection, radiation, and evaporation are high in most areas where foals are delivered, resuscitated, and

managed, and one must take care to minimize cold stress in the newborn and the critically ill foal. Supplementary heat, in the form of radiant heat lamps or warm air circulating blankets, may be required.

Fluid therapy should be used conservatively during postpartum resuscitation, because the neonate is not volume depleted unless excessive bleeding has occurred. Some compromised newborn foals are actually hypervolemic. Fluid therapy for the neonate is discussed in more detail later in this chapter. Because the renal function of the equine neonate is substantially different from the adult's, fluid therapy cannot simply be scaled down from adult therapy.<sup>27-29</sup> If intravenous fluids are required for resuscitation and blood loss is identified, administration of 20 ml/kg of a non-glucose-containing polyionic isotonic fluid over 20 minutes (about 1 L for a 50-kg foal)—once intravenous access is established—can be effective. The author stresses non-glucose-containing polyionic intravenous fluids because hyperglycemia, but not hypoglycemia, immediately after fetal or neonatal asphyxia interfered with the recovery of brain cell membrane function and energy metabolism in neonatal piglets in one recent study.<sup>30</sup> These findings suggest that post-hypoxic-ischemic hyperglycemia is not beneficial and might even be harmful in neonatal hypoxic-ischemic encephalopathy. Indications for this shock bolus therapy include poor mentation; poorly palpable peripheral pulses; and the development of cold distal extremities, compatible with septic or hemorrhagic shock (or both). The patient should be reassessed after the initial bolus, and additional boluses should be administered as necessary. Ideally, the clinician should follow up on blood pressures and ECG readings and initiate appropriate inopressor therapy if needed. Again, these procedures are discussed in detail later in the chapter.

Glucose-containing fluids can be administered after resuscitation at a rate of 4 to 8 mg/kg/min (about 250 ml/hr of 5% dextrose or 125 ml/hr of 10% dextrose) to the average

50-kg foal, particularly in the obviously compromised foal. This therapy is indicated to help resolve metabolic acidosis, to support cardiac output (because myocardial glycogen stores likely have been depleted), and to prevent postasphyxial hypoglycemia. Under normal conditions the fetal-to-maternal blood glucose concentration gradient is 50% to 60% in the horse, and glucose is the predominant source of energy during fetal development.<sup>31,32</sup> Glucose transport across the placenta is facilitated by carrier receptors (glucose transporter [GLUT] receptors), and a direct relationship exists between maternal and fetal blood glucose concentration when maternal glucose is in the normal range.<sup>31</sup> The GLUT receptors in the placenta are stereospecific, saturable, and energy independent.<sup>33</sup> Although the enzyme kinetics for GLUT isoform 1 suggest that they are not saturable under conditions of euglycemia, equine maternal hyperglycemia results in increased fetal glucose concentration to a plateau point, likely caused by GLUT saturation.

At term the net umbilical uptake of glucose is 4 to 7 mg/kg/min, with most of the glucose being used by the brain and skeletal muscle.<sup>34-36</sup> The fetus develops gluconeogenesis only under conditions of severe maternal starvation. A certain percentage of the delivered glucose is used to develop large glycogen stores in the fetal liver and cardiac muscle in preparation for birth, and at birth the foal liver produces glucose at a rate of 4 to 8 mg/kg/min by using these stores. Fetal glycogen stores also are built using the substrates lactate, pyruvate, and alanine; fetal uptake of lactate across the placenta is about half that of glucose.<sup>31,37</sup> The transition to gluconeogenesis, stimulated by increased circulating catecholamine concentration from birth and by stimulation of glucagon release at the time the umbilical cord breaks, takes 2 to 4 hours in the normal foal, and glycogenolysis supplies needed glucose until feeding and glucose production are accomplished.<sup>38</sup> In the challenged foal glycogen stores may have been depleted and gluconeogenesis delayed, so provision of glucose at rates similar to what the liver would normally produce during this period is requisite.

## PERSISTENT PULMONARY HYPERTENSION

*Pamela A. Wilkins*

Persistent pulmonary hypertension (PPH) also is known as reversion to fetal circulation or persistent fetal circulation, and its genesis lies in the failure of the fetus to make the respiratory and cardiac transition to extrauterine life successfully or reversion of the newborn to fetal circulatory patterns in response to hypoxia or acidosis. Differentiating this problem from other causes of hypoxemia in the newborn requires some investigation, and multiple serial arterial blood gas analyses are necessary to confirm suspicion of this problem (see the section on arterial blood gas analysis, Respiratory Diseases Associated with Hypoxemia in the Neonate). However, the condition should be suspected in any neonate with hypercapnic hypoxemia that persists and worsens; these foals are in hypoxemic respiratory failure. The fetal circulatory pattern, with pulmonary hypertension and right-to-left shunting of blood through the patent foramen ovale and ductus arteriosus, is maintained in these cases.

Pulmonary vascular resistance falls at delivery to about 10% of fetal values, and pulmonary blood flow increases

accordingly.<sup>1</sup> Early in the postnatal period these two changes balance each other, and mean pulmonary and systolic pressures remain increased for several hours. Systolic pulmonary pressures can remain equivalent to systemic pressure for up to 6 hours of age in human infants, although diastolic pulmonary pressures are well below systemic diastolic pressures by 1 hour.<sup>2</sup> Mean pulmonary artery pressures fall gradually over the first 48 hours.<sup>3</sup> The direct effects of lung expansion and increasing alveolar oxygen tension probably provide the initial stimulus for pulmonary arteriolar dilation and partly result from direct physical effects, but vasoactive substances are released in response to physical forces associated with ventilation (e.g., prostacyclin).<sup>1</sup> Other vasoactive mediators thought to play a role in regulating pulmonary arteriolar tone include NO, prostaglandins D<sub>2</sub> and E<sub>2</sub>, bradykinin, histamine, endothelin-1, angiotensin II, and atrial natriuretic peptide. The increase in alveolar and arterial oxygen tensions at birth is required for completion of resolution of pulmonary hypertension. Much of this increase is thought to be mediated by NO, evidence for this being the parallel increase during gestation of the pulmonary vasodilation response to hyperoxia and the increase in NO synthesis.<sup>4</sup> However, inhibition of NO synthesis does not eliminate the initial decrease in pulmonary artery resistance occurring because of opening of the airways.<sup>5</sup>

When these mechanisms fail, PPH can be recognized. Right-to-left shunting within the lungs and through patent fetal conduits occurs and can result from many factors, including asphyxia and meconium aspiration, but in many cases the precipitating trigger is unknown. Inappropriately decreased levels of vasodilators (NO) and inappropriately increased levels of vasoconstrictors (endothelin-1) currently are being examined as potential mechanisms. One study of oxygen-dependent clone calves revealed increased neonatal and maternal endothelin concentrations.<sup>6</sup> Chronic in utero hypoxia and acidosis may result in hypertrophy of the pulmonary arteriolar smooth muscle.<sup>7</sup> In these cases reversal of PPH can be difficult and cannot be achieved rapidly.

Treatment of PPH is twofold: abolishment of hypoxia and correction of the acidosis, because both abnormalities only bolster the fetal circulatory pattern. Initial therapy is provision of oxygen intranasally at 8 to 10 L/min. Some foals respond to this therapy and establish neonatal circulatory patterns within a few hours. Failure to improve or worsening of hypoxemic respiratory failure after intranasal oxygen administration should prompt intubation and mechanical ventilation with 100% oxygen. This serves two purposes, one diagnostic and one therapeutic. Ventilation with 100% oxygen may resolve PPH and, if intrapulmonary shunt and altered ventilation-perfusion relationships are causing the hypoxic respiratory failure, arterial oxygen tension (Pao<sub>2</sub>) should exceed 100 mm Hg under these conditions. Failure to improve Pao<sub>2</sub> suggests PPH or large right-to-left extrapulmonary shunt caused by congenital cardiac anomaly. The vasodilators prostacyclin and telazolone cause pulmonary vasodilation in human infants with PPH, but the effects on oxygenation vary and the adverse effects (e.g., tachycardia, severe systemic hypotension) are unacceptable.<sup>8</sup> Recognition of NO as a potent dilator of pulmonary vessels has created a significant step forward in the treatment of these patients, because inhaled NO dilates vessels in ventilated portions of the lung while having minimal effects on the systemic circulation.<sup>9</sup> According to presently available evidence, use of inhaled NO in an initial concentration of about 20 ppm in the ventilatory gas seems reasonable for term and near-term foals with hypoxic respiratory failure and PPH

that fails to respond to mechanical ventilation using 100% oxygen alone.<sup>9,10</sup> The author has used this approach in the clinic, administering a range of 5 to 40 ppm NO with success.

## NEONATAL NEUROLOGICAL EXAMINATION AND SELECTED DISORDERS

Peter R. Morresey

The goals of the neonatal neurologic examination are similar to those of the adult horse: neuroanatomic localization of any lesions present to suggest a diagnosis and thereby help formulate a rational treatment plan. Examination of the neonate should make allowances for the relative lack of maturity of many body systems.

### ☞ NORMAL DEVELOPMENT

The neonatal foal has a strong desire to become sternally recumbent within minutes of birth.<sup>1</sup> Most foals stand within 1 hour of delivery, with pony foals standing sooner and larger breeds taking up to 2 hours. The reported range is 15 to 165 minutes.<sup>1</sup> Compromised neonates tend to remain recumbent longer. Initial attempts to stand are poorly coordinated, may be fleeting, and result in a wide-based stance. Once successful, the foal rapidly develops a more appropriate posture and the ability to ambulate freely in search of the mare.

The suckle reflex is present 5 to 10 minutes after birth. Foals actively suckle without the benefit of the udder. Even in the recumbent foal, extension of the tongue and suckling of air occurs. Although there are breed and size variations, most foals suckle the mare within 2 hours of birth, with greater than 3 hours considered an abnormal finding. The reported range of time until suckling is from 35 minutes to 7 hours.<sup>1</sup>

Foals tend to display a strong avoidance of handlers, seeking the shelter of the far side of the mare. If recumbent, they are easily roused, rise up, and seek the mare for suckling. When restrained within the first few hours of life, neonates become very relaxed (cataplectic).

### NEUROLOGIC EXAMINATION

The neurologic examination is part of a more comprehensive assessment of the neonate. History taking and a thorough physical evaluation of the entire foal should precede assessment of any individual body system. Included in the process should be a complete assessment of the mare's medical and reproductive health. It is important to develop a comprehensive, systematic, and repeatable approach to examination. This should include observation from a distance, evaluating conformation, mentation, and behavior. More specific aspects of the examination assess cranial nerve function and spinal reflexes.

#### BEHAVIOR

General behavior of the neonate centers on feeding, investigating the surrounding environment, and evaluating its association with the mare. The degree of affinity for the mare is an important indicator of abnormal behavior. Loss of affinity for the mare, or lack of vigorous pursuit of nutrition, may be

signs of hypoxic ischemic encephalopathy. Foals should struggle vigorously when first restrained; however, it is normal for them to become limp when compressed along their long axis and to display submissive behavior.

#### SUCKLE REFLEX

This reflex is present uniformly in normal foals. Loss of the suckle reflex may be the first indication of neurologic dysfunction and also be the last reflex to return once the foal recovers. Suckling is an instinctive process, although adequate cerebral function and an intact motor supply to the tongue (intact hypoglossal nerve) are necessary.

#### CRANIAL NERVE EXAMINATION

Evaluation of cranial nerve responses follows the familiar pattern of the adult, with allowance for the diminished strength of any reflex arcs. Care should be exercised by the examiner because vigorous head movements usually accompany any stimulus.

Pupillary light responses are sluggish at birth. In one study all foals had a positive pupillary light response on the first day post partum.<sup>2</sup> Pupil shape is rounded for the first 3 to 5 days of life, assuming a more adult-like shape after this period.<sup>3</sup> The pupillary light reflex arc is located in the brainstem and does not require a normal cerebral visual cortex.<sup>4</sup> Therefore the presence of an appropriate pupillary light response does not indicate the absence of a visual deficit.

Similar to that of mature horses, the pupillary light response in foals is biphasic, consisting of an initial rapid but small reduction in pupil diameter, followed by a slower and more complete constriction. Because of sympathetic stimulation from excitement or stress, the latter phase of this response can be overridden.<sup>4</sup>

The menace response may have to be learned or is due to an initial immaturity of the cerebellum.<sup>3,4</sup> The reflex is incompletely developed up to 2 weeks of age.

#### GAIT EVALUATION

Gait should be examined by observation at a short distance with the foal freely moving in the paddock or stall. Compared with those of adults, limb movements during ambulation of the neonatal foal can appear dysmetric, although this rapidly improves with exercise.<sup>4</sup> Foals that have undergone confinement have a delayed onset of an appropriate adult-like gait.

#### SPINAL REFLEXES

Spinal reflexes are assessed with the foal in lateral recumbency. The limbs respond to abrupt pressure on the sole of the hooves by rapidly extending. Although extensor tone predominates, continued gentle pressure will allow complete flexion of the limbs. Reflexes are hyperactive compared with adult responses. The crossed extensor reflex is brisk in response to withdrawal of the contralateral limb.

Spinal ataxia occurs in newborn foals but is less common than disease of cerebral origin. When diagnosed, it is most likely the result of congenital malformation, vascular accident, or trauma during the birth process.<sup>4</sup>

#### SEIZURE ACTIVITY

Recognition of seizure activity in the neonatal foal is problematic; however, it is essential to the successful management of neurologically compromised neonates. Subtle seizure signs include abnormal eye movement, tremors, excessive stretching when recumbent, excessive extensor tone, hyperaesthesia

to touch and manipulation, and apneustic breathing.<sup>1</sup> Overt seizure activity is easier to discern, with rapid nystagmus, paddling, hyperextension, and excessive mouth movements (“chewing gum fits”). Unobserved episodes may result in signs of physical trauma (e.g., nasolabial and gingival excoriation). Seizure activity is an indication of central (cranial to the foramen magnum) neurologic dysfunction.

## DIFFERENCES FROM THE ADULT EXAMINATION

In summary, neurologic responses of foals tend to be exaggerated compared with adults.<sup>5</sup> Posture and movement of the foal’s head is noticeably different from the adult’s, the occipitoatlantal joint being more flexed, with jerking head movements resembling cerebellar dysfunction in the adult. Foals are much more sensitive to touch than are adults, with exaggerated responses to all tactile stimuli. Cranial nerve (CN) responses are similar to those of the adult but accompanied by head movements, as described above. The globe has a ventromedial deviation in the normal neonate, assuming an adult positioning within 1 month. Care should be taken not to misconstrue strabismus resulting from cerebral dysfunction. The menace response is absent at birth and may take up to 14 days of age to develop. Responses of the sensory CN V motor CN VII reflex arc appear comparatively weak compared with those of the adult. Extensor limb muscle tone predominates, most noticeably when in lateral recumbency. Limb reflexes, however, are exaggerated, with a brisk crossed-extensor reflex present in the forelimbs up to 3 weeks of age. When the foal is ambulating, its gait is stilted, with the predominant extensor tone giving the appearance of hypermetria.

## NEUROANATOMIC LOCATION OF LESIONS<sup>6</sup>

The most common neurologic problems of foals include depression, seizure activity, abnormal behavior, loss of affinity for the mare, and loss of the suckle reflex. All these signs are referable to dysfunction of the brain. Expression of neurologic lesions depends on the stage of development during which the inciting damage occurred (Table 21-4).

## DIAGNOSTIC AIDS

### COMPLETE BLOOD COUNT AND SERUM CHEMISTRY

Assessment of the systemic health of foals with neurologic problems is essential. A complete blood count indicates the likelihood of systemic infection or potential for ongoing tissue hypoxia as a result of anemia. Serum chemistry evaluation gives insight into major organ system function. Assessment of immunoglobulin G (IgG) levels is a direct measure of the transfer of passive immunity from the mare, which is essential in the otherwise hypogammaglobulinemic neonatal foal. Blood gas evaluation assesses the integrity of pulmonary gas exchange and enables determination of acid-base status.

### CEREBROSPINAL FLUID ANALYSIS

Cytologic and microbiologic analysis of cerebrospinal fluid is essential in suspected cases of meningitis. Care should be taken to ensure that causes of increased intracranial pressure have been ruled out before aspiration from the atlanto-occipital space because herniation of the brain through the foramen magnum is possible.

## IMAGING

Both radiography and magnetic resonance imaging have been reported in the diagnosis of neonatal neurologic disease. Characteristic bony changes are present with congenital malformations, and disruption of bony structures by trauma can be visualized. Both plain and contrast studies are possible. Magnetic resonance imaging is invaluable in the assessment of soft tissue or vascular disruption.<sup>7,8</sup>

## PATHOPHYSIOLOGY OF NEUROLOGICAL DISEASE

Neonatal hypoxic-ischemic brain injury is the product of many biochemical cascades. Understanding of the mechanisms of this injury is largely derived from experimental studies involving neonatal laboratory and production animal species. Cerebral ischemia may result from systemic hypoxemia depressing myocardial performance. Reduced cerebral blood flow results in decreased delivery of oxygen and energy substrates to the brain, resulting in a combined hypoxic-ischemic insult. Anaerobic metabolism depletes the brain’s stores of glucose and high energy phosphates (adenosine-5'-triphosphate [ATP] and phosphocreatine), with resulting accumulation of lactate and inorganic phosphate.<sup>8</sup> Energy failure impairs glutamate uptake, resulting in extracellular accumulation, which in turn leads to tonic overstimulation of postsynaptic excitotoxic amino acid receptors (excitotoxicity). Reperfusion and reoxygenation in the early posts ischemic recovery period after this insult are themselves harmful.

Maternal infection is strongly associated with neonatal brain injury.<sup>9</sup> Intrauterine infection may indirectly injure the brain through the induction of sepsis and poor perfusion or directly by the production of inflammatory mediators that devitalize neurons.<sup>10</sup>

The neonatal brain is highly susceptible to free radical-mediated injury.<sup>11</sup> Under normal conditions mitochondrial function generates low concentrations of superoxide anion and hydrogen peroxide. These are scavenged by multiple enzyme systems, including superoxide dismutase, catalase, and glutathione peroxidase. Other nonenzymatic antioxidants include  $\alpha$ -tocopherol (vitamin E) and ascorbic acid (vitamin C). During reperfusion after ischemia, oxygen free radicals react with membrane phospholipids to form oxidized lipids with pro-inflammatory actions.<sup>12</sup>

Regardless of the inciting cause, neural injury results in an increased release of neurotransmitters that in turn generates an excess of second messengers, apoptosis, and increases in intracellular sodium and calcium.<sup>12</sup> Accumulation of sodium concurrent with failure of energy-dependent cell membrane ion pumps (e.g., Na<sup>+</sup>-K<sup>+</sup> ATPase) leads rapidly to cell swelling. Accumulation of calcium caused by glutamate excess and mediated by *N*-methyl *D*-aspartate (NMDA) receptors can lead to activation of calcium-dependent phospholipases, NO synthase, and proteases. Increased activation of phospholipase A<sub>2</sub> (PLA<sub>2</sub>) in postsynaptic neurons results in increased free arachidonic acid and platelet-activating factor (PAF), enhancing glutamate-mediated neurotransmission and further potentiating NMDA receptor activity, while decreasing glutamate reuptake. Cerebral ischemia induces cyclo-oxygenase-2 (COX-2) expression, facilitating metabolism of arachidonic acid to inflammatory lipid mediators. A self-reinforcing cycle is therefore initiated.<sup>13,14</sup>

TABLE 21-4

**Neuroanatomic Localization Based on Results of Neurologic Examination**

Evaluation	Pathways	Major Signs of Disorder
Behavior	Forebrain (mostly cerebrum)	Reduced affinity for dam, restlessness, head-pressing, compulsive walking
Alertness	All of brain	Lethargy, stupor, semicoma, coma
Avoidance, nasal	V,* pons, cerebral cortex II	Facial hypalgesia
Avoidance, visual	II, thalamus, cerebral cortex	Blindness
Head position	VIII, hindbrain	Head tilt, turn, body lean, walking in circles, ataxia, aystagmus
Eye position and movement	III, IV, VI, VIII, midbrain, hindbrain	Strabismus, nystagmus
Flick reflexes	V, VII, pons, hindbrain	Facial paralysis, facial hypalgesia, absent flick reflexes
Dazzle reflex	II, subcortex, midbrain, VII	Absent dazzle reflex
Pupillary light reflex	II, midbrain, III	Absent papillary light reflex
Suckle	V, VII, XII, pons, hindbrain, cerebrum	Weak or absent suckle
Swallow	IX, X, hindbrain	Flow of milk from the nose
Cervicofacial reflex	Cervical spinal nerves and spinal cord, VII, (hindbrain)	Diminished cervicofacial reflex
Cutaneous trunci reflex	Thoracic spinal nerves and spinal cord, brachial plexus, lateral thoracic nerve	Diminished reflex caudal to spinal cord lesion
Cutaneous sensation	Peripheral nerves, spinal cord, cerebral cortex	Cutaneous hypalgesia/anesthesia
Gait	VIII, cerebellum, hindbrain, spinal cord, peripheral nerves	Ataxia
Limb strength	Spinal cord, peripheral nerves	Limb weakness at or caudal to the level of the lesion
Flexor reflex (pelvic), patella, sciatic reflexes	Spinal cord, peripheral nerves (L3-S2)	Pelvic limb weakness, diminished or absent reflexes
Flexor reflex (thoracic), biceps, triceps reflexes	Spinal cord, peripheral nerves (C6-T2)	Weakness of thoracic with or without pelvic limbs, diminished or absent reflexes
Anal/tail clamp reflex	Spinal cord, cauda equine, peripheral nerves (S2-Co)	Reduced or absent anal/tail clamp reflex

From MacKay RJ: Neurologic disorders of neonatal foals, *Vet Clin North Am Eq Pract* 21:387-406, 2005.

Co, coccygeal spinal cord segments.

\*Roman numerals refer to cranial nerves.

A number of early equine neonatal studies have shown the presence of intracranial hemorrhage associated with neurologic compromise. Compared with a control group, convulsive foals that were receiving only treatments common at that time showed hemorrhage in various locations of the brain at necropsy in one early study.<sup>15</sup> Also present was necrosis of the cerebral cortex, diencephalon, and brainstem. Minimal hemorrhage occurred in the brains of control foals. In a second study CNS hemorrhage was found more frequently in premature foals compared with those born at full term, in foals born dead compared with live births, and in foals born after assisted delivery compared with foals born without intervention. Cerebral disease was associated with vascular accidents in the brain, and foals with spinal cord disease had hemorrhage restricted to that area.<sup>16</sup> In a third study, meningeal lesions were a common necropsy finding in foals dying perinatally.<sup>17</sup> There are no recent studies reporting similar findings, perhaps a reflection of improved treatment and fewer neonatal losses resulting from neurologic diseases.

## THERAPEUTIC RATIONALE FOR TREATMENT AGENTS

In addition to generalized supportive therapies, such as meeting metabolic requirements and fluid support, specific therapeutic agents are used in the treatment of neonatal neurologic disorders.

### MAGNESIUM

Magnesium ions ( $Mg^{2+}$ ) are essential for the function of a variety of cellular processes, including oxidative phosphorylation, glycolysis, cellular respiration, and synthesis of deoxyribonucleic acid (DNA), ribonucleic acid (RNA), and protein.<sup>18</sup> Magnesium ions also act as cofactors for many enzymes, including those involved in the maintenance of ion transport systems, DNA damage, and DNA repair. Alterations in magnesium ion homeostasis may therefore have significant physiologic consequences. Magnesium has been proposed as a pharmacologic intervention in brain injury

that inhibits secondary injury factors, including glutamate release, activity of the NMDA receptor, calcium channels, lipid peroxidation, free radical production, edema formation, and alterations of mitochondrial permeability. Magnesium treatment also reduces apoptosis and expression of p53-related proteins.<sup>19</sup>

The use of magnesium supplementation is controversial, however, with one meta-analysis review showing neither benefit nor harm resulting from its use in traumatic brain injury in human adults.<sup>20</sup>

### DIMETHYL SULFOXIDE

Dimethyl sulfoxide (DMSO) rapidly reduces increased intracranial pressure (ICP), increases cerebral perfusion pressure (CPP), and improves neurologic outcome without affecting systemic blood pressure and patient responsiveness.<sup>21</sup> Acting as a free radical scavenger agent, DMSO has a protective effect on the spinal cord during ischemic insult.<sup>22</sup> The production of free radicals has been implicated in neonatal brain injury.<sup>23</sup>

### KETAMINE

NMDA-receptor antagonism, in addition to being the most important mechanism causing the analgesic effects of ketamine, is also thought responsible for its purported neuroprotective action.<sup>24</sup> Blockade of excitatory transmission at the NMDA receptor provides an approach to the initial treatment of cerebral ischemia.<sup>25</sup> Blockage of excessive NMDA receptor stimulation allows regulation of intracellular calcium levels and attenuated induction of NO, reducing neuronal degeneration and death. Cellular morphology is preserved, cellular energy status and ATP production is protected, and reduced cell swelling was noted subsequent to anoxia-hypoxia or excitatory neurotransmitter injury.<sup>26</sup>

### CORTICOSTEROIDS

The use of anti-inflammatory corticosteroids during a CNS insult is controversial. Glucocorticoids increase expression of pro-apoptotic cell mediators and hypoxic-responsive genes, potentially enhancing a metabolic insult such as hypoxia.<sup>27</sup> A multicenter human medical trial showed an increase in mortality with corticosteroids, suggesting deleterious effects with traumatic head injury.<sup>28</sup>

### OSMOTIC AGENTS

**Mannitol and Hypertonic Saline** The primary mechanism of action is to draw water out of the intracellular and interstitial spaces, resulting in temporary brain shrinkage. Cardiac and hemodynamic effects also occur. Mannitol and hypertonic saline appear to be equally effective at reducing ICP in brain-injured patients. Equiosmolar doses of 20% mannitol and 7.5% saline have produced similar changes in ICP.<sup>29</sup>

### ANTIOXIDANTS

**Acetylcysteine** Free radical production (reactive oxygen species, reactive nitrogen species) is considered an important mediator of both inflammation and hypoxia-ischemia-induced perinatal brain injury. *N*-acetylcysteine has been shown to protect both gray and white matter during these events, likely the result of enhancement of antioxidative responses, attenuation of reactive oxygen species production, inhibition of apoptosis, and reduction of inflammation.<sup>30</sup>

**Vitamin C** Vitamin C (ascorbic acid) was shown to be neuroprotective when assessing damage percentage and

macroscopic appearance of brain injury and cell death. The protective effect was not dose dependent.<sup>31</sup>

**Vitamin E** Oxygen radical-mediated lipid peroxidation is an important factor in neuronal degeneration, as shown by the beneficial effects of agents with lipid antioxidant activity (vitamin E,  $\alpha$ -tocopherol) in models of spinal cord and brain injury. The slow CNS tissue uptake of vitamin E requires chronic dosing, making it an impractical agent for treatment of acute neural injury. The peroxy radical scavenging chromanol portion of vitamin E is the neuroprotective agent.<sup>32,33</sup>

## SELECTED CONGENITAL DISORDERS

### HYDROCEPHALUS

In one central Kentucky study, hydrocephalus was found to be present in 3% of deformed fetuses or newborn foals requiring euthanasia.<sup>34</sup> Detection by magnetic resonance imaging (MRI) has been reported.<sup>7</sup> Clinical signs were reported to be similar to hypoxic ischemic encephalopathy (HIE), with a depressed suckle reflex and failure to thrive. Marked dilation of the cerebral ventricles was present, with other intracranial structures reported as normal.

### OCCIPITOATLANTOAXIAL MALFORMATION

Although isolated cases occur in other breeds, occipitoatlantoaxial malformation (OAAM) is predominantly a condition of newborn to juvenile Arabian foals.<sup>35</sup> Presenting signs include a progressive ataxia and tetraparesis, although stillbirth and sudden death have been reported. Physical findings include a palpably abnormal atlas and axis, with reduced flexion and audible clicking upon manipulation of the head. Confirmation requires radiologic evaluation, with the presence of occipitoatlantal fusion, hypoplasia of the dens, and inappropriate localized ossification.<sup>7</sup>

### NARCOLEPSY AND CATAPLEXY

Narcolepsy is the sudden uncontrollable onset of deep sleep. Cataplexy is the sudden loss of muscle tone and strength, often leading to collapse. Consciousness is not affected with cataplexy; however, cataplexy often occurs concurrently with narcolepsy.

Both narcolepsy and cataplexy may transiently occur in Thoroughbred and miniature foals. The application of compressive manual restraint over a wide area of a foal's body may induce a cataplectic state, thought to be an adaptation to the restrictive in utero environment of late pregnancy.<sup>36</sup> Diagnosis is made by differentiating the condition from syncope, the result of transient cerebral hypoxia caused by a cardiac abnormality, and seizure activity.

## SELECTED ACQUIRED DISORDERS

### HYPOXIC ISCHEMIC ENCEPHALOPATHY

HIE is discussed in a preceding section and has been widely reviewed. Excitatory amino acids, calcium ions, free radicals, NO, pro-inflammatory cytokines, and products of lipid peroxidation are all thought to be involved in the syndrome. The immature brain is considered to have increased susceptibility

to excitotoxicity and free radical injury and a greater tendency to undergo apoptotic cell death.<sup>11,37</sup>

In addition to the neurologic manifestations of HIE, respiratory compromise, renal insufficiency, and gastrointestinal ileus with or without mucosal compromise can occur. Aberrant pulmonary function can result in abnormal gas exchange, in particular decreased ventilation leading to retention of carbon dioxide. As a result, central depression and abnormal blood acid-base balance may result. Renal compromise leads to electrolyte and fluid balance derangements. With the loss of normal gastrointestinal function, diarrhea and sepsis can result from intestinal bacterial overgrowth.

## TRAUMA

Traumatic injury should always be considered after the rapid onset of neurologic disease in the neonatal foal.<sup>1,4</sup> Overt signs of trauma may not be apparent and require diagnostic imaging to detect. The presence of blood at the nares or external auditory canal, palpable loss of symmetry of the skull, and the ability to elicit pain upon palpation of the cranium are strong evidence of trauma.

## BACTERIAL MENINGITIS

Presenting symptoms of bacterial meningitis may be indistinguishable from those of HIE. Bacterial meningitis is an occasional result of sepsis.<sup>38</sup> Organisms recovered from meningitis cases are the same as those present in sepsis. Inflammation of the meninges is suggested by reluctance to move the neck, opisthotonus, proprioceptive deficits, or stupor. As inflammation progresses, cerebral blood flow decreases, leading to ischemic damage and further neurologic dysfunction.

## ELECTROLYTE DERANGEMENTS

Abnormal electrolyte concentrations often result from systemic conditions such as sepsis, enteritis, rhabdomyolysis, acute renal failure, and ruptured urinary bladder. Acute adrenal insufficiency rarely occurs and can be confused with these conditions.<sup>39</sup> Disorders of sodium homeostasis disrupt osmotic equilibrium, leading to cell swelling (deficiency) or shrinkage (excess), with clinical signs ranging from depression to seizure activity.

## KERNICTERUS

Elevated levels of unconjugated bilirubin have been demonstrated in neonatal liver disease, neonatal isoerythrolysis, glucose-6-phosphate dehydrogenase deficiency, and other causes of intravascular hemolysis.<sup>40</sup> Newborn foals are more susceptible to hyperbilirubinemia and bilirubin encephalopathy than are adults because of increased bilirubin production, decreased hepatic bilirubin uptake and conjugation, and an underdeveloped blood-brain barrier that unconjugated bilirubin can easily cross. Mitochondrial function and calcium homeostasis are disrupted, inducing neuronal degeneration, necrosis, and apoptosis.

## BOTULISM

Botulism, caused by *Clostridium botulinum* (eight different toxins), is a progressive flaccid paralysis resulting from blocking of acetylcholine release at neuromuscular junctions (see Chapter

12). Diagnosis is aided by eliminating other causes of neurologic disease. Associated in adults with suspected spoiled feed ingestion, a toxicoinfectious form in the neonate is most commonly incriminated, similar to that seen in human infants with botulism, wherein the neonatal intestinal milieu allows germination of *C. botulinum* spores with subsequent liberation and local absorption of toxin.

Monovalent and polyvalent antitoxin preparations are available, but they are expensive. The antitoxin is most beneficial if used when foals first display suggestive signs. With antitoxin administration and intensive supportive care, recovery occurs in most cases, but severe intoxications may require mechanical ventilation; even so, the affected foal may succumb.<sup>41,42</sup> Death is generally due to respiratory failure secondary to paralysis of the muscles of respiration. Aspiration pneumonia and sepsis, resulting from prolonged recumbency, and decubital ulceration may occur if strict attention to prevention is not maintained.

## PERINATAL ASPHYXIA SYNDROME

Pamela A. Wilkins

HIE, currently referred to as *neonatal encephalopathy* in human literature, is one systemic manifestation of a broader syndrome of perinatal asphyxia syndrome (PAS), and management of foals that exhibit signs consistent with a diagnosis of HIE requires the clinician to examine other body systems and provide therapy directed at treating other involved systems.<sup>1</sup> Although PAS primarily manifests as HIE, the gastrointestinal tract and kidneys frequently are affected by peripartum hypoxia-ischemia-asphyxia, and one should expect complications associated with these systems. HIE also may affect the cardiovascular and respiratory systems, and endocrine disorders may emerge in these patients.

HIE has been recognized as one of the most common diseases of the equine neonate for generations.<sup>2-4</sup> Typically, affected foals are normal at birth but show signs of CNS abnormalities within a few hours after birth. Some foals are obviously abnormal at birth, and some do not show signs until 24 hours of age. HIE commonly is associated with adverse peripartum events, including dystocia and premature placental separation, but a fair number of foals have no known peripartum period of hypoxia, which suggests that these foals result from unrecognized in utero hypoxia (Box 21-2). Severe maternal illness also may result in foals born with PAS. In human beings ascending placental infection now is suspected as a major contributor to neonatal encephalopathy in infants, and the incidence of neonatal encephalopathy increases with the presence of maternal fever, suggesting a role for maternal inflammatory mediators.<sup>5</sup>

Perinatal brain damage in the mature fetus usually results from severe uterine asphyxia caused by an acute reduction of uterine or umbilical circulation. The loss of oxygen results in a substantial decrease in oxidative phosphorylation in the brain with concomitant decreased energy production. The Na<sup>+</sup>/K<sup>+</sup> pump at the cell membrane cannot maintain the ionic gradients, and the membrane potential is lost in the brain cells. In the absence of the membrane potential, calcium flows down its large extracellular-intracellular concentration gradient through voltage-dependent ion channels into the cell.

## BOX 21-2

## CAUSES OF HYPOXIA IN THE FETUS AND NEONATE

**Maternal Causes**

- Reduced maternal oxygen delivery
  - Maternal anemia
  - Maternal pulmonary disease with hypoxemia
  - Maternal cardiovascular disease
- Reduced uterine blood flow
  - Maternal hypotension (endotoxemia/colic)
  - Maternal hypertension (laminitis/painful conditions)
  - Abnormal uterine contractions
  - Anything that increases uterine vascular resistance
- Placental Causes
  - Premature placental separation
  - Placental insufficiency; for example, twins
  - Placental dysfunction
    - Fescue toxicity
    - Postmaturity
    - Placentitis
    - Placenta edema
- Reduced umbilical blood flow
  - General anesthesia of the dam
  - Congenital cardiovascular disease
  - Inappropriate fetal blood distribution
  - Fetal hypovolemia
  - Excessive length of umbilical cord

**Intrapartum Causes**

- Dystocia
- Premature placental separation
- Uterine inertia

- Oxytocin induction of labor
- Cesarean section
  - General anesthesia
  - Poor uterine blood flow because of maternal positioning
  - Decreased maternal cardiac output
  - Reduced umbilical blood flow
  - Effects of anesthetic drugs on fetus
- Anything that prolongs stage 2 labor

**Neonatal Period Causes**

- Prematurity
- Recumbency
  - Musculoskeletal disease
  - Sepsis
  - Prematurity
  - Mild hypoxic ischemic encephalopathy
- Pulmonary disease
  - Meconium aspiration
  - Milk aspiration
  - Persistent pulmonary hypertension
  - Septic pneumonia
  - Acute respiratory distress syndrome or acute lung injury
- Severe disturbance in breathing pattern
- Septic shock
- Anemia
  - Neonatal isoerythrolysis
  - Excessive umbilical bleeding
  - Fractured ribs(hemothorax) or long bone fracture
- Congenital cardiovascular disease

Adapted from Palmer JE: Perinatal hypoxic-ischemic disease. *Proceedings of the International Veterinary Emergency Critical Care Symposium*, San Antonio, Tex, 1998, pp. 717-718.

This calcium overload of the neuron leads to cell damage by activation of calcium-dependent proteases, lipases, and endonucleases. Protein biosynthesis is halted. Calcium also enters the cells by glutamate-regulated ion channels as glutamate, an excitatory neurotransmitter, is released from presynaptic vesicles following anoxic cellular depolarization. Once the anoxic event is over, protein synthesis remains inhibited in specific areas of the brain and returns to normal in less vulnerable areas of the brain. Loss of protein synthesis appears to be an early indicator of cell death caused by the primary hypoxic-anoxic event.<sup>6</sup>

A second wave of neuronal cell death occurs during the reperfusion phase and is thought to be similar to classically described postischemic reperfusion injury in that damage is caused by production and release of oxygen radicals, synthesis of NO, and inflammatory reactions.<sup>7</sup> Additionally, an imbalance between excitatory and inhibitory neurotransmitters occurs.<sup>6</sup> Secondary cell death also is thought to be caused by the neurotoxicity of glutamate and aspartate, resulting again from increased intracellular calcium levels.<sup>8,9</sup> In human infants the distribution of lesions with hypoxic-ischemic brain damage after prenatal, perinatal, or postnatal asphyxia falls into distinct patterns depending on the type of hypoxia-ischemia rather than on the postconceptual age at which the asphyxial event occurs.<sup>9</sup> Periventricular

leukomalacia was associated with chronic hypoxia-ischemia, whereas the basal ganglia and thalamus were affected primarily in patients experiencing acute profound asphyxia, providing direct evidence that the nature of the event determines the severity and distribution of neurologic damage in human beings. This has important implications in the design of neuroprotective strategies and therapies for neonates experiencing hypoxic-ischemic-asphyxial events. Evidence is overwhelming that the excitotoxic cascade that evolves during HIE extends over several days from the time of insult and is modifiable.<sup>8,9</sup>

Excitatory amino acid neurotransmitters and magnesium are known to play at least a minimal role in secondary cell death after brain injury; a fair body of literature regarding these factors has been generated over the last 10 years. The activation of the NMDA subtype of glutamate receptors is implicated in the pathophysiology of traumatic brain injury and is suspected to play a role in HIE.<sup>8-10</sup> Mechanically injured neurons demonstrate a reduction of voltage-dependent  $Mg^{2+}$  blockade of NMDA current that can be restored partially by increasing extracellular  $Mg^{2+}$  concentration or by pretreatment with calphostin C, a protein kinase C inhibitor.<sup>11</sup> Clinical trials investigating the efficacy of magnesium treatment following hypoxia in infants are ongoing, with few reports currently in the medical literature.<sup>12</sup>

Therapy for the various manifestations of hypoxia-ischemia involves control of seizures; general cerebral support; correction of metabolic abnormalities; maintenance of normal arterial blood gas values; maintenance of tissue perfusion; maintenance of renal function; treatment of gastrointestinal dysfunction; prevention, recognition, and early treatment of secondary infections; and general supportive care. Control of seizures is important because cerebral oxygen consumption increases fivefold during seizures. Diazepam or midazolam can be administered for emergency control of seizures (Table 21-5). If a single-bolus administration of diazepam or midazolam does not readily stop seizures or more than two seizures are recognized, treatment with midazolam by constant-rate infusion may be of benefit.<sup>11,13</sup> For very refractory seizures phenobarbital may be combined with midazolam by constant-rate infusion or given singly to effect. The half-life of phenobarbital can be long in the foal (100 hours), and the clinician should keep this in mind when monitoring neurologic function in these cases after phenobarbital administration.<sup>14,15</sup> If phenobarbital fails to control seizures, phenytoin therapy may be attempted. In cases of HIE ketamine and xylazine should not be used because of their association with increased ICP. The foal must be protected from injury during a seizure, and the patency of the airway must be ensured to prevent the onset of negative pressure pulmonary edema<sup>16</sup> or aspiration pneumonia.

Probably the most important therapeutic interventions are aimed at maintaining cerebral perfusion, which is achieved by careful titration of intravenous fluid support, neither too much nor too little (see the section on fluid therapy in neonates) and judicious administration of inotropes and pressors to maintain adequate perfusion pressures (see the section on pressor and inotrope therapy). Cerebral interstitial edema is only truly present in the most severe cases;<sup>17,18</sup> in most cases the lesion is intracellular edema and most of the classic agents used to treat cerebral interstitial edema (e.g., mannitol and hypertonic saline) are minimally effective treating cellular edema. The author occasionally uses thiamine supplementation in the intravenous fluids to support metabolic processes, specifically mitochondrial metabolism and membrane Na<sup>+</sup>,K<sup>+</sup>-ATPases,

involved in maintaining cellular fluid balance.<sup>19,20</sup> This therapy is rational and inexpensive, its efficacy is unproven. Only if cellular necrosis and vasogenic edema are present are drugs such as mannitol, hypertonic saline, or DMSO indicated, and again these cases are usually the most severely affected. The author has not used DMSO in neonates for the last decade and has not recognized a change in outcome by discontinuing its use. Naloxone has been advocated for treating HIE in human beings and in foals.<sup>21-23</sup> The use of naloxone in human neonatal resuscitation remains controversial; whether the effects are related to a reduction in acute neuronal swelling by osmotic effects or by a more direct receptor-mediated mechanism is currently unknown.<sup>24</sup> Some practitioners are using  $\gamma$ -aminobutyric acid adrenergic agonists to manage HIE in foals on the basis of evidence showing neuroprotection when used in ischemia alone and combined with NMDA antagonists.<sup>25-27</sup> The author currently has no experience with these compounds and cannot comment regarding their efficacy in foals. Regional hypothermia also is being investigated as a potential therapy for global hypoxia-ischemia; published data are consistent with the theory that cooling must be continued throughout the entire secondary phase of injury (about 3 days) to be effective.<sup>28</sup> Experimentally, this approach has resulted in dramatic decreases in cellular edema and neuronal loss; its practical application remains to be demonstrated.

Despite the lack of consensus regarding the use of magnesium to treat infants with HIE, the author has used magnesium sulfate infusion as part of the therapy for selected foals with HIE for the past several years. The rationale is based primarily on the evidence demonstrating protection in some studies and a failure of any one study to demonstrate significant detrimental effects. The clinical impressions of the author to date suggest that the therapy is safe and may decrease the incidence of seizure in patients. The author administers magnesium sulfate as a constant-rate infusion over 1 hour after giving a loading dose. The author has continued the infusion for up to 3 days without demonstrable negative effect beyond some possible trembling. Given the current evidence, a 24-hour course of treatment may be effective and sufficient in itself.

TABLE 21-5

#### Drugs Used to Control or Prevent Seizures in Foals

Drug	Dose	Route	Frequency	Comment
Diazepam	5-10 mg per foal	IV*	As needed	Short-term seizure control
Phenobarbital	2-3 mg/kg	IV	Bolus to effect	Bolus over 15-20 minutes; half-life can be prolonged; decreases thermoregulatory control, respiratory drive, and blood pressure
Phenytoin	5-10 mg/kg loading; 5 mg/kg maintenance	IV	Every 4 hr for first 24 hr; then b.i.d. (?)	Seizure control
Magnesium sulfate <sup>†</sup>	0.05 mg/kg/hr loading dose; 0.025 mg/kg/hr maintenance <sup>‡</sup>	IV	Constant-rate infusion for first hr and for maintenance	Discontinue if muscle tremors or hypotension occur; treat for 24-48 hours after hypoxic insult
Gabapentin	8 mg/kg	Oral	b.i.d. to t.i.d.	Seizure control

\*IV, Intravenous; *b.i.d.*, twice daily; *t.i.d.*, three times daily.

<sup>†</sup>To make 0.1 gm/ml solution, add 20 ml 50% MgSO<sub>4</sub> to 80 ml 0.9% NaCl.

<sup>‡</sup>Loading dose = 25 ml/hr of 0.1 gm/ml solution for 1 hour. Maintenance dose = 12 ml/hr of 0.1 gm/ml solution.

Foals with PAS often have a variety of metabolic problems, including hypoglycemia or hyperglycemia, hypocalcemia or hypercalcemia, hypokalemia or hyperkalemia, hypochloremia or hyperchloremia, hyperlactatemia, hyperphosphatemia, and varying degrees of metabolic acidosis. Although these problems must be addressed, the clinician should not forget the normal period of hypoglycemia that occurs post partum and should not treat aggressively, which might worsen the neurologic injury. Foals suffering from PAS also have frequent recurrent bouts of hypoxemia and occasional bouts of hypercapnia. Intranasally administered oxygen generally is needed in these cases as a preventive therapy and as direct treatment because the appearance of the abnormalities can be sporadic and unpredictable. Additional respiratory support, particularly in foals with centrally mediated hypoventilation and periods of apnea or abnormal breathing patterns, include caffeine (10 mg/kg loading dose; 2.5 mg/kg as needed, administered orally or rectally<sup>29</sup>), doxapram constant-rate infusion<sup>30,31</sup> and positive pressure ventilation. Mechanical ventilation of these patients can be rewarding and generally is required for less than 48 hours.

Blood pH should be monitored and maintained within the normal range. Metabolic alkalosis can develop in some of these foals and requires that the clinician tolerate some degree of hypercapnia. The pH level is important in evaluation and consideration of alternatives for treatment. If respiratory acidosis is not so severe as to affect the patient adversely (generally PaO<sub>2</sub> >70 mm Hg) and pH is within normal limits, the foal may tolerate hypercapnia.<sup>32</sup> The goal is to normalize pH. Foals with respiratory acidosis as compensation for metabolic alkalosis do not respond to caffeine and may be adversely affected by doxapram infusion or mechanical hyperventilation. Metabolic alkalosis in critically ill foals frequently is associated with electrolyte abnormalities, creating differences in strong ion balance. This pH perturbation is best handled by correcting the underlying electrolyte problem.

Maintaining tissue perfusion and oxygen delivery to tissues is a cornerstone of therapy for PAS to prevent additional injury. The oxygen-carrying capacity of the blood should be maintained; some foals require transfusions to maintain a PCV greater than 20%. Adequate vascular volume is important, but the clinician should take care to prevent fluid overload in the foal. Early evidence of fluid overload is subtle accumulation of ventral edema between the front legs and over the distal limbs. Fluid overload can result in cerebral edema, pulmonary edema, and edema of other tissues, including the gastrointestinal tract, that interferes with normal organ function and worsens the condition of the patient. Perfusion is maintained by supporting cardiac output and blood pressure by judicious use of intravenous fluid support and inotrope-pressor support. For these patients to require inopressor therapy is not unusual, but in some cases the hypoxic damage is sufficiently severe to blunt the response of the patient to the drugs.

The kidney is a target for injury in patients with PPH, and for renal compromise to play a significant role in the demise of these foals is not unusual. Clinical signs of renal disease are generally referable to disruption of normal control of renal blood flow and tubular edema, leading to tubular necrosis and renal failure. These foals have signs of fluid overload and generalized edema. The clinician must balance urine output and fluid therapy in these cases to prevent additional organ dysfunction associated with edema. Although evidence has

accumulated that neither dopamine nor furosemide play a role in protecting the kidney or reversing acute renal failure, these agents can be useful in managing volume overload in these cases.<sup>33-35</sup> The aim is not to drive oliguric renal failure into a high-output condition but rather to enhance urine output.

Overzealous use of diuretics and pressors in these cases can result in diuresis, requiring increased intravenous fluid support, and can be counterproductive. The author's approach is more conservative. Low doses of dopamine administered as a constant-rate infusion of 2 to 5 µg/kg/min are usually effective in establishing diuresis by natriuresis. Large doses of dopamine (>20 µg/kg/min) can produce systemic and pulmonary vasoconstriction, potentially exacerbating PPH.<sup>36</sup> One can administer a bolus (0.25 to 1.0 mg/kg) or constant-rate infusion (0.25 to 2.0 mg/kg/hr) of furosemide, but once furosemide diuresis is established, electrolyte concentrations and blood gas tensions must be frequently evaluated because potassium, chloride, and calcium losses can be considerable and because significant metabolic alkalosis can develop from strong ion imbalances. The author does not aim for urine production rates of 300 ml/hr, reported as a urine output goal for critically ill equine neonates, but rather looks for urine output that is appropriate for fluid intake.<sup>37</sup> Although the average urine output for a normal equine neonate is about 6 ml/kg/hr (~300 ml/hr for a 50-kg foal), these values were obtained from normal foals drinking a milk diet with a large free water component.<sup>38-41</sup> The urine of normal newborn foals is dilute, reflecting the large free water load they incur by their diet. Fluid therapy in the critically ill neonate is discussed later in this chapter.

One final caveat regarding renal dysfunction in PAS is that therapeutic drug monitoring should be performed when it is available. Many antimicrobial agents used to manage these cases, most notably the aminoglycosides, depend on renal clearance, and aminoglycoside toxicity occurs in the equine neonate and exacerbates or complicates the management of renal failure originally resulting from primary hemodynamic causes.

Foals with PAS suffer from a variety of problems associated with abnormalities within the gastrointestinal tract.<sup>41</sup> Commonly, they have ileus, recurrent excessive gastric reflux, and gas distention. These problems are exacerbated by constant feeding in the face of continued dysfunction and continued hypoxia. Frequently, enteral feeding cannot meet these foals' nutritional requirements, and partial or total parenteral nutrition is required. Special attention must be paid to passive transfer of immunity (see the section on failure of passive transfer) and glucose homeostasis in these cases. Appearance of damage to the gastrointestinal tract can be subtle and lag behind other clinical abnormalities for days to weeks. Low-grade colic, decreased gastrointestinal motility, decreased fecal output, and low weight gain are among the most common clinical signs of gastrointestinal dysfunction, but more severe problems, including necrotizing enterocolitis and intussusception, have been associated with these cases. The return to enteral feeding must be slow in many of these foals. A currently debated topic is constant versus pulsed enteral feeding.<sup>42-44</sup> The author uses pulsed feeding through an indwelling small-gauge feeding tube. In many foals these tubes stay in place for weeks and cause no problems as the foals are returned to their dams for sucking or are trained to drink from a bottle or bucket.

Foals with PAS are also susceptible to secondary infection. Treatment of recognized infection is covered in the same section of this chapter as sepsis. If infection is recognized in these patients after hospitalization, the clinician should consider the likelihood of nosocomial infection and should direct antimicrobial therapy on the basis of known nosocomial pathogens in the NICU and their susceptibility patterns until culture and sensitivity results become available. The clinician should make repeat determinations of immunoglobulin G (IgG) concentration; additional intravenous plasma therapy may be beneficial. Nosocomial infections are often rapidly overwhelming, and acute deterioration in the condition of a foal with PAS should prompt a search for nosocomial infection.

The prognosis for foals with PAS is good to excellent when the condition is recognized early and aggressively treated in term foals. Up to 80% of these neonates survive and go on to lead productive and useful athletic lives.<sup>45-48</sup> The prognosis decreases with delayed or insufficient treatment and concurrent problems such as prematurity and sepsis.

### PREMATURITY, DYSMATURITY, AND POSTMATURITY

Pamela A. Wilkins

In human NICUs the survival rate for low-gestation-length infants has increased dramatically since the 1980s, coincident with improvements in obstetric and neonatal care. The now routine, well-validated use of antenatal steroid and artificial surfactant therapies has contributed greatly to the enhanced survival of this patient population, although the use of these particular therapies is not common or frequently indicated in the equine NICU.<sup>1,2</sup> However, with improved care, outcomes in the equine NICU population have improved also, with survival of premature patients in many NICUs exceeding 80%.<sup>3</sup> In the equine population gestation length is much more flexible than in the human population; however, the definition of the term *prematurity* requires re-examination. Traditionally, *prematurity* is defined as a preterm birth of less than 320 days of gestation in the horse. Given the variability of gestation length in the horse, ranging between 310 days to more than 370 days in some mares, a mare with a usual gestation length of 315 days possibly could have a term foal at 313 days, whereas a mare with a usual gestation length of 365 days may have a premature foal at 340 days, considered the normal gestation length. Foals that are born post term but are small are termed *dysmature*; a postmature foal is a post-term foal that has a normal axial skeletal size but is thin to emaciated. Dysmature foals may have been classified in the past as small for gestational age and are thought to have suffered placental insufficiency, whereas postmature foals usually are normal foals that have been retained too long in utero, perhaps because of an abnormal signaling of readiness for birth, and have outgrown their somewhat aged placenta. Postmature foals become more abnormal the longer they are maintained, may suffer from placental insufficiency, and are represented best by the classic foal born to a mare ingesting endophyte-infested fescue.<sup>4</sup> Box 21-3 compares the characteristics of premature and dysmature foals with those of postmature foals.

The causes of prematurity, dysmaturity, and postmaturity include the causes of high-risk pregnancy presented in

#### BOX 21-3

### CLINICAL CHARACTERISTICS OF PREMATURE/DYSMATURE AND POSTMATURE FOALS

#### Premature/Dysmature

- Low birth weight
- Small frame; thin
- Poor muscle development possible
- Flexor laxity common
- Periarticular laxity
- Hypotonia more common
- High chest wall compliance
- Low lung compliance
- Short, silky hair coat
- Domed forehead
- Floppy ears; poor cartilage development
- Weak suck reflex
- Poor thermoregulation
- Gastrointestinal tract dysfunction
- Delayed maturation of renal function; low urine output
- Entropion with secondary corneal ulcers
- Poor glucose regulation

#### Postmature

- Normal to high birth weight
- Large frame; thin
- Poor muscle development possible
- Flexor contraction common
- Hypertonia more common
- Long hair coat
- Fully erupted incisors
- Weak suck reflex
- Poor thermoregulation
- Gastrointestinal tract dysfunction
- Delayed maturation of renal function; low urine output
- Poor glucose regulation
- Delayed time to standing
- Hyperreactive
- Poor postural reflexes

Adapted from Palmer JE: Perinatal hypoxic-ischemic disease. *Proceedings of the International Veterinary Emergency Critical Care Symposium*, San Antonio, Tex, 1998, pp. 722-723.

**Box 21-1.** Iatrogenic causes include early elective induction of labor based on inaccurate breeding dates or misinterpretation of late-term colic or uterine bleeding as ineffective labor. Most causes remain in the category of idiopathic, with no discernible precipitating factor. Despite the lack of an obvious cause, premature labor and delivery does not just happen, and even if undetermined, the cause may continue to affect the foal in the postparturient period. All body systems may be affected by prematurity, dysmaturity, and postmaturity, and thorough evaluation of all body systems is necessary.

Respiratory failure is common in these foals, although the cause usually is not surfactant deficiency. Immaturity of the respiratory tract, poor control of respiratory vessel tone, and weak respiratory muscles combined with poorly compliant lungs and a greatly compliant chest wall contribute

to respiratory failure in these cases. Most require oxygen supplementation and positional support for optimal oxygenation and ventilation. One must extend effort to maintain these “floppy foals” in sternal recumbency. Some foals may require mechanical ventilation. These foals also require cardiovascular support but are frequently unresponsive to commonly used pressors and inotropes: dopamine, dobutamine, epinephrine, and vasopressin. Careful use of these drugs and judicious intravenous fluid therapy are necessary. The goal should not be one of achieving specific pressure values (e.g., mean arterial pressure of 60 mm Hg) but of adequate perfusion. Renal function, reflected in low urine output, is frequently poor initially in these cases because of the delay in making the transition from fetal to neonatal glomerular filtration rates.<sup>5</sup> The delay can result from true failure of transition or from hypoxic-ischemic insult. The clinician should approach fluid therapy cautiously in these cases; initial fluid restriction may be in order to avoid fluid overload. Many premature, dysmature, or postmature foals have suffered a hypoxic insult and have all of the disorders associated with PAS, including HIE. Treatment is similar to that of term foals with these problems. These foals also are predisposed to secondary bacterial infection and must be examined frequently for signs consistent with early sepsis or nosocomial infection.

The gastrointestinal system of these foals is not usually functionally mature, which may result from a primary lack of maturity or from hypoxia. Dysmotility and varying degrees of necrotizing enterocolitis are common, as are hyperglycemia and hypoglycemia. Hyperglycemia generally is related to stress, increased levels of circulating catecholamines, and rapid progression to gluconeogenesis, whereas hypoglycemia is associated with diminished glycogen stores, inability to engage gluconeogenesis, sepsis, and hypoxic damage.<sup>6</sup> Immature endocrine function is present in many of these foals, particularly regarding the hypothalamic-pituitary-adrenal axis, and contributes to metabolic derangements.<sup>7,8</sup> Enteral feeding should be delayed, when possible, until the foal has stable metabolic and cardiorespiratory parameters. On initiating enteral feeding, one should provide small volumes initially and slowly increase the volume over several days.

Musculoskeletal problems are common, particularly in premature foals, and include significant flexor laxity and decreased muscle tone. Postmature foals often are affected by flexure contracture deformities, most likely because of decreased intrauterine movement as they increase in size. Premature foals frequently exhibit decreased cuboidal bone ossification that predisposes them to crush injury of the carpal and tarsal bones if weight bearing is not strictly controlled. Physical therapy in the form of standing and exercise is indicated in the management of all these problems, but one should take care to ensure that the patient does not fatigue or stand in abnormal positions. Bandaging of the limbs is contraindicated because this only increases laxity, although light bandages over the fetlock may be necessary to prevent injury to that area if flexor laxity is severe. The foals are predisposed to angular limb deformity and must be observed closely and frequently for this problem as they mature.<sup>9</sup>

The overall prognosis for premature, dysmature, and postmature foals remains good with intensive care and good attention to detail. Many of these foals (up to 80%) survive and become productive athletes.<sup>3</sup> Complications associated with sepsis and musculoskeletal abnormalities are the most significant indicators of poor athletic outcome.

## SEPSIS

Pamela A. Wilkins

The last 20 years have seen an explosion of new therapeutic agents purportedly useful for treating sepsis. Unfortunately, clinical trials investigating these new therapies have failed to demonstrate a positive effect, have shown negative results, or have resulted in diametrically opposed study results, one showing a benefit and another showing no benefit or a detrimental effect. On a positive note, the survival rate of foals being treated for sepsis has improved. Work was done regarding foal diseases and their treatment in the 1960s, but the field did not attract much serious attention until the 1980s. Since that time almost every major veterinary college and many large private referral practices have constructed NICUs or their equivalent. Next to hypoxic ischemic asphyxial syndromes, sepsis is the primary reason for presentation and treatment at these facilities. Neonatal septicemia of the horse has been the subject of five international workshops,<sup>1-5</sup> and a perinatology lecture covering some aspect of neonatal sepsis has been presented at almost every large continuing education meeting attended by equine veterinarians.

Consensus criteria conferences in the early 1990s defined *sepsis* and *septic shock* for human beings.<sup>6,7</sup> *Sepsis* was defined as the systemic response to infection manifested by two or more of the following conditions as a result of infection: (a) temperature greater than 38° C or less than 36°; (b) heart rate greater than 90 beats/min; (c) respiratory rate greater than 20 breaths per minute or PaCO<sub>2</sub> less than 32 torr; and (d) white blood cell count greater than 12,000 cell/μl, less than 4000 cell/μl, or greater than 10% immature (band) forms. *Septic shock* was defined as sepsis-induced hypotension or the requirement for vasopressors-ionotropes to maintain blood pressure despite adequate fluid resuscitation along with the presence of perfusion abnormalities that may include lactic acidosis, oliguria, or acute alteration in mental status. These definitions, and several others, are broadly accepted and have been adapted to studies of neonatal sepsis in foals.<sup>8,9</sup> Many of the treatment modalities in human medicine have been applied in some manner to the equine neonatal patient. Additional definitions include the following: systemic inflammatory response system (SIRS), multiple organ system dysfunction (MODS), and multiple organ failure syndrome (MOFS). (SIRS is sick, MODS is sicker, and MOFS is dying.) The compensatory anti-inflammatory response syndrome (CARS) ideally balances SIRS and keeps it from reinforcing itself by way of positive feedback cytokine loops. If balance is achieved, recovery is possible. Imbalance progresses to septic shock, MODS, and MOFS. In horses MODS usually is manifested as respiratory (acute lung injury [ALI] and acute respiratory distress syndrome [ARDS]); renal, gastrointestinal, hepatic, and CNS dysfunction; and coagulopathy.<sup>9-13</sup> Managing the septic patient involves early recognition and support of the patient or intervening in the face of multiple clinical consequences, termed *CHAOS* (cardiovascular compromise, homeostasis, apoptosis, organ dysfunction, suppression of the immune system).<sup>14</sup> Inflammatory mediators are involved in all these processes and can be beneficial or detrimental, depending on timing and opposing responses. Neutrophils, platelets, lymphocytes, macrophages, and endothelial cells are involved, and the number of implicated inflammatory molecules grows daily.

Sepsis in the foal initially can be subtle, and the onset of clinical signs varies depending on the pathogen involved and the immune status of the foal. For the purposes of this chapter, the discussion is limited to bacterial sepsis, but the foal also is susceptible to viral and fungal sepsis, which can resemble bacterial sepsis. Failure of passive transfer (FPT) of immunity can contribute to the development of sepsis in a foal at risk.<sup>15,16</sup> (See Chapter 1 for further discussion of FPT.) Testing for and treatment of FPT have received attention in the veterinary literature. It remains true, however, that foals brought to NICUs that have an ultimate diagnosis of sepsis usually have FPT.<sup>17,18</sup> The current recommendation is that foals have IgG levels greater than or equal to 800 mg/dl for passive transfer to be considered adequate. Other risk factors for the development of sepsis include any adverse events at the time of birth, maternal illness, or any abnormalities in the foal. Although the umbilicus frequently is implicated as a major portal of entry for infectious organisms in the foal, the gastrointestinal tract is the most likely primary portal of entry.<sup>19</sup> Other possible portals of entry include the respiratory tract and wounds.

Early signs of sepsis include depression, decreased suck reflex, increased recumbency, fever, hypothermia, weakness, dysphagia, failure to gain weight, increased respiratory rate, tachycardia, bradycardia, injected mucous membranes, decreased capillary refill time, shivering, lameness, aural petechia, and coronitis.

If sepsis is recognized early, these patients may have a good outcome, depending on the pathogen involved. Gram negative sepsis remains the most commonly diagnosed, but increasingly gram positive septicemia is being recognized.<sup>11-13,20,21</sup> Foals in intensive care units and at referral hospitals have an additional risk of nosocomial infection. It is important to try to isolate the involved organism early in the course of the disease. If possible, the clinician should obtain blood cultures and, if localizing signs are present, samples as deemed appropriate.

Cultures should be aerobic and anaerobic. Recently, work has been done evaluating real-time polymerase chain reaction (PCR) technology in sepsis in the foal as a means of identifying causative organisms.<sup>22-24</sup> Until antimicrobial sensitivity patterns are obtained for the pathogen involved, broad spectrum antimicrobial therapy should be initiated (Table 21-6). Intravenously administered amikacin and penicillin are good first-line choices, but renal function should be closely monitored. Other first-line antimicrobial choices might include high-dose ceftiofur sodium or ticarcillin-clavulanic acid. The clinician should treat FPT if present. Intranasal oxygen insufflation at 3 to 10 L/min should be provided even if hypoxemia is not present, with caution taken to avoid hyperoxia, to decrease the work of breathing and provide support for the increased oxygen demands associated with sepsis.<sup>25</sup> Should arterial blood gas analysis reveal significant hypoventilation, caffeine

TABLE 21-6

#### Antimicrobial Drug Dosages Used in Foals in the Neonatal Intensive Care Unit

Drug	Dose	Route	Frequency	Comments
Amikacin sulfate	25-30 mg/kg	IV	s.i.d.	Requires therapeutic drug monitoring: peak >60; trough <2
Ampicillin trihydrate	20 mg/kg	Oral	t.i.d.	Poor absorption noted in foals >2-3 weeks of age
Sodium ampicillin	50-100 mg/kg	IV	q.i.d.	–
Amoxicillin trihydrate	20-30 mg/kg	Oral	t.i.d.	Poor absorption noted in foals >2-3 weeks of age
Cefotaxime	50-100 mg/kg	IV	q.i.d.	–
Cefuroxime (Ceftin)	30 mg/kg/day	Oral	b.i.d., t.i.d.	Total daily dose is divided into 10 mg/kg t.i.d. or 15 mg/kg b.i.d.
Cephalexin	10 mg/kg	Oral	q.i.d.	–
Ceftiofur (Naxcel)	10 mg/kg	IV	q.i.d.	Give slowly over 20 minutes as double-diluted volume in 0.9% saline
Chloramphenicol palmitate	50 mg/kg	Oral	q.i.d.	Public health concerns
Chloramphenicol succinate	10-25 mg/kg	IV	q.i.d.	Public health concerns
Enrofloxacin	2.5-10 mg/kg	IV, Oral	s.i.d.	Chondropathy and arthropathy reported in foals
Erythromycin stearate	20-30 mg/kg	Oral	t.i.d. to q.i.d.	Avoid warm temperatures and high humidity; colitis reported in dams of foals receiving this drug
Erythromycin lactiobionate	5 mg/kg	IV	Every 4-6 hours	–
Gentamicin sulfate	8.8 mg/kg	IV	s.i.d.	Requires therapeutic drug monitoring: peak >40; trough <2
Imipenem	10-20 mg/kg	IV	q.i.d.	Seizures reported as adverse reaction

TABLE 21-6

Antimicrobial Drug Dosages Used in Foals in the Neonatal Intensive Care Unit—cont'd				
Drug	Dose	Route	Frequency	Comments
Metronidazole	15 mg/kg 25 mg/kg	Oral, as needed	q.i.d. b.i.d.	Anorexia can occur
Potassium penicillin Sodium penicillin	20,000-50,000 U/kg	IV	q.i.d.	Give potassium penicillin slowly over 5 to 10 minutes
Rifampin	5 mg/kg	Oral	b.i.d.	Always administer with second antimicrobial because of rapid development of resistance
Ticarcillin	50-100 mg/kg	IV	q.i.d.	–
Ticarcillin and clavulonic acid (Timentin)	50-100 mg/kg	IV	q.i.d.	–
Trimethoprim-sulfonamide	30 mg/kg	Oral	b.i.d.	–
Fluconazole	8 mg/kg loading; 4 mg/kg	Oral	b.i.d.	–

 IV, Intravenous; *s.i.d.*, once daily; *t.i.d.*, thrice daily; *q.i.d.*, 4 times daily; *b.i.d.*, twice daily.

TABLE 21-7

Inotrope and Pressor Medications Used in the Neonatal Intensive Care Unit*				
Drug	Dose	Route	Comment	
Dopamine	3-20 µg/kg/min	IV-CRI <sup>†</sup>	Follow the rule of 6: 6 × mass of foal (kg) = number of milligrams to add to 100 ml saline (1 ml/hr) = 1 µg/kg/min	
Dobutamine	3-40 µg/kg/min	IV-CRI		
Epinephrine <sup>‡</sup>	0.2-2 µg/kg/min	IV-CRI		
Norepinephrine <sup>‡</sup>	0.2-3 µg/kg/min	IV-CRI		

Data from Connolly Neonatal Intensive Care Unit, Kennet Square, Pa.  
 \*One should use these medications to effect and should monitor blood pressure during their use.  
<sup>†</sup>IV-CRI, Intravenously at constant-rate infusion.  
<sup>‡</sup>For epinephrine and norepinephrine, apply a “rule of 0.6” where 0.6 × mass of foal (kg) = number of mg drug to add to 100 ml saline so 1 ml/hr = 0.1 µg/kg/min.

may be administered orally or rectally, or doxapram can be given by constant-rate infusion to increase central respiratory drive. Mechanical ventilation may be necessary in cases of severe respiratory involvement, such as with acute lung injury or ARDS. If the foal is hypotensive, the clinician may administer pressor agents or inotropes by constant-rate infusion (Table 21-7). Inotrope and pressor therapy generally is restricted to referral centers where these drugs can be given as constant-rate infusions and blood pressure can be monitored closely. Some practitioners use nonsteroidal anti-inflammatory agents and, in specific circumstances, corticosteroids. These drugs should be used judiciously because they may have several negative consequences for the foal, including renal failure and gastric or duodenal ulceration.<sup>26-28</sup>

Recent work from several laboratories investigating possible functional decreased adrenal responsiveness in neonatal foals with sepsis may support the judicious use of corticosteroid therapy in selected cases, but a consensus is not yet established.<sup>29,30</sup>

Nursing care is one of the most important aspects of treating septic foals. Foals should be kept warm and dry. They should be turned at 2-hour intervals if they are recumbent. Feeding septic foals can be a challenge if gastrointestinal function is abnormal, and parenteral nutrition may be needed. If at all possible, foals should be weighed daily and blood glucose levels monitored frequently. Some foals become persistently hyperglycemic on small glucose infusion rates. These foals may benefit from constant-rate low-dose insulin infusions (Table 21-8). Recumbent foals must be examined frequently for the development of decubital sores, the appearance of corneal ulcers, and heat and swelling associated with joints and physes.

The prognosis for foals in the early stages of sepsis is fair to good. Once the disease has progressed to septic shock the prognosis decreases, although short-term survival rates are as good as those in human critical care units. Long-term survival and athletic outcomes are fair. Racing-breed foals that make it to the track perform similarly to their age-matched siblings.<sup>31</sup>

TABLE 21-8

Miscellaneous Drugs Used in the Neonatal Intensive Care Unit				
Drug	Dose	Route	Frequency	Comments
Aminophylline	2-3 mg/kg	IV	b.i.d. to q.i.d.	Monitor theophylline levels. Therapeutic: 6-12 µg/l Toxic: >20 µg/l
Caffeine	10 mg/kg loading dose 2.5 mg/kg maintenance	Orally as needed	s.i.d., b.i.d.	Steady state level: 5-20 µg/l Toxic: >50-75 µg/l
Dimethyl sulfoxide	1 g/kg	IV	Once	Administer as 5% to 10% solution; dimethyl sulfoxide is hypertonic
Heparin	40-100 U/kg	SQ/IV	b.i.d.	–
Insulin (protamine zinc)	0.15 U/kg	IM/SQ	b.i.d.	–
Insulin (regular)	0.00125-0.2 U/kg/hr	IV	Constant-rate Infusion	Pretreat lines: insulin adsorbs to lines

## NUTRITIONAL MUSCULAR DYSTROPHY (WHITE MUSCLE DISEASE)

Pamela A. Wilkins

Nutritional muscular dystrophy or white muscle disease is a vitamin E/selenium-responsive muscle disease of horses of all ages that is probably caused by a dietary deficiency of selenium and vitamin E.<sup>1</sup> The condition occurs most commonly in geographic areas with low selenium levels in the soil, generally the northeastern, northwestern, Great Lakes, and mid-Atlantic regions of the United States.

Two forms of the disease are described in foals: the fulminant form, in which the foal is found acutely dead, and the subacute form. In the fulminant form death usually is attributed to myocardial lesions resulting in cardiovascular collapse. The subacute form is characterized by dysphagia and gait abnormalities primarily caused by stiffness of the muscles of locomotion. Paralysis, if present, is not flaccid as in botulism. Abnormal function of respiratory muscles may complicate the clinical situation. Aspiration pneumonia may be present because of problems associated with swallowing; the tongue and pharyngeal muscles frequently are affected in the early stages of disease.<sup>1</sup> Foals with severe disease may have widespread muscle necrosis leading to hyperkalemia, which can be severe and result in death of the foal. Serum activities of the muscle enzymes creatine kinase and aspartate aminotransferase may be greatly increased. Diagnosis is confirmed at necropsy or ante mortem by determination of decreased whole blood or serum selenium concentration or decreased glutathione peroxidase activity in the blood of the foal before supplementation. Myoglobinuria and acute renal failure are not uncommon in these foals.

Treatment of foals with nutritional muscular dystrophy is primarily supportive. The clinician should address all metabolic abnormalities. Some foals require intranasal oxygen

tinsufflation. Affected foals are unable to suck effectively, and enteral (through an indwelling nasogastric tube) or parenteral nutritional support should be provided. Because of the high likelihood of aspiration pneumonia, broad spectrum antimicrobial therapy should be administered parenterally. The patient should be kept quiet and should be stimulated minimally. Affected foals should receive parenteral (intramuscular) vitamin E and selenium supplementation. Selenium is toxic in large doses. The prognosis for severely affected foals is guarded. For less severely affected foals, the prognosis is good with appropriate treatment. The disease can be prevented by ensuring that mares receive sufficient vitamin E and selenium while pregnant and by supplementing foals with parenteral injections of vitamin E and selenium at birth in endemic areas. A more complete discussion of the pathophysiology of this disease and the nutritional management is presented elsewhere in this text.

## HEPATIC DISEASES OF FOALS

Bryan Waldrige

### CLINICOPATHOLOGIC DIAGNOSIS

Activities of certain hepatic enzymes (alkaline phosphatase,  $\gamma$ -glutamyltransferase) and serum concentrations of some hepatic indices (bilirubin, bile acids, triglycerides) in clinically normal foals are significantly different from those of adult horses, especially during the neonatal period. For this reason absolute reference ranges used for adult horses cannot reliably be used to diagnose hepatic disease in foals.<sup>1</sup> The relatively greater ratio of hepatic mass to body weight and increased induction, production, or release of liver-specific enzymes in young animals may account for increased  $\gamma$ -glutamyltransferase (GGT) and other hepatic enzyme activity in foals.<sup>1,2</sup> Sorbitol dehydrogenase (SDH) and aspartate transaminase (AST) are more reliable clinicopathologic indicators of hepatocellular

disease in foals.<sup>1,3</sup> These enzymes have more narrow standard deviations in foals, and their normal reference ranges are closer to those of adults. Therefore, if hepatic disease is suspected in a foal, further diagnostic procedures, such as clinical examination, ultrasonography and liver biopsy, are useful and often necessary to confirm the diagnosis.

### SERUM ALKALINE PHOSPHATASE

Several studies have reported significantly increased serum alkaline phosphatase (ALP) activity in foals compared with that of adult horses.<sup>2,4,5</sup> Serum ALP activity is highest in foals during the first 2 weeks of life.<sup>2,4</sup> Alkaline phosphatase activity in foals remains elevated for at least 90 days<sup>6</sup> and usually decreases to adult ranges by 1 year of age.<sup>2</sup> The normal wide individual variation and large standard deviation of ALP activity in foals limits its effectiveness to diagnose hepatobiliary disease.<sup>1</sup> Increased ALP activity in foals is mainly of hepatic origin.<sup>2,5</sup> However, some of the elevation of activity in young growing animals is due to increased osteoblastic activity and bone formation.<sup>1,4,5</sup>

### γ-GLUTAMYLTRANSFERASE

Foals also have significantly increased GGT activity compared with that of adult horses.<sup>1-4,6</sup> GGT activity in foals ranges from 1.5 to 3 times normal adult values for the first 3 to 4 weeks of life.<sup>1,2</sup> Increased GGT activity in foals is most different from that of adult horses between 7 to 21 days of age.<sup>4</sup> Similar to ALP activity, there is a normal wide individual variation in foal GGT activity, which restricts its diagnostic ability to identify hepatic disease.<sup>1</sup>

Unlike neonatal ruminants, the source of increased GGT activity in foals is endogenous and not secondary to ingestion of colostrum.<sup>2,6</sup> Colostral GGT activity is lower in mares than in ewes and cows.<sup>6</sup> In foals measurement of postsuckle GGT activity is not associated with serum IgG concentration<sup>2</sup> and cannot be used to determine colostrum intake.<sup>6</sup> Hepatic GGT activity in young animals is increased, and this may account for some of the increased GGT activity in foals.<sup>1,2</sup>

### SERUM BILE ACIDS

Serum bile acid (SBA) concentration in neonatal foals is significantly greater than normal reference ranges in adult horses.<sup>3</sup> SBA concentration is highest at birth and then gradually decreases. One study<sup>3</sup> reported that SBA concentrations remain elevated for at least 6 weeks post partum. Speculated mechanisms of increased SBA concentration in foals include increased hepatic production or decreased excretion into bile, gastrointestinal flora differences that affect the conjugation of bile acids, and enhanced intestinal absorption. Hepatic uptake of SBA and excretion into bile require active transport, which may not be fully functional in foals. Elevated serum concentrations of bilirubin or triglycerides can interfere with measurement of SBA. However, the degree of neonatal hyperbilirubinemia or hyperlipemia apparently is not correlated with increased SBA concentration in foals.

### BILIRUBIN

Neonatal hyperbilirubinemia appears to be a normal transient event during the first 2 weeks of life.<sup>3,4</sup> Bilirubin concentrations are highest in young foals and drop to normal ranges

for adult horses by 7 to 14 days of age.<sup>3,4</sup> One study<sup>4</sup> reported that both total and unconjugated bilirubin concentrations in foals were increased over adult values from birth through 7 to 14 days post partum. Neonatal hyperbilirubinemia may occur as a result of hemolysis of fetal erythrocytes or immature hepatic function. The fetal liver's ability to excrete bilirubin is also minimal. Bilirubin must be excreted across the placenta in fetuses, and conjugation may be delayed in neonates as the liver gains full function.

### TRIGLYCERIDES

Hyperlipidemia can be normal during the neonatal period. Triglyceride concentrations in foals tend to be highest during the first 2 weeks of life and moderately increased for up to 6 weeks of age.<sup>3,4</sup> Some authors have suggested that triglyceride concentrations in foals may decrease as hepatic function develops and triglycerides are used to synthesize other lipoproteins.<sup>4</sup>

### PORTOSYSTEMIC SHUNTS

Portosystemic shunts (PSSs) are infrequently reported in foals. Most PSSs have been extrahepatic,<sup>7-9</sup> and there is a single case report of an intrahepatic PSS.<sup>10</sup> Another case report<sup>11</sup> describes an apparent arteriovenous anomaly of the portal vein that functioned as a PSS. Clinical signs of a PSS can be intermittent and are attributed to hepatoencephalopathy. These include abnormal behavior, depression or lethargy, ataxia, blindness, wandering or circling, head pressing, and being small for age.<sup>7-11</sup> Clinical signs often do not occur until the foal has been weaned.<sup>9</sup> Milk diets may have a protective effect against clinical signs until weaning, when the foal consumes solid feed with higher protein content.

Clinicopathologic findings with PSS include hyperammonemia and elevated SBA concentration with normal to mildly increased hepatic enzyme activity.<sup>7,10</sup> One case series of four PSSs in foals and calves<sup>10</sup> reported that blood ammonia concentrations in animals with PSSs were at least 7 times greater than matched controls. The authors considered elevated blood ammonia concentration more reliable than increased SBA in diagnosing PSS. Microcytic, normochromic erythrocytes have been reported in three foals,<sup>9,10</sup> one of which was anemic.<sup>9</sup> The exact pathogenesis of poikilocytosis with PSS is unknown but may be due to altered erythrocyte membranes or iron metabolism.<sup>10</sup> Leukocytosis with neutrophilia has also been reported in several cases.<sup>11-13</sup> Cerebrospinal fluid (CSF) with PSS is usually normal.<sup>7,9,11</sup> In one case<sup>10</sup> CSF was xanthochromic with increased nucleated cell count and total protein, suggestive of hemorrhage and inflammation.

Histopathologic lesions seen on a liver biopsy with PSS can include arteriolar proliferation in the area of the portal triad,<sup>7,8</sup> widespread hepatocyte atrophy,<sup>7</sup> bile duct hyperplasia, periportal fibrosis, poorly developed portal triads, and apparent absence of hepatic portal veins.<sup>8</sup>

Intraoperative contrast portography is the most reliable diagnostic technique to identify the location and extent of a PSS.<sup>10</sup> Jejunal mesenteric vein catheterization may be performed using a ventral midline,<sup>8-10</sup> flank,<sup>7</sup> or a right paracostal incision with resection of the eighteenth rib.<sup>10</sup> A right paracostal incision with resection of the eighteenth rib may provide better exposure and improve surgical access to the PSS, portal system, and liver.<sup>10</sup> A mesenteric vein is catheterized, and 50 to 80 ml of iodinated contrast media is injected.<sup>7-10</sup>

Images of the PSS can then be obtained using radiography or fluoroscopy. Radiographs taken near the end of contrast injection may provide better images than fluoroscopy in foals.<sup>10</sup> In normal foals contrast media should opacify the portal vein, intrahepatic portal system, and hepatic veins without opacifying the vena cava.<sup>9</sup> If a PSS is present, contrast media can be seen opacifying the portal vein and caudal vena cava by way of the PSS, without significant hepatic perfusion.<sup>8-10</sup>

Nuclear hepatic scintigraphy using intravenous <sup>99m</sup>technetium radiocolloid can be used to determine hepatic radiocolloid uptake and hepatic perfusion index.<sup>7</sup> The hepatic perfusion index of a normal foal was 0.8 and 2.3 in a PSS-affected foal, which suggested decreased portal circulation through the liver of the affected foal. Static images of the liver of the PSS-affected foal taken 15 minutes after injection of contrast showed that its liver was smaller than that of the normal foal. The major disadvantage of nuclear hepatic scintigraphy is that the type and location of the PSS cannot be determined.<sup>7,9</sup>

Ultrasound examination of a foal with PSS revealed no parenchymal abnormalities, but the liver appeared smaller than normal.<sup>8</sup> A large blood vessel that apparently communicated with the caudal vena (intrahepatic PSS) was identified in another foal.<sup>10</sup>

Surgical correction of PSS has been attempted with two extrahepatic PSSs<sup>9,10</sup> and one intrahepatic PSS.<sup>10</sup> One foal with a surgically corrected extrahepatic PSS is reported to have survived.<sup>10</sup> The filly was clinically healthy and neurologically normal 2 years postoperatively but was small for her breed (Belgian).

## ☞ TYZZER'S DISEASE

Tyzzer's disease is a peracute rapidly fatal infectious hepatitis of foals 7 to 42 days of age.<sup>11-13</sup> The etiologic agent of Tyzzer's disease is *Clostridium piliforme*, a gram negative, spore-forming, obligate intracellular bacterium.<sup>11,12</sup> *C. piliforme* is found in soil and manure.<sup>12</sup> It is believed that foals are exposed through ingestion of contaminated soil or feces from infected adult horses.<sup>11,12</sup>

Clinical signs of Tyzzer's disease may include only acute death.<sup>12</sup> Other clinical signs include lethargy, recumbency, seizures, pyrexia, icterus, diarrhea, tachycardia, tachypnea, dehydration, and those associated with hepatoencephalopathy.<sup>11-13</sup> The mean survival time after appearance of clinical signs was 34.5 plus or minus 20.1 hours (range 16 to 62 hours) in a series of confirmed cases.<sup>11</sup> The mean age of affected foals was 18.7 plus or minus 12.1 days (range 6 to 45 days). Ultrasound examination of the liver may reveal hepatomegaly with increased echogenicity of the hepatic parenchyma or an increased vascular pattern.<sup>11,13</sup>

Clinicopathologic abnormalities include severe hypoglycemia, metabolic acidosis, increased hepatic enzyme activity, hemoconcentration, and hyperfibrinogenemia.<sup>11,13</sup> Cerebrospinal fluid in one case<sup>13</sup> was sterile and xanthochromic with normal protein concentration. Cytologic examination of CSF revealed erythrocytosis, mildly increased mononuclear cells, and rare nondegenerate neutrophils.

Definitive antemortem diagnosis of Tyzzer's disease is difficult. If available, *C. piliforme* can be detected using the PCR on liver biopsies.<sup>11</sup> Histopathologic lesions observed in liver biopsies include multifocal coagulative necrosis of hepatocytes surrounded by degenerate hepatocytes and inflammatory cells.<sup>11,12</sup> Filamentous, intracellular organisms near the periphery of lesions can be seen using silver-type (Warthin-Starry) stains.<sup>11,13</sup> Postmortem lesions include hepatomegaly

with multifocal areas of light discoloration, generalized icterus, peritoneal effusion, petechiation, and abdominal lymphadenopathy.

Successful treatment of one liver biopsy PCR-confirmed case of Tyzzer's disease<sup>11</sup> and three suspected cases<sup>12,13</sup> have been reported. Treatment of Tyzzer's disease is largely supportive of hepatic failure. The PCR-confirmed case<sup>11</sup> was treated with intravenous balanced electrolyte solutions, dextrose and bicarbonate supplementation, intranasal oxygen, omeprazole (4 mg/kg/day, administered orally), vitamin E (20 U/kg/day, PO), total parenteral nutrition, and enteral feeding. A presumptive case of Tyzzer's disease<sup>13</sup> was successfully treated similarly with the addition of DMSO (1 g/kg/day, PO) and xylazine for seizure control. Antimicrobial therapy used in these cases included ampicillin (30 mg/kg, PO every 8 hours) and gentamicin (6.6 mg/kg/day, IV), followed by sulfamethoxazole-trimethoprim (30 mg/kg, PO every 12 hours)<sup>13</sup> or sodium penicillin (10,000 U/kg, IV every 6 hours) and sulfamethoxazole-trimethoprim (14 mg/kg, IV every 12 hours).

Cases of Tyzzer's disease on farms tend to be fairly isolated and sporadic, but clusters of cases may occur on a single farm.<sup>13</sup> A study investigating risk factors for Tyzzer's disease in foals associated with a Thoroughbred breeding farm in California<sup>12</sup> found that foals born between March 13 and April 13 were more than seven times more likely to develop *C. piliforme* infections than were foals born at any other time during foaling season. The reason for the increased risk may have been due to environmental and management conditions or that the number of horses arriving and leaving the farm was highest at this time. Although not statistically significant, foals born to visiting (nonresident) mares and mares younger than 6 years of age were approximately three times more likely to develop *C. piliforme* infections. This difference could be attributed to decreased colostrum quality in younger mares or the arrival of mares that were naive to *C. piliforme*. Additionally, strain-specific antibody may be necessary to protect foals from multiple serotypes of *C. piliforme*.

## ☞ CHOLANGIOHEPATITIS

Cholangiohepatitis occurs in foals despite intensive treatment and broad spectrum antimicrobial therapy. Bacteremic or septicemic foals also may have hepatocellular damage secondary to endotoxemia or hepatic abscessation. Ideally, suspected cholangiohepatitis is treated on the basis of a liver biopsy culture. However, in foals presumptive therapy can be based on blood culture and sensitivity results, if available. The addition of empiric therapy with sulfamethoxazole-trimethoprim (30 mg/kg, PO every 12 hours) often is helpful in foals that develop apparent cholangiohepatitis while receiving broad spectrum antimicrobials. Gastric and duodenal ulcers are an important etiology of reflux or ascending cholangiohepatitis in foals.<sup>14</sup> Duodenal ulceration, thickening, or spasm near the major duodenal papilla can cause reflux of ingesta, gastric acid, and bile salts through the common bile duct. It is important to include aggressive anti-ulcer prophylaxis and treatment whenever treating suspected cholangiohepatitis in foals.

## ☞ NEONATAL ISOERYTHROLYSIS

Neonatal isoerythrolysis (NI) is the most common cause of icterus in foals and is discussed in detail later in this chapter.<sup>15</sup> Hepatic disease and elevated activities of hepatic enzymes

are fairly common with NI in foals secondary to anemia and hypoxia. Hepatocellular injury caused by iron and bilirubin accumulation also may contribute to elevations in bilirubin and liver enzyme activity. Total and direct bilirubin, AST, ALP, and SDH activities may be increased in NI-affected foals. Foals with the lowest hematocrit concentrations tended to have the highest SDH activities in one study.<sup>15</sup> Liver biopsies of two very anemic (hematocrit  $\leq$  11%) NI-affected foals revealed hepatic necrosis, bile duct hyperplasia, diffuse hemosiderosis, and Kupffer's cell hyperplasia consistent with hepatic iron uptake.

## ☞ GLYCOGEN BRANCHING ENZYME DEFICIENCY

Glycogen branching enzyme deficiency (GBED) in Quarter Horse foals is associated with neonatal mortality, flexural limb deformities, seizures, recumbency, and respiratory or cardiac failure (see Chapter 11).<sup>16</sup> Clinicopathologic abnormalities related to GBED are leucopenia; intermittent hypoglycemia; and elevated activities of creatine kinase, AST, and GGT. Accumulations of amylase-resistant, abnormal polysaccharide in liver and skeletal or cardiac muscle can be found on histopathologic examination after periodic acid Schiff's staining. The amount of abnormal polysaccharide in tissues is age-dependent and is more likely to be seen in older foals.

## FAILURE OF PASSIVE TRANSFER

*Debra C. Sellon, Pamela A. Wilkins*

Causes, diagnosis, and treatment of FPT of immunity are discussed in detail in Chapter 1. FPT occurs when a foal fails to ingest a sufficient quantity of high-quality colostrum. FPT may result from the following: failure of the foal to suck from the dam for any reason and failure of the dam to produce sufficient quantity of high-quality colostrum. Box 21-4 presents causes of FPT. Several methods are available for measuring IgG concentration in blood; the most reliable are enzyme-linked immunosorbent assay and single radial immunodiffusion technology-based tests.<sup>1-7</sup> Foals usually are tested at 24 hours of age, but they can be tested earlier if colostrum ingestion has occurred and a concern exists regarding the passive transfer of immunity status of the foal, with the recognition that additional increases in IgG concentration may occur with additional time.<sup>8,9</sup> The concentration of IgG in the blood of the foal has been used as an indicator of the adequacy of passive transfer, but the actual blood concentration at which FPT is diagnosed has been challenged in recent years.<sup>10-12</sup> Foals with sepsis commonly have a serum IgG concentration of less than 800 mg/dl.<sup>13,14</sup> Foals with FPT are more likely to die from sepsis.<sup>15,16,17-19</sup> One should consider the IgG concentration only as a marker for adequacy of colostrum absorption. All the measured IgG is unlikely to be directed against the specific pathogen affecting any particular neonate, and IgG is not the only immune protection afforded the foal by colostrum. Many factors that confer local and more general immunity to the newborn are present in colostrum; these include growth factors, cytokines, lactoferrins, CD14, leukocytes, and other yet to be described proteins.<sup>20-27</sup> By considering IgG a marker of adequacy for passive transfer, similar to GGT in calves, the clinician can choose a replacement that is more beneficial to

### BOX 21-4

#### CAUSES OF FAILURE OF PASSIVE TRANSFER

##### Maternal Causes

- Premature lactation
  - Placentitis
  - Twins
  - Premature placental separation
- Poor colostrum quality
  - Maiden mares
  - Older mares
- Failure of lactation
  - Aglactia
  - Fescue toxicosis

##### Foal Causes

- Failure to ingest colostrums
  - Weakness
  - Prematurity
  - Musculoskeletal deformity
  - Perinatal asphyxia syndrome
- Failure to absorb colostrums
  - Prematurity
  - Necrotizing enterocolitis

the patient.<sup>27</sup> After FPT is identified, treatment depends on the current condition of the foal and its local environment. Foals not presently ill and on well-managed farms with low population density and low prevalence of disease may not require treatment if their IgG concentration is between 400 and 800 mg/dl. Critically ill neonates with FPT in an equine NICU are by definition ill and in an environment with high disease prevalence. These patients require immediate treatment of FPT and frequent reassessment of their passive immunity status. Critically ill foals often fail to demonstrate the expected increase in blood IgG concentration based on grams of IgG administered per kilogram of body mass compared with healthy, colostrum-deprived foals.<sup>17,28,29</sup> Sick foals also demonstrate a more rapid decline in IgG concentration than do healthy foals because they use and catabolize available protein.

Foals with FPT may be treated by oral or intravenous administration of various products containing IgG. One can attempt oral administration of additional colostrum or IgG-containing products such as plasma, serum, or lyophilized colostrum in foals younger than 12 to 24 hours of age.<sup>30-32</sup> Depending on the age of the foal and the maturity and function of the gastrointestinal tract, this treatment may be effective. Many NICUs and large breeding farms maintain colostrum banks for this purpose. Plasma should be administered intravenously if the foal is not expected to absorb additional colostrum or if the enteral route is unavailable. Commercially available hyperimmune plasma products designed for use in foals are available and can be stored frozen. Plasma and banked colostrum should be stored in a non-frost-free freezer to minimize protein loss associated with freeze-thaw cycling.<sup>33</sup> Plasma should be administered through special tubing with an inline filter, and clinicians should monitor patients closely for transfusion reactions.<sup>34</sup> Serum and concentrated IgG products may be used, but the practitioner should be aware that many of these products

focus on IgG retention and not on other factors associated with passive transfer of immunity. IgG concentration should be measured after transfusion, and additional plasma should be provided as necessary. Administration of plasma to critically ill foals without FPT may be beneficial through provision of other factors present in the plasma. In these situations fresh frozen plasma or fresh plasma may be best, particularly if transfusion of clotting proteins is desired.

## NEONATAL ISOERYTHROLYSIS

*Debra C. Sellon, Pamela A. Wilkins*

Neonatal isoerythrolysis is a hemolytic syndrome in newborn foals caused by a blood group incompatibility between the foal and dam and is mediated by maternal antibodies against foal erythrocytes (alloantibodies) absorbed from the colostrum. The disease most often affects foals born to multiparous mares and should be suspected in foals younger than 7 days of age with clinical signs of icterus, weakness, and tachycardia. A primiparous mare can produce a foal with NI if she has received a prior sensitizing blood transfusion or has developed placental abnormalities in early gestation that allowed leakage of fetal red blood cells into her circulation. Many are the causes of jaundice in newborn foals, including sepsis, meconium impaction, and liver failure, but these usually can be differentiated readily from NI by measuring the PCV, which is usually less than 20% in foals with neonatal NI.

Foals with NI are born clinically normal and then become depressed and weak and have a reduced suckle response within 12 to 72 hours of birth. The rapidity of onset and severity of disease are determined by the quantity and activity of absorbed alloantibodies. Affected foals have tachycardia, tachypnea, and dyspnea. The oral mucosa is initially pale and then becomes icteric in foals that survive 24 to 48 hours. Hemoglobinuria may occur. Seizures caused by cerebral hypoxia are a preterminal event.

The salient laboratory findings are anemia and hyperbilirubinemia. Most of the increased bilirubin is unconjugated, although the absolute concentration of conjugated bilirubin generally is increased well above normal. Urine may be red to brown and is positive for occult blood.

### ☞ CAUSE AND PATHOGENESIS

The natural development of NI has several prerequisites. First the foal must inherit from the sire and express an erythrocyte antigen (alloantigen) that is not possessed by the mare. Blood group incompatibility between the foal and dam is not particularly uncommon, but most blood group factors are not strongly antigenic under the conditions of exposure through previous parturition or placental leakage. Factor Aa of the A system and factor Qa of the Q system are highly immunogenic, however, and nearly all cases of NI are caused by antibodies to these alloantigens. The exception is in the case of mule foals in which a specific donkey factor has been implicated.<sup>1-3</sup> Mares that are negative for Aa or Qa or both are considered to be at risk for producing a foal with NI. The risk involves approximately 19% and 17% of Thoroughbred and Standardbred mares, respectively. Second, and perhaps most important, the mare must become sensitized to the incompatible alloantigen

and produce antibodies to it. The mechanism for this is not known in many instances but generally is believed to result from transplacental hemorrhage during a previous pregnancy involving a foal with the same incompatible blood factor.<sup>3</sup>

Sensitization through transplacental contamination with fetal erythrocytes earlier in the current pregnancy is possible, but an anamnestic response is generally necessary to induce a pathogenic quantity of alloantibodies.<sup>4</sup> Research shows that 10% of Thoroughbred mares and 20% of Standardbred mares have antibodies to the Ca blood group antigen without known exposure to erythrocytes.<sup>3</sup> Some common environmental antigen is postulated, possibly to lead to production of anti-Ca antibodies. Data suggest that these natural antibodies may suppress an immune response to other blood group antigens because mares negative for Aa that have anti-Ca antibodies often do not produce antibodies to Aa of the erythrocytes in their foals that also contain Ca antigen. This antibody-mediated immunosuppression is thought to result from the destruction of fetal cells before the dam mounts an immune response to other cell surface antigens. Natural alloantibodies have not been associated with NI in horses.

After the mare becomes sensitized to the erythrocytes of her foal, alloantibodies are concentrated in the colostrum during the last month of gestation. Unlike the human neonate, who acquires alloantibodies in utero and thus is born with hemolytic disease, the foal is protected from these antibodies before birth by the complex epitheliochorial placentation of the mare. Thus the final criterion for foal development of NI is ingestion in the first 24 hours of life of colostrum-containing alloantibodies specific for foal alloantigens. Immunoglobulin-coated foal erythrocytes are removed prematurely from circulation by the mononuclear phagocyte system or are lysed intravascularly by way of complement. The rapidity of development and severity of clinical signs are determined by the amount of alloantibodies that was absorbed and their innate activity. Alloantibodies against Aa are potent hemolysins and generally are associated with a more severe clinical syndrome than antibodies against Qa or other alloantigens. The highest alloantibody titers are likely to be produced by mares that were sensitized in a previous pregnancy and then subsequently re-exposed to the same erythrocyte antigen during the last trimester of the current pregnancy. Prior sensitization of a mare by blood transfusion or other exposure to equine blood products may predispose to NI.<sup>4</sup>

### ☞ DIAGNOSIS

A tentative diagnosis of NI can be made in any foal that has lethargy, anemia, and icterus during the first 4 days of life. Blood loss anemia caused by birth trauma is attended by pallor. Icterus caused by sepsis or liver dysfunction would not be associated with anemia. The definitive diagnosis of NI must be based on demonstration of alloantibodies in the serum or colostrum of the dam that are directed against foal erythrocytes. The most reliable serodiagnostic test for neonatal NI is the hemolytic crossmatch using washed foal erythrocytes, mare serum, and an exogenous source of absorbed complement (usually from rabbits). Although this test is impractical in a practice setting, a number of qualified laboratories routinely perform this diagnostic service. The direct antiglobulin test (Coombs' test) may demonstrate the presence of antibodies on foal erythrocytes; however, false-negative results occur frequently. Most human or veterinary hematology laboratories can perform

routine saline agglutination crossmatching between mare serum and foal cells. Because some equine alloantibodies act only as hemolysins, agglutination tests may yield false-negative results. Most field screening tests of colostrum have not proved to be reliable enough for practical use.

## ☪ TREATMENT

If NI is recognized when the foal is younger than 24 hours old, the dam's milk must be withheld in favor of an alternative source of milk during the foal's first day of life. This can be accomplished by muzzling the foal and feeding it through a nasogastric tube. The minimum necessary amount of milk is 1% of body mass every 2 hours (e.g., a 50-kg foal should receive 500 ml or 1 pint of mare's milk or milk replacer every 2 hours). The udder of the mare should be stripped regularly (at least every 4 hours) and the milk discarded. In most instances clinical signs are not apparent until after the foal is 24 hours old, when colostrum antibodies have been depleted or the absorptive capacity of the foal's intestine for immunoglobulin has diminished. Withholding milk at this point is of minimal benefit.

Supportive care to ensure adequate warmth and hydration is paramount. The foal should not be stressed, and exercise must be restricted. Confining the mare and foal to a box stall is best. Intravenous fluids are indicated to promote and minimize the nephrotoxic effects of hemoglobin and to correct any fluid deficits and electrolyte and acid-base imbalances. Antimicrobials may be necessary to prevent secondary infections.

One should monitor foals carefully for the necessity of blood transfusion, although transfusion should be used only as a lifesaving measure. When the PCV drops below 12%, blood transfusion is warranted to prevent life-threatening cerebral hypoxia. Erythrocytes from the dam are perfect in terms of nonreactivity with the blood of the foal; however, the fluid portion of the blood of the mare has to be removed completely from the cells to prevent administration of additional harmful alloantibodies to the foal. One can pellet the erythrocytes of the dam from blood collected in acid-citrate-dextrose solution by centrifugation or gravity and then aseptically draw off the plasma by suction apparatus or syringe and replace it with sterile isotonic (0.9%) saline. The cells are thoroughly mixed with the saline, and then the centrifugation or sedimentation is repeated, followed by aspiration and discarding of the saline. This washing process should be repeated at least three times. One then can suspend the packed erythrocytes in an equal volume of isotonic saline for administration. Erythrocyte washing by centrifugation is more desirable than gravity sedimentation because antibody removal is more complete and packed cell preparations can be prepared more quickly (each gravity sedimentation requires 1 to 2 hours). Packed red blood cells are advantageous in overcoming the problem of volume overload.

When equipment or conditions do not allow the safe use of dam erythrocytes, an alternative donor is necessary. Because the alloantibodies absorbed by the foal generally are directed against Aa or Qa and because the latter are highly prevalent among most breeds of horses, a compatible blood donor is difficult to identify. The odds of finding a donor without Aa or Qa are higher in Quarter Horses, Morgans, and Standardbreds than in Thoroughbreds and Arabians. Previously blood-typed individuals negative for Aa and Qa and free of alloantibodies are optimal. Between 2 and 4 L of blood or 1 to 2 L of packed erythrocytes should be given over 2 to 4 hours. These

allogeneic cells have a short life span and represent a large burden to the neonatal mononuclear phagocyte system, which may cause increased susceptibility to infection. In addition, these cells sensitize the foal to future transfusion reactions. All potential harm must be measured against the benefit in each situation.

If a mule foal is the patient, blood from a female previously bred to a donkey should not be used. In cases in which transfusion will be delayed, a compatible donor cannot be identified, or the PCV is so low as to be life-threatening (hemoglobin <5 mg/dl), the clinician may administer polymerized bovine hemoglobin products, if available, at a dose of 5 to 15 ml/kg.<sup>4</sup> Dexamethasone (0.08 mg/kg) may be used to treat peracute NI if the PCV is less than 12% and transfusion may be delayed or is not fully compatible, but dexamethasone has detrimental effects on blood glucose regulation in the neonate, and because the antibody in question is of maternal origin, corticosteroid therapy in immunosuppressive doses probably is not indicated. Intranasal oxygen insufflation (5 to 10 L/min) may be beneficial. Most foals with NI have adequate passive transfer of immunity, but antimicrobial therapy is indicated to protect against secondary sepsis resulting from the compromised condition of the foal. Supportive care and good nursing care, which includes keeping the foal warm and quiet, are essential. The PCV is expected to decline again 4 to 7 days after transfusion.<sup>5</sup>

## ☪ CLIENT EDUCATION

The prognosis for NI in foals depends on the quantity and activity of absorbed antibodies and is indirectly proportional to the rate of onset of signs. In peracute cases the foal may die before the problem is recognized, whereas foals with slowly progressive signs often live with appropriate supportive care.

Like most diseases, NI is much more effectively prevented than treated.<sup>6</sup> Any mare that has produced a foal with NI may well produce another affected foal; thus all subsequent foals should be provided with an alternative colostrum source and the colostrum of the dam discarded unless she is bred to a stallion with known blood type compatibility. Because mares negative for Aa and Qa alloantigens are most at risk of producing affected foals, they should be identified by blood typing. Subsequently, breeding of these mares may be restricted to Aa- and Qa-negative stallions, thus eliminating the possibility of producing an affected foal. In breeds with a high prevalence of Aa or Qa alloantigens (e.g., Thoroughbreds and Arabians), a stallion negative for these and suitable on the basis of other criteria may be difficult to identify. If these "at risk" mares are bred as desired, their serum should be screened in the last month of pregnancy for the presence of erythrocyte alloantibodies. Mares with low or equivocal titers must be tested closer to the time of parturition. If alloantibodies are detected, the colostrum of the dam should be withheld and the foal then should be provided with an alternative colostrum source. Maternal alloantibodies to Ca do not appear to mediate NI in foals and actually may be preventive by removing potentially sensitizing cells from the circulation; therefore foals should not be deprived of colostrum from mares possessing anti-Ca antibodies, even when Ca is present on their erythrocytes. Rarely, the antigens De, Ua, Pa, and Ab have been associated with NI in foals; however, to consider mares without these alloantigens to be at risk for NI is not practical.

## IMMUNE-MEDIATED THROMBOCYTOPENIA AND NEUTROPENIA

Debra C. Sellon, Pamela A. Wilkins

Immune-mediated thrombocytopenia and neutropenia have only recently been described in foals, although they have been widely recognized in human neonates for many years.<sup>1-5</sup> In the first few days of life, affected foals have normal body condition with mild to moderate dehydration, depression, lethargy, and reluctance or inability to suckle. Petechia and ecchymoses of the mucous membranes are common. Some affected foals have crusting miliary dermatitis, especially in the pectoral and groin regions. Clinical pathologic evaluation reveals marked thrombocytopenia (frequently  $<10,000/\mu\text{l}$ ) and neutropenia. The pathogenesis of this disorder is similar to that of NI. It is an alloimmune disorder resulting from ingestion of maternal antibody directed against the foal's platelets or neutrophils. Affected foals may be predisposed to sepsis. The diagnosis is confirmed by appropriate testing for platelet- and neutrophil-associated antibody.<sup>6</sup> Other causes of neonatal thrombocytopenia and neutropenia, particularly sepsis, must be ruled out. Future foals born to the mare seem likely to be at risk for developing similar problems, and these foals should be treated in the same manner as those with NI: prevented from sucking from the dam and provided with an alternative source of passive immunity in the form of banked colostrum or intravenous plasma. An alternative nutritional source, such as foal milk replacer, should be provided to the foal for the first 24 hours of life, and the foal should be muzzled while it is in the company of its dam for that period. Treatment is primarily supportive, but in the case of severe thrombocytopenia, transfusion of platelet-enriched fresh plasma may be indicated. Granulocyte colony-stimulating factor has been used in foals with neutropenia, but substantial efficacy has yet to be demonstrated. Broad spectrum antimicrobial therapy may be prudent in cases of alloantibody-associated neutropenia. Treatment with immunosuppressive doses of corticosteroids is probably unwarranted, given the increased risk of infection, because the antibody in question is of maternal origin. Corticosteroids occasionally may be warranted if the thrombocytopenia is considered to be life threatening.

Other specific diseases of the immune system of foals, severe combined immunodeficiency, selective IgM deficiency, transient hypogammaglobulinemia, agammaglobulinemia, and other unclassified immunodeficiencies are covered in detail elsewhere in this text.

## DISEASES OF THE RESPIRATORY TRACT

Pamela A. Wilkins

### RESPIRATORY DISTRESS

The neonate can experience respiratory distress immediately after birth because of several congenital respiratory tract or cardiac anomalies. Chief among these causes are bilateral

choanal atresia, stenotic nares, dorsal displacement of the soft palate caused by anatomic deformity or neurologic impairment, accessory or ectopic lung lobes, lung lobe hypertrophy, lung lobe dysplasia, cardiac anomalies with right-to-left shunting, and miscellaneous causes such as subepiglottic cysts and severe edema of the larynx.<sup>1-8</sup> These situations must be evaluated and treated immediately, and they should be considered as true emergencies.

Foals with airway occlusion can be recognized by the lack of airflow through the nostrils despite obvious attempts to breathe and by respiratory stridor. These foals may demonstrate open-mouth breathing, and their cheeks may puff outward when they exhale. One foal with congenital bilateral choanal atresia was recognized during extrauterine intrapartum resuscitation because a nasotracheal tube could not be passed. Under most circumstances an effective airway can be established by orotracheal intubation, but some foals require an emergency tracheostomy. The clinician diagnoses the underlying problem by endoscopy or radiography in most cases. Treatment of choanal atresia and cystic structures is surgical, whereas severe laryngeal edema and laryngeal paralysis frequently respond to medical management. Until the underlying problem is resolved in these cases, broad spectrum antimicrobial therapy should be administered and the foal fed by intubation or total parenteral nutrition. Colostrum can be given, but because these foals frequently develop aspiration pneumonia if allowed to suck from their dams, intravenously administered plasma also may be necessary to provide sufficient passive immunity.

### RESPIRATORY DISEASES ASSOCIATED WITH HYPOXEMIA IN THE NEONATE

Arterial blood gas determinations are the most sensitive indicator of respiratory function readily available to the clinician. The most convenient arteries for sampling are the metatarsal arteries and the brachial arteries. Portable arterial-venous blood gas analyzers now are making arterial blood gas analysis more practical in the field, and the technique is no longer reserved for large referral practices. Managing a critically ill equine neonate without knowledge of arterial blood gas parameters is nearly impossible. Pulse oximetry is useful, but these monitors only measure oxygen saturation of hemoglobin. Desaturation can occur rapidly in critically ill neonates. The utility of these monitors in the foal has yet to be demonstrated clearly, particularly in cases of poor peripheral perfusion.<sup>9</sup> The most common abnormalities recognized with arterial blood gas analysis are hypoxemia with normocapnia or hypocapnia and hypoxemia with hypercapnia. *Hypoxemia* is defined as decreased oxygen tension of the arterial blood (decreased  $\text{PaO}_2$ ), and *hypoxia* is defined as decreased oxygen concentration at the level of the tissue, with or without hypoxemia. Hypoxia results from hypoxemia, decreased perfusion of the tissue bed in question, or decreased oxygen-carrying capacity of the blood resulting from anemia or hemoglobin alteration.

Five primary means by which hypoxemia may develop are (1) low concentration of oxygen in the inspired air, such as in high altitude or in an error mixing ventilator gas; (2) hypoventilation; (3) ventilation-perfusion mismatch; (4) diffusion limitation; and (5) intrapulmonary or intracardiac right-to-left shunting of blood. Hypoxemia is not an uncommon finding in neonates but must be evaluated in terms of the current age of the foal and its position.<sup>10,11-14</sup> One also must consider the

TABLE 21-9

Normal Arterial Blood Gas Values for Foals*					
Gestational Age	Postnatal Age	Position	pH	Paco <sub>2</sub> (Mm Hg)	Pao <sub>2</sub> (Mm Hg)
Term†	2 minutes	Lateral	7.31 ± 0.02	54.1 ± 2.0	56.4 ± 2.3

difficulty encountered in obtaining the sample because severe struggling can affect the arterial blood gas results. Table 21-9 presents normal arterial blood gas parameters for varying ages of foals. The normal foal has a small shunt fraction (approximately 10%) that persists for the first few days of life and contributes slightly to a blunted response to breathing 100% oxygen compared with the adult. Hypoxemia frequently occurs in foals with prematurity, PAS, and sepsis, although other conditions also result in hypoxemia in the neonate. In the early stage of sepsis-associated hypoxemia, Paco<sub>2</sub> may be within normal limits or decreased if the foal is hyperventilating for any reason. If the lung is involved significantly in the underlying pathologic condition, such as with severe pneumonia, acute lung injury, or ARDS, increased Paco<sub>2</sub> may well be present, representing respiratory failure.<sup>15,16</sup>

Hypoxemia usually is treated with intranasal humidified oxygen insufflation at 4 to 10 L/min. Hypercapnia is not a simple matter to treat. The clinician must try to distinguish between acute and chronic hypercapnia. Acute hypercapnia usually is accompanied by a dramatic decrease in blood pH of 0.008 pH units for each 1 mm Hg increase in Paco<sub>2</sub>. This acidemia can promote circulatory collapse, particularly in the concurrently hypoxic or hypovolemic patient. The effects of more chronic CO<sub>2</sub> retention are less obvious because the time course allows for adaptation. The pH change is less, about 0.003 pH units per 1 mm Hg increase in Paco<sub>2</sub>, because it is balanced by enhanced renal absorption of bicarbonate by the proximal renal tubule. Most foals with ARDS are in the acute stages of respiratory failure, but chronic adaptation begins to occur within 6 to 12 hours and is maximal in 3 to 5 days. An increase in bicarbonate is evident, particularly if the acidemia is primarily respiratory in origin. Intravenous administration of sodium bicarbonate to correct respiratory acidosis-acidemia should be done cautiously in these foals because CO<sub>2</sub> retention may only be increased. Also, it is important to remember that 1 mEq of sodium is administered with each mEq of bicarbonate, and hypernatremia has been seen in foals treated exuberantly

with sodium bicarbonate. Foals with hypercapnia of several days' duration also may develop a blunted respiratory drive to increased CO<sub>2</sub>. In these foals oxygen administration, although essential to treat hypoxemia, may further depress ventilation and further decrease pH. This effect is caused by a loss of hypoxic drive after oxygen therapy. These foals should be considered as candidates for mechanical ventilation if the Paco<sub>2</sub> is greater than 70 mm Hg or is contributing to the poor condition of the foal, such as causing significant pH changes.<sup>15,16</sup> If hypercapnia is caused by central depression of ventilation, as frequently occurs in foals with PAS, one can administer caffeine (10 mg/kg loading dose; then 2.5 mg/kg as needed) rectally or orally in foals with normal gastrointestinal function. Other clinicians may recommend constant-rate infusions of doxapram hydrochloride for these foals.<sup>17,18</sup> If this therapy fails, mechanical ventilation should be considered. Mechanical ventilation of foals with central respiratory depression is rewarding and may be necessary for only a few hours to days. A special category is the foal with botulism exhibiting respiratory failure caused by respiratory muscle paralysis. These foals do well with mechanical ventilation, although the duration of mechanical ventilation is more prolonged, frequently more than 1 week. Foals with primary metabolic alkalosis usually have compensatory respiratory acidosis. Treatment of hypercapnia is not necessary in these cases because it is in response to the metabolic condition. These foals do not respond to caffeine, and they should not be ventilated mechanically if this is the only disorder present.

## ☪ BACTERIAL PNEUMONIA

In the neonate bacterial pneumonia usually results from sepsis or aspiration during sucking. Foals with sepsis can develop acute lung injury or ARDS as part of the systemic response to sepsis, and this frequently contributes to the demise of foals in septic shock.<sup>19,20</sup> The best way to diagnose bacterial pneumonia is by cytologic examination and culture of a transtracheal

aspirate, but blood culture may aid in early identification of the causative organism and allow for early institution of directed antimicrobial therapy. A second frequent cause of bacterial pneumonia in the neonate is aspiration caused by a poor suck reflex or dysphagia associated with PAS, sepsis, or weakness. The clinician must take care to ensure that aspiration is not iatrogenic in foals being bottle fed. Auscultation over the trachea while the foal is sucking helps identify occult aspiration. Occult aspiration pneumonia should be suspected in any critically ill neonate that is being bottle fed or is sucking on its own and has unexplained fever, fails to gain weight, or has a persistently increased fibrinogen level.

Older foals develop bacterial pneumonia, frequently following an earlier viral infection.<sup>21</sup> Bacterial pneumonia is discussed in depth elsewhere in this text, but a few comments specific to the foal are necessary. The clinician should auscultate and percuss the thorax of the foal, but results may not correlate closely with the severity of disease. The most commonly isolated bacterial organism in foal pneumonia is *Streptococcus equi* subsp. *zooepidemicus*, and one may isolate it alone or as a component of a mixed infection.<sup>21-23</sup> Transtracheal aspirate for culture and cytologic examination is recommended because mixed gram positive and gram negative infections are common, and antimicrobial susceptibility patterns can be unpredictable. The obtained aspirate should be split and samples submitted for bacterial culture, virus isolation, and cytologic examination. Additional diagnostics include radiography, ultrasonography, and serial determination of white blood cell counts (with differential) and blood fibrinogen concentrations. Treatment includes administration of appropriate antimicrobial therapy. Some foals may benefit from nebulization with saline, antimicrobials, or other local products.<sup>24</sup> Ascarid larval migration through the lung can mimic bacterial pneumonia.<sup>25</sup> In these cases the foal may not respond to antimicrobial therapy and should be dewormed with ivermectin. Deworming the mare within 1 month of parturition and frequently deworming the foal prevent ascarid migration pneumonia in most foals.

A special category of bacterial pneumonia in foals is *Rhodococcus equi* bronchopneumonia. This pneumonia of young foals was described first in 1923.<sup>26</sup> The organism, originally known as *Corynebacterium equi*, is a gram positive pleomorphic coccobacillus usually less than 1  $\mu\text{m}$  in diameter and 2  $\mu\text{m}$  in length. *R. equi* has an acid-fast staining characteristic under some growing circumstances because of the presence of mycolic acid in its cell wall, similar to *Mycobacterium* and *Nocardia* species. Mycolic acid promotes granuloma formation. The organism is able to multiply in and destroy macrophages as it prevents phagosome lysosome fusion.<sup>27,28</sup> The organism is thought to be an opportunistic pathogen, and it lives in the soil of most geographic areas. Foals are affected most frequently between the ages of 1 and 6 months, when maternally derived immunity has begun to wane. The disease is insidious, and foals may have significant pulmonary involvement before developing noticeable clinical signs.

Phagocytosis of *R. equi* by equine macrophages is not associated with a functional respiratory burst and, at least in human beings, the L-arginine-NO pathway is not required for intracellular killing of this organism.<sup>29,30</sup> Optimal binding of *R. equi* to mouse macrophages in vitro requires complement and is mediated by Mac-1, a leukocyte complement receptor type 3 (CR3, CD11b/CD18).<sup>31</sup> Opsonization of *R. equi* with specific antibody is associated with increased

phagosome-lysosome fusion and enhanced killing of *R. equi*, suggesting that the mechanism of cellular entry is important.<sup>27</sup> Neutrophils from foals and adult horses are fully bactericidal, and killing of *R. equi* is enhanced considerably by specific opsonizing antibody.<sup>32</sup>

The ability of *R. equi* to induce disease in foals likely depends on host and microbial factors. Knowledge of the virulence mechanisms of *R. equi* was speculative until the discovery of the virulence plasmid.<sup>33</sup> As opposed to most environmental *R. equi* organisms, isolates from clinically affected foals typically contain 85- to 90-kb plasmids encoding an immunogenic virulence-associated protein (VapA) that is expressed on the bacterial surface in a temperature-regulated manner.<sup>34</sup> Plasmid-cured bacteria lose their ability to replicate and survive in macrophages and are cleared from the lungs within 2 weeks of intrabronchial challenge without producing pneumonia.<sup>35</sup> However, expression of VapA alone is not sufficient to restore the virulence phenotype. Six other genes have approximately 40% overall amino acid identity with VapA, and the identification of multiple genes with considerable homology suggests that these genes constitute a virulence-associated gene family in *R. equi*.<sup>36</sup> Other candidates for virulence factors include capsular polysaccharides and cholesterol oxidase, choline phosphohydrolase, and phospholipase C exoenzymes ("equi factors"), but their roles have not been defined clearly.

The primary manifestation of disease caused by *R. equi* infection is severe bronchopneumonia with granuloma, abscess formation, or both. Up to 50% of foals diagnosed with bronchopneumonia also have extrapulmonary sites of infection.<sup>37</sup> As the pneumonia progresses, clinical signs may include decreased appetite, lethargy, fever, tachypnea, and increased effort of breathing characterized by nostril flaring and increased abdominal effort. Cough and bilateral nasal discharge are inconsistent findings. A smaller percentage of affected foals may have a more devastating, subacute form. These foals may be found dead or have acute respiratory distress with a high fever and no previous history of clinical respiratory disease.

Hyperfibrinogenemia is the most consistent laboratory abnormality in foals with *R. equi* pneumonia. Neutrophilic leukocytosis (>12,000 cells/ $\mu\text{l}$ ), with or without monocytosis, is common.<sup>38</sup> Thoracic radiography is a useful diagnostic aid, frequently revealing a prominent alveolar pattern with poorly defined regional consolidation, abscessation, or both. Ultrasonography is a helpful diagnostic tool when the disease involves peripheral lung tissue.<sup>39</sup> Although a number of serologic tests have been described, serologic diagnosis of *R. equi* infections is controversial and difficult because exposure of foals to this organism at a young age leads to production of antibody without necessarily producing clinical disease.<sup>40,41</sup> Bacteriologic culture combined with cytologic examination of a tracheobronchial aspirate remains the most definitive method for accurate diagnosis of *R. equi* pneumonia. However, foals without clinical disease exposed to contaminated environments may have *R. equi* in their tracheae from inhalation of contaminated dust; therefore culture results should be interpreted in the context of the overall case presentation.<sup>42</sup> Culture results in one study were as sensitive as PCR-based assays and offered the advantage of allowing in vitro antimicrobial susceptibility testing.<sup>43</sup> However, PCR is likely to be a useful tool, and results from a second trial suggest that the assay is more sensitive and specific than culture of tracheobronchial aspirates for diagnosis.<sup>44</sup>

The combination of erythromycin and rifampin has long been considered the treatment of choice for *R. equi* infections in foals, and the combination reduces the likelihood of resistance to either drug. The recommended dosage regimen for rifampin is 5 mg/kg every 12 hours or 10 mg/kg every 24 hours orally. The recommended dose of estolate or ethylsuccinate esters of erythromycin is 25 mg/kg every 8 or 12 hours orally.<sup>45</sup> Recently, azithromycin has been recommended for treatment of *R. equi* infection at a dosage of 10 mg/kg orally every 24 hours for 5 to 7 days and then every other day.<sup>46</sup> Alternatively, clarithromycin at 7.5 mg/kg every 12 hours orally, in combination with rifampin, may be used. In a retrospective comparison of rifampin with either erythromycin, azithromycin, or clarithromycin, clarithromycin-rifampin was superior to other treatment options for treatment of pneumonia caused by *R. equi* in foals in a referral population.<sup>47</sup> Severely affected foals may require intranasal oxygen insufflation, intravenous fluid support, and nutritional support. Treatment generally continues for 4 to 10 weeks until all clinical and laboratory evidence of infection is resolved. Although well tolerated by most foals, erythromycin can result in soft feces. Although this diarrhea is generally self-limiting and does not require cessation of therapy, affected foals should be carefully monitored. An idiosyncratic reaction characterized by severe hyperthermia and tachypnea has been described in foals treated with erythromycin during periods of hot weather.<sup>48</sup> Affected foals should be moved to a colder environment and treated with antipyretic drugs and alcohol baths if necessary. *Clostridium difficile* enterocolitis has been reported in the dams of nursing foals given oral erythromycin.<sup>49</sup> The dam is exposed to active erythromycin by coprophagy or by drinking from a communal water source where the foal has rinsed its mouth.

Prevention of *R. equi* pneumonia on farms with recurrent problems is problematic. The most studied prophylactic measure to date has been the administration of plasma that is hyperimmune to *R. equi* to foals within the first week of life and then again when maternal immunity begins to wane, at approximately 30 days of age.<sup>50-57</sup> No effective vaccination protocols for the dam or foal have been described to date. Farm management is important in preventing disease, and control measures include frequent manure removal, avoidance of overcrowded conditions, and planting of dusty or sandy soils.<sup>50</sup>

The prognosis for *R. equi* bronchopneumonia is fair to good in foals with the more chronic form of the disease. Foals with acute respiratory distress have a more guarded prognosis, as do foals with sites of significant extrapulmonary infection. The long-term prognosis for survival for foals with *R. equi* bronchopneumonia is good, and many foals perform as expected as athletes.<sup>58</sup>

## ☪ VIRAL PNEUMONIA

The most commonly identified causes of viral pneumonia in foals are EHV-1 and EHV-4, equine influenza, and equine arteritis virus (EVA). These infectious diseases are discussed in detail in Chapter 9. EHV-1 is probably the most clinically important viral respiratory disease of foals, but outbreaks of EVA in neonates have occurred and are devastating.<sup>59-66</sup> Adenovirus is reported sporadically and is a problem in Arabian foals with severe combined immunodeficiency.<sup>67-69</sup>

In the neonate infection with EHV-1 or EVA is almost uniformly fatal, and antemortem diagnosis is difficult, even

once an outbreak on a particular farm is identified. Several factors appear common to foals with EHV-1, including icterus, leucopenia, neutropenia, and petechial hemorrhage, but these problems also are identified in foals with severe sepsis.<sup>62,70,71</sup> The antiviral drug acyclovir (10 to 16 mg/kg orally or rectally 4 to 5 times per day) has been used in cases of EHV-1 in neonates, with some evidence of efficacy in mildly affected foals or foals affected after birth.<sup>71</sup> Although acyclovir has poor oral bioavailability in adult horses, the pharmacokinetics remain unexamined in foals.<sup>72</sup> It is possible that valacyclovir, an oral prodrug of acyclovir, may prove useful in the future.<sup>73</sup> If viral pneumonia is a possibility, blood and tracheal aspirates should be collected at presentation for bacterial and virus isolation. The lungs of foals with EHV-1 or EVA are non-compliant, and pulmonary edema may be present. Mechanical ventilation of these cases may prolong life, but death is generally inevitable because of the magnitude of damage to the lungs. Foals suspected of having EHV-1 or EVA should be isolated because they may be shedding large quantities of virus and pose a threat to other neonates and pregnant mares. Foals with EVA generally are born to seronegative mares, and intravenous treatment with plasma with a high titer against EVA may prove beneficial because passive immunity appears to have a significant role in protecting neonates against this disease.<sup>66,74</sup>

Older foals and weanlings may be affected by herpesviruses. Disease is usually mild, although a fatal pulmonary vasculotropic form of the disease has been described recently in young horses.<sup>75,76</sup> The clinical signs of disease are indistinguishable from influenza and include a dry cough, fever, and serous to mucopurulent nasal discharge, particularly if secondary bacterial infection occurs. Rhinitis, pharyngitis, and tracheitis may be present. Treatment of affected foals is primarily supportive. Foals also may become infected with EHV-2. The predominant clinical signs are fever and lymphoid hyperplasia with pharyngitis.<sup>77,78</sup> Diagnosis is by virus isolation.

## ☪ OTHER CAUSES OF RESPIRATORY SIGNS IN FOALS

### FRACTURED RIBS

Rib fractures have been recognized in 3% to 5% of all neonatal foals and can be associated with respiratory distress.<sup>79,80</sup> Potential complications of rib fractures include fatal myocardial puncture, hemothorax, and pneumothorax. Rib fractures frequently are found during physical examination by palpation of the ribs or by auscultation over the fracture sites. The diagnosis is confirmed by radiographic and ultrasonographic evaluation. Often, multiple ribs are affected on one side of the chest. Specific treatment generally is unnecessary, but direct pressure on the thorax is never recommended. Some patients may benefit from surgical stabilization of certain fractures, particularly those overlying the heart.<sup>81</sup>

### PNEUMOTHORAX

Pneumothorax can occur spontaneously; as a complication of excessive positive pressure ventilation<sup>80,82</sup>; or after tracheostomy, surgery, or trauma. Any foal being ventilated mechanically that suddenly has respiratory distress and hypoxemia

should be evaluated for pneumothorax. Diagnosis is by auscultation and percussion of the thorax, but one can confirm the diagnosis with radiographic and ultrasonographic evaluation of the thorax. Needle aspiration of air from the pleural space also confirms the diagnosis. Treatment is required when clinical signs are moderate to severe or progressive and involves closed suction of the pleural space. Subcutaneous emphysema can complicate treatment of this problem.

### IDIOPATHIC TACHYPNEA

Idiopathic or transient tachypnea has been observed in Clydesdale, Thoroughbred, and Arabian breed foals. In human infants transient tachypnea can be related to delayed absorption of fluid from the lung, perhaps because of immature sodium channels.<sup>83</sup> In foals tachypnea generally occurs when conditions are warm and humid and is thought to result from immature or dysfunctional thermoregulatory mechanisms. Clinical signs of increased respiratory rate and rectal temperature develop within a few days of birth and may persist for several weeks. Treatment involves moving the foal to a cooler environment, body clipping, and provision of cool water or alcohol baths. These foals frequently are treated with broad spectrum antimicrobial drugs until infectious pneumonia can be ruled out.

### ATYPICAL INTERSTITIAL PNEUMONIA

A syndrome of bronchointerstitial pneumonia and acute respiratory distress has been described in older foals and appears to be a distinct entity from ARDS in neonatal foals in association with sepsis.<sup>19,20,84</sup> The underlying cause has not been identified, but the genesis is probably multifactorial, with several potential pathogens being implicated. Affected foals have acute respiratory distress with significant tachypnea, dyspnea, nostril flare, and increased inspiratory and expiratory effort. Auscultation reveals a cacophony of abnormal sounds, including crackles and polyphonic wheezes in all lung fields. Loud bronchial sounds are audible over central airways, and bronchovesicular sounds are lost peripherally. Affected foals are cyanotic, febrile, and unwilling to move or eat. Foals may be found acutely dead. Laboratory abnormalities include leukocytosis, hyperfibrinogenemia, and hypoxemia with hypercapnic acidosis. Foals can be severely dehydrated and have coagulation changes consistent with disseminated intravascular coagulation. Hypoxic injury to other organs, primarily the kidneys and liver, can occur. Thoracic radiographs reveal a prominent interstitial pattern overlying a bronchoalveolar pattern that is distributed diffusely throughout the lung. This syndrome is a respiratory emergency. Treatment is broad based and includes administration of oxygen, nonsteroidal anti-inflammatory agents, broad spectrum antimicrobial therapy, nebulization, judicious intravenous fluid therapy, nutritional support, and corticosteroid therapy. Hyperthermia in the foal must be managed. Corticosteroid therapy appears to have been life-saving in most of the reported surviving foals. Because this syndrome is associated with high environmental temperatures in some areas, prevention involves control of ambient temperatures, not transporting foals during hot weather, and keeping foals out of direct sun on hot days, particularly foals being treated with erythromycin for suspected or confirmed *R. equi* infection.<sup>85</sup>

## DISEASES OF THE URINARY TRACT

Pamela A. Wilkins

### UROPERITONEUM

Uroperitoneum has been recognized as a syndrome in foals for more than 50 years.<sup>1,2</sup> Classically, affected foals are 24 to 36 hours old when clinical signs are first recognized.<sup>3</sup> Previous reports had a proportionately larger affected male than female population.<sup>4-6</sup> The hypothesis was that colts were more at risk because their long, narrow, high-resistance urethra was less likely to allow bladder emptying, resulting in rupture of a full bladder during parturition when high pressures were applied focally or circumferentially around the bladder.<sup>1</sup> More recent reports suggest that such extreme sex bias may have been an artifact of small case numbers in the early reports.<sup>6,7</sup>

Rupture or disruption of any structure of the urinary tract can occur. The dorsal wall of the bladder has been reported as a frequent disruption site, with the ventral wall less likely to be involved.<sup>3</sup> The urachus appears to be the next most commonly affected structure. A few cases of ureteral and urethral defects have been reported.<sup>3,6</sup> Sepsis does not appear to favor one site over the others.<sup>6,7</sup>

The pathophysiology of uroperitoneum is not yet understood fully. The high pressure exerted on a full bladder during parturition once was thought to be the main cause. Full bladder and obstruction caused by a partial umbilical cord torsion at parturition, strenuous exercise, and external trauma have been reported as causes.<sup>8</sup> A few reports describe smooth and noninflamed edges of torn tissue, suggesting the possibility of congenital bladder wall defects.<sup>6,9,10</sup> Sepsis leading to urinary tract rupture and uroperitoneum may occur in foals hospitalized for a variety of unrelated problems. The onset of clinical signs of uroperitoneum may be insidious in these foals, and diagnosis may be less obvious.<sup>6,7</sup>

Clinical signs associated with uroperitoneum in the neonatal foal typically include straining to urinate, dribbling urine, and a stretched-out stance. Weakness, tachycardia, tachypnea, and not sucking well are also common. A distended abdomen may be evident, and one may feel a fluid wave on ballottement of the abdomen. Occasionally, urine accumulates in the scrotum and should not be confused with hernia. Foals also may show signs of sepsis, including fever, injected mucous membranes, diarrhea, and disease of other body systems.

Laboratory findings vary depending on the duration of the uroperitoneum and on the presence and severity of sepsis. Classic findings include hyperkalemia, hyponatremia, and hypochloremia arising from equilibration of urine electrolytes and water with blood across the peritoneal membrane.<sup>3-5</sup> The usual foal diet of milk, which is high in potassium and low in sodium, promotes the electrolyte abnormalities. Foals that develop uroperitoneum while receiving intravenous fluids may not have classic electrolyte imbalances at the time clinical signs are recognized.<sup>6,7</sup> Increased serum creatinine concentration is often present, whereas blood urea nitrogen concentrations occasionally, but not consistently, are increased.<sup>3-5</sup> Metabolic acidosis and hypoxemia may be present. Some patients also have serum hypo-osmolality.<sup>4</sup> Foals should be tested for FPT. One of the most sensitive laboratory tests for uroperitoneum is

the ratio of peritoneal to serum creatinine. A ratio greater than or equal to 2:1 is considered diagnostic of uroperitoneum. Peritoneal fluid should be collected and tested for creatinine concentration, as well as for cytologic findings, bacteriologic culture, and sensitivity. Cytologic evaluation of peritoneal fluid is necessary to identify concurrent peritonitis or other gastrointestinal compromise. An electrocardiogram should be performed on initial evaluation of a foal with suspected uroperitoneum because hyperkalemia may result in bradycardia, increased duration of the QRS complex, a shortened Q-T interval, increased P-wave duration, prolonged P-R interval, or atrioventricular conduction disturbances. Other possible cardiac sequelae to hyperkalemia include cardiac arrest, third-degree atrioventricular block, ventricular premature contractions, and ventricular fibrillation.<sup>3,8</sup>

For any foal exhibiting signs of dyspnea, tachypnea, or hypoxemia, thoracic radiographs should be taken before induction of anesthesia to rule out pleural effusion, pneumonia, or ARDS, which could complicate ventilation and oxygenation during anesthesia and the postoperative period. Foals with uroperitoneum are frequently hypoxemic before surgical relief, particularly those in which the problem is the primary complaint, likely because of increased intra-abdominal pressure and the development of abdominal compartment syndrome.<sup>11,12</sup> Ultrasonography has become the tool of choice in the diagnosis of uroperitoneum and is a useful tool available to the practitioner.<sup>13</sup> Free peritoneal fluid is readily imaged, and tears in the bladder are readily visible. The empty bladder with a significant defect, in a fluid-filled abdomen, will collapse on itself and often have a U shape. Urachal and urethral lesions can also be visualized. Six of eight foals in one study had urinary tract lesions identified sonographically, and all 31 foals of another study underwent sonographic evaluation; a significant correlation between ultrasonographic findings and location of the lesion at surgery existed.<sup>5,6</sup>

Initial treatment aims to stabilize the patient and correct any electrolyte and acid-base abnormalities and provide fluid volume replacement. Until laboratory data are available, 0.9% or 0.45% saline with 5% dextrose should be used. A potassium concentration of greater than 5.5 mEq/L can be life threatening. Hyperkalemia can be managed by peritoneal drainage to decrease whole-body potassium stores using teat cannulae, Foley catheters, large-gauge (16 or 14) intravenous catheters, or human peritoneal dialysis catheters. Fluid replacement at least should equal the amount of fluid removed from the abdomen to prevent acute hypotension caused by expansion of previously collapsed capillary beds. Abdominal drainage also helps ventilation and decreases the work of breathing by decreasing pressure on the diaphragm. Calcium gluconate, glucose, sodium bicarbonate, or insulin may be administered intravenously to decrease serum potassium concentrations. These maneuvers do not correct the whole-body potassium overload, however, and once therapy is discontinued, hyperkalemia can reappear until the urine is removed from the abdomen. Hyponatremia should be corrected slowly. Because of the real possibility of concurrent sepsis, blood cultures should be obtained before preoperative administration of antimicrobials. Broad spectrum coverage (penicillin and amikacin or ceftiofur sodium) is recommended until culture results become available. Therapeutic drug monitoring should be performed when using aminoglycoside therapy. However, because the peak value may be depressed as a result of the increased volume of distribution represented by the volume

of urine in the abdomen, the clinician should not adjust the dose on the basis of a low peak until a new peak is obtained after surgical correction of the uroperitoneum. Foals with FPT should be treated with adequate volumes of intravenously administered plasma.

After addressing the metabolic abnormalities, the clinician may consider surgical management. Medical management using an indwelling Foley catheter has been described.<sup>14</sup> Preoperative medical stabilization reduces anesthetic risk. Safer inhalant agents such as isoflurane also have decreased risk. Removal of the internal umbilical remnant at the time of surgery is usual. One should consider culturing any removed umbilical remnant and submitting the remnant for histopathologic evaluation. Urinary tract rupture can recur. Sepsis, hypoxemia, pneumonia, peritonitis, and ARDS complicate the management of uroperitoneum. Many affected foals are persistently oxygen dependent for several days after surgical correction, and serial arterial blood gas analyses should be performed before intranasal oxygen supplementation is discontinued.

Prognosis is associated closely with concurrent illness, especially septicemia. Uncomplicated uroperitoneum resulting from a defect in the bladder has a good prognosis. If the location of the lesion is other than the bladder, the prognosis is not as favorable.<sup>6</sup> Foals with septicemia have a much poorer prognosis.<sup>6-8</sup>

## ☿ ACUTE RENAL FAILURE

Acute renal failure most often occurs as a complication of prenatal asphyxial syndrome, sepsis, or aminoglycoside therapy. Acute renal failure also has been reported after oxytetracycline administration in foals.<sup>15</sup> The dose of oxytetracycline commonly used to treat flexural deformities in foals is approximately 10 times the antimicrobial dose. Many foals treated in this manner also have suffered some degree of perinatal asphyxia, which damages the kidney, because of prolonged parturition precipitated in part by the flexural deformity. Evaluation of renal function in these foals before the administration of the first dose of oxytetracycline and continued monitoring of serum creatinine concentrations before the administration of subsequent doses of this nephrotoxic compound would seem reasonable. Hemodialysis has been used as therapy in one of these cases, but prevention is important because these foals may fail to respond to usual therapy for oliguric renal failure and are euthanized.<sup>15</sup>

## ☿ CONGENITAL RENAL DISEASE

The most commonly reported congenital deformity of the kidney of the foal is renal hypoplasia and dysplasia, which may have a heritable component.<sup>16,17</sup> Renal arteriovenous malformations also have been reported.<sup>18</sup> Ectopic ureters and fenestrated ureters have been described in the foal.<sup>19-21</sup> Congenital renal defects, among others, were reported in three weak, recumbent neonatal foals born to mares being treated for equine protozoal myeloencephalitis.<sup>22</sup> Mares received sulfadiazine or sulfamethoxazole-trimethoprim, pyrimethamine, folic acid, and vitamin E orally. The foals were anemic, leucopenic, azotemic, hyponatremic, and hyperkalemic. Serum folate concentrations were lower than those reported in the literature for clinically normal brood mares. Treatment was unsuccessful. Necropsy revealed lobulated kidneys with

thin cortices and a pale medulla. The authors postulated that oral administration of sulfonamides, 2,4-diaminopyrimidines (pyrimethamine with or without trimethoprim), and folic acid to mares during pregnancy is related to congenital defects in newborn foals.

## ☞ UMBILICAL DISORDERS

The umbilicus serves as the conduit for nutrition and gas exchange between the dam and the fetal foal. The urine from the foal is expelled through this structure into the allantoic cavity. The author has recognized cases of in utero bladder distention in the fetus that were associated with multiple twists decreasing urine flow or focal stenosis creating the same effect. Foals born with this condition did not have bladder rupture associated with parturition but did have other severe abnormalities that eventually resulted in their demise, primarily premature delivery with failure to adapt to extrauterine life.<sup>23</sup> At birth the umbilicus breaks, leaving a small external remnant and a large internal remnant. The umbilicus long has been regarded as the primary site of entry of pathogens into the neonate, although this has been challenged recently. Treatment of the umbilicus after birth involves dipping it (preferably just the most distal component) with various caustic compounds. The most current recommendation is to treat the umbilicus with dilute chlorhexidine, povidone-iodine, or dilute iodine solutions just a few times after birth. Exuberant treatment of the umbilical stump with caustic solutions can lead to scalding of the ventral abdomen and may promote patency of the urachus. The ultrasonographic appearance and measurements of the umbilical arteries, urachus, and umbilical vein of foals from 6 hours to 4 weeks of age have been described in detail.<sup>24</sup> A 7.5-MHz sector scanner transducer placed across the midline of the ventral portion of the abdominal wall of the foal works best because of the superficial location of these structures. The mean ( $\pm$  SD) diameter of the umbilical vein was  $0.61 \pm 0.20$  cm immediately cranial to the umbilical stalk,  $0.52 \pm 0.19$  cm midway between the umbilicus and liver, and  $0.6 \pm 0.19$  cm at the liver. The urachus and umbilical arteries of normal foals have a mean total diameter of  $1.75 \pm 0.37$  cm at the bladder apex. The umbilical arteries scanned along either side of the bladder have a mean diameter of  $0.85 \pm 0.21$  cm. These measurements and the ultrasonographic appearance of the internal umbilical structures from clinically normal foals can be used as references to diagnose abnormalities of the umbilical structures in neonatal foals.<sup>24,25</sup> The most common abnormalities of these structures are focal abscess formation, hematoma, and urachal tear.

## HERNIA

Herniae traditionally have been thought to develop from failure of closure at the umbilical stump after birth. However, the closure of the body wall defect at the umbilicus was studied in relation to the development of umbilical herniae in a large group of normal foals followed from birth until 5 months of age or from birth until 11 months of age.<sup>26</sup> At birth approximately half of these foals had a defect in the body wall at the umbilicus that was termed a *palpable umbilical ring*. In 18 foals this defect disappeared within 4 days, but in one foal the ring did not close and a hernial sac with abdominal contents was palpable. This foal was considered to be the only foal to have a truly congenital umbilical hernia. Twelve foals developed an

umbilical hernia between 5 and 8 weeks of age. The prevalence of umbilical herniae was much higher than in other studies, possibly because of the prospective nature of the study. On the basis of this study, the great majority of umbilical herniae would appear not to result from failure of closure but rather to be acquired after birth. One should consider the palpable ring structure within the body wall at the umbilicus a variant of normal in the foal and should not call it a hernia until the foal is at least 1 month of age.

In one study of 147 horses treated for umbilical herniae over a 13½-year period, only 8.8% developed complications in association with umbilical defects.<sup>27</sup> Six horses had intestinal incarceration; the incarceration was reduced manually in three horses before admission and resolved without treatment in two others. The hernia was surgically reduced in one horse. Herniorrhaphy was performed on four of the five horses in which the incarceration did not require surgical reduction, and the fifth was managed conservatively. The study confirmed that complications of umbilical herniae are rare in horses; however, when they do develop, they may be one of various forms, some of which are insidious in onset. The primary differential diagnosis for an external swelling in the umbilical stump region is an external abdominal abscess, which will be firm, variably painful, warm, and nonreducible. Ultrasonographic evaluation readily can confirm either possibility.

## OTHER CONGENITAL ABNORMALITIES

One report describes a 3-day-old foal that died from intestinal strangulation caused by a remnant of vitelline vein that extended between the umbilicus and the portal vein.<sup>28</sup>

## PATENT URACHUS

Patent urachus frequently is recognized in the abnormal neonate, probably because of the increased recumbency and decreased movement of these patients. Cauterization of a patent urachus is no longer recommended except in cases that persist for long periods of time (>1 month) after the foal becomes more active. Surgical resection may provide relief in some foals, but most cases resolve without treatment if given enough time. Foals with a patent urachus may posture and strain frequently to urinate; some of this may be associated with irritation or local infection of the urachus. These symptoms can be alleviated by administration of broad spectrum antimicrobial therapy that obtains high drug concentrations in the urine (e.g., trimethoprim-sulfa drug combinations) and by oral administration of phenazopyridine hydrochloride (Pyridium), a dye that anesthetizes the urinary tract epithelial surfaces (see Table 21-8). This dye turns the urine orange and stains everything yellow-orange that it or the urine touches but can provide a great deal of relief to foals with this problem.

## UMBILICAL REMNANT INFECTION

The umbilicus has been considered the traditional point of entry of bacteria into the septic neonate, and septic foals were referred to as having “navel ill” and “joint ill” in the past. Although the gastrointestinal tract is now thought to be the route of entry in most septic neonates, infection of the umbilicus—termed *omphalitis*, or *omphalophlebitis* if the

vessels are involved—still occurs as a single focus of infection or along with more generalized infection. External signs, such as swelling, heat, pain, ventral edema, or purulent discharge may be present in some foals, but usually external signs are minimal and infection is suspected because of infection in another site (e.g., an infected joint), fever, or otherwise unexplained increased blood fibrinogen concentration. The diagnosis is confirmed by ultrasonographic evaluation of the internal umbilical remnant. Any of the umbilical structures may be involved. A complete description of the evaluation is available in the relevant veterinary literature, but the examination is performed best using a 7.5-MHz probe with a stand-off and with the foal standing.<sup>24</sup> The usual finding is that the affected structure is larger than expected. A fluid-filled core and echogenic shadows consistent with gas may be apparent in some cases. Interpretation requires some experience, and the examiner should be familiar with variants of normal, such as gas shadows associated with a patent urachus and enlarged vessels caused by hematoma formation, so that treatment is not initiated inappropriately.

Two options for treatment are surgical and medical. Medical treatment is preferable in cases in which the lesion is well localized and small and in foals with a medical condition that is not amenable to anesthesia and surgical intervention. Broad spectrum antimicrobial therapy should be instituted and may need to be continued for 2 to 3 weeks. Most affected foals respond to medical therapy. Frequent reevaluation of the abnormality is necessary, every 5 to 7 days initially, and blood fibrinogen concentrations should be measured at re-evaluation because they should stabilize and decrease with effective treatment. Failure to respond to therapy in 10 days to 2 weeks suggests that an empiric change in the antimicrobial used may be necessary. In foals that are refractory to medical management or in which the lesion is large, surgical excision of the entire umbilical remnant may be desirable.

## DISEASES OF THE GASTROINTESTINAL TRACT

*Pamela A. Wilkins*

### ☉ COLIC IN THE NEONATE

Colic in the foal can be difficult to diagnose accurately because rectal examination is not possible. However, many diagnostic aids, the most important of which is ultrasonography, are available to help differentiate medical from surgical causes of abdominal discomfort in the foal.

### ☉ OBSTRUCTION

Intestinal accidents of all types described in adult horses, with the possible exception of enteroliths, occur in foals. Intussusception, volvulus, displacement, diaphragmatic hernia, and intraluminal and extraluminal obstruction have been reported in foals. Abdominal ultrasonographic and radiographic evaluation greatly aids diagnosis. Treatment is primarily surgical. Foals with PAS and intestinal dysmotility are at increased risk of intussusception and displacement, and Miniature breed foals appear to be at increased risk for fecolith formation.

### ☉ MECONIUM RETENTION AND IMPACTION

Meconium retention or impaction is a common cause of abdominal discomfort in newborn foals. Most foals defecate shortly after their first meal. The usual practice for most owners or veterinarians attending the birth of a foal is to administer an enema to aid this process. In the past phosphate-based commercially available enemas (e.g., Fleet) were used frequently, but if used excessively these types of enemas can create problems of their own, including rectal irritation and hyperphosphatemia. The best enema is warm soapy water made with a mild soap such as liquid Ivory soap that can be administered through soft rubber tubing using gravity flow. Foals with significant meconium retention become colicky within the first few hours of life as gas accumulates within the bowel. Frequently, the meconium can be palpated through the abdominal wall unless gas distention and abdominal tympany is advanced. Additional diagnostics can include abdominal ultrasonography and radiography, particularly if it is necessary to rule out other, more serious types of colic. These foals assume a classic stance with an arched back. The clinician must differentiate this stance from the stance assumed by foals with uroperitoneum, which is more extended. Foals with meconium retention may have simultaneous ruptured bladder, however, so the clinician must be sure to evaluate the foal fully for both problems. Foals that do not respond rapidly to enema administration need additional treatment, which can include giving mineral oil (2 to 4 ounces) by nasogastric tube. Persistent meconium retention resulting in significant abdominal distention is treated by muzzling the foal to prevent further milk intake and administering intravenous fluids at an appropriate maintenance rate. If constant-rate infusion is possible, 5% to 10% dextrose is the preferred fluid to use to provide some calories to the foal and approximate the free water needs of the foal. Dextrose should not be used as a bolus fluid. More aggressive treatment would include administration of retention enemas made using acetylcysteine, which serves as an irritant and increases secretion. A 4% acetylcysteine solution, pH 7.6, is made by adding 20 g of baking soda and 8 g of acetylcysteine to 200 ml of water. A 30-french Foley catheter is inserted approximately 2.5 to 5 cm into the rectum and the bulb is slowly inflated to occlude the rectum. Between 100 and 200 ml of the solution is administered by gravity flow and retained for 30 to 45 minutes by occluding the catheter.<sup>1</sup>

Extreme cases of meconium retention may require surgical intervention, but this is usually not necessary, and most cases resolve with medical management alone within 12 to 24 hours. Some foals require pain management. Nonsteroidal anti-inflammatory drugs should be used with caution in the neonate because of their effects on renal function and gastric mucosal blood flow (see the section on gastric ulcers). Many foals respond well to butorphanol administered intramuscularly at a dose of 0.05 to 0.1 mg/kg.<sup>2</sup> Intranasal oxygen insufflation is beneficial in foals with significant abdominal distention.<sup>3</sup>

One should evaluate foals with meconium impaction or retention for evidence of PAS because intestinal dysmotility is common with this condition. Colostrum is a laxative, and these foals also may suffer from FPT, with meconium retention resulting from the lack of adequate colostrum. These foals are also at risk of sepsis because the mucosal intestinal barrier probably has been disrupted and translocation of bacteria can

occur. Blood cultures should be obtained, and the foals should be monitored closely for signs of sepsis.

## ☞ CONGENITAL DEFECTS

Atresia within the gastrointestinal system of the foal occurs infrequently, but clinical signs are characteristic.<sup>4</sup> Acute colic occurs within the first few hours and is accompanied by abdominal distention similar to that produced by meconium retention. Three primary types of atresia are described in the foal: membrane atresia, cord atresia, and blind-end atresia. Antemortem diagnosis of atresia, short of abdominal exploratory surgery, is aided by the lack of meconium staining of the rectum or any administered enema fluids. Additional diagnostic tests may include administration of a barium enema for a radiographic study, colonoscopy, and abdominal ultrasonography. Abdominocentesis usually is normal until bowel rupture is imminent or has occurred. Affected foals may be made more comfortable by muzzling them to prevent further milk intake and by supplying them with fluids and nutrition intravenously. If surgical correction is attempted, broad spectrum antimicrobial therapy should be initiated and passive transfer status determined. Frequently, these foals are hypoxemic because of the abdominal distention, and oxygen supplementation is desirable.

## ☞ LETHAL WHITE SYNDROME

Solid white foals born to overo-overo matings of American Paint Horses may suffer from congenital aganglionosis of the ileum, cecum, and colon (see Chapter 15). These foals present similarly to foals with meconium impaction or atresia in that colic develops shortly after birth and involves progressive abdominal distention with feeding. The inherited defect is in the endothelin receptor gene.<sup>5-8</sup> No effective treatment exists, but the clinician should be aware that not all white foals of this mating are affected, and some simply may have meconium retention; therefore a short period of treatment may be warranted.

## ☞ NECROTIZING ENTEROCOLITIS

Necrotizing enterocolitis is considered the most common acquired gastrointestinal emergency of human infants.<sup>9,10</sup> The 1500 to 2000 infants who die every year from this disease in the United States and the large number of infants who develop short gut syndrome from this disease represent only the tip of the iceberg of the problems necrotizing enterocolitis causes. The pathogenesis of necrotizing enterocolitis is unknown but may result from a disturbance of the delicate balance among gastrointestinal perfusion, enteric organisms, and enteral feeding. Risk factors for necrotizing enterocolitis in human infants include prematurity, hypoxic-ischemic insult, and formula or breast milk feedings. The clinical spectrum of necrotizing enterocolitis is multifactorial and ranges from temperature instability, apnea, lethargy, abdominal distention, bilious residuals, septic shock, disseminated intravascular coagulation, and death. Medical management is usually adequate treatment for necrotizing enterocolitis, although surgical resection and anastomosis may be required in the most severe cases. In the neonatal foal necrotizing enterocolitis is probably one of the most underrecognized causes of gastrointestinal dysfunction and in the past has been attributed only

to infection with anaerobic organisms including *Clostridium perfringens* type C and *C. difficile*.<sup>11</sup> Although a specific form of enteritis in the foal is associated with intestinal infection by these organisms, most necrotizing enterocolitis is associated with prematurity or PAS in the infant and the foal.

Necrotizing enterocolitis should be suspected in any foal that is having difficulty tolerating oral feeding, demonstrating signs of ileus, or having episodes of colic and in any foal with occult blood, digested blood, or frank blood in the stool or reflux. Foals exhibiting any of these clinical signs should not be fed orally if possible and should receive parenteral nutrition until gastrointestinal function returns to near normal. The mucosal barrier of the intestine is unlikely to be fully intact, and these foals are at risk for sepsis resulting from bacterial translocation. These foals should receive broad spectrum antimicrobial therapy, and if any evidence of coordinated gastrointestinal motility is apparent, sucralfate should be administered orally as a protectant.

## ☞ GASTRIC ULCERS

Gastric ulcer disease has been recognized in foals, and lesions vary in anatomic distribution, severity, and cause. In clinically normal neonatal foals (<30 days of age), gastric ulcers and mucosal desquamation have been documented (see Chapter 15).<sup>12-15</sup> Because of these reports and other early reports of death caused by ruptured clinically silent ulcers in neonatal foals, for years many clinicians believed prophylactic treatment of critically ill neonates with antiulcer medication was necessary.<sup>16-18</sup> Recently, this paradigm has been challenged.

The pathophysiology of gastric ulcer disease is described most reasonably as an imbalance in protective and aggressive factors.<sup>19-21</sup> These protective factors are responsible for maintaining a healthy gastrointestinal tract by promoting adequate mucosal blood flow, adequate mucus and bicarbonate production, prostaglandin E<sub>2</sub> production, epithelial growth factor production, gastric afferent innervation, epithelial cell restitution, and gastroduodenal motility. Probably the most important factor is maintenance of mucosal blood flow. Hypoxia, NO, prostaglandins, and gastric afferent innervation influence mucosal blood flow. The aggressive factors include gastric acid, bile salts, pepsin, and enzymes. Few specific causes have been found for gastric ulcer disease in foals. Excessive administration of nonsteroidal anti-inflammatory drugs can result in ulceration of the glandular and squamous epithelium because of an inhibition of prostaglandin production, which leads to a decrease in mucosal blood flow and an increase in acid production. Nonsteroidal anti-inflammatory drugs also can impair the healing of lesions and should be used with caution in neonatal equine medicine.<sup>20,21</sup>

In the critically ill neonate, the suspected cause of gastric ulcers has shifted away from an excessive amount of intraluminal gastric acid toward gastric mucosal ischemia caused by hypoxia, low blood flow conditions, or both.<sup>22</sup> Perforating gastric ulcers are more likely a manifestation of necrotizing enterocolitis than of excessive gastric acid. Shock, sepsis, or trauma can result in gastric mucosal ischemia, allowing for the disruption of epithelial cell integrity and permitting damage by aggressive factors or providing an environment suitable for the establishment of bacterial colonization.<sup>22,23</sup> Impairment of mucosal blood flow also may result in reperfusion injury, allowing the formation of gastric ulcers. In the sick neonatal

foal (<7 days of age), a wide variability in the intragastric pH has been documented depending on the type of disease, severity, and milk intake frequency and volume, suggesting that in the critically ill equine neonate, ulcer prophylaxis using histamine antagonists or proton pump inhibitors is not only unnecessary but also unlikely to work.<sup>24</sup>

Clinically significant gastric ulcers can occur in the squamous, glandular, or both portions of the stomach as a primary problem or the result of another problem. Clinical signs include diarrhea, abdominal pain, restlessness, rolling, lying in dorsal recumbency, excessive salivation, and bruxism. In the neonatal foal the only clinical signs present may be depression or partial anorexia until a more catastrophic event, such as perforation, occurs. Some lesions in the gastric mucosa extend from the pylorus into the proximal duodenum and can result in stricture of the pylorus and proximal duodenum. These foals usually are older (>1 month of age) and have a greater volume of reflux. Bruxism and ptyalism also are more prominent in these older foals.

The most sensitive and specific method for diagnosing gastric ulcers is visualization by endoscopic examination.<sup>12</sup> Unfortunately, the use of gastric endoscopy has led to recognition of relative nonlesions and ulcers resulting from other problems and of clinically significant disease states. The clinician should not stop simply when ulceration of the stomach is recognized with endoscopy but should examine that patient fully for other potential sources of the clinical signs. Other diagnostic tests may help in determining the severity of the ulcers, including fecal occult blood or gastric blood assessments, contrast radiography, abdominal ultrasound, and abdominocentesis. Endoscopy of the foal stomach carries an additional risk of exacerbating colic in the short term, unless the examiner ensures that as much introduced air as possible is evacuated from the stomach at the end of the procedure.

The presence of a brown gastric reflux fluid may indicate the presence of bleeding ulcers or necrotizing enterocolitis. Blood in the feces of the neonate is more consistent with a diagnosis of necrotizing enterocolitis, which can be associated with gastric ulcers. Contrast radiography is useful if one suspects delayed gastric emptying or pyloric or duodenal stricture in older foals. If a stricture has occurred, a delay in complete emptying of barium from the stomach (>2 hours) will be apparent.<sup>14</sup> Abdominal ultrasound may be useful to visualize free abdominal fluid and gastric or small intestinal distention if a perforation is suspected. Portions of the descending duodenum can be visualized, and a thickened duodenum should increase the index of suspicion for duodenal stricture. Abdominocentesis also may confirm perforation.

Traditional therapy for gastric ulceration includes mucosal adherents, histamine type 2 receptor antagonists, proton pump inhibitors, and antacids.<sup>25</sup> The most widely used mucosal adherent is sucralfate, which is a hydroxy aluminum salt of sucrose. The main therapeutic action of sucralfate is to bind to the negatively charged particles in the ulcer crater.<sup>25,26</sup> At a pH less than 2, sucralfate is converted to a sticky viscous gel, which adheres to the ulcer crater and remains adhered for 6 hours, but at a higher pH sucralfate remains in a suspension. Sucralfate is still effective because it inhibits pepsin and buffers hydrogen ions. Other important actions of sucralfate include stimulating production of prostaglandin E, which maintains mucosal blood flow; increasing bicarbonate secretion; stimulating mucus secretion; decreasing peptic activity; and binding epidermal growth factor. The histamine type 2 receptor

antagonists include cimetidine, ranitidine, and famotidine. These compounds block the interaction of histamine with the histamine type 2 receptor on the parietal cell, resulting in inhibition of gastric acid secretion. Clinically normal neonatal foals have a highly acidic gastric fluid that is influenced by sucking. Intravenous and oral administration of ranitidine increases intragastric pH in normal foals, but critically ill neonatal foals have a blunted response to ranitidine administration.<sup>24,27</sup> One possible conclusion reached from these studies is that in critically ill neonatal foals, gastric ulcers may not be caused by an increased intraluminal gastric acidity.

The most commonly used proton pump inhibitor is omeprazole. Omeprazole inhibits the secretion of hydrogen ions at the parietal cell by irreversibly binding to the H<sup>+</sup>,K<sup>+</sup>-ATPase proton pump of the cell. Most of the lesions in older foals were healed after daily administration of omeprazole for 28 days.<sup>28</sup> Omeprazole effectively increases intragastric pH in normal neonatal foals and in ill neonatal foals that have decreased pH before treatment, suggesting a functionally intact gastric mucosa in those foals.<sup>29,30</sup> The efficacy of omeprazole in treating very ill foals without the ability to generate gastric acid has not been demonstrated, but it is likely similar to that of ranitidine in critically ill foals.<sup>27</sup> Table 21-10 summarizes the therapeutic agents for treating gastric ulcers in foals.

Prophylactic treatment of critically ill neonates for gastric ulcers has been standard therapy for years because of the evidence of clinically silent ulcers. This approach may not be appropriate for several reasons. An increased incidence of nosocomial pneumonia and systemic sepsis is associated with high gastric pH in human patients in intensive care.<sup>31-33</sup> Patients in intensive care units treated prophylactically with histamine type 2 receptor antagonists are more likely to develop pneumonia during ventilation therapy and gastric colonization with potentially pathogenic bacteria or yeast.<sup>31,34</sup> An acidic environment appears to protect against airway colonization by bacteria of intestinal origin and bacteria translocated across the gastrointestinal tract. Pathogenesis of ulcers in the neonatal foal most likely does not involve increased intraluminal gastric acid but instead may be caused by decreased mucosal perfusion associated with shock, hypoxia, and hypoxic-ischemic insult to the gastric mucosa. One report revealed that gastric ulcer disease in equine NICU patients is independent of pharmacologic prophylaxis.<sup>35</sup> In this study the incidence of gastric ulcers found in these foals at necropsy had decreased significantly despite decreased treatment. The decrease was attributed to overall improvement in management of these cases. Similarly, in a human intensive care unit, the incidence of stress ulcers decreased independent of the use of prophylaxis.<sup>22,36</sup> Early treatment of sepsis, sufficient oxygenation, improved monitoring, institution of enteral feedings, and improved nursing care may contribute to the reduction in gastric ulcers in the neonatal patient. Use of histamine type 2 receptor antagonist and proton pump inhibitors apparently may not be necessary; however, in some instances sucralfate may be useful. Sucralfate reduced the rate of bacterial translocation in a rat model during hemorrhagic shock and also may prohibit the generation of acute gastric mucosal injury and progression to ulcer formation induced by ischemia-reperfusion.<sup>37,38</sup> In a human medical intensive care unit, airway colonization by new pathogens occurred more frequently in patients receiving agents that increased gastric pH than in those receiving sucralfate.<sup>31,39</sup> In the critically ill neonatal foal, risk factors for gastric ulceration

TABLE 21-10

Therapeutic Agents for Treating Gastric Ulcers in Foals				
Drug Category	Drug	Dose	Route	Frequency
Mucosal protectant	Sucralfate	10-20 mg/kg	Oral	t.i.d. to q.i.d.
Histamine type 2 receptor antagonist	Cimetidine	10-20 mg/kg	Oral	every 4 hr
	Ranitidine	6.6 mg/kg	IV*	every 4 hr
Proton pump inhibitor	Omeprazole	5-10 mg/kg	Oral	b.i.d. to q.i.d.
		0.8-2.2mg/kg	IV	q.i.d.
		4 mg/kg	Oral	s.i.d.
Antacids	Milk of Magnesia	1-2 mg/kg	Oral	s.i.d. (prophylaxis)
		2-4 oz	Oral	s.i.d. to b.i.d.
	Maalox	240 ml	Oral	every 4 hr

\*t.i.d., Three times daily; q.i.d., four times daily; IV, intravenous; b.i.d., twice daily; s.i.d., once daily.

have not been identified clearly, although foals treated routinely with nonsteroidal anti-inflammatory drugs may be at increased risk for gastric lesions. Prophylactic treatment for gastric ulcers in critically ill neonates may not be necessary, and the clinician should consider carefully the pros and cons of their use before their administration.

## DIARRHEAL DISEASES OF FOALS

Pamela A. Wilkins

### ☞ FOAL HEAT DIARRHEA

Foal heat diarrhea is a mild, self-limiting form of diarrhea that occurs in foals between 5 and 14 days of age, about the time of the "foal heat" in the dam. The definitive cause of foal heat diarrhea has yet to be described, but the condition may be associated with dietary changes or changes in gastrointestinal function that occur around that time. This form of diarrhea is not caused by *Stongyloides westeri* infestation, as previously postulated.<sup>1</sup> Foals with foal heat diarrhea are not systemically ill and should not require therapy. Any foals with diarrhea should be evaluated fully at this time for other possible causes of diarrhea, particularly if they are unwell or exhibit anorexia or dehydration.

### ☞ VIRAL DIARRHEA

Viral diarrhea usually occurs in large groups of mares and foals that are housed together. Rotavirus is an isolate from the feces of up to 40% of foals with diarrhea worldwide, alone or with another pathogen.<sup>2,3</sup> The virus infects and denudes the microvilli, resulting in increased secretion combined with decreased absorption. The virus interferes with disaccharidase function and alters the function of the intestinal sodium-glucose co-transport proteins. The initial clinical signs are anorexia and depression, with profuse watery diarrhea occurring shortly thereafter. Severely affected foals may become significantly dehydrated and have electrolyte abnormalities,

primarily hyponatremia and hypochloremia with metabolic acidosis. These foals generally require intravenous fluid support, whereas less severely affected foals may require only symptomatic therapy. However, none of the available tests are particularly sensitive, and the virus also may be found with other intestinal pathogens. Definitive diagnosis is by detection of the virus in the feces of foals with diarrhea. Vaccination of pregnant mares has been suggested as a means of prevention, with preliminary results suggesting efficacy.<sup>4,5</sup> Although a definitive role for adenovirus has not been established in the foal, adenovirus is a common co-isolate from foals with rotaviral diarrhea.<sup>6</sup> An equine coronavirus has been isolated from an immunocompetent foal with diarrhea, and a second report of coronavirus diarrhea was published recently.<sup>7,8</sup> One case report suggests that a parvovirus caused diarrhea in the foal.<sup>9</sup>

Treatment of viral diarrhea in foals is primarily supportive. Intravenous fluid and parenteral nutritional support may be necessary in severe cases. Very young foals may benefit from intravenous plasma administration and broad spectrum antimicrobial coverage to limit bacterial translocation. Sucralfate can be administered orally in these cases as a gastrointestinal protectant and to discourage bacterial translocation. Foals with moderate to severe metabolic acidosis may benefit from sodium bicarbonate administration if their ventilatory function is normal. Nonspecific therapy of diarrhea is discussed elsewhere in this text.

### ☞ BACTERIAL DIARRHEA

Because diarrhea frequently is the primary presenting complaint in foals with sepsis, this differential diagnosis should be ruled out in foals younger than 1 week of age. All neonatal foals with diarrhea should be evaluated for possible sepsis, and a blood culture should be included whenever possible.

*C. perfringens* and *C. difficile* are recognized increasingly as serious pathogens of the foal.<sup>10-13</sup> Foals with either pathogen generally have abdominal pain, dehydration, and profuse watery diarrhea. Some foals may have red-tinged or frankly bloody feces, which carries a poorer prognosis. Most foals with this type of diarrhea require intensive care or, at the minimum, intravenous fluid administration. Outbreaks

of this type of diarrhea on farms occasionally occur, and the dam may have a role in transmission of the bacteria. Diagnosis is by recognition of the offending organism by Gram stain of the feces, by bacterial isolation from the feces, and by the presence of toxins associated with the organisms. Specific treatment includes oral administration of metronidazole and broad spectrum antimicrobial coverage as prophylaxis for bacterial translocation-associated sepsis in younger foals. Foals with severe blood loss in their feces may require transfusion of whole blood.

*Salmonella* spp., *Escherichia coli*, *Bacteroides fragilis*, and *Aeromonas hydrophila* have been implicated in diarrhea in foals. *Salmonella* organisms generally are associated with septicemia in foals, and although some convincing evidence exists for a role for *E. coli* in foal diarrheal disease, the extent of *E. coli* as a pathogen of the gastrointestinal tract in foals has yet to be described fully.<sup>14-18</sup> Approximately 50% of foals presenting with a complaint of diarrhea of any etiology will be bacteremic at the time of initial examination.<sup>19</sup>

Proliferative enteropathy is a transmissible enteric disease caused by *Lawsonia intracellulare*.<sup>20,21</sup> Most foals have been weaned before the appearance of clinical signs of depression, rapid and significant weight loss, subcutaneous edema, diarrhea, and colic. Poor body condition with a rough hair coat and a potbellied appearance are common in affected foals. Clinicopathologic abnormalities included hypoproteinemia, leukocytosis, anemia, and increased serum creatine kinase concentration. Postmortem examination reveals characteristic intracellular bacteria within the apical cytoplasm of proliferating crypt epithelial cells of the intestinal mucosa. Antemortem diagnosis of equine proliferative enteropathy is based on clinical signs, hypoproteinemia, and the exclusion of other common enteric pathogens. Fecal PCR analysis may be positive for the presence of *L. intracellulare*, and affected foals develop antibodies against *L. intracellulare*.<sup>22</sup> Treatment with erythromycin estolate alone or combined with rifampin for a minimum of 21 days is recommended, with additional symptomatic treatment when indicated.

## ☞ PROTOZOAL DIARRHEA

*Cryptosporidium* spp. cause gastroenteritis and diarrhea in many animal species and are not host-specific. *Cryptosporidium* has been implicated as the causal agent of diarrhea in foals, but the organism is isolated from the feces of diarrheic foals and normal foals with the same frequency and concentration, making a clear role for the organism difficult to elucidate.<sup>23-25</sup> Diarrhea caused by *Cryptosporidium* in other species and that described for foals is generally self-limiting, with a clinical course of between 5 and 14 days. Immunosuppressed patients, including foals compromised by concurrent disease, are thought to be at increased risk for complications resulting from infection with this organism.<sup>23,24</sup> Treatment is symptomatic. Cryptosporidiosis is a disease with zoonotic potential, and appropriate precautions, including use of gloves and frequent hand washing, are necessary if organisms are identified in the feces of any patients so as to prevent spread to other patients and personnel. *Eimeria leukarti*, *Trichomonas equi*, and *Giardia equi* have been identified in the feces of normal horses and horses with diarrhea. Transmission studies have failed to produce reliable clinical signs, and the prevalence and significance of these organisms in the genesis of foal diarrhea remain unknown.

## ☞ PARASITIC DIARRHEA

*Strongyloides westeri* is a common parasitic infection of foals.<sup>2,26,27</sup> Transmission is transmammmary, and patent infection is recognizable in the foal by 8 to 12 days of age. This nematode previously was associated anecdotally with foal heat diarrhea, but the association has not been demonstrated clearly. The diarrhea is generally mild and is treated effectively by deworming with benzimidazole or ivermectin anthelmintics.<sup>1</sup>

*Strongylus vulgaris* fourth-stage larvae cause diarrhea in young foals during migration through the arterioles of the cecum and descending colon. Clinical signs may resemble those of thromboembolic colic.<sup>26,27</sup> The prepatent period is about 6 months, and diagnosis is based on clinical examination, clinicopathologic changes, and farm deworming history. Patients with diarrhea associated with this parasite may have peripheral leukocytosis, neutrophilia, eosinophilia, and hypoproteinemia. Appropriate deworming with ivermectin (label dose), fenbendazole (10 mg/kg/day orally for 5 days), or thiabendazole (440 mg/kg/day orally for 2 days) is recommended, with the last two drug dosages being larger than the label dose. Cyathostomiasis, or diarrhea resulting from the sudden emergence of encysted cyathostome larvae, is an unusual cause of diarrhea in the foal.

## NEONATE THERAPY

Pamela A. Wilkins

## ☞ FLUID THERAPY IN NEONATES

The clinician managing critically ill neonates must recognize that intravenous fluid therapy simply cannot be scaled down from adult management approaches. Fluid management of the ill neonate, particularly over the first few days of life, must take into consideration that the neonate is undergoing a large transition from the fetal to the neonatal state and that important physiologic changes are taking place.<sup>1</sup> These transitions include shifts in renal handling of free water and sodium and increased insensible losses because of evaporation from the body surface area and the respiratory tract. The newborn kidney has a limited ability to excrete excess free water and sodium, and the barrier between the vascular and interstitial space is more porous than that of adults. Water and sodium overload, particularly in the first few days of life, can have disastrous long-term consequences for the neonate.<sup>2-4</sup> In the ill equine neonate, excess fluid administration frequently manifests as generalized edema formation and excessive weight gain, frequently equivalent to the volume of excess fluid administered intravenously. In cases in which antidiuretic hormone secretion is inappropriate, as in some foals with PAS, generalized edema may not form, but the excess free water is maintained in the vascular space. This syndrome of inappropriate antidiuretic hormone secretion is recognized in the foal that gains excessive weight not manifested as edema generally, with decreased urine output and electrolyte abnormalities such as hyponatremia and hypochloremia.<sup>5</sup> The foal manifests neurologic abnormalities associated with hyponatremia. The plasma or serum creatinine concentration varies in these cases, but urine always is concentrated compared with the normally dilute, copious amounts of urine produced by foals more than

24 hours of age on a milk diet. If measured, serum osmolarity is less than urine osmolarity. The treatment for this disorder is fluid restriction until weight loss occurs, electrolyte abnormalities normalize, and urine concentration decreases. If unaware of this differential diagnosis, the clinician may assume mistakenly that the neonate is in renal failure, and the condition can be exacerbated by excessive intravenous fluid administration in an attempt to produce diuresis.

The problem of appropriate fluid management in critically ill neonates has been recognized by medical physicians for years and has resulted in changes in fluid management of these patients. The approach taken has been one of fluid restriction, in particular sodium restriction but also free water restriction, and has resulted in improved outcome and fewer complications, such as patent ductus arteriosus and necrotizing enterocolitis.<sup>4,5</sup> The calculations used for maintenance intravenous fluid support in these patients take into consideration the ratio of surface area to volume and partially compensates for insensible water losses. Maintenance fluids are provided as 5% dextrose to limit sodium overload and provide sufficient free water to restore intracellular and interstitial requirements. The calculation for maintenance fluid administration is shown in Table 21-11.<sup>6</sup>

As an example, the average 50-kg foal would receive 1000 ml/day for the first 10 kg of body mass, 500 ml/day for the next 10 kg of body mass, and 750 ml/day for the remaining 30 kg of body mass for a total of 2250 ml/day. This translates to an hourly fluid rate of about 94 ml/hr.

One should adjust the fluid and sodium requirements for ongoing losses exceeding the maintenance requirements. These losses can take the form of diarrheal losses and excessive urine output, such as those with glucose diuresis and renal damage resulting in an increased fractional excretion of sodium. The normal fractional excretion of sodium in neonatal foals is less than that of adult horses, usually less than 1%.<sup>7</sup> In the critically ill foal, the sodium requirement can be met with as little as 140 mEq of sodium per day, less than administered in a single liter of normal equine plasma. Sodium deficits can be addressed by separate infusion of sodium-containing fluids, although this may not be necessary if one considers the sodium being administered in other forms, including drugs administered as sodium salts and any constant-rate infusions (e.g., pressors, inotropes) that are being provided as solutions made with 0.9% sodium chloride.

The author has used this approach to fluid therapy for the last few years and believes that the percentage of foals suffering from generalized edema—and related problems—has decreased. If one takes this approach to fluid therapy, the weight of the patient should be taken once, or even twice, daily, and fluid intake and output should be monitored as closely as is practical. Any weight gains or losses that are larger than anticipated should be evaluated. Urine output should

not be expected to approach the reported normal of 300 ml/hr for a 50-kg foal because the free water administered is limited, unless the patient is experiencing diuresis (glucosuria, resolution of the syndrome of inappropriate antidiuretic hormone secretion, resolution of previous edematous state, renal disease). The urine specific gravity should be obtained several times daily and the fractional excretion of sodium determined at regular intervals. If the volume of urine produced by the patient is measured accurately, the clinician can determine sodium losses accurately and obtain creatinine clearance values. Blood pressure measurements should be obtained at regular intervals throughout the day because hypotension can be a problem in these patients, particularly in septic foals and foals suffering from PAS, and it may be necessary to increase fluid therapy to maintain adequate vascular volume. Patients with hypotension may require inotrope and pressor support.

## ☞ PRESSOR AND INOTROPE THERAPY IN NEONATES

Inotrope and pressor therapy generally is restricted to referral centers, where these drugs can be administered as constant-rate infusions and blood pressure can be monitored closely. Blood pressure can be monitored directly or indirectly by the use of cuffs placed on the base of the tail.<sup>8</sup> Both techniques have advantages and disadvantages. Although direct blood pressure measurements are considered the gold standard and are generally more accurate, the difficulty in placing and maintaining arterial catheters and lines in these patients severely restricts the utility of this method. Indirect techniques can be inaccurate and are affected by cuff size and placement. However, indirect techniques are easier to use in the NICU and can be useful if trained staff are using the equipment. Once the appropriate cuff size has been identified, that cuff should be dedicated to that patient for the duration of the hospitalization to decrease variability caused by use of different cuffs. The blood pressure of all recumbent patients should be monitored at regular intervals, and trends upward or downward should prompt the clinician to make necessary adjustments.

Foals suffering from PAS and sepsis are the patients most at risk for significant hypotension and perfusion abnormalities.<sup>9-11</sup> Perfusion is maintained by supporting cardiac output and blood pressure with judicious use of intravenous fluid support and inotrope-pressor support. The author does not aim for any specific target systolic, mean, or diastolic pressure. Instead, the author monitors urine output, mentation, limb perfusion, gastrointestinal function, and respiratory function as indicators that perfusion is acceptable. For NICU patients to require inotrope and pressor therapy is not unusual, but in some cases hypoxic and septic damage is sufficiently severe to blunt the response of the patient to the drugs. Each patient must be approached as an individual, and no single inotrope-pressor protocol will suffice for all patients.

Dobutamine is a  $\beta$ -adrenergic inotrope that is frequently used as first-choice therapy in NICU patients. Its effects are  $\beta_1$  at the lower dose range. Neonates have a limited ability to increase stroke volume in an effort to maintain cardiac output, and tachycardia may be observed in these patients as heart rate increases to maintain cardiac output and vascular pressure. Dobutamine is useful after patients are volume replete for support of cardiac output. The dose range is between 2 to 20  $\mu$ g/kg/min, provided as a constant-rate infusion, with best results generally obtained between 2 and 5  $\mu$ g/kg/min. If larger

TABLE 21-11

### Calculations for Maintenance Fluid Administration

Body Mass	Amount of fluid
First 10 kg body mass	100 ml/kg/day
Second 10 kg body mass	50 ml/kg/day
All additional kilograms of body mass	25 ml/kg/day

doses are needed, a better approach might be to add a pressor to the treatment plan.

Dopamine has dopaminergic activity at low doses,  $\beta_1$  and  $\beta_2$  activity at moderate doses, and  $\alpha_1$  activity at high doses. Dopamine causes norepinephrine release, which has led to the suggestion that this is its major mode of action at higher doses. At doses greater than 20  $\mu\text{g}/\text{kg}/\text{min}$ , intrapulmonary shunting, pulmonary venous vasoconstriction, and reduced splanchnic perfusion may occur. Dopamine also produces natriuresis at lower doses through a direct effect on renal tubules. For these reasons dopamine has fallen out of favor in human critical care and at many veterinary referral institutions.<sup>12,13</sup>

Norepinephrine has  $\alpha_1$  and  $\beta_1$  activity but variable  $\beta_2$  activity, resulting in potent vasopressor effects; it has inotropic and chronotropic effects, but its chronotropic effect usually is blunted by vagal reflexes slowing the heart rate induced by the increase in blood pressure. In many critical care units, norepinephrine has become a pressor of choice and frequently is used along with dobutamine. Evidence suggests that splanchnic perfusion is maintained better with norepinephrine than with some other pressors, and norepinephrine is frequently paired with dobutamine.<sup>14</sup> The dose range is 0.2 to 2.0  $\mu\text{g}/\text{kg}/\text{min}$ , although larger doses have been used when necessary in certain patients.

Epinephrine has  $\alpha_1$ ,  $\alpha_2$ ,  $\beta_1$ , and  $\beta_2$  activity;  $\beta$  activity predominates and results in increased cardiac output and decreased peripheral resistance at low doses. Epinephrine has been associated with hyperglycemia, hypokalemia, lipolysis, increased lactate concentration, and increased platelet aggregation. The effect on renal function is controversial. Use of epinephrine usually is limited to those patients not responding to other pressors.

Vasopressin (antidiuretic hormone) is a pressor gaining a great deal of attention in the critical care literature.<sup>15-18</sup> Vasopressin appears to be depleted from the neurohypophysis in septic shock,<sup>16</sup> and short-term administration of vasopressin spares conventional vasopressor use, in addition to improving some measures of renal function.<sup>17</sup> Low-dose vasopressin infusion (0.5-2.0 mU/kg/min) increases mean arterial pressure, systemic vascular resistance, and urine output in patients with vasodilatory septic shock that are hyporesponsive to catecholamines. These data indicate that low-dose vasopressin infusions may be useful in treating hypotension in patients with septic shock.<sup>18</sup> The author has been using low-dose vasopressin in patients in her NICU for the past few years and has the clinical impression that blood pressure is defended more readily using this agent in concert with other management strategies. The author will use low-dose vasopressin constant-rate infusion with dobutamine constant-rate infusion as an initial inotrope-pressor therapy in cases requiring pressure defense, although no prospective studies are available regarding this drug in veterinary medicine.

# TOXICOLOGIC PROBLEMS

## CHAPTER 22

*Patricia Talcott\**

In today's world any list of substances that are toxic or potentially toxic is probably incomplete. Industrial societies continue to produce new and different compounds that are potentially hazardous or fatal to human beings and many species of animals. Knowledge of toxic compounds and the mechanisms whereby they produce disease also is changing constantly, so certain substances that previously were thought to be inert now are known to affect the health of animals or human beings. As the saying goes, almost everything is toxic in the right dose.

It behooves the veterinary clinician to be as informed as possible about the potentially toxic substances found in an animal's environment. Not all toxins are distributed uniformly in nature (this is particularly true of toxic plants), so another reasonable assumption would be that in any given geographic area, certain toxicities are much more common than others.

Many factors influence the toxicity of a given substance, and a detailed discussion is not within the scope of this chapter. Books cover the specific aspects of toxicity and all the different mechanisms that come into play when a specific substance causes harm to a specific animal at a specific point in time. The reader is referred to other sources for information regarding general toxicologic principles and measurements and quantification. It is important to note that age, species of animal, reproductive status, nutritional status, management, diet, and numerous other factors relating to the animal can influence the toxicity of a given substance. Other factors related to the compound itself—such as its bioavailability, its chemical form or structure, its concentration—also can influence the toxicity of a substance at any point.

Most toxins do not damage a solitary tissue, organ, or organ system preferentially but frequently affect several organs or body systems at the same time. Although for clinical signs to be related predominantly to a single organ system is not unusual, multiple organ involvement is the rule rather than the exception. This fact necessitates a thorough physical examination and evaluation of any animal presented for diagnosis of possible toxicosis. The clinician should

evaluate all body systems horses that are suspected of having a toxicity.

The clinical manifestations of many toxicologic problems do not occur immediately but rather some time after initial exposure to the toxin. This delay can make diagnosis and treatment difficult. For this reason many cases of suspected toxicity are treated empirically. If a specific antidote is available or indicated, however, it should be used in the treatment regimen (Box 22-1).

In this chapter the toxins have been divided into broad categories of general clinical signs. A toxin is discussed most completely under the system to which the major clinical signs are referable. One must remember, however, that most toxins involve more than one organ system, so a number of toxins can be found in several categories.

### BOX 22-1

#### GENERAL RULES REGARDING TREATMENT OF SUSPECTED TOXICOSES

1. Removal of the toxicant or animal from the environment
2. Removal of the toxin from the body of the animal, if possible
3. Cleaning of the skin or contact surface with suitable agents if the route of exposure is dermal
4. Evacuation of the gastrointestinal tract by appropriate means if contamination resulted from ingestion of the toxin
5. Maintenance of normal body functions and physiologic processes by means of basic supportive care measures, such as fluid administration and blood pH and electrolyte modification
6. Elimination of the toxin from the system of the animal as expeditiously as possible
7. Measures to prevent reexposure or recontamination of the animal by the toxic substance

\*The authors wish to acknowledge David G. Schmitz, whose original work has been incorporated into this chapter.

## TOXICOSES DISPLAYING SIGNS RELATING TO THE GASTROINTESTINAL SYSTEM

There is a wide range of toxic agents capable of inducing signs of gastrointestinal disease. Signs vary from mild to peracute and life threatening. Determination that a toxicosis is the cause of a problem such as diarrhea or colic sometimes is difficult, time consuming, and relatively costly.

### ☉ PLANTS

#### OAK (*QUERCUS SPECIES*)

##### CLINICAL SIGNS

Oak blossoms, buds, leaves, stems, and acorns can be toxic to most animals. Most reports of toxicosis in livestock involve cattle and sheep, with a rare occurrence in the horse. Clinical signs attributed to acorn toxicosis in horses are acute onset of severe abdominal pain, rectal straining, hemorrhagic diarrhea, and pronounced intestinal borborygmi. Acorn parts may be apparent in feces. Occasionally, horses are found dead; other signs are hemoglobinuria and elevated heart and respiratory rates.

##### PATHOPHYSIOLOGY

The toxicity of oak is attributed to a group of structurally similar compounds called *gallotannins* and their metabolites. Digallic acid is the major active metabolite produced by oak tannins. After bacterial fermentation digallic acid is converted to gallic acid and pyrogallol, both of which are considered toxic.<sup>1</sup> Pyrogallol and gallic acid are toxic to renal tubules and result in acute tubular necrosis, anuria, electrolyte abnormalities, and uremia.<sup>1,2</sup> Pyrogallol is also responsible for causing hemorrhagic gastroenteritis, subcutaneous hemorrhage, and hemolysis. Tannic acid itself is thought to result in increased vascular permeability, hemorrhage, and subsequent fluid loss into body spaces.<sup>1</sup>

##### DIAGNOSIS

The diagnosis of oak toxicity is based on clinical signs and a history of potential exposure to the plant. Under adequate forage conditions horses would seem to find large quantities of oak leaves and acorns distasteful; therefore most horses with oak trees in their environment do not develop toxicity. Toxicosis is more likely to result when abnormal conditions coupled with environmental factors (e.g., lack of access to normal forage or feed) result in large numbers of oak leaves and acorns becoming accessible to horses.

Laboratory findings compatible with oak toxicosis include dehydration or hemoconcentration to varying degrees, azotemia, hyperphosphatemia, hypocalcemia, and hypoproteinemia. Abnormal urine findings might include occult blood, proteinuria, and casts. An increase in gallic acid equivalent content in urine also has been used to support exposure to oak trees.<sup>1</sup> However, oak trees are not the only plant that can contain these tannins, and normal and toxic ranges of gallic acid in urine have not been well established in livestock.

Necropsy findings suggestive of oak toxicosis include pericardial, thoracic, and peritoneal effusion; gastrointestinal and mesenteric edema; and pale and swollen kidneys that may

bulge on cut surface. The intestinal tract may contain large quantities of acorn parts, and colonic ulceration has been reported.<sup>1</sup>

##### SPECIFIC TREATMENT AND MANAGEMENT

No specific antidote for oak toxicity is available. Animals should be allowed no further access to oak. Treatment of the acutely affected animal aims to maintain fluid and acid-base balance and to correct any electrolyte abnormalities. Balanced polyionic fluids given intravenously to promote diuresis are the basic therapy. This therapy should be supplemented with calcium, bicarbonate, and other electrolytes as necessary. Anuric animals may gain additional benefit from furosemide at 1 mg/kg intravenously or dimethyl sulfoxide (DMSO) at 1 g/kg given intravenously as a 10% solution in addition to fluid therapy. The clinician should attempt evacuation of the intestinal tract using mineral oil or another suitable laxative.

The prognosis for affected horses is guarded. A paucity of information exists regarding mortality rates in affected horses, but death caused by ingestion of acorns has been reported.<sup>1</sup>

#### CASTOR BEAN (*RICINUS COMMUNIS*)

##### CLINICAL SIGNS

Castor beans contain ricin, a protein phytotoxin that acts as a potent proteolytic enzyme with significant antigenic qualities.<sup>2</sup> A latent period ranging from hours to several days usually occurs before the onset of clinical signs in affected horses. The bean is apparently distasteful to horses, and intoxication most likely occurs when the bean inadvertently is mixed into the feed source. To cause problems, the bean must be broken apart by chewing; beans swallowed intact are thought to pass through the gastrointestinal tract uneventfully.

The most commonly reported clinical signs of castor bean toxicosis described in the literature are varying degrees of abdominal pain, diarrhea, depression, incoordination, profuse sweating, and increased body temperature. Muscle twitching, convulsions, and prominent cardiac contractions occasionally are observed. If the horse absorbs enough ricin, signs of shock and anaphylaxis predominate.<sup>2,3</sup> Death may ensue as soon as 24 to 36 hours after ingestion.

Ricin is reported to be toxic to horses. One reference cites a ricin dosage of 0.1 µg/kg as a lethal dose,<sup>2</sup> and a second source indicates 25 g of castor beans is lethal.<sup>3</sup> A published report in 1945 describes seven deaths attributed to castor bean toxicosis from a stable of 48 horses in London in 1931.<sup>4</sup> The exact number of affected horses was not reported. A review of the literature suggests that castor bean (ricin) toxicosis in human beings and dogs is not nearly as lethal as reported in the literature of the early twentieth century.<sup>5,6</sup> Whether this holds true for horses is open to speculation.

##### PATHOPHYSIOLOGY

The oil extract of the bean contains ricinoleic acid. Within the small intestine ricinoleate acts to reduce net absorption of fluid and electrolytes and stimulates peristalsis.<sup>7</sup> The fibrous residue of the seed contains the water-soluble toxalbumin ricin. Ricin is absorbed from the gastrointestinal tract and is a potent inhibitor of protein synthesis. Ricin contains two polypeptide chains. Chain B, a lectin, binds to the cell surface to facilitate toxin entry into the cell. Chain A disrupts protein synthesis by activating the 60S ribosomal subunit. The red

blood cell–agglutinating properties of ricin are independent of these toxic effects.<sup>8</sup>

### DIAGNOSIS

Diagnosis is made by a combination of history of exposure to the plant; clinical signs; and the identification of seeds in feed material, gastric contents, or feces. Analyses for ricin content in urine, as well as other samples, are available from certain laboratories.<sup>8</sup>

### TREATMENT

Ricin has no specific antidote. Initial therapy aims to combat shock, alleviating abdominal pain and evacuating the bowel. Maintenance of fluid and electrolyte balance is important. Various sedatives and analgesics may be useful to control abdominal pain, if present. Oral administration of laxatives and protectants such as mineral oil and charcoal may be warranted. Antihistamines also have been recommended.<sup>2</sup>

## POKEWEED (*PHYTOLACCA AMERICANA*)

### CLINICAL SIGNS

Pokeweed intoxication in horses is an uncommon occurrence. However, one text reports that horses show signs of gastrointestinal irritation and abdominal discomfort as the primary clinical signs. The plant also produces a burning sensation of the oral mucous membranes and may cause a hemolytic crisis. Fatalities caused by pokeweed ingestion are said to result from respiratory failure and convulsions.<sup>2</sup>

### PATHOPHYSIOLOGY

The plant contains phytolaccine, a powerful gastrointestinal irritant that in human beings causes symptoms ranging from a burning sensation of the alimentary tract to severe hemorrhagic gastritis. Five nonspecific mitogens that have hemagglutinating and mitotic activity have been isolated. These substances vary in concentration in the plant throughout the growing season. Noncardiac steroids and triterpenoid glycosides (saponins) also are present in significant quantities, but their role in pokeweed toxicity is unknown.<sup>8</sup> Saponins may potentiate gastrointestinal toxicity and produce vasodilation when given parenterally.

### DIAGNOSIS AND TREATMENT

No specific diagnostic test is available. Horses suspected of having toxicosis must be treated symptomatically. The clinician should attempt to evacuate the gastrointestinal tract using laxatives. Adsorbents such as charcoal and protectants may be useful. If the horse develops a hemolytic crisis, ancillary therapy such as whole-blood transfusions may be lifesaving. Fluid and electrolyte balance must be maintained in these horses in an attempt to prevent or minimize hemoglobin- or hypoxic-induced nephrosis.<sup>2</sup>

## NIGHTSHADE (*SOLANUM SPP.*)

### CLINICAL SIGNS

A number of species of *Solanum* spp. have been incriminated in causing toxicity in horses. However, these plants rarely are a source of natural intoxication to horses. Reported clinical signs are referable to the gastrointestinal and central nervous systems. The primary gastrointestinal signs observed

are salivation, abdominal pain, increased borborygmi, and diarrhea. Signs of central nervous system (CNS) dysfunction include mydriasis, dullness, depression, weakness, and progressive paralysis, which can lead to prostration and death.<sup>2,9,10</sup>

### PATHOPHYSIOLOGY

Solanine is a toxic substance found in *Solanum* species; it is a water-soluble glycoalkaloid capable of producing local irritation<sup>2,3,8</sup> and is absorbed poorly from the gastrointestinal tract. Intravenous doses caused ventricular fibrillation in rabbits, and intraperitoneal doses caused mild to moderate inhibition of specific and nonspecific cholinesterase activity.<sup>8</sup> It has been shown that exposure to *Solanum* plants can potentiate the effects of ivermectin in horses.<sup>11</sup>

### DIAGNOSIS AND TREATMENT

No specific diagnostic test is available to confirm a diagnosis of *Solanum* toxicosis. Animals suspected of having toxicosis should be treated symptomatically. Evacuation of the gastrointestinal tract using laxatives and protectants may be indicated. Charcoal also has been recommended for treatment of toxicosis in human beings.<sup>8</sup> The clinician should monitor the fluid, electrolyte, and acid-base status of affected animals and make corrections as needed.

## JIMSONWEED, THORNAPPLE (*DATURA SPP.*)

### CLINICAL SIGNS

Several species of *Datura* grow throughout North America, all of which can produce signs of toxicosis in livestock. However, these plants are rarely a source of natural intoxication in horses, probably because of the unpalatability of the plant.<sup>9,10</sup> One report of equine acute toxicosis resulted when ingested feed was contaminated heavily with jimsonweed seeds. According to this report, one horse was affected acutely and died because of gastric rupture and gas-filled intestinal loops. A second horse was treated for several days before being euthanized. Clinical signs observed in the treated horse included abdominal distention with gas-filled intestinal loops, prolonged ileus, mydriasis, tachycardia, hyperpnea, and dry mucous membranes.<sup>12</sup>

### PATHOPHYSIOLOGY

The toxic substances found in *Datura* spp. are the tropane alkaloids atropine (a racemic mixture of D- and L-hyoscyamine) and scopolamine (L-hyoscyne).<sup>9,10,12</sup> These substances exert an antimuscarinic effect by competitive inhibition with acetylcholine for receptor sites, resulting in attenuation of the physiologic response of neuroeffector junctions to parasympathetic nerve impulses. Blockade of the muscarinic receptors of different tissues accounts for the various clinical signs observed.

### DIAGNOSIS AND TREATMENT

Toxicity is suspected when animals exhibit signs compatible with atropine overdose. Identification of seeds or plant material in ingesta, gastric lavage contents, or feedstuffs may support a diagnosis. Treatment is largely symptomatic and includes immediate removal of the offending feed or plants, evacuation of the gastrointestinal tract, and supportive care. The use of pilocarpine and physostigmine to counteract the atropine-like effects of these alkaloids has been

recommended by some, but this treatment is considered controversial.<sup>9,10</sup>

## ☉ MISCELLANEOUS AGENTS

### DI-OCTYL SODIUM SULFOSUCCINATE

Di-octyl sodium sulfosuccinate (DSS) is an anionic surface active agent commonly used to treat constipation and intestinal impaction in horses. The recommended dose of DSS is 17 to 66 mg/kg, with a maximum dose of 200 mg/kg.<sup>2,13</sup>

#### CLINICAL SIGNS

Signs of overdose commence within 60 to 120 minutes in affected horses. Initial signs are restlessness and increased intestinal sounds accompanied by steadily increasing heart and respiratory rates. Abdominal pain, watery diarrhea, and dehydration become apparent soon afterward, and horses gradually deteriorate to lateral recumbency and death in 14 to 72 hours.

#### PATHOPHYSIOLOGY

Much information about the pharmacologic action of DSS remains uncertain.<sup>7</sup> The primary organ of involvement is the small intestine, where epithelial denudation, villous atrophy, and submucosal edema and congestion occur. DSS has been suggested possibly to cause epithelial detachment by lowering the surface tension on the basement membranes of intestinal epithelial cells.<sup>13</sup> Once detachment occurs, loss of fluid and electrolytes into the intestinal lumen is possible. The absorptive capacity of the epithelium is lost, and the osmotic effect of intestinal content causes further loss of fluid into the lumen. With extensive mucosal damage, the horse also becomes much more susceptible to endotoxemia. The rapid death in affected animals is caused by hypovolemic shock, endotoxemia, and circulatory collapse resulting from the loss of fluids and electrolytes into the intestinal lumen.

#### DIAGNOSIS AND TREATMENT

Diagnosis of DSS toxicity depends on observation of the aforementioned clinical signs along with oral DSS administration. No specific antidote for DSS exists, and once clinical signs commence, treatment is aimed at supporting circulation and combating the effects of systemic endotoxin. Specific treatment for circulatory collapse and endotoxemia is covered elsewhere, but medications that might be useful include polyionic electrolyte solutions, electrolyte supplementation, corticosteroids, nonsteroidal anti-inflammatory drugs (NSAIDs), bicarbonate, and orally administered gastrointestinal protectants.

### INORGANIC ARSENIC

Arsenic is found in a number of products, including insecticides, herbicides, defoliants, rodenticides, livestock dips, medications, wood preservatives, paint pigments, detergents, and certain insulation materials.<sup>14,15</sup> Horses are most likely to be exposed to arsenic by eating contaminated or treated forage being exposed accidentally to stored or improperly discarded pesticides.<sup>15</sup> Horses cannot receive a significant exposure through cribbing on arsenic-treated wood. However, if arsenic-treated lumber

is burned, ingestion of the arsenic-laced ash could be problematic.

#### CLINICAL SIGNS

The clinical signs associated with arsenic toxicity are essentially those of a severe gastrointestinal irritant. Most toxicities result from inorganic forms of arsenic, and signs are similar in several animal species.

In peracute cases the animals may be found dead with no premonitory signs. Acute signs of toxicity include severe colic, staggering, weakness, salivation, diarrhea that may contain blood or shreds of mucosa, and signs of shock that indicate cardiovascular collapse. Death usually occurs in 1 to 3 days.<sup>14-16</sup> In subacute poisoning animals may live for several days, exhibiting signs of depression, anorexia, colic, diarrhea that may contain blood and mucus, polyuria followed by anuria, and subsequent shock before death. Horses that are poisoned by topical application of arsenic can show signs of blistering and edema of the skin.<sup>14</sup> Chronic arsenic poisoning rarely occurs in domestic animals.

#### PATHOPHYSIOLOGY

Many factors play a role in the development of arsenic toxicosis in horses. In general, horses that are debilitated, weak, or dehydrated are more susceptible to toxicosis than normal animals. The formulation of the compound (trivalent arsenicals are more toxic than pentavalent forms), the solubility of the compound, the route of exposure, the rate of absorption from the gastrointestinal tract, and the rate of metabolism and excretion by the individual animal are factors that can influence the toxicity of the various arsenic formulations.<sup>14</sup> The most hazardous preparations are products in which the arsenical is in a highly soluble trivalent form, usually trioxide or arsenite. Sodium arsenite is 3 to 10 times more toxic than arsenic trioxide. The average total oral lethal doses of these compounds for the horse are 10 to 45 g arsenic trioxide and 1 to 3 g sodium arsenite.<sup>14,15</sup>

Soluble forms of arsenic are absorbed from all body surfaces. Less soluble arsenicals are absorbed poorly from the gastrointestinal tract and essentially are excreted unchanged in the feces. After absorption trivalent arsenic is excreted readily by way of the bile into the intestine, and pentavalent arsenic is excreted by the kidney. Regardless of whether an introduced arsenical is in the trivalent or pentavalent form, all the major actions can be attributed to the trivalent form.<sup>14</sup>

All arsenicals are thought to exert their effects by reacting with sulfhydryl groups in cells. Trivalent arsenic acts primarily by combining with the two sulfhydryl groups of lipoic acid, thereby inactivating this essential cofactor necessary for the enzymatic decarboxylation of the keto acids pyruvate, ketoglutarate, and ketobutyrate. By inactivating lipoic acid, arsenic inhibits the formation of acetyl, succinyl, and propionyl coenzymes A. The net effect is the blocking of fat and carbohydrate metabolism and cellular respiration.<sup>14,15</sup> Trivalent arsenic may inactivate sulfhydryl groups of oxidative enzymes and the sulfhydryl group of glutathione and other essential monothiols and dithiols. Arsenic also causes a local corrosive action on the intestine.<sup>15</sup>

Arsenic seems to prefer tissues rich in oxidative enzymes such as the liver, kidney, and intestine. The capillary endothelial cells in these organs appear sensitive to arsenic because it relaxes capillaries and increases capillary permeability. Blood vessels with smooth muscle in their walls also dilate. In the intestinal tract the mucosa easily sloughs away because of the

accumulation of fluid in the submucosa. In the kidney renal tubular degeneration occurs.<sup>15</sup>

### DIAGNOSIS

The clinical signs described previously should cause the practitioner to consider inorganic arsenic poisoning. Antemortem laboratory findings are consistent with gastrointestinal, hepatic, and renal damage. Feces may contain blood, mucus, and increased numbers of white blood cells. The liver enzymes sorbitol dehydrogenase, lactate dehydrogenase (LDH), AST, and  $\gamma$ -glutamyltransferase (GGT) may be increased in serum, and urine might contain protein, red blood cells, and casts. Urine arsenic concentration in affected animals often exceeds 2 ppm.<sup>14</sup>

Postmortem findings are characteristic of severe gastroenteritis and may include hepatic lipidosis and necrosis. In horses in which arsenic poisoning is suspected, the liver, kidneys, stomach, intestinal contents, milk, blood, and urine should be evaluated.

### TREATMENT

Specific therapy for arsenic toxicity is dimercaprol (or British antiLewisite [BAL]). This chelating agent forms a nontoxic and easily excretable complex with arsenic. However, BAL may mobilize stored arsenic in tissues and cause an initial exacerbation of clinical signs by allowing more arsenic to circulate to the intestine and liver. BAL also can be toxic in sufficient doses. Signs of overdose include tremors, convulsions, coma, and death. In horses the recommended dose is 3 mg/kg intramuscularly as a 5% solution in a 10% solution of benzyl benzoate in peanut oil. This dose is administered every 4 hours for the first 2 days, every 6 hours on the third day, and twice daily for the next 10 days until recovery.<sup>15</sup>

Sodium thiosulfate also has been advocated for treatment of arsenic toxicosis, but its efficacy is questionable. The recommended dose for horses is 20 to 30 g orally in 300 ml of water, plus 8 to 10 g intravenously in a 10% to 20% solution.<sup>15</sup>

Symptomatic care of affected animals includes evacuation of the gastrointestinal tract with laxatives and oral demulcents to coat the intestinal tract. The clinician should evaluate fluid, acid-base, and electrolyte indices and provide support if necessary. Aggressive intravenous fluid diuresis is advocated by many to maintain adequate hydration and enhance urinary arsenic excretion. Because endotoxemia may develop as a result of the intestinal and liver lesions, prophylactic administration of flunixin meglumine at a dosage of 0.25 mg/kg every 8 hours may be beneficial. Other therapy to prevent shock and cardiovascular collapse also may be indicated.

## ALUMINUM

One report describes an unexpectedly high incidence of horses on the same farm showing clinical signs compatible with granulomatous enteritis and the presence of abnormally high levels of aluminum in various body organs and tissues of the affected horses.<sup>17</sup> Clinical signs included weight loss with or without diarrhea, hyperkeratosis, ulcerative colitis, and neurologic deficits compatible with cervical stenotic myelopathy. Laboratory abnormalities included hypoalbuminemia and elevated serum concentration of alkaline phosphatase in some horses. All horses had histologic evidence of granulomatous inflammation of the gastrointestinal tract in varying degrees of severity and distribution. Granulomas occurred in the mucosa, submucosa, and serosa of the small and large intestines and in

the abdominal lymph nodes, portal areas of the liver, and pancreas. Aluminum was found within granulomas, and elevated aluminum levels were present in kidney and liver tissue.

Chronic environmental exposure to aluminum was postulated as a cause for the condition. Environmental factors (e.g., soil pH, moisture content, plants) may have an effect on the bioavailability of aluminum, and it has been suggested that repeated exposure may induce hypersensitivity to aluminum in these horses. In human beings aluminum is known to induce nonimmunologic (foreign body) and immunologic granulomas after administration of aluminum-containing vaccines and hyposensitization products.<sup>18</sup> The association between high environmental concentrations of aluminum and increased incidence of generalized granulomatous inflammation in horses warrants further investigation.

## PETROLEUM DISTILLATES

Horses can be exposed to excessive amounts of crude oil or petroleum distillates through contamination of rangeland with by-products of the oil industry or by iatrogenic application, because petroleum distillates commonly are used as carrier agents for many insecticides.

### CLINICAL SIGNS

The most frequently noted signs associated with ingestion of petroleum products are essentially those of gastrointestinal and respiratory dysfunction. Petroleum products are irritating to mucous membranes, and hence prominent signs of gastrointestinal dysfunction might include salivation and fluid feces. The feces actually may contain oil or oily substances. Chronically affected animals also may exhibit anorexia and weight loss over several days to weeks.

Signs of respiratory dysfunction are a common manifestation of excessive petroleum exposure. Aspiration of the oil or fumes is irritating to pulmonary tissue, and aspiration pneumonia is probably the most serious consequence of petroleum toxicity.<sup>14</sup> Signs of toxicity include increased respirations, anorexia, depression, weight loss, a variable degree of fever, and possibly increased nasal discharge.

Products that are applied inadvertently to the skin might cause some degree of respiratory embarrassment, but they are more likely to cause signs related to the absorption of excessive hydrocarbons.<sup>15</sup> Topically applied agents also may cause signs associated with a contact irritant.

### PATHOPHYSIOLOGY

The toxicity of crude oil is correlated with the gasoline, naphtha, and kerosene content in the oil. Crude oil rich in these low-temperature distillates is more toxic than petroleum containing a great deal of sulfur but less of the low-temperature distillates.<sup>15</sup> Petroleum products are irritating to mucous membranes, and their oiliness makes them difficult to remove from skin and mucous membranes and virtually impossible to remove from the respiratory epithelium. Once aspirated, they serve as a focus for foreign body pneumonia that may progress to abscessing pneumonia, pleuritis and pleural effusion, and death.

### DIAGNOSIS

History of possible exposure, clinical signs, and pathophysiologic signs are important in establishing a diagnosis. Suspected contents (i.e., gastrointestinal content or feces) may be mixed with water, and any oil that is present will float to the surface

and be readily visible. Analytic chemistry methods sometimes can be used to establish the identity of an oil.<sup>14</sup>

### TREATMENT

Treatment is supportive. The clinician should evacuate and protect the gastrointestinal tract by using laxatives and demulcents. Products applied to the skin can be removed with warm soapy water followed by thorough rinsing. Products such as mechanic's hand degreasers can be tried first to remove fat-soluble compounds. Aspiration pneumonia may be frustrating to treat, and supportive care such as fluids and electrolytes, NSAIDs, and broad spectrum antimicrobial therapy is potentially helpful.

### SLAFRAMINE

Slaframine is an indole alkaloid produced by *Rhizoctonia leguminicola*, a mold that infects red clover, alfalfa, and other legumes.<sup>14,15,19</sup> *R. leguminicola* is a ubiquitous soil fungus that infects certain legumes during conditions of high rainfall or humidity.<sup>19</sup> The toxin can survive and persist in dried and baled hay.<sup>14</sup>

### CLINICAL SIGNS

The most consistently reported clinical sign is excessive salivation characterized by profuse, viscous, clear saliva.<sup>19</sup> Salivation may begin 30 to 60 minutes after eating the affected feed, and response from one feeding may persist for up to 24 hours. Other, less commonly reported clinical signs include anorexia, polyuria, and sometimes watery diarrhea.<sup>14</sup> One case of abortion in an affected mare has been reported.<sup>19</sup> Clinical signs generally abate 48 to 96 hours after the infected feed is removed from the diet.<sup>14</sup>

### PATHOPHYSIOLOGY

Slaframine apparently is activated by liver microsomes after absorption. The active compound seems to have direct histaminergic effects or possibly a histamine-releasing effect, which is borne out in laboratory animal studies in which clinical signs responded better to antihistamines than to atropine.<sup>15</sup>

### DIAGNOSIS

The combination of acute clinical signs of excessive salivation coupled with digestive disturbances and identification of *R. leguminicola* in forage generally is adequate to establish a diagnosis. It is possible to analyze slaframine in feeds, but usually such tests are unnecessary.<sup>14</sup>

### TREATMENT

No specific treatment usually is necessary. Animals generally recover uneventfully 48 to 96 hours after withdrawal of the contaminated forage.<sup>14</sup> Atropine and antihistaminic therapies have been suggested to help control clinical signs,<sup>14,15</sup> but their efficacy is questionable.

### PENTACHLOROPHENOL

Documented instances of horses becoming intoxicated with pentachlorophenol are rare. However, because pentachlorophenol was used routinely as a wood preservative and because other domestic animals, including cattle and swine, have been poisoned, some aspects of this toxin require description. Exposure potentially occurs as a result of the horse drinking from a container containing pentachlorophenol or lying on recently treated lumber or contaminated soil.

The chlorophenols (which include pentachlorophenol) generally are not water soluble but are soluble in oils and organic solvents.<sup>15,20</sup> Pentachlorophenol is volatile and can give off toxic vapors.<sup>15</sup> The chlorophenols are absorbed readily from the gastrointestinal tract, by inhalation, and from intact skin and are excreted rapidly by the kidney.<sup>15,20</sup>

Several factors affect the toxicity of chlorophenols. High ambient temperature, physical activity, poor body condition, oily or organic solvent vehicles, prior exposure, and hyperthyroid states serve to enhance toxicity in human beings and other animal species. Cold temperatures, antithyroid drugs, and increased amounts of body fat help diminish the toxicity.<sup>15</sup>

The mechanism whereby the chlorophenols exert their toxicity involves the energy production sites of mitochondria, where they uncouple oxidative phosphorylation. The chlorophenols act at sites of adenosine triphosphate (ATP) production to decrease or block their production without blocking the electron transport chain. Free energy from the electron transport chain then is converted to body heat. As the body temperature is increased, the heat-dissipating mechanisms are overcome and metabolism is increased. The electron transport chain responds by using more oxygen in an effort to produce ATP, but much of the free energy is liberated as more body heat. Eventually, the oxygen demand overcomes the oxygen supply, and energy reserves become depleted.<sup>15</sup>

### CLINICAL SIGNS

Clinical signs, if observed, may include fever, tachycardia, dyspnea, sweating, lethargy, incoordination, weakness, cyanosis, collapse, and death. Less severely affected animals may primarily manifest signs of hyperthermia and oxygen deficiency.<sup>15</sup> Pentachlorophenol in high doses to pregnant animals also is reported to cause embryonic and fetal deaths but is not teratogenic.<sup>14</sup>

### DIAGNOSIS AND TREATMENT

Pentachlorophenol toxicity is associated with the combination of clinical signs and blood pentachlorophenol levels greater than 40 ppm. No specific treatment is available, but saline diuresis has been suggested to be helpful in certain instances of human toxicosis.<sup>14</sup>

### CHLORATES

Chlorate salts (sodium chlorate or potassium chlorate) are used as herbicides and defoliant. Horses may become exposed by grazing in recently sprayed areas or by ingesting sodium chlorate when it is mistakenly substituted for sodium chloride as a feed additive.

### CLINICAL SIGNS

Initial signs are those of gastrointestinal irritation and include colic and diarrhea. Hematuria and hemoglobinuria also are present early in the disease course. Within hours the horse shows dyspnea, cyanosis, and increased respiratory effort. Death can occur suddenly, without obvious signs.<sup>14</sup>

### PATHOPHYSIOLOGY

Chlorates are absorbed readily from the intestine, and once absorbed they continue to exert their damaging effects as long as they are present.<sup>14,15</sup> A dose of 250 g is reported to be lethal to horses.<sup>14</sup>

Chlorates cause toxic changes by three different mechanisms of action:

1. Direct irritation of the gastrointestinal tract
2. Oxidation of hemoglobin to methemoglobin
3. Inducement of hemolysis

The net effect of methemoglobinemia and hemolysis is a severe compromise in the oxygen-carrying capacity of blood, and animals may be so severely affected that they die as a result of anoxia.<sup>15</sup>

### DIAGNOSIS

The prolonged, extensive methemoglobinemia found in affected animals should alert the veterinarian to the possibility of chlorate poisoning. A history of exposure to chlorates also should accompany these clinical signs before a presumptive diagnosis is made. Analysis of blood, urine, or ocular fluid can help determine chlorate concentration, and because chlorates normally are not found in animals, their presence in a sample would confirm poisoning if clinical signs, history, lesions, and response to therapy also suggest this diagnosis.<sup>15</sup>

### TREATMENT

After making the diagnosis, the clinician should immediately seek out the chlorate source and remove it from the horse's environment. Methemoglobinemia is treated with methylene blue at a dose of 4.4 mg/kg given as a 1% solution by intravenous drip. This dose may be repeated in 15 to 30 minutes if a clinical response is not obtained.<sup>2,15</sup> Other recommended therapeutic measures include gastric lavage with 1% sodium thiosulfate and the oral administration of intestinal protectants and demulcents.<sup>2,14</sup> Blood transfusion and oxygen supplementation may be beneficial in certain instances.<sup>15</sup>

## PYRIMINIL (VACOR)

Pyriminil currently is not commercially available, but in previous years it was marketed as a rodenticide. Reports of toxicosis in horses are rare,<sup>21</sup> and no deaths caused by pyriminil ingestion have been reported.<sup>21,22</sup>

### CLINICAL SIGNS

Reported signs in affected horses include severe muscular fasciculation, profuse sweating, dehydration, and mydriasis with a weak pupillary response. Hindlimb weakness, ataxia, persistent inappetence, and abdominal pain also have been reported.<sup>21</sup> Hyperglycemia is a fairly consistent laboratory finding.<sup>14,21</sup>

### PATHOPHYSIOLOGY

Pyriminil is absorbed from the gastrointestinal tract and excreted in the urine. Pyriminil acts as a nicotinamide antagonist, but its exact mechanism of action is unknown.<sup>2,14,22</sup> Pyriminil also has been shown to damage the pancreatic  $\beta$ -cells and to depress glucose uptake by erythrocytes.

### DIAGNOSIS

A presumptive diagnosis is based on compatible clinical signs and history of exposure to the rodenticide.

### TREATMENT

Specific therapy for pyriminil toxicity is reported to be nicotinamide. However, the use of this drug in human beings appears to be effective only when given within 1 hour of ingestion of

pyriminil. The reported dosage is 50 to 100 mg nicotinamide intramuscularly every 4 hours for up to eight injections. This dosage is followed by 25 to 50 mg orally 3 to 5 times daily for 7 to 10 days.<sup>14</sup> Other therapies that may be beneficial include gastric lavage and the oral administration of mineral oil and activated charcoal.<sup>14,22</sup> Apparently, affected horses recover because no deaths caused by pyriminil toxicosis have been recorded.

## TETRACHLORODIBENZODIOXIN

The polychlorinated dibenzodioxins include a large number of isomers that differ chemically only in the number and location of chlorine atoms on the dioxin nucleus but that vary greatly in their toxic potential to various animal species. Of the 75 possible isomers of polychlorinated dibenzodioxin, the specific isomer designated 2,3,7,8-tetrachlorodibenzodioxin (TCDD; dioxin) is most toxic and generally is considered the most toxic synthetic molecule known. TCDD was once a contaminant of certain herbicides and is a by-product of certain chemical manufacturing and combustion processes.<sup>14</sup> It can also be found in soil as a naturally occurring compound or as a result of contamination by industrial waste. As recently as a few years ago, dioxins have been found in ball clay that had been used as a binding agent for livestock feed. Currently, dioxins are more of a tissue residue issue for production animals rather than a toxicologic hazard for livestock. The chemical is a highly stable contaminant in the environment, with a half-life in soil of approximately 1 year.<sup>23</sup>

### CLINICAL SIGNS

In one reported outbreak the initial signs began 4 days after exposure and included abdominal pain, polydipsia, anorexia, severe weight loss, alopecia, skin and oral ulcers, conjunctivitis, dependent edema, joint stiffness, and laminitis. A total of 85 horses were exposed, 58 became ill, and 43 subsequently died. The length of illness varied from 4 to 132 weeks in the terminally ill horses, with those having a heavier exposure exhibiting a shorter disease course (average of 32 weeks) than others (average of 74 weeks). In addition, abortions occurred in pregnant mares, and many foals that were exposed only in utero died at birth or shortly thereafter.<sup>23</sup> Other reported signs in animals included gastrointestinal hemorrhage with necrosis and ulceration of the gastrointestinal mucosa, cerebrovascular hemorrhage, hepatotoxicity, and thymic and peripheral lymph node atrophy.<sup>14,23</sup>

### PATHOPHYSIOLOGY

Tetrachlorodibenzodioxin is absorbed readily by oral and dermal routes, and following absorption appears to be retained primarily by liver and adipose tissue. The mechanism of action of TCDD in various organs is not well defined. TCDD is known to induce microsomal mixed function oxidases in liver and kidney, and hepatic  $\delta$ -aminolevulinic acid synthetase and aryl hydrocarbon hydroxylase, but the role of these processes in the induction of toxicity of TCDD remains to be elucidated.<sup>14</sup> TCDD also induces immunosuppression by causing thymic and peripheral lymph node atrophy.

### DIAGNOSIS

A combination of the described clinical signs and possible exposure to industrial waste oil products should alert the veterinarian to the possibility of TCDD toxicity. Dioxin content

is confirmed in various tissues by means of gas-liquid chromatography and mass spectroscopy, but few laboratories offer this service, and the analysis is generally expensive.<sup>14</sup>

A characteristic liver lesion seen at necropsy in a number of horses was microscopic evidence of bile stasis, hepatocyte necrosis, bile duct proliferation, and extensive fibrosis that was pronounced around the central veins but minimal in the peripheral liver lobules. Other microscopic changes noted were thickened vascular walls and endothelial proliferation in the smaller blood vessels of several different organs.<sup>23</sup>

## TREATMENT

No known antidote exists for TCDD toxicity once clinical signs develop. After their onset, the clinician can offer only symptomatic and supportive care, and one should use every precaution to prevent laminitis. Soil and activated charcoal appear to bind strongly to TCDD and inhibit its absorption, so if known ingestion has occurred, immediate oral administration of activated charcoal may have beneficial effects by reducing the amount absorbed.<sup>14</sup>

## CANTHARIDIN TOXICOSIS (BLISTER BEETLE TOXICOSIS)

Cantharidin toxicosis results from ingestion of dead blister beetles that become entrapped in hay during harvesting. Essentially all reports are of horses being fed alfalfa hay or alfalfa products, but anecdotal reports exist of horses intoxicated by ingesting grass hay. More than 200 species of blister beetles inhabit the continental United States, but toxicity results primarily from beetles of the genus *Epicauta*.<sup>24</sup> Depending on the species of beetle, as few as a half dozen ingested beetles can be problematic. The liquid form of cantharidin is suspected in the malicious poisoning of horses.

Cantharidin is the sole toxic principle and is contained in the hemolymph, genitalia, and possibly other tissues of the beetle. Cantharidin is a highly irritating substance that causes acantholysis and vesicle formation when in contact with skin or mucous membranes, and the substance is absorbed from the gastrointestinal tract and rapidly excreted by the kidney. Storage of hay does not reduce the toxicity of cantharidin.<sup>24</sup>

## CLINICAL SIGNS

The signs associated with toxicosis are many, varied, and dose dependent. Horses affected with a minimal dose may show only signs of depression, anorexia, and occasionally polyuria, whereas horses ingesting a lethal dose may show signs of profound shock, gastrointestinal and urinary tract irritation, myocardial dysfunction, and hypocalcemia.<sup>24,25</sup> The onset and duration of clinical signs vary from hours to days, but horses that succumb to cantharidin generally die within 48 hours of onset of signs. Horses that live longer than 48 hours have a better prognosis for recovery if no complications arise.

The most commonly observed clinical signs include varying degrees of abdominal pain, anorexia, depression, and repeatedly submerging the muzzle in water or frequently drinking small amounts of water. The respiratory and cardiac rates are elevated, and cardiac contractions are occasionally forceful enough to be observed through the thoracic wall. Mucous membranes are congested and cyanotic, and capillary refill time is prolonged. The feces may be watery in consistency but rarely contain blood or mucus. Profuse sweating is typical

of more severely affected horses and may be a sign of severe abdominal pain. Affected horses often make frequent attempts to void urine. The urine is grossly normal early in the disease course but later may become tinged with blood or contain clots of blood. Gross hematuria, if it occurs, is usually in the later stages of the disease process. Less commonly observed signs include synchronous diaphragmatic flutter; erosions of the gingival and oral mucous membranes; and occasionally a stiff, short-strided gait similar to that seen in acute myositis. Sudden death also has been reported.<sup>24</sup>

## PATHOPHYSIOLOGY

The mechanism of action of cantharidin at the cellular level has not been elucidated fully. Acantholysis and vesicle formation result from disrupted cell membranes. Cantharidin does not have a direct effect on membranes but is thought to interfere with oxidative enzymes bound to mitochondria. These enzyme systems are involved directly in active transport across the plasma membrane, and their failure results in cell death caused by significant permeability changes in the cell membrane.<sup>24</sup>

Hypovolemic shock and pain develop rapidly in more severely affected horses. The normal transfer of fluid, nutrients, and electrolytes across the intestinal mucosa is disrupted because of the morphologic changes induced by cantharidin. Although renal tubular damage is not severe enough to cause death, changes in the renal tubular epithelium also may be related to the development of fluid, acid-base, and electrolyte abnormalities.<sup>24,25</sup>

Hypoproteinemia develops later in the disease course, probably as a result of protein loss across the damaged intestinal mucosa. Protein also is lost into the peritoneal space, and a minor amount may be lost through the urine.<sup>24</sup>

The profound hypocalcemia and hypomagnesemia that may occur in many horses have not been explained fully. Calcium loss, derangement of calcium homeostasis, or a combination of both is the most likely explanation because the acute onset of the disease eliminates reduced intake as a possible cause. Calcium can be lost through urine and sweat and as protein-bound calcium through the damaged intestinal wall. An influx of intracellular calcium also may occur in certain tissues. Whether cantharidin has an effect on calcium-binding sites on proteins or in cells is unknown.<sup>24</sup>

The low urine specific gravity in most horses may be caused by decreased permeability of the collecting ducts to water. Other findings, however, point to a mild pathologic insult as a cause of the low urine specific gravity. These findings include the facts that a low specific gravity occurs suddenly within hours of toxin exposure; specific gravity returns to normal in 2 to 4 days in surviving horses; only mild to moderate changes are noted in other renal function tests; and the histologic renal lesions are mild, and neither acute nor chronic renal failure is associated with cantharidin toxicosis in horses.<sup>24</sup>

Myocardial necrosis is a common finding in affected horses and may be caused by the direct effect of cantharidin on cardiac muscle. Dose-related intracellular changes involving the mitochondria, cristae, nuclear chromatin, sarcoplasmic reticulum, and myofibrils have been observed in the cardiac muscle of rabbits that were given cantharidin. A proposed mechanism for these changes suggests that an excessive transport of calcium into the myocardial cells occurs, leading to an intracellular calcium overload. This overload may result in a high-energy phosphate deficiency within the cell, leading to necrosis and cell death.<sup>24</sup>

## DIAGNOSIS

The clinician should consider cantharidin toxicosis when horses exhibit signs of abdominal pain, depression, or polyuria, and their diet contains alfalfa hay or alfalfa products. The diagnosis can be made when horses have clinical signs and laboratory findings compatible with cantharidin toxicosis and beetles are found in the hay. Because the beetles can be difficult to identify in hay, it should be thoroughly searched. Cantharidin can be assayed using high-pressure liquid chromatography and gas chromatography–mass spectrometry techniques.<sup>24,26</sup> Samples to be tested are serum, urine, kidney, and stomach content from horses in which cantharidin toxicosis is suspected.

Laboratory findings are nonpathognomonic, but several abnormalities typically are noted. Packed cell volume (PCV) and serum protein concentrations are elevated early, but hypoproteinemia frequently develops after about 24 hours. Mild hypokalemia can occur but is not a striking feature of this disease. Blood urea nitrogen (BUN) concentration may be elevated moderately, and hyperglycemia is almost always present initially.<sup>24</sup>

Serum calcium and magnesium concentrations are significantly decreased in most horses and remain low for longer than 48 hours if untreated. The urine generally contains red blood cells and has a low specific gravity, even in the face of clinical dehydration. Abnormal peritoneal fluid findings include increased protein concentration but relatively normal fibrinogen and white blood cell values. Feces are often positive for occult blood. Serum creatine kinase (CK) activity may be elevated in more severely affected horses and augurs a poor prognosis.<sup>24</sup> Although not diagnostic, laboratory findings of prolonged hypocalcemia and hypomagnesemia and elevated CK concentration may help differentiate cantharidin toxicosis from other causes of acute abdominal crisis.

## TREATMENT

No specific antidote is available for cantharidin. Once the diagnosis is suspected, all suspect feed should be removed from the horse's environment and all hay carefully examined for the presence of beetles.

Horses suspected of having cantharidin toxicosis should be given mineral oil as soon as possible. The oil helps evacuate the bowel and also may help reduce the amount of cantharidin available for absorption because cantharidin is lipid soluble. Activated charcoal given through a nasogastric tube also may have beneficial effects.<sup>24</sup>

Polyionic fluids should be administered intravenously throughout the disease course to correct dehydration and promote diuresis. Diuretics also may be given once the horse is volume loaded. Analgesics usually are required because of the severity of the abdominal pain, and glucocorticoids may be necessary to aid in treating shock. Calcium gluconate should be administered to elevate the serum calcium concentration, and calculated deficits of magnesium should be replaced by slow intravenous infusion.<sup>24</sup>

## PHOSPHORUS

Elemental phosphorus can be available in red and white forms. Red phosphorus is used in manufacturing fertilizers and safety matches and is considered inert and relatively nontoxic. White phosphorus was used as a rodenticide and can be found in pastes containing from 1.5% to 5% phosphorus. The reported toxic dose for horses is 0.5 to 2. g.<sup>14</sup>

## CLINICAL SIGNS

The toxic manifestations of phosphorus poisoning are generally threefold: Toxic signs commence within hours of ingestion; are followed by a latent period of 48 hours to several days, when the animal may appear to have recovered; and finally recur with greater severity.

The initial signs are characterized by severe abdominal pain, and gastrointestinal irritation, with occasional episodes of diarrhea. Blood may be present in feces. Cardiac arrhythmias may occur during this phase, and if the dose is sufficiently large, cyanosis, shock, incoordination, and coma can develop, and the animal may die before the second and third stages develop.<sup>14</sup>

The latent period may occur from 48 to 96 hours after the onset of clinical signs, and during this time the animal may appear normal. The third stage is characterized as a recurrence of severe abdominal pain, and signs of liver dysfunction may become evident. Icterus and a tendency to bleed from the gingiva, stomach, intestine, or kidney may be evident.<sup>14</sup>

## PATHOPHYSIOLOGY

Phosphorus is absorbed from the gastrointestinal and respiratory tracts. Although dermal exposure may cause skin irritation or burning, absorption does not occur by this route. The mechanism of action of phosphorus is unknown but is noted for causing irritation and necrosis of affected tissue. Phosphorus is also known to cause peripheral vasodilation.<sup>14</sup>

## DIAGNOSIS AND TREATMENT

Clinicopathologic abnormalities reflect hepatic and renal damage. Hypoglycemia may be pronounced, and liver enzymes such as AST, lactate dehydrogenase (LDH), and sorbitol dehydrogenase are elevated. Renal damage is reflected by increased BUN and creatinine concentrations. Albumin, blood, and increased concentrations of amino acids may be present in the urine. The phosphorus concentration in blood is usually normal. Although elemental phosphorus in tissues can be assayed, in time a large portion may be oxidized to phosphates, thereby making confirmation of poisoning difficult by chemical means.<sup>14</sup>

No specific antidote is available for phosphorus in toxication. Therapy is essentially symptomatic and supportive.

## THALLIUM

Thallium is toxic to all animals, including human beings, but clinical reports of toxicity are extremely rare. However, an oral dose of thallous acetate 27 mg/kg has been suggested as potentially lethal to horses.<sup>15</sup> Thallium has been used historically as a rodenticide, but its use now is limited and restricted only to government agencies.

## CLINICAL SIGNS

Thallium ingestion can result in acute, subacute, or chronic syndromes. In the acute form clinical signs in animals usually begin within 1 to 4 days of ingestion. Initial signs are those of severe gastrointestinal insult and include vomiting or regurgitation, severe hemorrhagic diarrhea, abdominal pain, and anorexia. Labored breathing is apparent early in the disease course, and motor paralysis and trembling may occur. Signs suggesting renal dysfunction also may occur.<sup>14</sup>

The subacute form generally manifests signs in 3 to 7 days after ingestion. Signs of gastric distress and motor disturbances

are less marked than in the acute form, but they persist for a longer time. In this form reddening of the skin and pustule formation occur. A pronounced reddening of the oral mucous membranes also seems to be unique to this particular toxicosis. Other clinical signs observed include conjunctivitis, hair loss, and crusty skin lesions. Secondary bacterial infections also may develop in affected animals.<sup>14</sup>

The chronic stage requires 7 to 10 days to appear. Signs of gastrointestinal and nervous system dysfunction are mild, but hair loss and dry, scaly skin become pronounced.<sup>14</sup>

### PATHOPHYSIOLOGY

Thallium is absorbed readily from the intestinal tract or through the skin; is distributed to all body tissues, although higher levels accumulate in the kidneys and liver; and is excreted principally in feces and to a lesser extent in urine; and undergoes an enterohepatic cycle for resorption and excretion.<sup>15</sup>

Thallium is thought to combine with mitochondrial sulfhydryl enzymes at a specific yet unknown place in the scheme of sulfur metabolism. Thallium therefore interferes with oxidative phosphorylation within cells. Recent evidence suggests that thallium exchanges for potassium in muscle and nerve cells primarily and also has a necrotizing effect on the intestinal tract, kidney, and occasionally the brain.<sup>14,15</sup>

### DIAGNOSIS

Thallium toxicosis is suspected on the basis of clinical signs, and urine can be assayed for thallium content. The finding of thallium in tissue in any amount is diagnostic, but liver and kidney levels tend to be higher than in other tissues.

### TREATMENT

Chelation therapy using diphenylthiocarbazone (dithizon) at a dosage of 70 mg/kg administered orally thrice daily has been recommended for use in dogs.<sup>14</sup> However, cats react adversely to this agent. Its effect in horses is unknown.

Potassium chloride may aid in the elimination of thallium and can be given intravenously or orally, but the oral route is contraindicated in animals that also are being treated with an ion exchange agent.

One can attempt to trap thallium in the intestine with the ion exchange agent potassium ferric cyanoferrate-II (potassium-prussian blue). Experimentally, potassium-prussian blue is not absorbed from the intestinal tract and acts to immobilize the thallium ion by exchanging with the potassium of potassium-prussian blue. Once trapped, thallium is not released readily from potassium-prussian blue, and fecal excretion of thallium increases.<sup>15,38</sup>

Other forms of symptomatic therapy include intestinal protectants and demulcents, fluid and electrolyte support, analgesics, oral activated charcoal, and general nursing care.<sup>15</sup>

## TOXICOSES CAUSING SIGNS OF CENTRAL NERVOUS SYSTEM STIMULATION

Dealing with horses showing signs of CNS stimulation can be one of the most difficult and challenging situations faced by the equine internist. Signs can be hard to control, and clients' emotions often run high at the sight of a horse showing

severe or uncontrollable signs such as hyperexcitability, exaggerated gait abnormalities, and seizures. The immediate clinical emphasis is usually on minimizing the risk or severity of self-induced trauma. Etiologic diagnosis may be difficult and protracted.

## PLANTS

### LOCOWEED

A nervous syndrome in horses, cattle, and sheep has long been associated with eating plants of the genera *Astragalus*, *Swainsona*, and *Oxytropis*. This group of plants is large. The *Astragalus* species that grow in North America number more than 300. Not all species of *Astragalus* and *Oxytropis* are toxic, however, and some species make nutritious forage for livestock.<sup>1</sup> Some debate still exists regarding the taxonomy of these species, but because the clinical signs that they induce are essentially the same, they are discussed together.

The toxic species of locoweeds produce three different syndromes in livestock. Some species contain nitroglycosides, which cause methemoglobinemia and competitive inhibition of certain cellular enzymes; others accumulate toxic levels of selenium; and a third group contains alkaloids that cause locoism.<sup>1,2</sup> The first group of plants is of minor importance to the horse, and the selenium concentrators are discussed in the section on selenium toxicosis. A discussion of the clinical syndrome locoism follows.

The species of locoweeds that have been associated with locoism include *Astragalus lentiginosus* (36 varieties); *Astragalus mollissimus* (11 varieties); *Astragalus wootonii* (2 varieties); *Astragalus thurberi*; *Astragalus nothoxys*; *Oxytropis sericea*; *Oxytropis lambertii*; and *Oxytropis saximontana*.<sup>1</sup> Additional *Astragalus* species incriminated in causing disease include *Astragalus argillophilus*, *Astragalusbisulcatus*, and *Astragalus earlei*.<sup>60</sup> Geographically, locoweeds are found from western Canada southward to include the western United States and northern Mexico.<sup>1</sup>

### CLINICAL SIGNS

Locoweeds cause a number of problems in livestock, including neurologic and reproductive dysfunction, emaciation, and habituation.<sup>1</sup> Typical signs exhibited by affected horses include a slow, staggering gait; depression; an unthrifty appearance; emaciation; muscular incoordination; and nervousness, especially when the animal is under stress. The affected horse may become solitary and hard to manage and may have difficulty eating and drinking. In some animals sexual activity may become suppressed. Visual impairment also occurs in some horses, and mares ingesting locoweeds during pregnancy have been known to abort or produce foals with various limb deformities.<sup>2,3</sup> Horses that are affected chronically are generally useless for riding or draft purposes because their behavior is so unpredictable.<sup>1</sup>

The onset of clinical signs varies from as short as 2 weeks to as long as 2 months after the horse starts to graze the plant. The plants generally are considered unpalatable to horses, but once they start to ingest the plant, they seem to become addicted to it and will search it out.<sup>1</sup> The addiction can extend to subsequent growing seasons, so clinical signs can worsen progressively in successive years if animals continue to graze the plant.<sup>2</sup> Affected horses can recover if feeding or grazing is discontinued before they become too emaciated and if

nutritious forage is provided.<sup>1</sup> However, the syndrome eventually may lead to death in chronically affected horses.<sup>2</sup>

### PATHOPHYSIOLOGY

The indolizidine alkaloids swainsonine and swainsonine N-oxide have been suggested as the toxic principles in locoweeds.<sup>2</sup> These alkaloids were first recovered from *Swainsona* species in Australia.<sup>1,2</sup> Evidence suggests that these alkaloids are actually mycotoxins, or toxins produced by endophytes located within the plant. Swainsonine inhibits  $\alpha$ -mannosidase, a lysosomal enzyme essential in the cellular metabolism of oligosaccharides. As a result, mannose-rich oligosaccharides accumulate in lysosomes and disrupt cellular function. These accumulations are visible microscopically as intracytoplasmic vacuoles. Vacuolization of the renal cortical tubular cells can occur as early as 4 days after ingestion of locoweed begins, and neurons of the CNS, including Purkinje cells, may show vacuolization by 8 days. The vacuoles disappear shortly after consumption ceases in the early stages of disease, but if grazing is prolonged, permanent cellular damage occurs. Continuous feeding of the plant for 30 days or longer results in vacuolization of almost all tissues of the body except skeletal and cardiac muscle.<sup>2</sup>

Neurologic signs result from vacuolization of the axons, glial cells, and Purkinje cells of the cerebellum and cerebral cortex. The weight loss and emaciation result from impairment of the liver, pancreas, thyroid, and parathyroid glands. Vacuolization of cells of the retina and decreased lacrimation are responsible for impaired vision in some animals. Vacuoles also occur in lymph nodes, placenta, testicles, and lymphocytes.<sup>1,2</sup> The pathogenesis and lesions of locoism are similar to mannosidosis, a heritable lysosomal storage disease of Angus and Murray Grey cattle.<sup>2</sup>

### DIAGNOSIS AND TREATMENT

A few laboratories test for swainsonine and mannosidase activity in a variety of biologic specimens. The diagnosis is suspected when horses show clinical signs compatible with locoism and have a history of exposure to the plant. Laboratory testing is nonspecific, and test results are expected to be consistent with multiple organ dysfunction. Microscopic lesions of intracytoplasmic vacuolization in various organs, including the CNS, are compatible with a diagnosis of locoism.<sup>1,2</sup> Peripheral lymphocytes that contain intracytoplasmic vacuoles also are considered indicative of locoism, if clinical signs are present.<sup>2</sup>

No effective cure exists for horses with chronic locoism that have had clinical signs for some time. Mild cases usually resolve in 1 to 2 weeks once ingestion ceases, so successful recovery from locoism depends on early recognition of the disease syndrome and prevention of further consumption. Reserpine has been suggested to be helpful in relieving some of the clinical signs of locoism in horses.<sup>2</sup>

### NERVOUS ERGOTISM

Two forms of ergotism are observed in domestic animals, a nervous or convulsive form and a gangrenous form. Horses appear rarely to be affected with ergotism, but the nervous form is reported to occur much more frequently in horses than the gangrenous form.<sup>4,5</sup> Ergotism is caused by a number of alkaloids contained in *Claviceps purpurea*, a fungus infecting grains such as wheat, barley, rye, and oats and wild grasses such as quackgrass, smooth bromegrass, wheatgrass, bluegrasses,

and wild rye. The fungal mass, or sclerotium, replaces the seed or kernel of the plant and may have the same general configuration as the seed but is usually larger, dark colored, and hard. Ergotism is rarely of concern in dry seasons, but abundant fungal growth can occur during wet periods.<sup>4</sup> Although well-documented cases of ergotism caused by *C. purpurea* in horses are absent in the literature, a nervous syndrome typical of *Claviceps paspali* poisoning has been observed in horses in Australia. However, the cause of the clinical signs in these horses was suggested to have been the tremorogenic mycotoxins in *C. paspali* rather than the alkaloids found in ergot.<sup>6</sup>

### CLINICAL SIGNS

The first sign of nervous ergotism in animals is reported to be dizziness or an unsteady gait. This phase may be interrupted by convulsions and temporary posterior paralysis and drowsiness.<sup>4</sup> Other behavioral effects that have been described include incoordination, lameness, difficulty in breathing, excessive salivation, and diarrhea.<sup>5</sup>

### PATHOPHYSIOLOGY

Approximately 40 different alkaloids have been isolated from *C. purpurea*. All of these alkaloids are derivatives of the tetracyclic compound 6-methylergoline, a lysergic acid base structurally similar to a number of biogenic amines such as dopamine, serotonin, and norepinephrine.<sup>4,7</sup> The most pharmacologically potent alkaloids in ergot are ergonovine, ergotamine, ergotsine, ergocristine, ergocryptine, and ergocornine.<sup>4</sup> Additionally, tyrosine, tryptophan, tyramine, histamine, histidine, choline, and acetylcholine have been isolated from ergot sclerotia, but their clinical significance is uncertain.<sup>7</sup>

The mechanism whereby ergot alkaloids induce CNS signs in horses has not been elucidated. Of the ergot alkaloids known to affect the CNS in human beings, bromocriptine is the prototype. Bromocriptine is a long-acting dopamine agonist that has central stimulating effects and may cause hypotension. Another ergot alkaloid, isoergine (lysergic acid amide), has one tenth the mind-altering potency of the structurally related compound lysergic acid diethylamide (LSD). LSD is thought to produce hallucinations by a series of complex agonist and antagonist actions on several central monoamine neurotransmitters, particularly serotonin.<sup>7</sup>

### DIAGNOSIS AND TREATMENT

The diagnosis of nervous ergotism in horses is based primarily on clinical signs and eliminating other causes of CNS stimulation. One can assay the ergot alkaloid content of feed.<sup>4</sup>

No specific antidote exists for ergot alkaloid toxicity. Treatment of affected horses is largely symptomatic. Recommendations for control include using ergot-free feed, rotating crops, plowing deeply (because shallow cultivation and seeding leave the sclerotia near the soil surface, where they can germinate more readily), and mowing surrounding grasses to limit the spread of fungus into the cultivated crop.<sup>5</sup> Pasture grasses that may be infested with ergot should be mowed before the development of seedheads because *Claviceps* replaces the seed or kernel of the plant.

### BLUE-GREEN ALGAE (CYANOBACTERIA)

The occurrence of cyanobacterial poisoning in livestock is not uncommon in many areas. Most cases of toxicity involve other grazing animals, principally cattle and sheep, but horses are

reported to be susceptible.<sup>8</sup> Toxicity may occur during times that favor algal growth in surface water. The most important factors that favor rapid algal growth are a nutrient source (e.g., nitrogen, phosphate); quiet, calm weather conditions; and warm water temperature. Therefore toxicosis is most likely to occur during periods of warm weather (i.e., late spring through fall), when surface water may be contaminated with fertilizer runoff or organic waste high in nitrogen, such as that from feedlots.<sup>8,9</sup> However, it is important to note that livestock toxicities caused by cyanobacteria have been reported in the winter months in the Northern hemisphere. In more temperate areas cyanobacterial blooms can be a year-round occurrence.

At least eight genera of cyanobacteria are known to be toxic: *Anabaena*, *Aphanizomenon*, *Microcystis* (*Anacystis*), *Coleosphaerium*, *Gloeotrichia*, *Lyngbya*, *Nodularia*, and *Nostoc*, but the first three are of most concern in veterinary medicine. Toxins produced by cyanobacteria are either neurotoxic or hepatotoxic; therefore signs of poisoning are typically neurologic or hepatic, but rarely both are observed in an animal (even though some blooms are mixed). Most blooms are composed of one predominant cyanobacterial organism. *Microcystin* (*Anacystin*) organisms produce the hepatotoxin microcystin; and *Anabaena* and *Aphanizomenon* produce the neurotoxins anatoxin-a and anatoxin-a(s).

### CLINICAL SIGNS

Common signs of cyanobacterial poisoning associated with microcystins may include rapid appearance of abdominal pain, diarrhea, muscle tremors, dyspnea and cyanosis, prostration, and death. Animals surviving several days may exhibit hemorrhagic diarrhea, muscle tremors, signs of liver damage, and secondary photosensitization.<sup>8,9</sup> Animals exposed to neurotoxic blooms frequently develop signs within a few minutes (<1 hour) of ingestion and may show rapid onset of CNS dysfunction with seizures, prostration, and death.

### PATHOPHYSIOLOGY

*Anabaena* and *Aphanizomenon* species may contain the low-molecular-weight alkaloid anatoxin-a. This toxin produces a potent postsynaptic depolarizing neuromuscular-blocking action that has a curare-like effect. Death results from respiratory arrest. Blooms of some *Aphanizomenon* species may produce small amounts of the neurotoxin (saxitoxin) and at least three related toxic compounds of unknown structure.<sup>7,8</sup> Saxitoxin blocks sodium conductance through excitable membranes, which subsequently stops nerve action potential. Death resulting from saxitoxin is caused by respiratory neuromuscular paralysis.<sup>8</sup> Anatoxin-a(s) can also be produced by these organism, whose action is to inhibit acetylcholinesterase activity. *Microcystis* species of cyanobacteria can produce the cyclic hepatotoxin microcystin.<sup>7,8</sup> The immediate cause of death is hemorrhagic shock resulting from massive hepatocellular necrosis and collapse of the hepatic parenchyma.<sup>10</sup>

### DIAGNOSIS AND TREATMENT

Analytic methods are now available that can isolate and identify the cyanobacteria organism and the toxins from affected animals (gastric contents, liver) or suspect water. Because the concentrations of cyanobacteria and toxins can vary tremendously over a short time, recovery of the organism or toxin from water may not be possible when clinical signs are noted in exposed animals. A diagnosis can be based on history of exposure to a water source when conditions favoring

cyanobacterial overgrowth are present, coupled with onset of compatible clinical signs and analysis of tissues and water for the toxin. One can analyze water samples to identify specific blue-green algae, the presence of which may help support a diagnosis of algal toxicity if toxin testing is not feasible.<sup>8</sup>

No specific antidote is available, and animals often are found dead before treatment can be initiated.<sup>8</sup> Algal growth in surface water can be controlled by a variety of herbicides and copper sulfate. When water is treated with these compounds, it is important to ensure that the compounds are being used in a safe manner for all susceptible livestock.

## ☞ PESTICIDES

### ACETYLCHOLINESTERASE-INHIBITING INSECTICIDES

The carbamate pesticides are composed of cyclic or aliphatic derivatives of carbamic acid, and numerous ones are commercially available.<sup>8,11</sup> A partial list of these compounds is carbaryl, aldicarb, carbofuran, methiocarb, methomyl, and oxamyl. Carbamates are absorbed readily through the lungs, gastrointestinal tract, and skin. Carbamates do not accumulate in any particular tissue but do cross the rat placenta and depress fetal acetylcholinesterase; they are not metabolized readily in the fetus.<sup>11</sup> In human beings the carbamates generally penetrate the blood-brain barrier poorly and therefore may produce few CNS signs.<sup>7</sup> Carbamates do not require activation by liver enzymes to exert their effect. Toxicity data are not complete for several domestic animals, but lethal doses of the different compounds vary from less than 1 mg up to several hundred mg per kg of body weight. Carbamates are not stable in the environment and are fairly insoluble in water, but organic solvents and oils can carry the compounds across cell barriers.<sup>11</sup> It is important to note that not all so-called carbamate pesticides inhibit acetylcholinesterase activity, so the clinician must determine exactly which carbamate compound the animal is exposed to and determine its mechanism of action.

### CLINICAL SIGNS

Clinical signs can commence a few minutes to several hours after exposure but are short-lived. The clinical episode frequently is less than 36 to 48 hours in duration, with the animal succumbing or recovering during this time.<sup>8,11</sup>

Signs of toxicity in horses reflect muscarinic and nicotinic cholinergic overstimulation. The signs suggestive of muscarinic cholinergic overstimulation include profuse salivation, severe gastrointestinal disturbances characterized by hypermotility, severe pain, abdominal cramps and diarrhea, excessive lacrimation, miosis, sweating, dyspnea, cyanosis, and urinary and fecal incontinence. Affected animals also may cough frequently as a sign of excessive accumulation of respiratory tract secretions. The signs reflected by nicotinic overstimulation include excessive stimulation of the skeletal muscles. The muscles of the face, eyelids, and tongue, in addition to the general musculature, may twitch. Some animals exhibit signs of generalized tetany that causes them to walk in a stiff-legged fashion. This hyperactivity may be followed by weakness and paralysis of the skeletal muscles.<sup>8</sup>

Signs of CNS involvement in domestic food-producing animals may include hyperactivity reflecting excessive stimulation of the CNS, but domestic animals rarely exhibit

convulsive seizures (however, this can occur at high dose exposures). CNS depression is reported to be more common than CNS stimulation.<sup>8</sup>

### PATHOPHYSIOLOGY

Carbamates induce excessive stimulation of the parasympathetic nervous system by inhibiting acetylcholinesterase and pseudocholinesterase. The carbamate pesticides occupy the anionic and esteratic sites of acetylcholinesterase, with the esteratic site being carbamylated. Acetylcholinesterase can hydrolyze carbamate pesticides but at a slower rate than that for acetylcholine. Therefore carbamates are reversible inhibitors of acetylcholinesterase, but toxicosis occurs when the amount of pesticide is large enough that the rate of carbamylation of acetylcholinesterase exceeds the rate of hydrolysis of pesticide by the enzyme.<sup>11</sup> As a result, acetylcholine accumulates in neuroeffector and synaptic regions, resulting in the observed clinical signs of parasympathetic overstimulation.

The continuous stimulation of secretory glands leads to excessive salivation and accumulation of fluid within the respiratory tract and within the lumen of the bowel. Extensive pulmonary edema may occur and, along with bronchoconstriction, can lead to death in affected animals.<sup>8</sup>

Carbamates are removed from the circulation largely by spontaneous hydrolysis of the carbamate-cholinesterase complex. In addition, blood esterases can inactivate a portion of the circulating carbamate, and certain liver microsomal enzymes break down the compounds within hours of exposure.<sup>7,11</sup> The clinical signs associated with carbamate toxicity are generally rather short-lived, with recovery occurring in less than 36 to 48 hours in most animals.

### DIAGNOSIS AND TREATMENT

The clinician is most likely to make a diagnosis on the basis of a history of possible exposure, clinical signs, and response to atropine treatment. Chemical analyses of biologic samples for carbamate residues can be rewarding; finding the pesticide in stomach contents, the liver, or feed samples may confirm the diagnosis.<sup>8</sup>

Cholinesterase activity in blood and brain tissue can also be used as a screening tool to determine exposure to this group of compounds. However, discretion must be used when interpreting these results because recommended therapeutic levels of carbamates applied to animals can result in some depression of blood cholinesterase activity. In one author's opinion, clinical signs of acute carbamate toxicity are associated with blood cholinesterase activity of less than 50% to 75% of normal values. Because the inactivation of cholinesterase by carbamates involves a much weaker and less stable binding than that by organophosphates, one should not dilute blood samples from suspect animals and should refrigerate them and analyze them as soon as possible.<sup>8</sup>

Affected animals should be treated as quickly as possible. Initial therapy should consist of atropine sulfate at 0.2 mg per kg of body weight. This initial dose should be divided, with approximately one fourth of the dose administered intravenously and the remainder given subcutaneously or intramuscularly. Repeated doses of atropine may be required but should be used only to counteract the parasympathetic signs. The skeletal muscle tremors may not respond to atropine therapy.<sup>8</sup>

Orally administered adsorbents such as activated charcoal may be useful in binding ingested pesticide, and aqueous cathartics may further aid in evacuation of the intestinal

tract. Mineral oil probably should not be given orally in suspect cases because organic solvents and oils can carry the compound across cell barriers. Dermally exposed animals should be washed with soap and water and rinsed thoroughly to prevent further exposure. Oximes such as pralidoxime are of questionable benefit in treating carbamate toxicosis, and their use may worsen the condition of the animals.<sup>8,11</sup> The cost of this drug may be a prohibiting factor in their use in horses.

### ORGANOPHOSPHATES

The organophosphate pesticides are being used increasingly in a variety of ways. Some of the typical uses for these compounds include animal insecticides and parasiticides; plant insecticides, soil nematocides, fungicides, herbicides, and defoliant; insect repellents; and chemosterilants.<sup>11</sup> Horses can become intoxicated in several ways because these products are used so commonly in their environment.

A wide variety of organophosphorus compounds have been developed, and their toxicity varies greatly among compounds and among animal species. Osweiler, Carson, Buck, et al. have tabulated a good list of various organophosphorus compounds and their relative toxicities.<sup>8</sup> In addition to variations in compound toxicity, a number of physicochemical factors also can affect the toxicity of organophosphorus compounds. The toxicity of these compounds decreases as they are degraded by sun, water, microbes, alkali, or metal ions such as iron or copper. An increase in toxicity may occur by storage activation, a process in which highly toxic isomers of certain pesticides are formed spontaneously in polar solvents or water. This reaction is speeded by heat. Parathion, malathion, fenthion, chlorpyrifos, diazinon, and coumaphos are some of the compounds that can undergo this type of storage activation.<sup>11</sup> The storage activation phenomena provide good reasons to use only freshly prepared preparations of organophosphate compounds on horses.

Other factors that can influence the toxicity of a particular organophosphorus compound are ambient temperature (higher temperatures may increase the toxicity of certain compounds); the vehicle in which the pesticide is dispersed; the age and sex of the animal; and the presence of other chemicals that may alter organophosphate toxicity. The combined effects of two organophosphates may be synergistic or antagonistic, and drugs that compete with organophosphates for target esterases, such as succinylcholine, phenothiazine, and procaine, may enhance organophosphate toxicity. In addition, drugs that have neuromuscular-blocking properties (e.g., inhalant anesthetics, magnesium ions, certain aminoglycoside antibiotics, and the depolarizing and nondepolarizing neuromuscular-blocking agents) also may enhance organophosphate toxicity. The organophosphates are poorly soluble in water but are soluble in organic solvents, fats, and oils. Oily vehicles or organic solvents also can facilitate passage of the organophosphates through the skin.<sup>11</sup>

### CLINICAL SIGNS

Clinical signs of organophosphate toxicity are similar to those of carbamate toxicity and essentially are those of overstimulation of the parasympathetic nervous system, skeletal muscles, and CNS.

Overstimulation of muscarinic cholinergic sites results in profuse salivation and lacrimation; serous or seromucous nasal discharge; increased respiratory sounds and coughing resulting

from bronchoconstriction and excessive bronchial secretions; profound gastrointestinal disturbances of increased motility, abdominal pain, and diarrhea; bradycardia; miosis; sweating; and frequent urination. Signs of nicotinic cholinergic overstimulation include muscle fasciculations, tremors, twitching, spasms, and a stiff or rigid gait. CNS signs frequently include anxiety, restlessness, and hyperactivity.<sup>8,11</sup> If the exposure is not severe enough to result in the death of the horse, the horse may require several days to recover completely; compounds that are more chlorinated can be stored in fat reserves and therefore have a longer half-life.<sup>11</sup>

### PATHOPHYSIOLOGY

Organophosphates can be absorbed from the gastrointestinal tract and lungs and through the skin. After absorption, they are distributed throughout the body, but most do not accumulate in any particular tissue. Most of the organophosphates must be activated by hepatic microsomal oxidative enzymes before they become potent esterase inhibitors. Phosphorothiolate and the phosphate class of organophosphates do not require activation and can inhibit esterases immediately after entering the bloodstream.<sup>11</sup>

Organophosphates act as irreversible inhibitors of true cholinesterase and pseudocholinesterase in mammals. They irreversibly phosphorylate the esteratic site of cholinesterases throughout the body. As a result, endogenous acetylcholine is not inactivated. Therefore acetylcholine accumulates in neuromuscular junctions; in parasympathetic postganglionic sites in smooth muscle, cardiac muscle, and glands; in all autonomic ganglia; and in cholinergic synapses within the CNS. The result is overstimulation of these sites, leading to clinical signs of toxicosis.<sup>8,11</sup>

Lethal amounts of organophosphates cause death by the combined effects of nicotinic, muscarinic, and central cholinergic overstimulation or receptor paralysis. These effects include hypotension, bradycardia, bronchoconstriction and excessive bronchial secretion, inability of the respiratory muscles to work properly, cyanosis, and central respiratory depression. The animal actually dies of asphyxia.<sup>11</sup>

Detoxification of organophosphates is accomplished mostly by serum and liver esterases. However, other enzymes in the liver and other tissues may attack the pesticides at rates dependent on the class of pesticide, the species, and the age of the animal. Water-soluble metabolites may be formed rapidly and the pesticide excreted quickly in the urine.<sup>8,11</sup>

### DIAGNOSIS AND TREATMENT

The clinician should suspect organophosphate toxicosis when the horse has a history of possible exposure within the past 48 hours, along with characteristic signs of parasympathetic overstimulation. One can analytically test for organophosphate residues in body tissues or specimens and in other suspect materials. Some tissue specimens analyzed for organophosphate content yield negative results because some of the compounds do not stay in tissues long after the animal has been exposed.<sup>8,11</sup>

A test for cholinesterase activity in blood or brain tissue is a rapid screening tool that can assist in determining if an animal has been exposed to excessive amounts of a cholinesterase inhibitor. Blood or brain cholinesterase activity values of less than 50% to 75% of normal can be compatible with exposure of the animal to excess organophosphates or other cholinesterase inhibitors (false inhibition can be observed if

the patient is anemic). It should be noted that some depression of blood cholinesterase activity occurs when therapeutic levels of organophosphates or carbamates are used, so these results should be considered with discretion.<sup>8,11</sup>

Treatment to help control the muscarinic overstimulation should involve immediate use of atropine sulfate at 0.2 mg per kg of body weight. Approximately one fourth of this dose should be given intravenously, and the remainder should be given subcutaneously or intramuscularly. It may be necessary to repeat this dose at 3- to 6-hour intervals. Because atropine does not block the nicotinic cholinergic effects, the horse may continue to show signs of muscle fasciculation or tremors.<sup>8,11</sup> Atropine should be used with great discretion in the horse so as not to cause further complications, such as gut stasis with atropine overdosage (see the section on atropine).

The oximes, such as pralidoxime and pralidoxime chloride, act specifically on the organophosphorus-enzyme complex to free the enzyme and also react directly with the organophosphate to form a nontoxic complex that is excreted in urine. However, the use of these products in horses may not be economically feasible. The recommended dose varies between 20 mg/kg<sup>98</sup> and 25 to 50 mg/kg given as a 20% solution intravenously, slowly, over several minutes. Oximes are reported to work best in the presence of atropine, so they should be given to the animal after atropine administration. Treatment with the oximes can be repeated if signs reappear.<sup>11</sup>

Other treatment measures include removal of the source, if possible; use of orally administered activated charcoal; laxatives to aid in evacuation of the bowel; washing with soap and water and thorough rinsing if dermal exposure has occurred; and supportive therapy such as fluids and electrolyte administration, if necessary. Drugs that should not be used when treating organophosphate toxicosis include phenothiazine tranquilizers, succinylcholine, and morphine.<sup>8,11</sup>

### CHLORINATED HYDROCARBONS

The current use of chlorinated hydrocarbon pesticides is limited and severely restricted because of their persistence in the environment and their incorporation into the food chain. However, certain agents still are being used, primarily as contact insecticides and as ectoparasiticides.<sup>8,11,12</sup> A partial list of compounds includes lindane, aldrin, dieldrin, endosulfan, endrin, and methoxychlor.

The chlorinated hydrocarbon insecticides are poorly soluble in water but are soluble in organic solvents and oils. Oily vehicles or organic solvents can facilitate penetration of the insecticide through intact skin. Because this group of compounds also is characterized by volatility, exposure to the pesticide can occur through inhalation of the vaporized compound.<sup>11</sup> Because these compounds accumulate in body tissues, primarily adipose tissue, signs of toxicosis can result from repeated exposure to lesser amounts or after a single excessive dose.<sup>12</sup> Toxicity varies greatly among the different compounds, and Osweiler, Carson, Buck, et al.<sup>8</sup> have tabulated the toxicity of a number of these compounds for various animal species.

### CLINICAL SIGNS

The chlorinated hydrocarbons generally act as diffuse stimulants (less commonly as depressants) of the CNS, with the onset of signs ranging from several minutes to several days

after exposure. The signs displayed may be progressively severe or explosive and fulminating.<sup>8</sup> Initially, the animal may be hypersensitive, apprehensive, or belligerent. These behavioral aberrations may progress to abnormal posturing or frenzied or maniacal behavior. Nervous signs can begin with hypersensitivity and muscle fasciculations beginning around the head and facial area and proceeding caudally eventually to include the hind quarters. These muscle spasms can occur intermittently or continuously. Clonic-tonic seizures often follow and may result in death or be followed by intermittent periods of CNS depression. Autonomic manifestations of profuse salivation, mydriasis, diarrhea, urination, and bradycardia or tachycardia with arrhythmias may occur. Some animals may lose coordination and stumble while walking, walk aimlessly, or move in circles. Other notable signs may include increased rate and depth of respiration and fluid sounds in the lungs. Death may occur within minutes, hours, or days or not at all.<sup>8,11,12</sup>

### PATHOPHYSIOLOGY

Chlorinated hydrocarbon pesticides gain entry into the body by way of the gastrointestinal and respiratory tracts and absorption through the skin. Once they enter the bloodstream, they are thought to bind to serum lipoproteins and are distributed throughout the body. Eventually, an equilibrium is reached in which the pesticide concentration varies among different body compartments. Most of the absorbed pesticide is stored in fat, but brain and fetus also can accumulate significant amounts.<sup>8,11</sup>

Adipose tissue is the main storage tissue for chlorinated hydrocarbons and as such can retain some of these compounds for an extended period. The pesticide is mobilized slowly from fat, which can account for its presence in blood and milk for weeks to months after a single exposure.<sup>11</sup>

The chlorinated hydrocarbons are broken down by liver microsomal enzymes, and the pesticide and its metabolites are excreted in urine, bile, milk, and feces. This first stage of elimination is fairly rapid and may account for 40% to 50% of the compound being eliminated during the first 3 to 4 days after exposure.<sup>11</sup>

The exact mechanism of action of all of the chlorinated hydrocarbons is unknown, but they act as nonspecific stimulants of the CNS. A suggested mechanism is that some of these compounds easily enter neural membranes and prolong the time during which some of the sodium channels in the membrane are open during depolarization. In addition, potassium efflux from the cell is hindered. The net effect of these ion imbalances is a decreased transmembrane resting potential that causes a decreased firing threshold and an increased neuronal excitability.<sup>11</sup>

An increase in whole-brain free ammonia concentration and brain glutamine also occurs, but whether these changes are a cause or an effect of the sodium-potassium flux defect is unknown. However, the onset and disappearance of convulsions in animals is correlated with an increase and decrease of brain ammonia concentration.<sup>11</sup>

The depression produced by some chlorinated hydrocarbons may result from rapid depolarizing blockade of neurons of the reticular activating system. Excessive depolarization of the medullary neurons may be responsible for respiratory failure, which is the usual cause of death in chlorinated hydrocarbon pesticide toxicosis. The muscle tremors in chlorinated hydrocarbon toxicosis are thought to be partly central

in origin and partly caused by direct depolarizing effects on peripheral motor nerves.<sup>11</sup>

### DIAGNOSIS AND TREATMENT

The clinician can make a tentative diagnosis when animals are known to have been exposed to an insecticide and are exhibiting compatible signs of toxicosis. Tissue samples may be assayed for residues of the specific compound, but it is important to exercise caution when interpreting results because some of the compounds may be found in the fat of normal animals as a result of exposure to small concentrations in the environment. However, ppm concentrations may have diagnostic significance if history and clinical signs are consistent with chlorinated hydrocarbon poisoning. Brain and liver concentrations of this category of pesticides are reported to be better correlated with toxicosis than are concentrations in body fat.<sup>11</sup> Other suitable tissue specimens include blood, milk, kidney, and gastrointestinal contents.<sup>8</sup>

Because no specific antidote is available for the chlorinated hydrocarbons, treatment is symptomatic. For animals exhibiting convulsive seizures or neuromuscular hyperactivity, intravenous chloral hydrate or pentobarbital can be administered carefully to effect. Sedative doses of these two agents should control most of the behavioral, nervous, and locomotor signs. Sedation usually can be discontinued after 24 to 48 hours.

Oral exposure should be treated with saline cathartics and an adsorbent such as activated charcoal. If exposure was by the dermal route, the animal requires a thorough bathing with soap and water, followed by a thorough rinsing. As in all cases of pesticide toxicity, the source of contamination should be eliminated if possible.<sup>8,11</sup>

### STRYCHNINE

The present-day use of strychnine is primarily as a rodenticide. Although strychnine is available to the public through many retail outlets, instances of horses becoming intoxicated by strychnine are not common.<sup>8,11,13</sup> The approximate oral lethal dose for horses is 0.5 mg/kg.<sup>8</sup>

### CLINICAL SIGNS

The clinical manifestation of strychnine toxicosis can appear as rapidly as 10 minutes to 2 hours after ingestion. Initial signs include apprehension, nervousness, and muscle stiffness. These signs are followed by stiffness and tetanic spasms that may appear spontaneously or may be initiated by stimuli such as sound, touch, or light. These tetanic spasms may vary from a few seconds to a minute or more and are characterized by extreme extensor muscle rigidity. Apnea frequently occurs during the spasms. Sometimes, intermittent periods of relaxation occur between seizures but become less frequent as the clinical episode progresses. In lethal cases the convulsive spasms become more frequent until death eventually occurs during a seizure or as a result of exhaustion and anoxia. The entire clinical episode typically lasts less than 2 hours.<sup>8,11</sup> Additional signs that are reported in horses include sweating, incoordination, prostration, convulsions, and death within approximately 2 hours.<sup>11</sup>

### PATHOPHYSIOLOGY

Strychnine is absorbed rapidly from the intestinal tract but not from the stomach. The alkaloid nature of the compound promotes its ionization within an acid medium; hence minimal

absorption occurs from the stomach.<sup>8</sup> Once absorbed, strychnine is distributed readily throughout the body. Strychnine does not accumulate in any given tissue, but detectable concentrations can be found in the blood, urine, liver, and kidney.<sup>8,11</sup> Strychnine is metabolized in the liver by hepatic microsomal enzymes, and it and its metabolites are excreted in urine.<sup>8</sup> Excretion of strychnine is rapid, with most of a lethal dose being eliminated within 24 hours.<sup>11</sup>

Glycine is an inhibitory neurotransmitter in the spinal cord and medulla that serves to dampen or modulate efferent motor neuron activity. The purpose of this modulating effect is to provide smooth, coordinated muscle contraction and activity that are appropriate and consistent with the requirements for locomotion and respiration. Strychnine acts competitively to antagonize glycine by blocking its uptake at postsynaptic sites on receptors in the spinal cord and brainstem. The result of this blockade is hyperexcitation of muscle groups caused by lack of normal inhibition. Muscle reflex activity is allowed to proceed in basically an uncontrolled manner. All striated muscles are affected, but the more powerful extensor muscles tend to predominate and produce generalized rigidity and tonic seizures.<sup>8,11</sup>

### DIAGNOSIS AND TREATMENT

A tentative diagnosis of strychnine poisoning can be made on the basis of a history of possible exposure, characteristic limb rigidity, and a rapid recovery (i.e., less than 24 hours in many cases) in animals aggressively treated in time. To confirm the diagnosis, the clinician may submit tissue samples for evaluation. Stomach content is the most suitable specimen for analysis.<sup>8,11</sup> Many commercial strychnine baits contain grain (e.g., wheat, oat, barley, sorghum) dyed red or green; seeing this in the stomach contents allows the clinician to pursue strychnine poisoning as a differential diagnosis.

Treatment of strychnine poisoning is symptomatic because no specific antidote is available. The horse should be kept in a quiet environment with minimal stimulation. Of primary importance is maintenance of relaxation and prevention of asphyxia. Pentobarbital or chloral hydrate solutions should be given intravenously to produce effective sedation. Complete anesthetization of the horse usually is not necessary or desired. Other medications have been recommended for use in dogs and should be effective in horses as well. These medications include the centrally acting muscle relaxants methocarbamol (150 mg/kg intravenously) and guaifenesin (110 mg/kg intravenously), repeated as needed; diazepam and xylazine to control seizures; and inhalation anesthetics if necessary.<sup>8</sup> Oxygen therapy and assisted ventilation may be necessary in some animals.

Additional agents that are beneficial are activated charcoal given orally and followed by a laxative to evacuate the bowel. Acidification of urine with oral ammonium chloride at 132 mg/kg also may enhance excretion of strychnine, but the efficacy of this treatment is not well documented. Although toxic doses of strychnine may be depleted from the body in a short time, it may be necessary to maintain relaxation and sedation in the horse for 24 to 48 hours.<sup>8</sup>

### METALDEHYDE

Metaldehyde is used primarily as a molluscicide in snail and slug baits in coastal and low-lying areas. The baits are generally in the form of meal or pellets and are placed around crops or ornamental plants.<sup>8,11</sup> Horses can become poisoned

through inadvertent exposure to bags of bait. No specific toxicity studies could be found regarding horses, but reports indicate that horses may be more susceptible to toxicosis than dogs, in which the acute oral LD<sub>50</sub> may be as little as 60 to 100 mg/kg.<sup>11</sup> In two separate reports, horses died after ingestion of as little as 60 mg/kg<sup>67</sup> and 120 mg/kg. Experimentally, a parasitized yearling colt died after exposure to 0.1 mg/kg.<sup>15</sup>

### CLINICAL SIGNS

The clinical signs reported in horses include acute onset of signs within 1 hour after exposure; excessive sweating, profuse salivation, restlessness, hyperesthesia, incoordination, and tachycardia can be observed. One horse exhibited violent muscle spasms just before death.<sup>14</sup> Other signs include muscle fasciculations, clonic spasms, and rapid and deep respiratory movements.<sup>15</sup> Death occurs rapidly (3 to 5 hours) in horses exposed to a lethal amount of metaldehyde<sup>14,15</sup> and is thought to result from acute respiratory failure.<sup>11</sup> Dogs also are reported to exhibit signs of convulsions and elevated body temperature (often referred to as "shake and bake").<sup>8,11</sup>

### PATHOPHYSIOLOGY

Metaldehyde is absorbed readily from the gastrointestinal tract. Gastric hydrochloric acid enhances its decomposition to acetaldehyde, and metaldehyde and acetaldehyde are absorbed and readily cross the blood-brain barrier. The exact mechanism of action of metaldehyde is yet to be elucidated.<sup>11</sup>

### DIAGNOSIS AND TREATMENT

A history of possible exposure to a molluscicide coupled with the appropriate clinical signs can lead to a tentative diagnosis of metaldehyde toxicity. Stomach contents can be analyzed to detect metaldehyde or acetaldehyde, and a formaldehyde-like odor may be present in the stomach contents.<sup>8,11</sup>

No antidote is available for metaldehyde. Treatment is symptomatic and aimed at sedation; removing the compound from the stomach; and supportive therapy such as maintaining proper fluid, electrolyte, and acid-base indexes. Sedatives such as xylazine, acepromazine, and diazepam may be useful to control convulsive behavior. Methocarbamol may help control muscle spasms and fasciculations, and mineral oil can be given orally to aid evacuation of the gastrointestinal tract.<sup>8,11</sup>

### METHIOCARB

This molluscicide has been reported to cause toxicity in two horses: one died, and the other fully recovered.<sup>16,17</sup> In each instance the amount ingested was estimated to be from 100 to 125 g of a 4% weight per volume preparation.

### CLINICAL SIGNS

The onset of signs was rapid, beginning within a few minutes of ingestion. Muscle tremors, which became severe, and profuse sweating and salivation were noted. Both horses had increased heart and respiratory rates, and the surviving horse also exhibited signs of abdominal discomfort. Clinical signs gradually lessened until they became absent approximately 12 hours after onset in the surviving horse.<sup>17</sup> The horse that was fatally intoxicated died approximately 12 hours after initially showing signs. Postmortem findings included severe generalized pulmonary congestion with froth accumulation in the airways and a number of large hemorrhagic areas scattered throughout the intestinal tract.<sup>16</sup> Methiocarb is an

acetylcholinesterase-inhibiting carbamate compound; readers may wish to consult the section on carbamate and organophosphate pesticides for more information.

### TREATMENT

The specific antidote for methiocarb is atropine sulfate.<sup>16,17</sup> Repeated dosing may be necessary. Other suggested remedies include supportive therapy consisting of sedatives, calcium solutions, and mineral oil.<sup>17</sup>

## 4-AMINOPYRIDINE

4-Aminopyridine is used commercially as a bird repellent and often is mixed with grain before its distribution. In the one reported instance of 4-aminopyridine toxicity, affected horses were exposed to corn that contained the substance.<sup>18</sup>

### CLINICAL SIGNS

The two affected horses began showing signs of profuse sweating, severe convulsions, behavioral abnormalities, and rapid fluttering of the third eyelid. Both horses died within 2 hours of the onset of clinical signs and approximately 8 hours after ingesting the contaminated corn. No specific lesions were noted at necropsy. The estimated lethal dose of 4-aminopyridine for these two horses was 2 to 3 mg per kg of body weight.<sup>18</sup>

### PATHOPHYSIOLOGY

The mechanism whereby 4-aminopyridine causes death has not been elucidated. However, this substance readily crosses the blood-brain barrier and may enhance the release of acetylcholine and other neurotransmitters from presynaptic nerve endings.<sup>11,19</sup> The result is a stimulatory effect on the CNS.

### DIAGNOSIS AND TREATMENT

A diagnosis of suspected toxicity is confirmed by testing the suspect material and stomach contents of affected horses.<sup>18</sup> No specific antidote for 4-aminopyridine toxicity is suggested, but the clinician can give affected horses supportive therapy and mineral oil orally to enhance evacuation of the intestinal tract. Given the known mechanism of action of this compound, CNS depressants such as phenobarbital would seem to have some value in treating the CNS signs of affected horses. However, the efficacy of this treatment.

## LEVAMISOLE

Levamisole has not gained widespread use as an equine anthelmintic, principally because of its limited efficacy in destroying strongyles and because its toxic dose is close to its therapeutic dose. Levamisole is effective, however, in eliminating lungworms, ascarids, and adult pinworms from horses. The drug also has been used in human beings and other animal species in an attempt to enhance immune system function.

### CLINICAL SIGNS

Clinical signs associated with levamisole toxicity occur within 1 hour of administration and include hyperexcitability, muscle tremors, hyperactivity, excessive sweating, and lacrimation. Recumbency may follow these signs, but animals that recover generally appear normal within 12 hours after exposure.<sup>20-22</sup> Adverse effects are more likely after subcutaneous injection than oral drenching.<sup>22</sup> The toxic dose of 20 mg/kg is close to

the therapeutic dose of 15 mg/kg, and 20 mg/kg may cause death in some horses.<sup>11</sup>

### DIAGNOSIS AND TREATMENT

The diagnosis is suspected when horses exhibit clinical signs suggesting levamisole toxicosis and exposure is known to have occurred. No specific antidote is available, so therapy includes supportive care. Most animals recover uneventfully if a sublethal dose has been given.

## CARBON DISULFIDE

Carbon disulfide is seldom used as an anthelmintic in present times but has enjoyed widespread use in the past for treatment of infestation caused by *Parascaris equorum* and *Gastrophilus* species.<sup>23</sup> Carbon disulfide is a manufactured product used as a solvent for resins, pesticides, and waxes and as an agent to remove greases. The chemical is used widely as a fumigant to control insects in stored grain.<sup>8</sup> Carbon disulfide is an exceptional fat solvent and in the pure state is a clear, colorless volatile liquid with a sweet, aromatic odor resembling that of decaying cabbage. The chemical is well absorbed through the skin and lungs and after ingestion.<sup>7,8</sup>

### CLINICAL SIGNS

Reported signs of acute toxicity in animals include dyspnea and cyanosis, spasmodic tremors, vascular collapse, prostration, convulsions, coma, and death.<sup>8</sup> Signs referable to local irritation following inhalation might include salivation and coughing. A combination product of piperazine-carbon disulfide and phenothiazine caused transitory signs of overtranquilization and unsteady gait when dosed at 8 oz per 45 kg of body weight.<sup>23</sup> Whether any of these effects were related directly to carbon disulfide was not determined. Chronic exposure causes neuropsychiatric changes, peripheral neuropathies, and cranial nerve dysfunction in human beings,<sup>7</sup> but chronic exposure in horses is unlikely.

### PATHOPHYSIOLOGY

Because carbon disulfide is a potent fat solvent, local skin contact results in erythema and pain, and prolonged contact produces chemical burns and vesiculation.<sup>7</sup> The chemical is irritating to mucous membranes when inhaled or ingested.<sup>7,8</sup>

At the cellular level carbon disulfide acts to block enzymatic processes by reacting with nucleophilic compounds, including pyridoxamine, monoamine oxidase in the cerebrum, and dopamine decarboxylase. Carbon disulfide binds to microsomal enzymes, thereby reducing their activity, and produces a centrilobular hepatic necrosis. In addition, carbon disulfide chelates copper and zinc and therefore can produce disturbances in tract mineral balance.<sup>7</sup>

### DIAGNOSIS AND TREATMENT

No specific diagnostic test is available for use in animals suspected of suffering from carbon disulfide toxicosis. In one report affected animals had increased BUN and bilirubin concentrations, increased serum activities of AST and alanine aminotransferase, and increased serum cholesterol concentration. Affected horses also had depressed serum concentrations of protein-bound iodine and magnesium.<sup>23</sup>

In human beings the iodine-azide test is useful to identify carbon disulfide metabolites in urine,<sup>7</sup> but the efficacy of this procedure for diagnostic use in horses is unknown. Treatment

of toxicosis primarily involves removal of the source and symptomatic care.

## ☞ MISCELLANEOUS AGENTS

### NICOTINE

Nicotine is an alkaloid contained in tobacco leaves. Although toxicosis might result from ingestion of excessive amounts of tobacco leaves or cured tobacco in cigarettes or cigars, this route of toxicosis probably is rare in horses. Horses are more likely to be intoxicated by ingestion or exposure to the salt nicotine sulfate.<sup>8,11</sup> A concentrated solution of nicotine sulfate (Blackleaf 40) has been used to control leaf-eating insects and occasionally as a premises spray to control certain ectoparasites.<sup>8,12</sup> Horses may ingest this substance from spills of the solution, from open containers, or from foliage that has been sprayed with the product.<sup>11</sup> Topical exposure may result when horses are housed in stables where this product has been used for mite control.<sup>24</sup> The lethal dose of nicotine in the horse is 100 to 300 mg.<sup>8</sup>

#### CLINICAL SIGNS

The signs of nicotine toxicity are rapid in onset, often occurring within a few minutes after exposure. Initially, the signs noted are those of cholinergic overstimulation (i.e., excitement, increased respiration, and salivation). Increased peristalsis and diarrhea also can occur.<sup>8,12</sup> These signs are transitory and are followed rapidly by depression, muscle weakness and ataxia, slow and shallow respiration, and an increased heart rate. Convulsions also can occur. In fatal cases these signs progress to collapse, coma, and death within minutes to hours after the onset of clinical signs.<sup>8,11,12</sup>

#### PATHOPHYSIOLOGY

Nicotine is absorbed readily from the oral mucosa, respiratory tract, and gastrointestinal tract (excluding the stomach) and through intact skin.<sup>7,8</sup> If ingested, nicotine also can exert a direct, rapid caustic action on the mucosa of the mouth and throat, esophagus, and stomach.<sup>8</sup> The substance is metabolized primarily in the liver, and nicotine and its metabolites are excreted in urine. In human beings urinary acidification greatly enhances clearance of nicotine and its metabolites.<sup>7</sup>

Initially, and only for a short time, nicotine stimulates the autonomic nervous system ganglia, neuromuscular junctions, and some synapses in the CNS by depolarization of the postsynaptic membrane.<sup>7,8</sup> With toxicosis, however, the stimulation is followed rapidly by a depolarizing-type blockade of all these nicotinic cholinergic receptors.<sup>7,8,11</sup> Large doses result in a descending paralysis of the CNS, and death results from respiratory failure caused by paralysis of the diaphragm and chest muscles.<sup>8,11</sup> The effects of a sublethal dose should diminish in a few hours.<sup>11</sup>

#### DIAGNOSIS AND TREATMENT

No diagnostic lesions are present at necropsy. However, the distinct odor of nicotine may be present in stomach contents.<sup>8,11</sup> One can evaluate urine, blood, liver, kidney, and other tissues for nicotine content in suspect cases.<sup>8</sup>

Treatment often is ineffective because of the rapid course of the toxicosis. However, because no specific antidote exists for nicotine toxicity, affected horses should be treated symptomatically. If exposure has been through the skin, washing with soap and water, followed by thorough rinsing, is indicated.<sup>8</sup> After oral exposure, affected horses can be treated with oral laxatives, tannic acid, or potassium permanganate in an

attempt to reduce absorption of the toxin. Activated charcoal also may be beneficial in adsorbing residual nicotine in the intestinal tract.<sup>8,12</sup> Atropine sulfate is reported to be without value in affected horses because it does not protect vital nicotinic receptors in the respiratory muscles and the CNS from the effects of nicotine.<sup>11</sup> Artificial respiration becomes the only means of maintaining life once the respiratory depression reaches a critical level. This last-ditch effort usually fails.<sup>11</sup>

### AMMONIA

Ammonia toxicosis in the horse can occur in two ways: by primary exposure to ammonia gas or by secondary metabolism of urea to ammonia within the body (see the section on urea and nonprotein nitrogen substances).<sup>7,8</sup> Primary exposure to toxic concentrations of ammonia gas probably is rare in horses, even though ammonia is the air pollutant most frequently found in high concentrations in animal facilities. The concentrations of ammonia found in stables may be irritating to horses but probably will never reach lethal concentrations. Another source of ammonia toxicosis to horses might be compressed anhydrous ammonia, which is used as an agricultural fertilizer. An accidental spill or spray of anhydrous ammonia near a horse or livestock facility could have disastrous and possibly lethal results.<sup>8</sup> Human beings can detect the odor of ammonia at a concentration of 30 ppm, eye and nasal irritation occurs near 50 ppm, and severe pulmonary dysfunction results from concentrations greater than 1000 ppm. Immediate death occurs at concentrations nearing 1500 ppm.<sup>7</sup>

#### CLINICAL SIGNS

Signs associated with low concentrations of aerial ammonia are those of irritation to the eyes and respiratory tract. Excessive tearing, shallow breathing, coughing, and nasal discharge are common findings. Higher concentrations can induce laryngospasm and pulmonary edema.<sup>7</sup> Exposure to anhydrous ammonia can result in impairment of eyesight, permanent loss of eyesight, respiratory disease, and skin burns.<sup>8</sup>

#### PATHOPHYSIOLOGY

Ammonia is a highly water-soluble, irritating alkaline gas that causes liquefactive necrosis at high concentrations.<sup>7</sup> Because ammonia is so highly water-soluble, it readily reacts with the mucous membranes of the eye and the respiratory tract.<sup>8</sup>

#### DIAGNOSIS AND TREATMENT

A diagnosis of aerial ammonia toxicosis is based primarily on history and physical examination findings. Laboratory evaluation is of little value in establishing a diagnosis of inhalation exposure,<sup>8</sup> but laboratory evaluation can be useful to assess the degree of damage to the respiratory tract and evaluate the effectiveness of therapy.

Treatment involves removing the horse from the source of exposure. If exposure has been severe enough to result in ophthalmic or respiratory tract disease, these conditions should be treated accordingly.

### UREA AND NONPROTEIN NITROGEN SUBSTANCES

Urea and other nonprotein nitrogen substances, including various ammonium salts, are added to ruminant rations as a source of nonprotein nitrogen because ruminants can use

these compounds to provide a large percentage of their protein nitrogen requirements. Urea has additional uses as a fertilizer and as a substitute for salt in melting snow and ice in metropolitan areas.<sup>8,11</sup> Horses are only mildly susceptible to urea toxicosis, and it is highly unlikely that horses would ingest urea or urea-containing feedstuffs in amounts sufficient to cause clinical signs.<sup>8,12</sup> However, horses are more susceptible to toxicosis caused by ingestion of ammonium salts,<sup>8</sup> which may occur after accidental exposure to these substances. In horses urea is lethal when ingested at a rate of 4 g per kg of body weight, and ammonium salts are lethal at a dose of 1.5 g per kg of body weight.<sup>11</sup> Urea and other nonprotein nitrogen formulations are toxic to animals simply because they are hydrolyzed to ammonia, which is responsible for causing the derangements associated with toxicosis.

### CLINICAL SIGNS

The spectrum and intensity of signs in ruminants with urea toxicosis vary, and the same is probably true for horses. The clinical course is usually acute and rapid, often occurring from a few minutes to a few hours after consumption.<sup>8</sup> Occasionally, animals are found dead, or they may die quickly after exhibiting signs of weakness, dyspnea, colic, and terminal tonic convulsions. Other varied signs can be present. Behavioral abnormalities such as restlessness and dullness may be present. Excitement and even belligerency may follow these signs. Nervous signs such as hyperesthesia, tremors, and muscle twitching and spasms can occur. Autonomic nervous system derangements may include salivation, bradycardia, hypertension, and severe colic. More terminal signs may include increased and labored respirations, cardiac arrhythmias, frothing at the mouth, and cyanosis. Intermittent tonic-opisthotonic seizures also can be elicited near death. The onset of signs may range from 10 minutes to 4 hours, and death typically occurs within a few hours after exposure.<sup>11</sup>

### PATHOPHYSIOLOGY

Urea is hydrolyzed to ammonia by the action of the enzyme urease. This reaction is hastened by an alkaline pH, and in the horse these requirements are found in the cecum. In horses urea is absorbed from the small intestine and excreted in the urine. The only urea that might contribute to toxicity in the horse would be that excessive amount that reaches the cecum and is available for hydrolysis.<sup>12</sup>

In normal animals ammonia liberated from nonprotein nitrogen sources can be in the form of the ammonium ion. This ion is soluble, but its charge prevents it from being efficiently absorbed across membranes. Ammonia is also soluble; however, because it lacks an ionic charge, it can be absorbed readily across membranes to enter the bloodstream.<sup>11</sup> Ammonia is a normal by-product of tissue metabolism, and in hepatocytes it is converted to urea by the urea cycle or is incorporated into glutamic acid in the synthesis of glutamine. Toxicosis occurs when the amount of ammonia absorbed into the bloodstream exceeds the ability of the horse to detoxify it.<sup>11</sup>

The primary mechanism of ammonia toxicosis is thought to be inhibition of the citric acid cycle, but the exact mechanism by which this occurs is not known.<sup>11</sup> Ammonia saturation of the glutamine-synthesizing system has been suggested to have an inhibitory effect on the citrate cycle, creating a decrease in its intermediates and a subsequent decrease in cellular energy production and respiration. As the citrate cycle fails, cells begin to malfunction. Cellular energy and

respiration deficits may cause ultrastructural damage leading to degenerative changes and eventual cell death. The role of ammonia in causing signs of encephalopathy is controversial and not well understood.<sup>24</sup>

Laboratory abnormalities associated with ammonia toxicosis include elevated serum ammonia, potassium, phosphorus, lactic acid, glucose, and serum activity of the liver enzyme AST. Urine output decreases, and PCV increases as impending cardiac failure and shock ensue.<sup>11</sup>

The ultimate cause of death is inconsistent in urea toxicosis and poisoning by ammonium compounds. Cardiac failure may be induced by hyperkalemia, or ventricular fibrillation may result from the myocardial effects of ammonia itself. Convulsions may be prolonged and responsible for fatal anoxia. Pulmonary edema may be a complicating factor in some cases. Death also has been postulated to result from asphyxiation.<sup>11</sup>

### DIAGNOSIS AND TREATMENT

Animals that die of ammonia toxicosis exhibit no characteristic lesions. Generalized venous stasis and congestion of organs may be present, along with pulmonary edema and scattered petechiation and ecchymoses. A strong odor of ammonia may be present, but this is probably much more characteristic of ruminants than of monogastric animals.<sup>11</sup>

Clinical signs and history can be helpful in establishing a diagnosis. Blood and ocular fluid ammonia can be evaluated in the laboratory, but the results must be interpreted with caution.<sup>11</sup> Storage of the sample, length of time between death and time of sampling, and length of time between sampling and analysis can influence the blood ammonia concentration. Tissue specimens must be frozen immediately if they are to be analyzed.<sup>8</sup> Suspect feeds can also be analyzed for urea or total nitrogen content.

Treatment is often unrewarding because of the rapidity of onset. No specific antidote is available for ammonia, so therapy is mostly symptomatic. Orally administered laxatives such as mineral oil may be beneficial. The clinician should correct any deficits in fluid volume or abnormalities in acid-base or electrolyte concentrations. Horses that are convulsing can be controlled with pentobarbital, and a patent airway should always be maintained. Assisted ventilation, if necessary, is usually futile because of the poor survival rate of severely affected animals.<sup>11</sup>

## TOXICOSES CAUSING SIGNS RELATING TO CENTRAL NERVOUS SYSTEM DEPRESSION

As with toxic problems associated with other primary clinical signs, it can be difficult to determine the source of CNS depression. The principal task is to rule out the existence of primary cranial disease. Even with the availability of advanced imaging equipment, this can be difficult. Unless the clinical signs or history is definitive, the diagnosis of a toxic problem is often presumptive.

### ☞ PLANTS

#### BLACK LOCUST (*ROBINIA PSEUDOACACIA*)

The black locust tree has been described as toxic to horses.<sup>1,2</sup>

The toxic principle is classified as a lectin, which is present in seeds, sap, roots, wood, leaves, and bark of the plant. Lectin has been used in cytologic research because of its ability to stimulate glycoprotein biosynthesis and cell proliferation in lymphocytes of various animal species.<sup>3</sup> Horses may become intoxicated by ingesting the bark. Only small amounts of lectin are reported to precipitate clinical disease.<sup>2</sup>

The clinical signs reported are mental depression, weakness, posterior paralysis, irregular heart rate, pale mucous membranes, and anorexia. Abdominal discomfort and diarrhea of varying degrees also may be evident.<sup>1,2</sup>

No definitive diagnostic test is available. Treatment of suspected toxicosis is mostly symptomatic and should include removal of the source; evacuation of the intestinal tract; and maintenance of normal fluid, electrolyte, and acid-base indexes.

### **BRACKEN FERN (*PTERIDIUM AQUILINUM*)**

Bracken fern is found most commonly in forested areas, burns, or abandoned fields in the northern and western United States.<sup>2</sup> Toxicity can occur at any time of year, but horses are more likely to consume the plant in late summer and fall, when other forage is scarce. However, horses also might acquire a taste for the plant in pastures or when it is incorporated in bedding. Horses also can become intoxicated from hay contaminated with large amounts of bracken fern. The entire plant is considered to be toxic.<sup>1</sup>

#### **CLINICAL SIGNS**

Signs of toxicosis occur after the horse has been consuming the plant for 30 to 60 days. Horses also can exhibit signs even if they have not ingested bracken fern for 2 to 3 weeks.<sup>1</sup> The signs most frequently reported are incoordination, which may progress to severe ataxia; postural abnormalities, including arching of the back, crouching, and a base-wide stance; muscle fasciculations, which can progress to severe tremors; and bradycardia with cardiac arrhythmias early in the disease course, although tachycardia is most prevalent terminally. Terminal stages of the disease are characterized by signs of opisthotonus and clonic convulsions.<sup>1,2</sup> One report also describes an affected horse showing signs of colic and acute hemolytic anemia.<sup>4</sup>

#### **PATHOPHYSIOLOGY**

The agent in bracken fern that is toxic to horses is thiaminase.<sup>1,2</sup> Bracken fern also is reported to contain ptaquiloside,<sup>5</sup> which is capable of inducing bone marrow suppression, and a  $\beta$ -glucopyranoside, which may enhance the release of endogenous histamine.<sup>2</sup> The significance of these last two compounds in the development of toxicity in horses is unknown. Thiamine plays an integral role in carbohydrate, fat, and protein metabolism and acts as a cofactor in enzymatic pathways responsible for energy production. Thiamine is an important cofactor in the decarboxylation of pyruvate to acetyl coenzyme A, which subsequently enters the tricarboxylic acid cycle.

Thiamine deficiency acts to interrupt these cellular energy processes and also limits certain metabolic pathways available for pyruvate metabolism, resulting in the systemic accumulation of a variety of metabolites, including pyruvate and lactate.

#### **DIAGNOSIS AND TREATMENT**

History and clinical signs are helpful in arriving at a diagnosis. No pathognomonic lesions or laboratory abnormalities occur, but some laboratory findings may include elevated blood

pyruvate concentration and decreased plasma thiamine and red blood cell transketolase concentrations.<sup>2</sup>

Thiamine should be administered daily to affected horses at a dose of 0.25 to 0.5 mg per kg of body weight intravenously, subcutaneously, or intramuscularly for several days. Initially, thiamine can be given at a dose of 5 to 10 mg/kg intravenously, but this dose should be diluted in fluids and administered slowly because of the frequency of adverse reactions when thiamine is given intravenously. Thiamine deficiency usually can be prevented by dietary supplementation of yeast or cereal grains.<sup>2</sup>

### **EQUISETUM (*EQUISETUM ARVENSE*)**

*Equisetum*, commonly called *horsetail*, *maretail*, or *scouring rush*, has a geographic distribution similar to that of bracken fern. Like bracken fern, *Equisetum* is unpalatable to horses, and toxicosis usually results from hay contaminated with the plant.<sup>1,2</sup> Thiaminase is the toxic principle found in *Equisetum*, and the clinical signs, pathogenesis, and treatment are virtually identical to those of bracken fern.<sup>1,2</sup> Large amounts in the diet are necessary to induce clinical problems.

### **MILKWEED (*ASCLEPIAS SPECIES*)**

Several species of *Asclepias* have been reported to be toxic to large animals.<sup>2,6</sup> The plants are reported to be distasteful to animals and not commonly grazed, but the plant may become incorporated into hay. Affected animals are reported to have a weak, rapid pulse; dyspnea; loss of muscular control; and muscular spasms. Salivation, bloating, and convulsions also may occur.<sup>2,6</sup> Most animals that reach the convulsive stage die.<sup>6</sup> Numerous compounds have been isolated from *Asclepias* species, including resinoids and cardioactive glycosides. One resinoid produces smooth muscle spasms of the gastrointestinal tract.<sup>2</sup> The mechanism of action of the other toxins has not been elucidated. No specific antidote is available,<sup>2</sup> but supportive care, including evacuation of the gastrointestinal tract, is indicated.

### **YELLOW STARThISTLE (*CENTAUREA SOLSTITIALIS*) AND RUSSIAN KNAPWEED (*ACROPTILON REPENS*)**

Both yellow starthistle and Russian knapweed cause nigropallidal encephalomalacia in horses. These plants are found scattered over much of the western United States and are most abundant in nonirrigated pastures during the dry seasons of summer and fall. Both plants have a minimal moisture requirement and so may be the only green plants remaining in a dry season. Consequently, most poisonings occur during the summer or fall months.<sup>2,7,8</sup>

Horses apparently reject the plants when more suitable vegetation is available; the disease does not commonly occur in horses grazing improved pastures or grassland range.<sup>8</sup> However, some horses are reported to develop a craving for the plant and selectively seek it out.<sup>2</sup> Horses may eat the weeds, occasionally or frequently, without becoming ill, and continuous and protracted exposure to the plants is necessary for toxicosis to develop under experimental conditions. Feeding trials have shown that horses must consume an amount of weed equivalent to 59% to 200% of their body weight of

yellow starthistle and 59% to 63% of their body weight of Russian knapweed for 3 to 11 weeks of continuous feeding before clinical signs develop. The plants retain their toxicity when dried and incorporated into hay. All ages may be affected, but younger horses generally seem more prone to the disease. One study reported a median age of about 2 years in affected horses.<sup>8</sup> Equids appear to be the only animals that develop nigropallidal encephalomalacia when exposed to these plants.

### CLINICAL SIGNS

The onset of signs is always sudden, beginning with variable degrees of impairment of eating and drinking. Coordinated movements of prehension, mastication, and deglutition are often lacking. Affected horses are unable to chew adequately and propel the food to the back of the mouth. Some horses may show only faulty prehension, whereas others are unable to eat at all. Most horses, however, appear to be able to swallow if feed or water gains access to the posterior pharynx. More severely affected horses may attempt to drink by immersing their muzzles deeply into the water in an attempt to force water into the posterior pharynx.<sup>2,8-10</sup>

Hypertonicity of the facial muscles is a characteristic sign, particularly when feed is offered.<sup>2</sup> The horse often holds the mouth partially open with the lips retracted, resulting in a fixed facial expression. The tongue may protrude from the mouth, and many horses display constant chewing movements—hence the name “chewing disease.”<sup>2,10</sup>

Other characteristic signs include weight loss, mild to moderate depression, and yawning. Most horses can be roused readily from somnolence by mild stimulation. Few animals may show aimless, slow walking or circling early in the disease course. The gait is usually normal, but occasional deficits are apparent, including stiffness, slowness, ataxia, tetraparesis, and conscious proprioceptive deficits.<sup>2,10</sup> In cases of prolonged exposure, a wobbly, shuffling gait may occur because of weakness. Sensation and reflexes appear normal, and the animals are afebrile.<sup>10</sup>

Horses less severely affected may adopt unusual means of eating by scooping feed into the mouth. These animals may survive for months, but complete recovery has not been observed in confirmed cases of the disease. In some instances, however, residual signs may become almost undetectable.<sup>8</sup> Death of affected horses is from starvation and dehydration.

### PATHOPHYSIOLOGY

The pathogenesis of the necrotic brain lesions is unknown, but these plants have been postulated possibly to contain a specifically toxic substance or to lack some nutritional component necessary for the health and well-being of the horse.<sup>9,10</sup> Several sesquiterpene lactones and polyacetylenes have been isolated from these plants, but their significance remains undetermined.<sup>11</sup> Dipyrone has been postulated to be the inciting agent.

### DIAGNOSIS AND TREATMENT

The antemortem diagnosis of nigropallidal encephalomalacia is based largely on observation of clinical signs and prolonged exposure of the horse to the plants by grazing or by severely contaminated hay. If available, magnetic resonance imaging can identify characteristic lesions on T1-weighted, T2-weighted, and proton density images. These lesions do not contrast enhance after gadolinium-diethylenetriaminepentaacetic acid administration.<sup>12</sup> Characteristic necropsy findings

include unilaterally or, more commonly, bilaterally symmetric softening and necrosis in areas of the globus pallidus and substantia nigra. These areas usually are sharply defined and may be cavitory.<sup>2,10</sup>

No known treatment exists for affected horses. Prevention requires keeping horses from the plant and providing adequate, suitable forage.

## MILKVETCH AND TIMBER MILKVETCH (*ASTRAGALUS SPECIES*)

Most of the variants of *Astragalus miser* are referred to as *timber milkvetch* or *milkvetch*. These plants are found primarily in the western United States from northern Mexico to Canada and are essentially a cause of toxicosis to ruminants. Horses are reported to be poisoned by this group of plants, but there are no reports of the lesions.<sup>13</sup>

The disease in ruminants is characterized primarily by general depression, mental dullness, incoordination, and eventual hindlimb paralysis. Respiratory distress, cyanosis, and acute collapse also may occur. Acute and chronic forms of the syndrome are reported.<sup>13</sup>

The toxic principle, referred to as *miserotoxin*, is a  $\beta$ -D-glucoside of 3-nitro-1-propanol, which is metabolized in the intestinal tract to the highly toxic compound 3-nitro-1-propanol. Miserotoxin is broken down into inorganic nitrite and a three-carbon side chain. The nitrite is responsible for producing methemoglobinemia in animals but is not the primary cause of death.<sup>13</sup>

No specific antidote is recommended. Poisoning is prevented by controlling the plants with herbicides and preventing livestock from grazing the plant.

## MISCELLANEOUS AGENTS

### PROPYLENE GLYCOL

Propylene glycol is used commercially as a diluent for injectable drugs and as a glucose precursor in the treatment of hypoglycemia in ruminants. Horses may become intoxicated by the inadvertent use of propylene glycol if it is mistaken for a similar-appearing liquid paraffin preparation. Reports of toxicosis in horses are rare.<sup>14,15</sup>

Propylene glycol has a low oral toxicity in human beings. Approximately 45% of the absorbed dose is excreted unchanged by the kidney, whereas the remainder is metabolized by hepatic alcohol dehydrogenase to acetate, pyruvate, and lactate.<sup>16</sup>

### CLINICAL SIGNS

Adverse signs occur within 10 to 30 minutes after a toxic dose of propylene glycol. Initial findings include salivation and profuse sweating, ataxia, depression, and tachypnea. Additional signs can include cyanosis, seizures, and coma.<sup>14</sup> Diarrhea also has been reported in one horse experimentally given a large dose of propylene glycol.<sup>15</sup> Death has occurred 1 to 3 days after ingestion of excessive amounts of the product.<sup>14,15</sup>

### PATHOPHYSIOLOGY

Propylene glycol is metabolized by hepatic alcohol dehydrogenase to form acetate, lactate, and pyruvate. After a large exposure, excessive amounts of these products accumulate, resulting in severe systemic lactic acidosis.<sup>16</sup> The clinical signs

and toxicologic findings result from the effects of this severe acidemia on various body organs and tissues.

The acute oral LD<sub>50</sub> for horses has not been established, but the doses for rats, rabbits, and dogs are 32, 18, and 9 ml/kg, respectively. One 450-kg horse died after intubation with 3.8 L (7.6 ml/kg) of propylene glycol,<sup>14</sup> but other horses have survived this dose. Toxic signs were reported in horses receiving 1.9 to 7.6 L of propylene glycol, but the only death occurred in the horse getting 7.6 L.<sup>15</sup>

## DIAGNOSIS AND TREATMENT

Exposure to propylene glycol is confirmed by chemical analysis of serum and urine. Necropsy findings associated with propylene glycol toxicosis may be minimal.<sup>14</sup> The horse given 7.6 L exhibited sloughing of the gastric mucosa, diffuse enterocolitis, renal congestion, and brain edema.<sup>15</sup> Histopathologic findings typically include hepatic necrosis, renal tubular necrosis and infarcts, myocardial perivascular edema, and pulmonary edema.<sup>14,15</sup>

Because no specific antidote is available, treatment of propylene glycol toxicosis aims at alleviating the severe acidemia that develops and providing supportive care for the other organs and tissues that may become compromised. Sodium bicarbonate solutions should be given to treat the acidosis. When possible, the clinician should monitor blood pH and adjust bicarbonate administration according to need. Intravenous fluids should be given to aid diuresis and maintain normal fluid volume. Pulmonary and renal function should be thoroughly evaluated in affected horses, and precautions should be taken to prevent the development of further pulmonary edema. Such precautions may require the use of diuretics and careful monitoring of the fluid administration rate.

Serum electrolyte concentrations should be maintained in normal ranges, and oxygen therapy may be beneficial in horses exhibiting tachypnea and cyanosis. Activated charcoal has been recommended in treating human toxicosis.<sup>16</sup>

## TRICLOPYR

Triclopyr is a herbicide used to control hardwood species on road rights-of-way, industrial sites, and forest planting sites. Horses may become exposed to the herbicide by grazing areas that have been inappropriately treated with the product in the past.

An experimental study was conducted to determine the toxic level of triclopyr to ponies. Ponies given 60 mg/kg/day for 4 days did not show any clinical sign of illness. Ponies given 300 mg/kg/day for 4 days did develop clinical signs. This study indicated that the toxic dosage in ponies was 5 times the estimated maximal intake for the highest recommended usage rate as a herbicide.<sup>17</sup> Therefore poisoning from the proper use of this herbicide is unlikely.

## CLINICAL SIGNS

Initial signs of depression and decreased gastrointestinal motility were first noticed on the fourth day of the trial. Additional signs that developed were ataxia, weakness, muscle tremors, increased respiratory rate, cyanotic mucous membranes, and normal to slightly elevated body temperature. Some ponies became recumbent as clinical signs progressed. Two ponies died on the fifth and sixth days of the trial, and two other ponies were euthanized on the fifth day. The remaining two ponies were only mildly affected and recovered.

No significant changes were apparent in clinical chemistry values. Gross necropsy lesions consisted of pale livers and pale swollen kidneys, and a few horses had excessive intestinal fluid contents. Microscopic changes were mild and were those of nonspecific hepatosis and nephrosis.<sup>17</sup>

## PATHOPHYSIOLOGY

The mechanism whereby triclopyr produces clinical disease in horses has not been elucidated.

## DIAGNOSIS AND TREATMENT

Toxicosis caused by triclopyr appears highly unlikely under natural circumstances.<sup>17,18</sup> Diagnosis of suspect cases is based on clinical signs and a history of exposure to the herbicide. No specific antidote is available. Affected individuals require supportive and symptomatic care.

## LEUKOENCEPHALOMALACIA

Equine leukoencephalomalacia, a sporadically occurring disease of horses, ponies, donkeys, and mules, has a worldwide distribution. The disease usually is seasonal, with most cases occurring from late fall through early spring, and most outbreaks have been associated with a dry growing period followed by a wet period.<sup>19,20</sup>

This malady is caused by the mycotoxin fumonisin B1, a metabolite of *Fusarium moniliforme*. Equidae become affected usually by ingesting *F. moniliforme*-infected corn or corn screenings, but the problem also has been associated with the consumption of commercially prepared diets.<sup>19-22</sup> Infected kernels often have a pink to reddish-brown discoloration, and damaged kernels and cob parts may have a much greater concentration of fumonisin B1 than do undamaged kernels.<sup>20,22</sup> Feeds containing less than 10 ppm fumonisin B1 have not been associated with disease, but concentrations of greater than 10 ppm can be lethal to horses.<sup>23</sup>

## CLINICAL SIGNS

Two clinical syndromes are associated with fumonisin B1 intoxication. The more common is the classic neurotoxic syndrome, but hepatotoxicosis also occurs in some horses. Older animals may be more susceptible than younger animals, and clinical signs become evident approximately 3 to 4 weeks after daily ingestion of contaminated feed. Onset of signs is typically abrupt, and death usually occurs in 2 to 3 days.<sup>19,20</sup> Occasionally, horses that showed few to no premonitory signs are found dead.<sup>19</sup>

The neurologic syndrome is characterized initially by incoordination, aimless walking, intermittent anorexia, lethargy, depression, blindness, and head pressing. These signs may be followed by hyperexcitability, belligerence, extreme agitation, profuse sweating, and delirium.<sup>19,20</sup> Recumbency and clonic-tetanic convulsions may occur before death. Recovery from acute episodes has been reported, but some horses retain neurologic deficits.<sup>20</sup>

Clinical signs associated with the hepatotoxic syndrome are swelling of the lips and nose, somnolence, severe icterus and petechiae of mucous membranes, abdominal breathing, and cyanosis. Affected horses also have acute onset of clinical signs with death occurring within a few hours to days.<sup>19,20</sup>

## PATHOPHYSIOLOGY

The gross lesions typical of equine leukoencephalomalacia include liquefactive necrosis and degeneration of the cerebral hemispheres, but degenerative changes also can occur in the

brainstem, cerebellum, and spinal cord.<sup>19-22</sup> Necrotic areas can vary in size, and regions adjacent to the necrosis often are edematous and rarefied.<sup>20,21</sup>

Gross hepatic lesions in affected horses generally are not pronounced. The liver may be slightly swollen, have a yellowish-brown discoloration, and contain irregular foci or nodules scattered throughout the parenchyma. Histologic abnormalities noted in the liver may include centrilobular necrosis and fibrosis, fatty infiltration of hepatocytes, portal fibrosis, biliary stasis, and bile duct proliferation.<sup>19-21</sup>

The mechanism whereby these changes occur has not been well elucidated. The brain lesions may be induced by ingesting smaller quantities of infected corn over a long period of time, whereby ingestion of higher quantities may produce fatal hepatotoxicosis over a shorter time interval.<sup>20,24</sup>

Several metabolites of *F. moniliforme* have been identified in feeds associated with outbreaks of equine leukoencephalomalacia. These include fusarin C, moniliformin, fusaric acid, 2-methoxy-4-ethylphenol, fumonisin B1, and fumonisin B2.<sup>21,22</sup> Toxicity information about fumonisin B2 is unknown, but moniliformin, fusaric acid, and 2-methoxy-4-ethylphenol do not produce leukoencephalomalacia when injected intravenously into donkeys. Their role in the pathogenesis of the liver lesions in equine leukoencephalomalacia is likewise unknown. However, the neurologic and hepatotoxic syndromes can be produced by oral and intravenous administration of fumonisin B1.<sup>21</sup>

## DIAGNOSIS AND TREATMENT

The diagnosis of equine leukoencephalomalacia has been based mostly on observation of clinical signs coupled with a history of exposure to moldy corn. Typical postmortem lesions, when available, help confirm the diagnosis.

Clinicopathologic abnormalities are nonspecific and usually indicate some degree of liver dysfunction. Increased serum concentrations of bilirubin, AST, GGT, and LDH have been reported.<sup>19,21,24</sup> Cerebrospinal fluid abnormalities may include increased protein and total nucleated cell counts and an increased concentration of myelin basic protein.<sup>20,24</sup>

With identification of fumonisin B1 as the causative agent, analytic methods have been developed to assay this toxic metabolite in feed material. Feed containing greater than 10 ppm fumonisin B1 is not safe to feed to horses.<sup>23</sup> Because the disease requires a fairly prolonged exposure to infected corn, representative feed samples should be submitted for analysis. Feed currently being ingested may not be contaminated with the mold.

Treatment of equine leukoencephalomalacia is largely supportive. Horses that are hyperexcitable should be sedated to minimize injury to themselves and their handlers. Supportive therapy for hepatic dysfunction should be initiated if liver damage is evident, and some horses may require forced feeding and watering if they become unable to eat and drink. Mannitol or DMSO may be administered to aid resolution of cerebral edema, and laxatives and activated charcoal may be given to eliminate toxins already in the digestive tract, although their usefulness is probably minimal because this disease is not an acute intoxication. Contaminated feed should be removed immediately from all exposed horses, and pastured horses should be moved to pastures without access to corn. Preventive measures include providing suitable feed material to horses and storing grains, particularly corn, under conditions that discourage mold growth.

## TRICHOHECENES

The trichothecenes are a group of compounds elaborated primarily by *Fusarium tricinatum* and other *Fusarium* species. Only four of approximately 40 trichothecene derivatives have been found to occur naturally in feedstuffs. These four include T-2 toxin, deoxynivalenol, diacetoxyscirpenol, and nivalenol.<sup>25,26</sup> Of these, only one reported episode of T-2 intoxication in horses was found in the literature.<sup>26</sup> This group of mycotoxins more commonly causes gastrointestinal problems in other animals.

In the reported outbreak horses showed clinical signs and laboratory abnormalities similar to those of equine leukoencephalomalacia caused by fumonisin B1. Gross lesions in necropsied horses were also similar to those of equine leukoencephalomalacia. *F. tricinatum* was isolated from all suspect feed samples, and T-2 toxin was detected in varying concentrations in all examined feed samples. Other *Fusarium* metabolites detected in this outbreak included HT-2, verrucarins A and J, and roridin A. The toxicity of these metabolites in farm animals is not yet determined.<sup>26</sup>

## LEAD

Lead is reported to be one of the more common toxicants found in veterinary practice, but it rarely is a cause of poisoning for horses now. Materials that can serve as a source of lead toxicity to animals include lead-based paints, putty and caulking materials, used crankcase oil, greases, linoleum, leaded gasoline, solid lead solder, roofing materials, asphalt, and industrial effluents contaminating streams or forage. Discarded automobile batteries and water from lead plumbing also might serve as a source of toxicity.<sup>2,25</sup>

Acute and chronic forms of toxicosis can occur depending on the amount of lead ingested and the time frame in which ingestion occurs. Lead toxicosis in horses is usually chronic and is associated with some type of forage contamination.<sup>27,28</sup> Foliage near lead smelters often contains excessive lead, and grasses located near busy highways have been reported to contain high lead concentrations.<sup>2,28</sup> Horses appear to be much more sensitive than cattle to prolonged, low-dose exposure to lead, yet they are much less sensitive than cattle to short-term exposure of large doses.<sup>25,27</sup> The acute oral lethal dose of lead acetate in horses is 500 to 750 g total dose, but chronic toxicosis can arise when 1 to 7 mg/kg/day is ingested over a period of days, weeks, or months.<sup>25</sup>

Numerous factors can influence the toxicity of lead in horses. Young animals and malnourished animals are reported to be more susceptible than older animals; solid lead is not as toxic as the more soluble salts, which are absorbed more readily; and concurrent exposure to lead and cadmium results in increased severity of clinical signs of lead poisoning. In addition, lead may interact with other minerals to affect toxicity. High levels of dietary calcium cause decreased gastrointestinal absorption of lead.<sup>2,25,28</sup>

## CLINICAL SIGNS

The clinical signs of lead toxicity in horses are caused primarily by peripheral nerve dysfunction. The motor nerves are at greater risk, with minimal sensory perception loss in affected horses. Initially, affected horses may appear weak or have slight incoordination. Depression and weight loss become apparent and worsen over the disease course. Laryngeal and pharyngeal

paralysis, dysphagia, dysphonia, and proprioceptive deficits occur. As the disease progresses, horses may exhibit flaccidity of the rectal sphincter; paresis of the lower lip; and difficulty in prehension, mastication, and deglutition. Aspiration pneumonia resulting from dysphagia and regurgitation of food is common, and fine muscle tremors may occur intermittently. Terminally, horses may show severe incoordination, anorexia, emaciation, and almost complete pharyngeal and esophageal paralysis with inability to swallow food or water. Seizures also may occur terminally. Colic and diarrhea may be apparent, but they are not common signs.<sup>2,27,28</sup> Progression of these disease signs may require weeks.

Dietary lead crosses the placental barrier, and mares chronically exposed to lead in late pregnancy may deliver premature or small, weak foals. These foals are at greater risk of developing secondary disease complications.<sup>27</sup>

### PATHOPHYSIOLOGY

Lead enters the body primarily through ingestion. Inorganic lead cannot readily penetrate the skin, but organic forms such as tetraethyl lead and tetramethyl lead are absorbed through the skin. However, exposure of horses to organic lead compounds would seem to be a rare occurrence. Metallic lead shot or bullets lodged in tissues do not dissolve because tissue pH is too high.<sup>25</sup>

Metallic lead and lead sulfide are less absorbed than the acetate, carbonate, hydroxide, oxide, and phosphate salts. Less than 10% of ingested lead is absorbed across the gastrointestinal tract in adults, but if sufficient quantities of soluble salts are ingested, a significantly greater amount of lead can cross into blood. Even though intestinal absorption is inefficient, increases in blood lead concentrations can occur within 3 hours of dosing.<sup>2,25</sup>

Once absorbed, a large portion of lead is carried on erythrocyte membranes, where it is bound irreversibly to erythrocyte proteins. Much of the remaining lead becomes bound to albumin, and only a small proportion of the absorbed lead actually is free in serum. Unbound lead is in equilibrium with lead bound to erythrocytes and albumin, and distribution to various tissues takes place from the unbound fraction.

Much of the blood lead is removed in the liver. Within the liver, cellular trapping of lead is thought to occur by lead binding to cytoplasmic proteins called *metallothioneins*. Lead also accumulates within the renal cortex, where it becomes trapped as intranuclear lead protein inclusions in tubular epithelial cells. Unbound lead is excreted into milk, and it readily passes membrane barriers such as the placenta and the blood-brain barrier to become distributed in many body tissues.<sup>25</sup>

Unbound lead becomes immobilized and bound to bone substance, particularly in the physeal region, by an unknown mechanism. However, bone is considered to be the "sink" for lead and eventually may contain greater than 90% of the total body burden of lead. Deposition of lead into bone is a slow, gradual process, entailing redistribution of lead from other soft tissues. In this manner, bone serves as a detoxification mechanism under conditions of chronic exposure to small concentrations. Bone cannot hold an infinite amount of lead, however, and when saturation occurs, signs of toxicosis may appear suddenly because of rising blood and soft tissue concentrations after continued exposure.<sup>25</sup>

Bile and feces are thought to be the primary pathways of lead excretion, and feces may contain unabsorbed lead and lead that has undergone enterohepatic circulation. Gastrointestinal

secretions, including pancreatic secretions, also might be involved in elimination of lead from the body.<sup>2,25</sup>

The mechanism of action of lead at the cellular level is still under scrutiny. The known toxic effects of lead include inhibition of sulfhydryl groups of enzymes essential to cellular metabolism and inhibition of heme synthesis. Lead also is known to cause a decrease in local concentrations of the essential trace metals copper, iron, and zinc. These metals have important functions in mitochondrial enzymes, and interference by lead with these may adversely affect cellular respiration, oxidative phosphorylation, and the ATP synthetase complex.<sup>25</sup>

The peripheral neuropathy associated with lead toxicosis in horses is thought to be caused by peripheral nerve segmental demyelination, which impedes nerve impulse conduction and contributes to the clinical signs observed. The metabolic inhibitory effects of lead are speculated to cause the demyelination.<sup>25,27</sup>

Lead is known to damage the blood-brain barrier and capillary endothelial cells, resulting in cerebral edema and hemorrhage. Additionally, the damaged blood-brain barrier may allow cytotoxic solutes normally excluded from the brain to enter the brain substance.<sup>25</sup> Whether these mechanisms have any appreciable effect on the development of clinical signs observed in the horse is unknown.

Inhibition of heme synthesis is an important aspect of lead toxicosis in several animal species. This pathologic mechanism also occurs in the horse, but its significance to the overall disease course is limited. The result of heme metabolism interference and altered function of other erythrocyte proteins is a shortened erythrocyte half-life that can produce a normochromic, normocytic anemia, which is generally marginal in affected horses (PCV of 25% to 30%).<sup>27,28</sup> The anemia also may be accompanied by nucleated red blood cells and Howell-Jolly bodies in peripheral blood.<sup>28</sup>

Two enzymes in the heme synthesis pathway that are particularly susceptible to lead are  $\delta$ -aminolevulinic acid dehydratase (ALA dehydratase) and ferrochelatase. Inhibition of ALA dehydratase results in reduced levels of porphobilinogen in erythrocytes and an accumulation of ALA dehydratase, which is excreted in urine. Interference with ALA dehydratase also may be partly responsible for brain damage associated with lead toxicity in some species. Inhibition of ferrochelatase limits the formation of heme from protoporphyrin, resulting in an accumulation of unmetabolized porphyrins. These include protoporphyrin I, which is retained in the erythrocyte; uroporphyrins, which are excreted in urine; and coproporphyrins, which are excreted in feces. Lead also interferes with pyrimidine-specific 5'-nucleotidase activity, resulting in basophilic stippling of affected erythrocytes.<sup>2</sup>

Another important implication of lead toxicity is the suggestion that lead may be immunosuppressive by way of its interference with humoral and cell-mediated immune responses.<sup>2,25</sup>

### DIAGNOSIS AND TREATMENT

Confirmation of suspected lead poisoning often is based on determination of blood or tissue lead concentrations. Blood levels of 0.30 ppm or greater are diagnostic if horses are showing clinical signs, but blood lead concentrations do not reflect the severity of poisoning.<sup>27,28</sup> Lead concentrations greater than 5 ppm in liver and kidney and 30 ppm in bone are considered diagnostic of lead intoxication in horses.<sup>25</sup>

In instances of chronic toxicity, however, blood lead values may be within the normal reference range. In such instances diagnosis of toxicity may be aided by administration of calcium disodium EDTA, which chelates lead in bone stores and increases the lead concentration in blood. The soluble lead complexes then are excreted in urine, with a resultant many-fold increase in urinary lead concentration within a few hours of EDTA administration.<sup>2,25,26</sup> The recommended dose of calcium disodium EDTA is 75 mg/kg intravenously.<sup>2</sup>

Clinicopathologic aberrations include increased concentrations of erythrocyte ALA and erythrocyte porphyrins and decreased activity of erythrocyte ALA dehydratase. Increased amounts of coproporphyrins, uroporphyrins, and aminolevulinic acid are found in urine, but measurement of erythrocytic ALA dehydratase is considered more diagnostic than measurement of urinary ALA dehydratase content.<sup>2,25,27</sup> Increased blood concentration of zinc protoporphyrin also has been documented in an affected horse.<sup>29</sup> These analyses generally are not routinely run by veterinary diagnostic laboratories.

Hematologic abnormalities in affected horses include a marginal anemia frequently accompanied by metarubricytes and Howell-Jolly bodies in peripheral blood.<sup>2,28</sup> Anisocytosis, poikilocytosis, hypochromasia, polychromasia, and basophilic stippling also can occur. These changes are suggestive but not pathognomonic of lead toxicity in horses.<sup>2</sup> One also can measure the concentration of lead in soil and in forages. Poisoning in horses has been reported when grazed forage contains lead levels in excess of 300 ppm.<sup>2,27</sup>

Treatment of affected horses should include immediate elimination of the lead source, if possible, and prompt initiation of chelation therapy. Calcium disodium EDTA is the chelator of choice; it chelates osseous lead but not tissue-bound lead. The chelated lead then becomes soluble and is excreted by the kidney. The unsaturated bone stores then re-equilibrate with the lead in soft tissues. Calcium disodium EDTA can be administered by slow intravenous infusion at a dosage of 75 mg per kg of body weight daily for 3 to 5 days. A 2-day nontreatment period may follow to allow re-equilibration of soft tissue and bone and then an additional 5-day treatment regimen if needed. An alternative dosage schedule is 110 mg/kg intravenously twice daily for 2 days. After a 2-day nontreatment period, this same regimen may be repeated. The clinician should base the decision to continue therapy with EDTA on post-treatment blood lead concentrations and renal function tests.<sup>2</sup>

Additional therapy should include fluid and nutritional support. Although thiamine administration has been advocated along with chelation therapy in small animal and ruminant lead toxicosis,<sup>2</sup> its efficacy in treating horses with lead poisoning has not been investigated. Dietary calcium supplementation or sodium-magnesium sulfate, may have some beneficial effect by helping to reduce further gastrointestinal absorption of lead.

Methods aimed at reducing exposure to lead and preventing intoxication include appropriate cutting and disposal of contaminated forage, tilling or burning of the stubble, and addition of lime to the soil.<sup>27</sup> Use of alfalfa as a roughage also might be beneficial, possibly because of the high calcium content in alfalfa, because intoxication is more difficult to produce experimentally in horses when alfalfa is being fed and because increased dietary calcium decreases the gastrointestinal absorption of lead.<sup>2,27</sup>

## TOXICOSES CAUSING SIGNS RELATING TO THE CARDIOVASCULAR AND HEMOLYMPHATIC SYSTEMS

Certain plants and ionophores are the most frequently encountered causes of cardiac problems in horses. Manifestations associated with hemolysis and anemia also are possible.

### ☞ PLANTS

#### OLEANDER (*NERIUM OLEANDER*)

##### CLINICAL SIGNS

According to most research, sudden death is the most common sign attributed to oleander poisoning. Some reports suggest that affected horses exhibit lethargy, inappetence, and occasional signs of abdominal pain.<sup>1,2</sup> Profuse, watery, catarrhal, or bloody diarrhea also may occur within a few hours of ingestion.<sup>3</sup> Cardiac irregularities, including alternating bradycardia and tachycardia, may be accompanied by a variety of arrhythmias.<sup>3,4</sup> The extremities of the horse may feel cold to the touch, and mucous membranes may appear blanched. Profuse sweating and muscle twitching are followed by weakness and death. Death may occur less than 12 hours after ingestion.

The green plant apparently is unpalatable to horses. Most toxicities occur when leaves have been incorporated into lawn clippings and offered to horses. Drying does not affect the toxicity of the leaves; therefore leaves incorporated into hay also may be toxic. According to reports, 0.005% of an animal's body weight of green oleander is lethal.<sup>1</sup>

##### PATHOPHYSIOLOGY

Common oleander contains at least five cardiac glycosides that are found in all parts of the plant.<sup>1,3,5</sup> These glycosides (i.e., oleandrin, digitoxigenin, neriin, folinerin, rosagenin) inhibit the Na<sup>+</sup>,K<sup>+</sup>-ATPase (adenosine triphosphatase) system, resulting in hyperkalemia, conduction abnormalities, and ventricular arrhythmias. Which glycosides or metabolites cause specific abnormalities is unclear because of the undefined pharmacokinetics of the individual glycosides.<sup>5</sup>

##### DIAGNOSIS AND TREATMENT

Exposure to the plant along with the aforementioned clinical signs should alert the clinician to the possibility of oleander toxicity. The rapidity of onset of clinical signs or the finding of dead animals may preclude any effective treatment. Symptomatic therapy should be initiated in those animals in which toxicosis is suspected. Decontamination measures, such as evacuation of the intestinal tract by laxatives and enemas, may be useful. Atropine and propranolol have been advocated, but they must be used with extreme caution.<sup>3,4</sup> Fluids containing calcium should not be used because they may augment the effects of the glycoside on the myocardium.<sup>1</sup>

## WHITE SNAKEROOT (*EUPATORIUM RUGOSUM*) AND RAYLESS GOLDENROD (*ISOCOMA* *WRIGHTII*)

Cases of white snakeroot intoxication have been reported primarily in the eastern half of the United States, from Michigan south to Alabama and eastward.<sup>6</sup> The toxic principle is tremetol, which has been described as a fat-soluble, high-molecular-weight alcohol.<sup>7,8</sup> Tremetol poisoning is reported to be most prevalent in dry years or in circumstances in which animals are subjected to inadequate pasturage. The toxin is excreted slowly and therefore tends to accumulate in animals grazing the plant. Because of this cumulative effect, repeated small doses can result in toxicosis as well as a single, larger exposure to the plant. A total amount of green plant varying between 1% to 10% of body weight may be lethal to horses.<sup>6</sup> The toxic principle remains in the dried plant after freezing.<sup>8</sup> In the southwestern United States, rayless goldenrod is the source of tremetol, and ingestion of this plant produces the same clinical syndrome as that of white snakeroot intoxication.

### CLINICAL SIGNS

Depression; a stiff gait with frequent crossing of the hindlimbs; and patchy, profuse sweating seem to be the most profound signs of tremetol toxicity. Other, less frequently noted findings include muscle tremors, particularly of the shoulders and limbs; labored or shallow respirations; normal to subnormal body temperature; pupillary dilation; cardiac arrhythmias; and darkly discolored urine.<sup>6,8</sup>

The time of onset of signs varies considerably, from less than 2 days to as long as 3 weeks after the last exposure to the plant. Most horses showing clinical signs die. Recovery is reported to be rare and usually is prolonged and often incomplete. However, a recent report describes two horses that apparently fully recovered from suspected tremetol toxicity.<sup>8</sup> Death often follows within 1 to 3 days of the appearance of clinical signs.<sup>6</sup>

Routinely noted laboratory abnormalities include hematuria, hemoglobinuria and proteinuria, mild elevations in serum alkaline phosphatase activity, elevated AST concentration, and significant elevation of serum CK activity. Acidosis, hyperglycemia, and glucosuria also have been documented.<sup>6,8</sup>

Postmortem findings primarily consist of mild renal tubular degeneration and necrosis; nonsuppurative colitis; pulmonary congestion; increased amounts of pleural and peritoneal fluid; and moderate to severe centrilobular vacuolar changes in the liver. Other significant findings include pericarditis and extensive, patchy myocardial degeneration and necrosis. Extensive, minute epicardial hemorrhage also has been reported.<sup>6,8</sup> One reported case also exhibited moderate, multifocal degeneration of skeletal muscle.<sup>6</sup>

### PATHOPHYSIOLOGY

The mechanism whereby tremetol causes the aforementioned lesions and signs remains unknown.

### DIAGNOSIS AND TREATMENT

Diagnosis of tremetol toxicity is based on observation of the described clinical signs and concurrent clinicopathologic abnormalities. Additionally, evidence that the affected horses have been exposed to either plant should be present, and, when available, necropsy findings should be compatible with

those described for tremetol toxicity. Analysis for tremetol from suspect samples is not readily available.<sup>6</sup>

Treatment is symptomatic. The primary goal of therapy is promptly removing the horse from exposure to the plants and providing supportive care. The clinician should attempt to evacuate the horse's gastrointestinal tract with laxatives such as mineral oil. Activated charcoal also has been suggested as being beneficial in removing the toxin.<sup>8</sup> Based on observed histopathologic abnormalities, volume diuresis of affected animals seems appropriate, and the clinician should attempt to maintain normal acid-base and serum electrolyte concentrations. All affected horses and herdmates should receive adequate and suitable forage and ample fresh water.

## MAPLE (*ACER* spp.)

Several species of maple have been documented as causing hemolysis in horses; however, because of its widespread distribution, red maple is the most commonly identified species. All maples should be considered a potential risk to equines. Intoxication of the horse by leaves of the red maple tree is a seasonal disorder that occurs during the summer and fall months, primarily in the eastern United States.<sup>9,10</sup> Fresh leaves appear to present no problem to the horse, but wilted or dried leaves are toxic, and overnight freezing and storage of dried leaves for 30 days does not alter their toxicity.<sup>11</sup> Experimentally, dried leaves are toxic when administered at a dose of 1.5 mg per kg of body weight.<sup>10,11</sup> The toxin present in red maple leaves is unknown, but the clinical syndrome produced is one of acute hemolytic anemia with methemoglobinemia and Heinz body production.<sup>9-12</sup> Red maple toxicity has been recognized in horses<sup>12</sup> and Grevy's zebras,<sup>13</sup> and horses electively ingest the leaves when other suitable forage is available. Donkeys and mules should be considered potentially susceptible to maple's toxic effects.

### CLINICAL SIGNS

Signs of toxicity generally commence within 48 hours of ingestion. Affected horses show acute onset of lethargy, anorexia, weakness, and depression. Increased heart and respiratory rates are typical, and the animals are afebrile. Two outstanding characteristics of most affected horses are the obvious presence of icteric, pale, or brown mucous membranes and a brownish discoloration of blood and urine. Many horses appear cyanotic, and petechiae on mucous membranes have been reported. Signs of secondary acute renal failure also have been documented.<sup>12</sup> Death, when it occurs, generally happens 3 to 7 days after ingestion.<sup>9-12</sup> The mortality rate in naturally occurring and experimental cases is approximately 60%.<sup>14</sup>

The aforementioned signs are representative of naturally occurring instances of toxicity. In an experimental study, however, two patterns of toxicity were recognized. One group of ponies given dried leaves accumulated before September 15 exhibited signs of the typical hemolytic syndrome and died 3 to 5 days later. Ponies given leaves collected after September 15 died within 18 hours of dosing and exhibited clinical signs only of cyanosis and depression.<sup>11</sup> The reason for this disparity of signs was not offered.

### PATHOPHYSIOLOGY

Although the toxin in wilted or dried red maple leaves has not been well characterized, it produces an acute hemolytic anemia with methemoglobinemia and Heinz body production

in affected horses. The mechanism of erythrocyte damage has not been determined, but these hematologic abnormalities are characteristic of an oxidant.<sup>10-12</sup>

Heinz bodies are intracellular precipitates of oxidized hemoglobin that result from oxidant injury to erythrocytes. They damage the erythrocyte membrane and produce intravascular and extravascular hemolysis. Intravascular hemolysis results when erythrocyte membrane functions involving active and passive ion transport become impaired. The hyperpermeability changes that then occur alter the osmotic gradient of the erythrocyte and cause rupture of the affected red blood cell. Extravascular hemolysis occurs when the red blood cell remains intact, but the damaged erythrocyte is removed from circulation by cells of the reticuloendothelial system.<sup>9,10,12</sup>

Methemoglobin is formed when hemoglobin is oxidized from the ferrous to the ferric form of iron. A certain amount of direct oxidation of hemoglobin to methemoglobin occurs naturally, but erythrocytes are able to reduce methemoglobin back to hemoglobin. Excessive production of methemoglobin occurs under conditions of excessive oxidative stress or when methemoglobin reduction is impaired.<sup>9,11</sup> Although methemoglobin itself does not produce hemolysis, it is incapable of transporting oxygen and therefore contributes to hypoxia. When present in sufficient quantities, methemoglobin imparts a brown discoloration to peripheral blood and mucous membranes.

## DIAGNOSIS AND TREATMENT

Maple leaf toxicosis occurs under rather specific conditions but is characterized by an acute onset of hemolytic anemia with methemoglobinemia and Heinz body production. The typical clinical signs and conditions supporting maple leaf intoxication should be in evidence before making a diagnosis. Because the toxic principle is yet unidentified, no specific assay of feed or tissue specimens is available.

Hematologic abnormalities noted in affected horses include moderate to severe anemia (PCV often <10% in severely affected horses), hemoglobinemia, methemoglobinemia, Heinz bodies, anisocytosis, hyperbilirubinemia, and increased erythrocyte fragility. Blood chemistry analysis may reveal depletion of erythrocyte-reduced glutathione and increased serum concentrations of LDH, creatine phosphokinase, AST, and sorbitol dehydrogenase.<sup>9-12</sup> Transient hypercalcemia has been recorded in some horses,<sup>9</sup> and increases in BUN and creatinine concentrations are expected in horses undergoing significant renal insult secondary to hemolysis.<sup>12</sup> Urine analysis may indicate varying degrees of hemoglobinuria, hematuria, bilirubinuria, and proteinuria.<sup>9-11</sup>

Treatment of affected horses is primarily symptomatic. Exposure to red maple leaves should be eliminated immediately, and affected horses should be kept in a quiet, calm environment. Oxygen therapy may be beneficial in selected cases, and blood transfusions can be administered to severely affected individuals.

Balanced, polyionic fluid administration is important to maintain renal function and to aid in diuresis because affected horses may be at great risk of developing hemoglobin nephrosis and acute renal failure. Blood electrolyte and acid-base parameters should be monitored and abnormalities corrected as needed. Acute renal failure should be treated appropriately if it develops.

Other symptomatic therapies that have been suggested include nasogastric intubation with activated charcoal to

aid in binding toxin; dexamethasone to aid in stabilizing red blood cell membranes and decrease phagocytosis of damaged red blood cells; and ascorbic acid (30 mg/kg) given in intravenous fluids twice daily, which may reduce oxidative damage to red blood cells. Whether dexamethasone increases the risk of laminitis in affected horses is unknown, and the efficacy of ascorbic acid is questionable.<sup>14</sup>

Prevention of the disease is accomplished by preventing exposure of horses to dried maple leaves.

## ONION (*ALLIUM* SPP.)

Onion toxicosis in horses is a rare event and occurs when horses are fed large amounts of culled onions (from commercial onion farms) or are forced to eat wild onions because of inadequate available forage. Horses appear to avoid these plants when suitable forage is available.<sup>15,16</sup> The toxic principles in onions, n-propyl disulfide and sulfoxide, affect only circulating erythrocytes and cause oxidant injury to the red blood cell, with resultant Heinz body formation and subsequent hemolytic anemia. Severely affected horses succumb to onion toxicosis because of severe anemia or secondary renal failure caused by hemoglobin nephropathy.

The clinical signs, laboratory values and pathogenesis of the anemia are all similar to those of maple leaf toxicosis, with the exception that methemoglobin formation does not seem to be nearly as pronounced in onion toxicity as in the former. The carcasses of horses that die as a result of onion toxicosis may have an onion odor at necropsy.<sup>15</sup>

Affected horses may recover from onion toxicity if they are removed from the onion source soon enough and if anemia is not severe. Treatment is largely symptomatic and should include removal of the onion source and provision of adequate, suitable forage. Hematinics are of little value, but oxygen therapy and blood transfusions may be indicated in more severely affected animals.

Maintenance of renal function is of primary concern because affected horses are at risk of developing secondary hemoglobin nephropathy. The clinician should give balanced, polyionic fluids to promote diuresis and should correct electrolyte and acid-base abnormalities. Diuretics should be used with caution, but they may be of value in the volume-loaded horse.

## ☞ MISCELLANEOUS AGENTS

### COUMARIN DERIVATIVES

Coumarin normally is present in some species of sweet clover and has no anticoagulant action. However, certain molds present within the plant can convert coumarin to dicoumarol; hence the term *moldy sweet clover poisoning*. Dicoumarol also has been detected in sweet vernal grass. Coumarin derivatives are used widely as anticoagulants, with bishydroxycoumarin (dicoumarol) and 3-( $\alpha$ -acetylbenzyl)-4-hydroxycoumarin (warfarin sodium) being the first oral anticoagulants developed from coumarin.<sup>7</sup> These first-generation compounds are used therapeutically as anticoagulants and as rodenticides. There are currently 11 anticoagulants on the market, representing both first- and second-generation compounds. In horses warfarin has been used therapeutically to treat thrombotic disorders such as thrombophlebitis and navicular disease.<sup>17,18</sup> Horses may exhibit signs of toxicity while being medicated with warfarin if a therapeutic

concentration is exceeded. Rarely are horses exposed to anticoagulants used as rodenticides around buildings or feed storage areas. Second-generation anticoagulant rodenticides (e.g., brodifacoum and bromadiolone) have been developed because of acquired rodent resistance to the first-generation compounds. Because no indications exist for human or veterinary medicinal use of brodifacoum, toxicity associated with this compound is caused by accidental ingestion.<sup>19</sup>

### CLINICAL SIGNS

The clinical signs of toxicity noted with anticoagulants are largely those of a hemorrhagic diathesis. Onset of signs usually is acute and may include hematoma formation, epistaxis, anemia, weakness, pale mucous membranes, or ecchymoses of mucous membranes. Hematuria and melena can occur, and hemorrhage into various body compartments may result in secondary signs caused by malfunction of the involved organ or tissue. Occasionally, affected animals are found dead.<sup>20</sup> Multiple fractional doses of first-generation compounds given over several days may be more toxic to horses than a single larger dose.<sup>17</sup> Brodifacoum, however, differs from warfarin in that a single oral dose has the potential of causing illness and may even be lethal (estimated LD<sub>50</sub> of 1 to 2 kg per adult horse).<sup>19,21</sup>

The onset of clinical signs is delayed from the time of ingestion. In an experimental model the hypothermogenic effect of warfarin anticoagulation was noticed 60 hours after an acute dose.<sup>22</sup> This effect persisted for approximately 30 hours. The effect of brodifacoum, however, is much longer and may persist for weeks, despite its half-life of 1.22 days.<sup>19</sup> In an experimental study horses given a single dose of brodifacoum (0.125 mg/kg body mass) showed increased partial thromboplastin time (PTT) at 24 hours and one-stage prothrombin time (PT) at 48 hours after exposure. These values returned to pretreatment levels by day 12. However, two horses required 23 days for clotting times to return to normal. In these horses peak plasma concentration of brodifacoum occurred 2 to 3 hours after oral administration. Additionally, four of the six experimental horses showed clinical signs of depression, anorexia, and weight loss.<sup>21</sup>

### PATHOPHYSIOLOGY

Warfarin is absorbed readily from the gastrointestinal tract but also may be administered intravenously for therapeutic purposes.<sup>7,17</sup> Once absorbed, warfarin is highly bound (>90%) to plasma proteins, and some is stored in the liver.<sup>7,17,22</sup> The degree of anticoagulant protein binding in horses is not known but may be similar.<sup>19</sup> Warfarin is hydroxylated by hepatic enzymes to inactive compounds that are eliminated by the kidney. The metabolites have no anticoagulant effect,<sup>7</sup> and the biologic half-life of warfarin in the horse is approximately 13 hours.<sup>22</sup> Coumarins also cross the placenta and are secreted in milk.<sup>7</sup>

Protein binding of warfarin is reversible, and the protein-bound, pharmacologically inactive warfarin serves as a reservoir. The unbound portion remains fairly constant in plasma.<sup>7,17</sup>

A number of factors can influence the amount of unbound free warfarin in serum. Protein-bound drugs such as phenylbutazone, chloral hydrate, and sulfonamides may enhance the toxicity of warfarin by displacing warfarin from protein-binding sites. This allows a greater proportion of the drug to

be in the free form and thus able to exert its pharmacologic effect.<sup>7,20</sup> Corticosteroids and thyroxine may lower the therapeutic dose of warfarin by increasing clotting factor catabolism and receptor site affinity.<sup>17</sup>

Certain physiologic factors also may enhance the toxicity of warfarin. Hypoalbuminemia may result in fewer binding sites available, thereby increasing the amount of free drug. Hepatic dysfunction may impede metabolism of the anticoagulants, and reduced amounts of vitamin K in the diet may predispose to toxicity.<sup>7</sup>

Some drugs reduce the therapeutic response to a given dose of warfarin. Barbiturates, rifampin, and chloramphenicol induce hepatic microsomal enzyme activity, thereby accelerating the metabolism of warfarin. If these drugs are withdrawn during warfarin therapy, toxicosis may result.<sup>7,17</sup> Likewise, excessive dietary intake of vitamin K or vitamin K administration can reduce or inhibit the anticoagulant effects of warfarin.<sup>17</sup>

Warfarin acts as an anticoagulant by inhibiting production of the vitamin K-dependent clotting factors II, VII, IX, and X. Vitamin K is a cofactor in the synthesis of clotting factors II, VII, IX, and X and also acts on all clotting factor precursors to convert glutamyl residues to  $\gamma$ -carboxyglutamyl residues. During this carboxylation process vitamin K<sub>1</sub> is converted to vitamin K<sub>1</sub> 2,3-epoxide, an inactive metabolite. This epoxide returns to active vitamin K<sub>1</sub> by the action of the microsomal enzyme vitamin K<sub>1</sub> epoxide reductase. The coumarin anticoagulants inhibit vitamin K<sub>1</sub> epoxide reductase, thereby creating a vitamin K<sub>1</sub> deficiency. The result is decreased production and subsequent deficiency of the vitamin K-dependent clotting factors.<sup>5</sup> The delayed onset of action of the coumarin derivative anticoagulants results from this impediment to clotting factor synthesis rather than from a direct effect on the clotting mechanism per se.

The various blood clotting factors have different plasma half-lives. Factor VII has a shorter half-life than the other clotting factors, so the earliest laboratory indication of anticoagulant toxicity is a prolonged PT. As the other clotting factors become depleted, activated PTT also increases as toxicity continues.<sup>17</sup> The clinician should monitor horses given warfarin therapeutically for clotting abnormalities. Prolongation of PT by 1.5 to 2 times the baseline value has been suggested as the effective range of anticoagulation. However, some horses maintained in this range may show signs of hemorrhage.<sup>18</sup> In fact, reports in horses suggest that factor IX may be depleted from circulation more rapidly than factor VII, indicating that the PTT would be the more sensitive clotting assay to assess in horses after exposure to anticoagulants.<sup>19</sup>

### DIAGNOSIS AND TREATMENT

The diagnosis of warfarin or other coumarin-derivative anticoagulant intoxication is based on evidence of exposure to the compound, presence of a bleeding diathesis, and prolongation of PTT and PT. The platelet count, fibrinogen concentration, fibrin degradation product concentration, and antithrombin III activity remain within their respective normal ranges of activity.<sup>17,18</sup> However, in dogs exposed to toxic doses of anticoagulant rodenticides, fibrinogen and fibrinogen degradation products (FDPs) have been found to be elevated 50% of the time.

Blood, liver, stomach and intestinal contents, and feces can be submitted for analytic testing for the anticoagulant residues. Specimens should be frozen for transportation to the laboratory.<sup>20,22</sup>

In horses intoxicated by warfarin, discontinuance of warfarin therapy or removal of the product from the environment is of primary importance. Mineral oil may be used to enhance fecal excretion of any orally ingested warfarin products. Vitamin K<sub>1</sub> should be given at a dosage of 300 to 500 mg subcutaneously every 4 to 6 hours until PTT and PT return to their baseline values (5 to 7 days is generally sufficient). PTT and PT should be monitored daily for 3 to 4 days thereafter to ensure stability. The subcutaneous route of vitamin K<sub>1</sub> administration is preferable because of the possibility of adverse reactions if the product is given intravenously or intramuscularly. Intravenous injection of vitamin K<sub>1</sub> may result in transient restlessness, tachypnea, tachycardia, sweating, and anaphylactic reactions.<sup>23,24</sup> Intramuscular administration of vitamin K<sub>1</sub> results in erratic response times and therefore may be inappropriate for a hemorrhaging patient.<sup>23</sup> Alternative doses for vitamin K<sub>1</sub> administration are 0.3 to 0.5 mg/kg intravenously, and a dosage of greater than 0.5 mg/kg intravenously has been suggested to inhibit coumarin activity for several days.<sup>17</sup> If the intravenous route is chosen, vitamin K<sub>1</sub> should be diluted in 5% dextrose or saline and administered slowly.<sup>20</sup>

In horses intoxicated with long-acting anticoagulant rodenticides, treatment with vitamin K<sub>1</sub> may be required for 2 to 4 weeks or until coagulation status is normal 2 to 3 days after the last dose of vitamin K<sub>1</sub>. Affected horses were given vitamin K<sub>1</sub> (2.5 mg/kg) subcutaneously every 12 hours for 36 hours and then orally twice daily for the duration of treatment.<sup>19</sup>

If bleeding is serious, fresh blood or fresh plasma given intravenously may be necessary to control hemorrhage and help correct hypovolemia. Other supportive measures such as bandaging and keeping the animal in a quiet environment may be helpful. Alfalfa hay added to the diet may provide a natural source of vitamin K<sub>1</sub>.<sup>19</sup> Organ dysfunction induced by hemorrhage and hypoxia should be treated appropriately. The prognosis for horses intoxicated with anticoagulant compounds is good if the disorder is recognized early and appropriate therapy is instituted. For symptomatic patients the prognosis is highly dependent on the severity, site, and extent of blood loss.

To prevent warfarin toxicosis, the clinician should strive to minimize exposure to the product and carefully monitor the therapeutic use of the drug in the horse. Contraindications to its use include any clinical or laboratory suggestion of hepatic disease, hypoproteinemia, or other condition that might increase the risk of toxicity. The practitioner should evaluate the concurrent use of other medications, because they may affect the potential for toxicosis to develop, and re-evaluate the dosage of warfarin administered if other concurrent medications are changed. Additionally, the potential for traumatic injury in horses undergoing warfarin therapy should be minimized.

## DIMETHYL SULFOXIDE

Dimethyl sulfoxide, a by-product of the papermaking industry, is a colorless liquid originally used as an industrial solvent. The chemical is a polar compound that readily mixes with ethyl alcohol and many organic solvents; it is extremely hygroscopic and can absorb more than 70% of its weight of water from air. DMSO possesses some antimicrobial and antifungal activity, but its primary medical use has been as an anti-inflammatory agent and a transdermal transport agent.<sup>25</sup> More recently, DMSO has been used as a diuretic and has shown promising results when used to treat acute cranial and spinal cord trauma.<sup>25,26</sup>

The systemic toxicity of DMSO is considered to be low, and its greatest toxic potential appears to result from its combination with other agents.<sup>27</sup> However, in an experimental study rapid infusion of DMSO in 20% and 40% concentrations caused hemolysis, hemoglobinuria, diarrhea, muscle tremors, and signs of colic in some horses.<sup>28</sup> The LD<sub>50</sub> of DMSO has not been established for horses, but ranges between 2.5 to 9.0 g/kg as a single intravenous dose have been reported in a number of animal species.<sup>27</sup> A dose of 1 g/kg intravenously has been suggested for use in horses. This dose should be diluted to a 10% to 20% solution and administered slowly intravenously.<sup>26,27</sup>

DMSO produces hemolysis when given intravenously in concentrations of 20% to 50% or greater.<sup>25-27</sup> If hemolysis is severe, affected horses may be at increased risk of developing hemoglobin nephrosis. Concentrations of 10% or less are considered suitable for intravenous injection in horses.<sup>25,26,28</sup> Additionally, increased white blood cell adherence and fibrinogen precipitation have been reported when concentrations greater than 50% were administered.<sup>25</sup>

DMSO is a mild cholinesterase inhibitor, and its concurrent use with organophosphates or other cholinesterase inhibitors is not recommended.<sup>25,27</sup> DMSO also is known to induce histamine release from mast cells, but the significance of this phenomenon is uncertain.<sup>27</sup>

Skin reactions to topically applied DMSO sometimes occur. Varying degrees of erythema, pruritus, drying, hardening, and desquamation of normal skin may be evident. These reactions are usually self-limiting and typically diminish with repeated applications.<sup>27</sup>

The greatest risk of toxicity resulting from DMSO is probably a consequence of its concomitant use with other toxic or potentially toxic agents. DMSO may aid transport of a variety of toxic compounds across skin, thereby inducing toxicosis from the transported agent. For example, mercury toxicity has been reported in a horse that had a blister after DMSO and mercury were applied topically to a leg.<sup>29</sup> In such instances, the clinician should treat the specific toxic reaction (or reactions) appropriately. No specific antidote is recognized for DMSO, and it should always be used judiciously and conscientiously. The practitioner should heed the aforementioned precautions when administering the drug.

## BICARBONATE

Sodium bicarbonate is one of the most common alkalinizing agents used in animals, including horses. Sodium bicarbonate is indicated specifically to treat acute, severe metabolic acidosis because of its rapid effect on blood pH when given intravenously.<sup>30</sup> Sodium bicarbonate also has been used in performance horses to treat exertional myopathies and in attempts to prevent rhabdomyolysis. More recently, sodium bicarbonate administration in performance horses has been investigated because of its suggested role in limiting or preventing systemic lactic acidosis, thereby enhancing performance level.<sup>31,32</sup> The adverse effects of bicarbonate administration occur when it is given too rapidly or in excessive quantities or when it is given in the presence of certain systemic abnormalities.

## CLINICAL SIGNS

Animals, including horses, that suffer from an acute overdose of bicarbonate may exhibit signs of delirium, depression, and coma. Rapidly induced alkalosis also has been associated with cardiac dysrhythmias.<sup>30</sup>

Horses such as endurance horses or racehorses that are volume depleted and have sustained excessive electrolyte loss through sweat often have clinicopathologic changes of hypokalemia, hypochloremia, hypocalcemia, and metabolic alkalosis. When such horses are given bicarbonate, dramatic deleterious effects occur. These animals may exhibit signs of muscle fasciculation, synchronous diaphragmatic flutter, bruxism, and decreased respiratory rate. One also may note clinical evidence of further dehydration, such as increased capillary refill time, delayed jugular distensibility, diminished skin turgor, and decreased arterial pulse.<sup>32</sup>

### PATHOPHYSIOLOGY

The rapid administration or overdose of sodium bicarbonate has been associated with extracellular hyperosmolality, intracranial hemorrhage, and cerebrospinal fluid (CSF) acidosis. Hyperosmolality results from hyponatremia because sodium bicarbonate dissociates into sodium ions and bicarbonate ions. An abrupt increase in serum osmolality can lead to intracranial hemorrhage as intracellular water moves into the extracellular space. This extracellular fluid accumulation may result in engorgement of perivascular spaces, with subsequent tearing of bridge veins and resultant hemorrhage. The CSF acidosis results from the rapid diffusion of generated carbon dioxide into the CSF. Carbon dioxide enters the CSF almost instantaneously, establishing new steady-state levels within minutes. Bicarbonate ion, however, is slow to enter the CSF and requires hours to days to achieve new steady-state levels. With sodium bicarbonate administration the increasing amount of carbon dioxide generated readily enters the CSF disproportionately more than does the bicarbonate ion. As a consequence, the CSF becomes acidic.<sup>33</sup> These mechanisms, individually or collectively, are thought to be responsible for development of the clinical signs observed with rapid or excessive administration of sodium bicarbonate solution.

Another effect of alkalosis is a shift to the left of the oxyhemoglobin dissociation curve. This left shift indicates an increased affinity of hemoglobin for oxygen, with a resultant decrease in the amount of oxygen available for cellular use. This change in hemoglobin affinity for oxygen has been associated with cardiac dysrhythmias following rapidly induced alkalosis.<sup>30</sup>

Horses undergoing extensive exercise or horses that are treated with furosemide (primarily as prerace medication for exercise-induced pulmonary hemorrhage) are at risk of developing hypochloremic, hypokalemic metabolic alkalosis. When sodium bicarbonate is given to these volume-depleted horses with electrolyte loss and concurrent metabolic alkalosis, another deleterious series of events can result. Further reduction of the circulating fluid volume may occur, along with development of serum hyperosmolality, electrolyte abnormalities of hyponatremia, hypokalemia, hypochloremia, and hypocalcemia and further development of metabolic alkalosis.<sup>32</sup>

Excessive sodium bicarbonate produces hyperosmolality caused by hyponatremia because sodium bicarbonate dissociates into sodium and bicarbonate ions. The hypokalemia is explained partially by the intracellular shift of potassium in response to metabolic alkalosis, and the bicarbonate ion adds to the alkalosis already present. Furosemide administration causes urinary loss of potassium, chloride, and calcium, and sweating also can result in significant loss of chloride and calcium.

Additionally, rapid intravenous infusion of 5% sodium bicarbonate in normal horses results in hypochloremia.<sup>34</sup>

The muscle fasciculations and diaphragmatic flutter noted in some horses likely result from hypocalcemia.<sup>32</sup> The total serum calcium concentration may be within a normal range, but alkalosis causes a reduction in the amount of circulating ionized calcium. Because ionized calcium is responsible for neuromuscular function, reduction in this fraction can cause clinical signs of hypocalcemia.

### DIAGNOSIS AND TREATMENT

Horses being treated with sodium bicarbonate solutions should be monitored closely for clinical signs of alkalosis. Blood pH obviously is elevated, but rapid infusion of sodium bicarbonate or excessive use in horses already sustaining fluid and electrolyte loss can result in a number of clinicopathologic alterations. Affected horses typically exhibit increases in PCV, total serum protein, and serum bicarbonate and sodium concentrations. Additional findings of hypokalemia, hypochloremia, and hypocalcemia usually are present.

Treatment of affected horses involves cessation of bicarbonate administration and correction of the alkalosis and electrolyte abnormalities. Potassium chloride administration is indicated in horses with hypokalemic, hypochloremic metabolic alkalosis and is much more effective in correcting these electrolyte abnormalities than is sodium chloride. Potassium chloride also has been shown to cause a prompt, significant decline in venous blood pH in these horses.<sup>32</sup>

Apparently, hypertonic sodium bicarbonate solutions should not be used in dehydrated horses. The concurrent use of furosemide and sodium bicarbonate also appears to be contraindicated; if this is necessary, they must be used with extreme caution and close observation with laboratory assessment. Sodium bicarbonate should not be mixed with fluids containing calcium because insoluble complexes may form. The use of sodium bicarbonate orally in horses subjected to short-term intense exercise remains controversial.

### MONENSIN

Monensin is one of several biologically active compounds categorized as ionophore antibiotics (others include lasalocid, salinomycin, narasin, laidlomycin, maduramycin, and virginiamycin) because they can form lipid-soluble complexes with specific metal cations and transport them across biologic membranes. Monensin is produced by the fungus *Streptomyces cinnamonensis* and is selective in transporting sodium and potassium ions between intracellular and extracellular spaces.<sup>20,35,36</sup> Monensin is used routinely as a poultry coccidiostat and as a feed additive to improve feed efficiency in pasture and feedlot cattle. Horses are the domestic animals most sensitive to monensin toxicosis. The LD<sub>50</sub> and possibly a single acute toxic dose of monensin for the horse is 1 to 2 mg/kg.<sup>20</sup>

### CLINICAL SIGNS

Several syndromes of toxicity occur and seem to be dose related. Peracute toxicity may manifest as progressive, severe hemoconcentration; hypovolemic shock; and death within a few hours of ingestion. The acute form of the disorder is characterized by partial to complete feed aversion, abdominal pain, occasional watery diarrhea, intermittent profuse sweating, stiffness, progressive muscle weakness (especially in the hindquarters), progressive ataxia, tachycardia, hypotension,

dyspnea, and polyuria. Affected horses may show clinical signs for 1 to 4 days before death.<sup>36-38</sup> Horses surviving sublethal doses of monensin exhibit signs of reduced athletic performance, unthriftiness, and cardiac failure. Cardiac arrhythmias, including atrial fibrillation and tachycardia; a prominent jugular pulse; and pleural and pericardial effusion are apparent.<sup>20</sup> Intravascular hemolysis also may occur to a limited degree.<sup>35</sup>

### PATHOPHYSIOLOGY

The primary action of monensin is the selective transport of sodium and potassium ions between the intracellular and extracellular spaces. Two mechanisms have been suggested to explain the toxic action.

According to one theory, monensin interacts with the mechanism regulating potassium entry into cell organelles, especially the mitochondria.<sup>20</sup> Low concentrations of monensin lead to a net accumulation of potassium within the cell, whereas higher doses cause a net loss of potassium from the cell.<sup>35</sup> Because potassium is required for ATP hydrolysis by the mitochondria, the effect of monensin might be to inhibit ATP hydrolysis in mitochondria. As a result, cell energy production is decreased and can result in loss of cell function and death.<sup>20,35</sup>

The second hypothesis suggests that increased intracellular calcium concentration is the mechanism responsible for cell death. When the intracellular calcium concentration is increased, the mitochondria are forced to maintain calcium homeostasis by sequestering the excess calcium. This requires energy, which could take priority over ATP production. When the mitochondria become overloaded with calcium, oxidative phosphorylation is inhibited and less energy is produced to pump calcium out of the cell. When intracellular calcium levels reach a critical level, degradative enzymes are released, swelling of the mitochondria and sarcoplasmic reticulum occur, and cell necrosis and death follow.<sup>20,35</sup>

The heart is the primary target organ of monensin toxicosis, and electron microscopic studies of acute monensin toxicosis in ponies have shown structural changes in myocardial cells consistent with severe mitochondrial damage.<sup>39</sup> In horses ingesting a sublethal dose of monensin, the myocardial sarcolemma is damaged and is replaced by fibrous tissue in the healing process. Myocardial lesions are characterized microscopically by pale myofibers, loss of fiber striation, multifocal vacuolar degeneration, and scattered areas of necrosis. The result is a structurally weakened heart that can succumb to stress and cause acute collapse of the horse. Other lesions that may be present in affected horses include pericardial, pleural, and peritoneal effusions; hemopericardium; and epicardial hemorrhage. Chronically affected horses also may have hepatic congestion with centrilobular necrosis and hydropic degeneration of the renal tubules.<sup>20,35</sup>

### DIAGNOSIS

Monensin toxicosis is suspected when horses show clinical signs of feed refusal, abdominal discomfort, muscle weakness, and heart failure and when a possible exposure to contaminated feed has occurred. The practitioner can evaluate feeds, serum, liver, gastrointestinal content, and feces for the presence of monensin.

Clinicopathologic abnormalities are nonpathognomonic but include early signs of severe hemoconcentration and dehydration in horses affected peracutely. Serum potassium and

calcium may be decreased moderately in the first 12 to 16 hours but then tend to come back to normal levels. BUN and creatinine concentrations are elevated in horses acutely affected but return to normal in surviving animals. Other enzymes that show elevated serum activity include CK, AST, and LDH isoenzyme fractions 1 (cardiac muscle) and 2 (red blood cell origin). Total serum bilirubin also may be elevated.<sup>20,35</sup>

Abnormal findings in urine can include a progressive decrease in urine osmolality during the initial few hours of the disease course.<sup>20</sup> One also might expect elevations in urinary activity of renal tubular enzymes such as  $\gamma$ -glutamyl transferase and N-acetylglucosaminidase. Urinalysis abnormalities tend to correlate well with the degree of renal insult and are nonspecific indicators of renal damage.

### TREATMENT

No specific antidote exists for monensin. Horses that have ingested a large amount should be treated early and aggressively with polyionic fluids to combat hemoconcentration and hypovolemic shock. Electrolyte and acid-base analysis should be performed, if possible, and any deficiencies corrected. The clinician should attempt to evacuate the bowel of the horse using orally administered laxatives such as mineral oil; activated charcoal may help decrease the absorption of monensin. Affected horses should be kept as quiet and nonstressed as possible for weeks after exposure to allow the damaged myocardium to heal.<sup>20,35</sup> Administration of selenium and vitamin E should be considered; these compounds have been shown to be somewhat protective against the toxic effects of monensin in swine.

Digitalis glycosides should never be used in acutely affected horses because they and monensin have been shown to be synergistic and immediately fatal to cardiac muscle cells. Digitalis glycosides should be used only with great caution in the weeks after recovery from the toxic episode. Likewise, calcium should not be given to acutely affected horses for two reasons. First, serum hypocalcemia is transitory, and serum calcium usually recovers to normal by 24 hours. Second, calcium can be dangerously irritating to an already injured myocardium.<sup>35</sup>

It is important to note that affected horses are susceptible to cardiac damage, which is often permanent. A critical evaluation of cardiac function and the integrity of any previously intoxicated horse that is destined to return to some form of athletic endeavor is judicious.

### LASALOCID

Lasalocid, another carboxylic ionophore antibiotic, is a fermentation product of the mold *Streptomyces lasaliensis* that is used commercially as a poultry coccidiostat and as a feed additive to improve feed efficiency in ruminants.

### CLINICAL SIGNS

The signs observed in horses given toxic amounts of lasalocid are similar to those of monensin toxicosis. Affected horses exhibit depression, ataxia, paresis, and paralysis with partial to complete feed aversion. Once recumbent, some horses rise when given assistance. Most horses that survive appear normal 2 to 3 days after exposure. The lowest dose that has been reported to cause fatality was 15 mg per kg of body weight, but the LD<sub>50</sub> for a single oral dose of lasalocid was estimated to be 21.5 mg/kg. Death occurred between 31 and 96 hours after oral dosing in the nonsurvivors.<sup>40</sup>

Results of a toxic feeding study indicated that poultry rations containing approved concentrations of lasalocid (75 to 125 g per metric ton) are not toxic or lethal to horses. This study revealed that horses voluntarily reduced their feed intake with increasing amounts of lasalocid in the ration and refused to eat the commercial premix when it was offered in place of their normal ration.<sup>40</sup>

### PATHOPHYSIOLOGY

The mechanism of action of lasalocid is thought to be similar to that of monensin. Lasalocid is the least toxic of the ionophores and differs from monensin in that it accepts divalent as well as monovalent cations.<sup>7</sup>

### DIAGNOSIS

No signs or laboratory findings are pathognomonic for lasalocid toxicity. In horses in which it is suspected, feedstuffs, stomach contents, serum, liver, and feces can be analyzed for lasalocid content.

Abnormal laboratory findings in affected horses may include hypocalcemia, hypophosphatemia, and hypokalemia early in the disease course (within 24 hours of exposure), but these values return to normal ranges by 120 hours after ingestion. Serum activity of AST frequently is increased, as is total serum bilirubin and glucose concentrations. Occasionally, the BUN concentration is increased.<sup>40</sup>

### TREATMENT

Initial treatment should include removal of all suspected feed sources and the oral administration of laxatives to enhance evacuation of the gastrointestinal tract. Other nonspecific supportive care may be helpful, but horses receiving a sublethal dose probably will recover with minimal assistance. If a lethal dose is forced into an animal inadvertently, oral laxatives and adsorbents such as activated charcoal may help bind lasalocid and reduce the amount absorbed. Administration of selenium and vitamin E before the onset of signs may help alleviate the severity of the clinical signs once they occur.

### SALINOMYCIN

Salinomycin is an ionophore, also marketed as a coccidiostat, that is related more closely to monensin than is lasalocid. The ionic affinity of salinomycin is predominantly to sodium and potassium ions, and its mode of action and cellular effects are similar to those of monensin.<sup>7</sup>

In one report of affected horses, the clinical signs were similar to those of the other ionophore toxicoses. The range of clinical signs included partial to complete feed aversion, depression, occasional sweating, colic, dyspnea, weakness, ataxia, and recumbency. Occasionally, horses showed reduced performance for several weeks after exposure, but many horses that became recumbent were destroyed humanely. The clinicopathologic abnormalities exhibited by affected horses included elevated serum activities of CK, AST, and alkaline phosphatase.<sup>41</sup>

The diagnosis of salinomycin toxicity is hampered by the fact that none of the clinical signs are pathognomonic. However, one may assay suspect feed, gastrointestinal content, serum, liver, and feces for the presence and quantity of salinomycin.

Treatment of affected horses is mostly symptomatic because no specific antidote is available. Evacuation of the

bowel by laxatives may be helpful in reducing the amount of toxic material available for absorption. Fluid balance and electrolyte and acid-base indices should be maintained within normal ranges. Administration of selenium and vitamin E should be considered. Affected horses generally require an extended convalescence, and the clinician should consider the possibility of a persistent cardiomyopathy.<sup>41</sup> Affected horses should undergo a rigorous cardiac examination before returning to performance events.

### NITRATES AND NITRITES

Nitrates are an important component in the naturally occurring nitrogen cycle and as such are present in soils, ground-water, forages, row crops, weeds, animal tissues, and excreta. Nitrates also are used widely in fertilizers. Toxicity problems can arise when animals consume plants, feed, or water containing excessive amounts of nitrates or nitrites or when they ingest nitrate fertilizers. Nitrates naturally undergo microbial decomposition to nitrites, so nitrite toxicity can occur when animals ingest feed or water in which the nitrates have decomposed to yield large amounts of nitrites. This decomposition can occur in moist haystacks, water troughs, farm ponds, silages, and pig swills. Nitrite also is administered intravenously to treat cyanide poisoning, and overzealous use of this therapy can result in toxicity.<sup>7</sup>

The primary exposure to nitrate or nitrite for most animals is the plants they consume. Many plants and forages are known to be nitrate accumulators, and a number of factors influence the uptake of nitrates in plants. Nitrate concentration by plants is enhanced by low soil pH; low soil molybdenum, sulfur, or phosphorus content; low soil temperature; drought; soil aeration; decreased light; and use of phenoxyacetic acid herbicides such as 2,4-dichlorophenoxyacetic acid. Nitrate and nitrite accumulation in ponds and groundwater is caused by water runoff from nitrate-rich soils or by direct contamination with nitrates and nitrites.<sup>7,20</sup> Nitrates and nitrites are water soluble and are carried easily from feedlots, pigpens, and fertilized areas into the soil and subsequently into plants, wells, and ponds.

The most important aspect of nitrates is their ease of microbial conversion to nitrites. Nitrite is responsible for the primary signs associated with toxicity in nitrate poisoning.

### CLINICAL SIGNS

Although apparently rare, horses are reported to be susceptible to nitrate intoxication. Experimentally, an oral dose of 1 g/kg potassium nitrate caused illness but not death in horses. However, nitrites have been associated with death of horses under field conditions.

In monogastric animals nitrate ingestion is reported to produce gastrointestinal irritation with resulting emesis or enteritis. Salivation, diarrhea, colic, and frequent urination may be evident if the nitrate is sufficiently concentrated.

Signs of acute poisoning with nitrites usually begin 30 minutes to 4 hours after ingestion of high-nitrite feed or water. The most characteristic signs are those referable to respiratory insufficiency and include dyspnea, cyanosis, rapid and weak pulse, and anxiety. Exertion may exacerbate these signs and induce muscle tremors and collapse. The horse may have terminal clonic convulsions. The blood of affected animals is usually brown or chocolate-colored and this imparts a cyanotic or pale appearance to mucous membranes. Death may

occur in several hours or be delayed until 12 to 24 hours after ingestion.<sup>20,7</sup>

### PATHOPHYSIOLOGY

Nitrites are absorbed rapidly from the gastrointestinal tract into the bloodstream. The nitrite ion acts directly on vascular smooth muscle to cause relaxation and easily enters erythrocytes in exchange for chloride ion. Nitrite also can pass the placenta to enter fetal erythrocytes, which are especially sensitive to nitrite. The biologic half-life of blood nitrate in horses is 4.8 hours. Only small amounts of nitrate or nitrite are bound to plasma proteins.<sup>7,42</sup>

Nitrite causes acute poisoning by two mechanisms. The primary action of nitrite is to interact with hemoglobin to form methemoglobin. One molecule of nitrite interacts with two molecules of hemoglobin, causing the oxidation of normal ferrous hemoglobin to ferric hemoglobin, which is called *methemoglobin*. Methemoglobin is incapable of transporting oxygen to tissues, and if sufficient quantities are formed, severe oxygen deficiency can occur. Clinical signs become evident when methemoglobin levels approach 30% to 40%, and death occurs when 80% to 90% of hemoglobin is oxidized to methemoglobin.<sup>7,20</sup> However, death can occur in active animals with only 50% to 60% methemoglobin.<sup>7</sup>

Normally, methemoglobin is converted back to ferrous hemoglobin by two reducing enzyme systems. This conversion occurs slowly, and in instances of nitrate toxicity, methemoglobin formation far exceeds the ability of these enzyme systems to regenerate hemoglobin.<sup>7</sup>

The second action of nitrite is to cause direct relaxation of smooth muscle, particularly vascular smooth muscle. The mechanism by which this occurs is unknown, but the physiologic changes brought about by the vasodilating action of nitrite include pulmonary arterial, central venous, and systemic arterial hypotension and decreased cardiac output. These changes may contribute to tissue anoxia and act to enhance tissue oxygen starvation already initiated by methemoglobin.<sup>7</sup>

### DIAGNOSIS AND TREATMENT

The diagnosis of nitrate or nitrite toxicity is based on compatible clinical signs; methemoglobinemia; history of exposure to potential nitrate- or nitrite-containing plants, water, or fertilizers; and nitrate quantitation in blood. One should perform blood methemoglobin determinations soon after collection because methemoglobin is not stable in refrigerated, heparinized blood for more than a few hours. However, blood mixed with a phosphate buffer preserves the methemoglobin and allows shipment to a diagnostic laboratory. Forage, hay, and water samples can be analyzed for nitrate or nitrite content, as well as other body fluids such as ocular fluid collected post mortem.<sup>20</sup>

Treatment aims to reduce methemoglobin back to hemoglobin. Mildly affected animals may recover spontaneously if the toxic source is removed and if they are given sufficient time for normal methemoglobin reduction processes to occur. Intravenous methylene blue may be used to treat more severely affected horses at a suggested dosage of 4.4 mg/kg, given slowly as a 1% solution in isotonic saline. The dose may be repeated in 30 minutes if clinical response is unsatisfactory. Caution is necessary, however, because excessive amounts of methylene blue may directly oxidize hemoglobin to methemoglobin. Methylene blue is converted to leukomethylene

blue by an NADPH<sub>2</sub>-dependent system. Leukomethylene then reduces methemoglobin to hemoglobin. In this reaction leukomethylene blue is oxidized back to methylene blue but can be reconverted to leukomethylene blue as long as sufficient NADPH<sub>2</sub> is available. If this NADPH<sub>2</sub> system becomes saturated with methylene blue, excessive methylene blue may oxidize hemoglobin directly to more methemoglobin.<sup>7</sup> Because methylene blue is difficult to obtain, ascorbic acid has been suggested as a less effective alternative.

Other nonspecific therapies include blood transfusion, oxygen therapy, and laxatives such as mineral oil to aid evacuation of the gastrointestinal tract.<sup>7</sup>

### CYANIDE

*Hydrogen cyanide, cyanide, hydrocyanic acid, and prussic acid* are terms that refer to the same toxic substance. Horses become exposed primarily through ingestion of certain plants that contain cyanogenic glycosides, but compounds containing cyanide also have been used as fumigants, rodenticides, and fertilizers.<sup>7,20</sup>

Numerous plants or plant parts may accumulate large quantities of cyanide or cyanogenic glycosides, and a more complete description of them can be found elsewhere.<sup>43</sup> When these cyanogenic glycosides undergo hydrolysis, free HCN is formed. Plant cells contain degradative enzymes that can hydrolyze these glycosides, but under natural conditions the enzymes are kept separated spatially from the glycosides in intact cells. Damage to the plant cells by wilting, freezing, or stunting allows enzymatic degradation of the glycoside.<sup>20</sup> Rapid hydrolysis and release of HCN occur only when the plant cell structure is disrupted. When the glycoside is exposed to an acid medium, or when maceration of the plant occurs within the intestinal tract, hydrolysis and subsequent formation of HCN also occur.

A number of factors can influence the toxic potential of cyanogenic plants. Because plant cyanogenic glycosides and degradative enzymes are controlled genetically by a dominant gene, selectively breeding plants with low cyanogenic potential is possible. Therefore different species and varieties of forage contain varying cyanogenic content. The ability to genetically remove plants with high cyanogenic potential is one reason that plant-related cyanide toxicity is an uncommon event. Sudan and Johnson grass historically have been problematic forages for livestock. High-nitrogen fertilization, nitrogen and phosphorus imbalance in soil, and drought conditions also can influence cyanide potential in plants.<sup>20</sup>

Most of the cyanogenic activity in the plant is located in the leaves and seeds, and immature and rapidly growing plants have the greatest potential for high glycoside levels. Conditions that damage the plant, such as drought, wilting, or freezing, may allow for more rapid combination of glycoside and enzyme, thereby enhancing plant toxicity. Other factors that may affect toxicity are the size of the animal, speed of ingestion, the type of food ingested along with the cyanogen, and the presence of active degradative enzymes in the plant and in the digestive tract of the horse.<sup>20</sup>

### CLINICAL SIGNS

Because cyanide is such a potent, rapidly acting poison, affected animals commonly are found dead. On observation clinical signs may range from mild tachypnea and anxiousness to severe panting, gasping, and behavioral excitement.

Salivation, lacrimation, muscle tremors, defecation, urination, and mydriasis may be evident. These signs are followed by prostration, clonic convulsions, and death. The mucous membranes may have a bright red appearance, and blood color may be bright cherry red, although this is not commonly reported in cases. Clinical signs may last from only a few minutes to a few hours, but horses that survive longer than 90 to 120 minutes after exposure usually survive.<sup>4,7,20,43</sup>

### PATHOPHYSIOLOGY

HCN is absorbed rapidly from the gastrointestinal tract or from the lungs. After absorption, endogenous thiosulfate combines with the cyanide ion to form thiocyanate, which is relatively harmless. This reaction occurs in the liver and other tissues, and the generated thiocyanate is excreted in urine. Another inherent detoxification mechanism involves inactivation of HCN in the bloodstream by combining with the ferric iron of methemoglobin. However, because a small amount of methemoglobin normally is present in blood and endogenous stores of thiosulfate can be depleted rapidly, these two endogenous mechanisms of detoxification are overcome rapidly in cases of clinical toxicity.<sup>20</sup>

Excessive cyanide ion reacts readily with the trivalent (ferric) iron of cytochrome oxidase to form a stable cyanide-cytochrome oxidase complex. When iron is maintained in the ferric form, electron transport can no longer occur, and the chain of cellular respiration is brought to a halt. As a consequence, hemoglobin is unable to release its oxygen to the electron transport system, and cellular hypoxia results. This action occurs despite a large concentration of oxygen in the bloodstream. Cytochrome oxidase is most concentrated in tissues that have a high oxidative metabolic rate, such as the CNS and cardiac muscle. All tissues can be affected from this lack of usable oxygen, but death primarily is caused by anoxia in the brain.<sup>7,20</sup> The acute oral LD<sub>50</sub> of HCN is 2 to 2.3 mg/kg, and rapid intake of plant material equivalent to about 4 mg/kg is thought to be a lethal amount.<sup>7</sup>

### DIAGNOSIS AND TREATMENT

Cyanide poisoning should be considered when animals consuming cyanogenic plants are affected with acute signs of oxygen starvation and bright red blood. The presence of cyanide is confirmed chemically, and samples of forage, blood, liver, muscle, brain, and heart may be submitted. All samples should be frozen as soon as possible and shipped.<sup>7,20</sup> Plant materials containing greater than 200 ppm HCN and concentrations in brain and ventricular myocardium greater than 100 mg/100 g wet weight are considered significant.<sup>7</sup>

Treatment aims at splitting the cyanide-cytochrome oxidase complex, with subsequent removal of the cyanide complex, and augmenting available thiosulfate in the bloodstream. Sodium nitrite displaces the cyanide molecule from the cytochrome enzyme and changes some of the hemoglobin to methemoglobin, which then competes with cytochrome oxidase for the cyanide ion. In this process methemoglobin and the cyanide ion form cyanomethemoglobin, and cytochrome oxidase subsequently is regenerated. Sodium nitrite should be used cautiously because of the possible danger of producing nitrite toxicosis, but it can be administered intravenously at dosages ranging from 6 mg/kg, given as a 20% solution,<sup>44</sup> to 15 to 25 mg/kg.<sup>7</sup>

Sodium thiosulfate reacts with the cyanide ion in the blood or liberated from cyanomethemoglobin and forms thiocyanate, which is essentially harmless and is excreted in urine. Sodium

thiosulfate also can be given intravenously at dosages ranging from 60 to 660 mg/kg, as a 20% solution,<sup>4</sup> to 1.25 g/kg. Sodium nitrite and thiosulfate are not easy to obtain; thus these compounds rarely are used to treat clinically affected animals. In small animals a commercially available kit containing a vitamin B<sub>12</sub> precursor, hydroxocobalamin, is currently recommended. An additional recommended therapy includes large doses of mineral oil. The cobalt in the vitamin B<sub>12</sub> preparation may bind additional cyanide in the circulation, and mineral oil aids evacuation of the gastrointestinal tract. Animals that survive 24 hours usually do not require further treatment.<sup>7</sup>

### SODIUM FLUOROACETATE (1080)

Sodium fluoroacetate and fluoroacetamide are highly toxic to many animal species. They have been used as rodenticides and in predator control, and because of their toxicity, their use in the United States is highly restricted. The compounds are odorless, tasteless, and water soluble and typically are incorporated into baits composed of carrot chunks, bread, bran, or meats. In the United States these compounds often are mixed with a dye before being placed in baits. Horses may become intoxicated by inadvertent exposure to these baits.<sup>7,20</sup>

### CLINICAL SIGNS

Sodium fluoroacetate causes signs primarily related to cardiac dysfunction in herbivores. The onset of signs usually occurs from 30 minutes to 2 hours after ingestion. When signs begin, they usually have an acute onset and follow a rapid, usually violent course. Significant cardiac arrhythmias with rapid, weak pulse and eventual ventricular fibrillation are typical findings. Horses may exhibit staggering, trembling, restlessness, urination, and defecation. Moaning and bruxism may occur along with profuse sweating and signs of colic. Terminal convulsions also may occur. Ventricular fibrillation is the cause of death, and some horses may be found dead with no outward signs of struggle.<sup>7,20</sup>

### PATHOPHYSIOLOGY

Fluoroacetate is absorbed readily from the gastrointestinal tract, lungs, or open wounds but not through intact skin. After absorption, fluoroacetate is distributed throughout the body and does not accumulate in any specific tissue. The acute oral LD<sub>50</sub> of fluoroacetate in horses is 0.35 to 0.55 mg/kg.<sup>7</sup>

After entry into cells, fluoroacetate can replace acetyl coenzyme A, combining with oxaloacetate to form fluorocitrate. Fluorocitrate then competes with citrate for the active site of aconitase, a Krebs cycle enzyme, and also inhibits succinate dehydrogenase, which catalyzes succinate metabolism. The inhibition of these two enzymes and the subsequent accumulation of citrate block the Krebs cycle, leading to decreased glucose metabolism, energy stores, and cellular respiration. These actions occur in all cells, but organs with high metabolic rates (e.g., brain, gastrointestinal tract, and heart) are affected most severely.<sup>5,7,20</sup>

The short latent period between ingestion and onset of signs occurs because fluoroacetate must be converted to the more toxic fluorocitrate. The accumulation of toxic levels of fluorocitrate therefore requires some time.<sup>20</sup>

### DIAGNOSIS AND TREATMENT

Diagnosis of fluoroacetate toxicity must rely heavily on history of potential exposure, compatible clinical signs, and absence of other pathologic findings. Laboratory detection of these

compounds can be difficult, but suspect baits, stomach contents, liver, kidney, and urine are the best samples to submit for evaluation.<sup>7,20</sup> Significantly increased kidney citrate levels suggest 1080 toxicity.<sup>7</sup>

Laboratory abnormalities in affected animals might include hyperglycemia and lactic acidemia.<sup>20</sup> However, these findings are inconclusive and accompany many disease states in the horse.

Therapy is largely supportive and apparently unrewarding in horses already showing signs of toxicity. The practitioner may attempt intestinal decontamination using orally administered mineral oil and activated charcoal. If hypocalcemia develops, calcium gluconate or calcium chloride may be administered. Glycerol monoacetate at 0.1 to 0.5 mg/kg, administered intramuscularly with treatments repeated hourly, has been suggested but may not be effective after onset of clinical signs.<sup>4,20</sup>

### TOXICOSES CAUSING SIGNS RELATING TO THE EPITHELIUM, SKELETAL SYSTEM, AND GENERAL BODY CONDITION

Toxicoses causing these clinical signs can be among the most difficult to diagnose. Signs often are mild or moderate and quite nonspecific. In some cases the history is nonspecific, and the possibility of exposure to a toxin is difficult to evaluate.

## ☞ PLANTS

### BLACK WALNUT (*JUGLANS NIGRA*)

Ingestion of shavings and aqueous extracts from black walnut trees is responsible for a toxic syndrome in horses characterized by acute onset of laminitis and variable degrees of limb edema.<sup>1-3</sup>

#### CLINICAL SIGNS

Horses begin showing signs of toxicity within 10 to 12 hours of being bedded with black walnut shavings. The primary signs are those of laminitis and include reluctance to move, shifting weight from limb to limb, increased digital pulse and temperature of the hoof, and positive response to hoof testers. The laminitis may vary from mild to severe.<sup>1-3</sup> Another characteristic finding is that of limb edema, which can become pronounced. Additional signs noted may include increased respiratory rate with flared nostrils, anorexia and lethargy, and abdominal pain.<sup>2</sup> Horses removed from the bedding after clinical signs have developed have a good prognosis for full recovery.<sup>1,2</sup>

#### PATHOPHYSIOLOGY

The toxic principle involved in this toxicosis is unidentified. Juglone, a naphthoquinone found in roots, bark, and nuts of black walnut trees, was suggested in the past to be the causative agent.<sup>1-3</sup> Further work has shown, however, that an aqueous soluble toxin other than juglone that is found in the heartwood is more likely to be responsible for generation of clinical signs.<sup>3</sup> The mechanism of action of this soluble toxin

has not been elucidated fully, but it has been shown to reversibly enhance vasoconstriction of isolated digital vessels in vitro induced by administration of epinephrine potentiated with hydrocortisone.<sup>4</sup>

#### DIAGNOSIS AND TREATMENT

Diagnosis of black walnut-induced laminitis is based primarily on known exposure to shavings containing the plant and subsequent development of clinical signs. The treatment of laminitis is covered elsewhere in this text, but horses have a good prognosis for recovery if they are removed from the offending bedding. Black walnut shavings should not be used as bedding for horses.

### WILD JASMINE (*CESTRUM DIURNUM*)

*Cestrum diurnum* (wild jasmine, day cestrum, day-blooming jessamine, king-of-the-day, Chinese inkberry) is a tropical to subtropical plant native to the West Indies that has been introduced and cultivated widely as an ornamental in warmer parts of the United States, including Florida, Texas, and southern California. The plant grows rapidly from seeds, and birds may contribute to its spread because of their appetite for ripe berries that contain seeds. The plant is naturalized in Hawaii and India. It also tends to multiply along fence rows, on roadsides, and in neglected pastures and fields. Horses show signs of disease after ingestion of the plant for several weeks to months.<sup>5</sup>

#### CLINICAL SIGNS

Affected horses show signs primarily of weight loss and lameness. Weight loss occurs over several weeks to months in spite of normal appetite. Lameness usually is of increasing severity and may begin with signs of generalized stiffness. Eventually, the fetlock joints may become overextended, and horses may exhibit kyphosis. The flexor tendons and particularly the suspensory ligament become sensitive to palpation. The lameness may grow so severe that euthanasia becomes necessary.<sup>5</sup> Signs of renal failure also may become evident in isolated cases.

#### PATHOPHYSIOLOGY

*Cestrum diurnum* and certain other members of the Solanaceae family contain a potent steroid glycoside with vitamin D-like activity. The toxic agent is a 1,25-dihydroxycholecalciferol (1,25[OH]<sub>2</sub>D<sub>3</sub>) glycoside found in the leaves of the plant.<sup>6,7</sup> Normally, vitamin D<sub>3</sub> is acquired from the diet or is produced in the skin by a reaction dependent on ultraviolet light. Vitamin D<sub>3</sub> is hydroxylated in the liver to yield 25-hydroxycholecalciferol, which subsequently is hydroxylated in the kidney to 1,25(OH)<sub>2</sub>D<sub>3</sub>. This compound is the most active form of the vitamin and acts to increase calcium absorption and stimulate production of calcium-binding protein in the intestine.<sup>6</sup>

The normal rate of production of 1,25(OH)<sub>2</sub>D<sub>3</sub> is regulated by a negative feedback mechanism. Calcium or phosphorus deprivation stimulates the production of 1,25(OH)<sub>2</sub>D<sub>3</sub>, and a decreased rate of production occurs when calcium or phosphorus is present in adequate amounts.<sup>6</sup>

This natural feedback mechanism is bypassed when 1,25(OH)<sub>2</sub>D<sub>3</sub> is supplied exogenously, as in the case of ingestion of *C. diurnum*. As a consequence, excessive calcium-binding protein is synthesized in the intestine, and excessive amounts of calcium and phosphorus are absorbed. If the calcium load exceeds the capacity of the kidney to excrete it, soft tissue mineralization (dystrophic calcification) and osteopetrosis occur.<sup>6</sup>

In horses that have ingested toxic amounts of *C. diurnum*, calcification of the flexor tendons, suspensory ligament, and other elastic tissues appears to predominate over deposition of calcium into other soft tissues. Osteopetrosis is thought to result from sustained hypercalcemia and secondary elevation of calcitonin.<sup>5</sup>

### DIAGNOSIS AND TREATMENT

A diagnosis of toxicosis is suspected when horses exhibit signs of weight loss and lameness and they are known to have had prolonged access to *C. diurnum*. Affected horses typically are hypercalcemic, but serum phosphorus concentration usually is within a normal range. Renal dysfunction, if present, may be characterized by elevations in BUN and creatinine concentrations. Urine analysis may indicate an increased fractional excretion of sodium, potassium, and phosphorus, along with other laboratory findings associated with renal failure. Horses should be denied access to *C. diurnum* plants.

### HAIRY VETCH (*VICIA VILLOSA*)

One report of toxicosis suspected to result from ingestion of hairy vetch is described.<sup>8</sup> The affected horse was a 1-year-old crossbred female that required euthanasia because of severe weight loss and bilateral corneal ulceration with perforation.

The clinical signs reported were weight loss despite good appetite, fluctuating body temperature, subcutaneous swelling that started around the lips and spread to involve the rest of the body, and bilateral corneal ulceration with eventual perforation.

The only recorded abnormal laboratory findings consisted of elevated serum concentrations of LDH and AST measured 2 weeks after onset of clinical signs. Histologic lesions consisted of multifocal to diffuse granulomatous inflammation of the heart, lungs, kidneys, skin, lymph nodes, ileum, colon, skeletal muscle, and choroid.

The toxic substance has not been identified, and no specific therapy has been recommended. A similar toxic condition occasionally occurs in other livestock grazing hairy vetch, with most cases of toxicosis occurring between April and July.

### PHOTOSENSITIZING PLANTS

Many plants can cause photosensitive reactions in horses. Some plants contain photodynamic substances that are absorbed from the gastrointestinal tract intact or in a form metabolically altered into an active compound (primary photosensitizing plants). Other plants may cause photodermatitis after liver dysfunction, in which the photodynamic toxin is a metabolite normally excreted in bile (secondary photosensitivity). Because of hepatic damage induced by the plant, these metabolites enter the circulation, and subsequent interaction with light results in clinical manifestation of disease. Box 22-2 lists plants<sup>9-11</sup> known to induce photosensitization in herbivores.

### CLINICAL SIGNS

Signs of photosensitization are similar, regardless of the cause, and vary in degree. Factors that influence the severity of signs include the amount of reactive pigment present in the skin at a given time; the degree of exposure to light of appropriate wavelength; and the severity of hepatic damage, if hepatogenous photosensitization is the cause.<sup>11</sup>

#### BOX 22-2

### PLANTS INDUCING PHOTOSENSITIZATION IN HERBIVORES

#### Primary Photosensitizers

*Ammi majus* (bishop's weed): contains furocoumarins  
*Avena fatua* (oatgrass)  
*Brassica* (rape)  
*Cooperia pedunculata*  
*Cymopterus watsonii* (spring parsley): contains furocoumarins  
*Erodium* (trefoil)  
*Fagopyrum sagittatum* (buckwheat): contains the naphthodi-anthrone derivative fagopyrin  
*Hypericum perforatum* (St. John's wort, Klamath weed): contains the naphthodianthrone derivative hypericin  
 Perennial ryegrass  
*Ricinus communis* (castor bean)  
*Rutaceae*  
*Trifolium* (clover)  
*Umbelliferae*

#### Secondary or Hepatogenous Photosensitizers

Agave lecheguilla (lecheguilla)  
 Blue-green algae  
*Brachiaria brizantha*  
*Brassia hyssopifolia*  
*Brassica napus* (cultivated rape)  
*Holocalyx glaziovii*  
*Lantana* spp.  
*Lippia rehmanni*  
*Myoporum laetum* (ngaio)  
*Narthecium ossifragum* (bog asphodel)  
*Nolina texana* (sacahuiste)  
*Panicum* spp. (panic grass, kleingrass)  
*Pithomyces chartarum* and *Periconia minutissima*  
*Senecio* spp. (ragwort, groundsel)  
*Tetradymia canescens* (gray horsebrush)  
*Tetradymia glabrata* (spineless horsebrush)  
*Tribulus terrestris* (puncturevine)

#### Other Photosensitizers

*Avena* (oats)  
*Euphorbia maculata* (milk purslane)  
*Kochia scoparia* (summer cyprus, fireweed)  
*Medicago* (alfalfa)  
*Polygonum* spp. (smartweed)  
*Sorghum vulgare* (Sudan grass)  
*Trifolium* (clover)  
*Vicia* spp. (vetches)

Restlessness and discomfort usually are the first evident signs. Erythema may be apparent, followed by edema of affected areas. Blister formation and subsequent serum exudation and scab formation occur as the condition progresses. Affected sites usually are painful when touched, and animals often attempt to protect themselves from direct sunlight.<sup>9,11</sup>

The light-colored or nonpigmented areas of skin are affected most severely, particularly the face, nose, back, escutcheon, and coronary band. Severely affected animals

also may have involvement of pigmented areas of skin, and secondary self-trauma and bacterial infection may arise from attempts to rub the affected areas. Horses may lose patches of skin that slough in large, leathery plaques.<sup>9,11</sup>

### PATHOPHYSIOLOGY

Plants causing primary photosensitization contain a photodynamic agent that is absorbed from the gastrointestinal tract intact or that is later metabolically altered into an active compound. Secondary photosensitizing plants induce hepatic damage of sufficient magnitude to inhibit adequate clearance of photodynamic agents. Normally, these photodynamic toxins are metabolites excreted in bile. When the liver is damaged sufficiently or bile flow is hindered, these metabolites enter the circulation. Phylloerythrin, a normal chlorophyll breakdown product, is considered the only important photodynamic substance in instances of secondary photosensitization.<sup>12</sup> These photodynamic agents then are circulated throughout the body, eventually reaching the dermal capillaries.

Interaction of long-wave ultraviolet light with these photodynamic agents circulating in the skin capillaries results in chemical excitement of these substances. As a consequence, free radicals form that are highly inflammatory and cause degradation of cell phospholipid membranes, polypeptide proteins, and nucleic acids.<sup>9,13</sup> These processes disrupt the cells and ultimately result in the dermal lesions noted with this toxicity.

### DIAGNOSIS AND TREATMENT

Clinical signs of photosensitivity are fairly typical and seldom are confused with other afflictions of skin. When clinical signs become evident, the horse should be evaluated thoroughly for evidence of hepatopathy because primary and secondary photosensitivity produce the same clinical signs. If hepatic disease is present, the clinician should ascertain the cause and institute appropriate therapy.

Primary photodynamic agents can be identified with several biologic assay systems, but this is rarely done. A mouse assay system and a microbial assay using *Candida albicans* are available for this purpose.<sup>9</sup>

Specific therapy for photodermatitis is not available. Horses should be removed from direct sunlight until skin lesions are healed and the offending plant is removed from the environment. Various topical agents may be used to facilitate skin healing. Superficial bacterial dermatitis should be treated with appropriate antibiotics, and NSAID therapy may be beneficial during the initial stages of the disease process.

## TALL FESCUE (*FESTUCA ARUNDINACEA*)

The causative agent of the disorder associated with grazing tall fescue is *Neotyphodium coenophialum*<sup>14</sup> (formerly identified as *Acremonium coenophialum*), a fungal endophyte that grows within the stem, leaf sheaths, and seeds of tall fescue.<sup>15,16</sup> This endophyte is highly indigenous to many areas of the United States and may contaminate as much as 90% of fescue pastures in certain geographic areas.<sup>15</sup>

### CLINICAL SIGNS

Horses grazing or being fed tall fescue hay preparations may develop a condition termed *summer slump* or *summer syndrome*.<sup>9,17</sup> The disorder is characterized by anorexia, weight loss, poor hair quality, pyrexia, and hypersalivation. Additionally, mares may sustain a variety of pregnancy- and

reproduction-related disorders. Typical findings include the presence of a thick, tough placenta; prolonged gestation; abortion; birth of dead or weak foals; and high perinatal foal mortality.<sup>18</sup> Mares frequently are affected with agalactia, retained placenta, and rebreeding difficulties as well.<sup>9,13,15</sup>

### PATHOPHYSIOLOGY

The fungus produces multiple toxins, including peramines, lolines, and ergopeptine alkaloids. Peramines have no apparent effect on animal health, but the lolines (N-acetyl loline and N-formyl loline) present in *Neotyphodium* are pyrrolizidine alkaloids. However, the hepatotoxicity characteristic of pyrrolizidine alkaloids has not been observed with tall fescue toxicosis in any species.<sup>16</sup>

The ergopeptine alkaloids appear to be responsible for most of the abnormalities associated with fescue toxicosis. Ergotamine, ergosine, ergovaline, ergoine, ergocristine, ergocryptine, and ergocornine have been isolated, but ergovaline and ergosine are most prominent. Ergovaline is thought to account for 84% to 97% of the ergopeptine concentration of infected tall fescue. The concentration of ergot alkaloids in tall fescue tends to increase with nitrogen fertilization and drought stress, and toxicity varies from season to season and year to year depending on the percentage of endophyte present, drought stress, nitrogen fertilization, and probably other factors.<sup>16</sup>

Agalactia occurs for a variety of reasons. First, ergopeptines are dopamine D<sub>2</sub>-receptor agonists, and dopamine is thought to be the major inhibitor of prolactin secretion in the body. Second, ergot alkaloids inhibit adrenocorticotrophic hormone secretion, resulting in reduced fetal cortisol concentration that subsequently causes reduced progesterone secretion by the placenta. Third, these alkaloids decrease tissue binding of estradiol, which can lead to an elevated serum concentration of estradiol-17β<sup>16</sup> (normally, serum estradiol concentrations decline near parturition). The interaction of appropriate levels of prolactin, progesterone, and estradiol-17β plays a major role in preparing the mammary gland for lactation. The combination of reduced concentrations of prolactin and progesterone and elevated concentration of estradiol-17β likely is the major cause of the agalactia and impaired udder development in affected mares.

The gestation period may be prolonged because ergopeptines have been hypothesized to block corticotropin-releasing hormone activity in the foal, which results in a lack of fetal production of adrenocorticotrophic hormone and cortisol. Because increased fetal cortisol concentration acts to signal the mare for parturition, lack of fetal production of corticotropin-releasing hormone, adrenocorticotrophic hormone, and cortisol may contribute to extended gestation periods in affected mares.<sup>16</sup>

The placental abnormalities frequently noted have been suspected to be associated with vasoconstriction. Edema, fibrosis, and mucoid degeneration of arteries in placentae from affected mares have been observed.<sup>17</sup> These changes were thought to be consistent with anoxia, which was hypothesized to be associated with vasoconstriction. Ergovaline and N-acetyl loline, which are present in infected fescue, have vasoconstrictive properties.<sup>16</sup>

Ergot alkaloids also may have a negative effect on fertilized ovum implantation in the endometrium, resulting in reduced reproductive efficiency of affected mares. In the mare the effects of ergopeptines on implantation are inconclusive, but ergocryptine, ergocornine, ergosine, and ergovaline are capable of interrupting early pregnancy in the rat.<sup>16</sup>

Foals born alive to affected mares may be hypothyroid, although the mechanism responsible for this is unknown.<sup>18</sup> High perinatal foal mortality probably also is influenced byagalactia and poor colostrum antibody production by the mare, resulting in failure of passive transfer with associated septicemia and failure of the foal to thrive.<sup>16</sup>

### DIAGNOSIS AND TREATMENT

Diagnosis often is empiric, based on clinical signs and access to fescue pasture or hay during late gestation. Affected mares typically have reduced serum concentrations of prolactin and progesterone and elevated levels of estradiol-17 $\beta$ . Reduced-serum concentrations of triiodothyronine, adrenocorticotropic hormone, cortisol, and total progestogens may be present in affected foals. Hay and pasture samples also may be evaluated for the presence of endophytes and ergovaline.<sup>16</sup>

Treatment of gravid mares past their foaling date should include removal from fescue as quickly as possible. Domperidone given orally once daily at 1.1 mg/kg during the last 15 days of gestation may be efficacious in helping establish udder development and lactation. Postfoaling mares may benefit from domperidone (1.1 mg/kg orally) administered once daily for several days in an attempt to stimulate milk production.

Prevention requires removing mares from fescue pasture or hay during late gestation. In one study fescue removed from the diet at 300 days of gestation was not associated with any problems in mares.<sup>17</sup> Thus the most critical time for exposure to infected fescue in pregnant mares seems to be during the last 30 days of pregnancy. Local or regional authorities can provide important information regarding current methods of managing infected pastures.

### HOARY ALYSSUM (*BERTEROA INCANA*)

Toxicosis in horses related to ingestion of hoary alyssum was first reported in 1992.<sup>19,20</sup> This plant is a member of the Cruciferae (mustard) family and can behave as an annual, biannual, or perennial. Hoary alyssum grows primarily in the northeastern and northcentral United States and Canada but also is reported in the states of Oklahoma, Washington, Oregon, Idaho, and California and in Europe. The plant tends to flourish under conditions of drought, frost, and overgrazing and in areas of poor soil.<sup>20,21</sup> Toxicity has been reported in horses grazing contaminated pasture, eating plant-contaminated hay, and being fed oats containing hoary alyssum seed.<sup>19-22</sup> Reported cases are more prevalent during summer months after ingestion of recently cut hay, but toxicosis has resulted from feeding hay stored for 9 months.<sup>20</sup>

#### CLINICAL SIGNS

Not all horses exposed to hoary alyssum develop clinical signs of toxicosis. An estimated 45% of horses exposed to the plant under field conditions did not develop any signs of illness. However, the most common clinical signs observed under field and experimental conditions were varying degrees of fever, edema of one to four limbs, and laminitis. Horses affected with laminitis rarely are reported to develop rotation of the distal phalanges. These signs typically commence within 24 hours of ingestion (although this varies depending on the amount of plant material ingested) and in most cases subside within 2 to 4 days after removal of the source.<sup>20</sup> Other signs noted have been lethargy, short-term diarrhea, and abdominal discomfort.<sup>21</sup> Early parturition and abortion are rare occurrences

in pregnant mares.<sup>19,21</sup> Rarely, individual horses are affected more severely and exhibit clinical signs of endotoxemia, hypovolemic shock, acute renal failure, and ventral rotation of the distal phalanges. Death can occur in these horses.<sup>20,22</sup>

Pregnant mares may be more susceptible to toxicity and develop more severe clinical signs, however. In one report 23 of 29 broodmares developed signs of fever, tachycardia, tachypnea, distal limb edema, and mild to severe laminitis.<sup>21</sup> Of these mares 15 subsequently developed moderate to profuse bloody diarrhea, dehydration, abdominal pain, hematuria, and oliguria. Four of these mares were euthanized, and two had necropsy findings of hemoperitoneum, hemothorax, and ventral rotation of distal phalanges. Three of the mares aborted spontaneously, but no abnormalities were noted in the placentae or fetuses.

### PATHOPHYSIOLOGY

The toxic agent in hoary alyssum remains unknown,<sup>20</sup> as does the mechanism of action of the toxic substance (or substances). However, red blood cell destruction appears to occur by way of hemolysis or some other mechanism.<sup>20,21</sup> No consistent laboratory abnormalities have been noted in an experimental feeding trial and in most field cases.<sup>20</sup> However, laboratory findings in more severely affected horses include significant red blood cell hemolysis; elevations in serum concentrations of creatinine, urea nitrogen, phosphorus, alkaline phosphatase, AST, CK, sorbitol dehydrogenase, and total bilirubin; neutropenia; proteinuria; hematuria; hemoglobinuria; and occult blood in feces and gastric fluid.<sup>20-22</sup> Which of these abnormalities are the direct result of the toxin and which result from physiologic deterioration of various organs is unknown.

### DIAGNOSIS AND TREATMENT

A diagnosis is suspected on the basis of history of exposure to the plant and clinical signs. No specific therapy is indicated, but horses immediately should be denied access to the plant, and all contaminated hay and grain should be removed. One should initiate symptomatic treatment with fluids, NSAIDs, and gastrointestinal tract evacuation. Activated charcoal (1 to 3 g/kg administered through a nasogastric tube) has been suggested to help prevent absorption of the unknown toxin.<sup>22</sup> Intravenous DMSO should be used with caution because it has the potential to cause intravascular hemolysis, thereby compounding the red blood cell destruction caused by the toxin.<sup>20,22</sup> Most horses recover uneventfully in 2 to 4 days after removal of the plant and provision of supportive care.

## ☪ MISCELLANEOUS AGENTS

### IODINE

Iodine toxicosis or iodism is a rarely reported cause of toxicosis in horses. When iodism occurs, it most likely is caused by iatrogenic administration of iodine-containing substances. Many rations contain iodine in the form of various iodized salts, and sodium iodide and potassium iodide, along with the organic iodide compound ethylenediamine dihydroiodide, are used to treat various medical conditions.<sup>9,23</sup>

#### CLINICAL SIGNS

Nonpruritic generalized alopecia and diffuse scaliness of the skin were reported in a horse given 45 g of ethylenediamine dihydroiodide twice daily for 14 days.<sup>24</sup> Other reported clinical signs include goiter after excessive iodine intake, increased

secretions of the respiratory tract, nasal discharge, intermittent nonproductive cough, and excessive lacrimation.<sup>9,12,24</sup> Pregnant mares receiving excessive amounts of iodine may produce weak foals with enlarged thyroid glands. Such foals have a high mortality rate.<sup>9</sup>

### PATHOPHYSIOLOGY

Organic and inorganic forms of iodine are absorbed rapidly and almost completely from the gastrointestinal tract in the ionic form and are distributed throughout the body. Iodine is excreted primarily in the urine, but smaller amounts are present in feces, sweat, and milk.<sup>12,23</sup> The only known metabolic role of iodine is involvement in synthesis of the thyroid hormones thyroxine and triiodothyronine.<sup>12</sup>

Oral iodine salts, whether organic or inorganic, taken in higher doses stimulate nerve receptors in the stomach wall. Subsequently, the vagus nerve becomes stimulated and causes reflex secretion by cells in the upper respiratory tract.<sup>12,25</sup> Excessive iodine intake causes thyroidal organic iodine formation to increase to a maximal amount, and then a sharp decline in organic iodine formation occurs. Excessive iodine also inhibits release of organic iodine from the thyroid gland if the gland is stimulated by thyroid-stimulating hormone. The net results are clinical signs of increased amount and viscosity of respiratory tract secretions and occasional goiter development.<sup>25</sup> The mechanism underlying the development of the dermal lesions associated with iodism is unknown.<sup>24</sup>

### DIAGNOSIS AND TREATMENT

Diagnosis of iodism is based on a history of exposure to high levels of iodine for a prolonged time coupled with compatible clinical signs of nasal discharge and excessive lacrimation, intermittent nonproductive cough, and nonpruritic generalized alopecia and scaling. Serum iodine concentrations, which are elevated in cases of iodism, can be measured, but blood levels decrease rapidly to near background levels within a few days if iodine exposure ceases.<sup>12</sup> Serum concentrations of thyroxine and triiodothyronine may be below normal reference values in affected horses.<sup>24</sup>

Treatment consists of removing the source of the iodine. Because iodine is mobilized rapidly and excreted from tissues, clinical signs usually subside rapidly when excessive iodine is removed.<sup>12,23,24</sup>

### SNAKE VENOM

The venomous snakes in North America belong to the families Crotalidae (pit vipers), Elapidae (cobra), and Viperidae (true vipers). Most poisonous snakebites reported in human beings are inflicted by members of the Crotalidae family, and the same is probably true for horses as well. Of this family *Crotalus* (rattlesnakes), *Agkistrodon* (copperhead, cottonmouth), and *Sistrurus* (pigmy rattlesnake, massasauga) are the three genera most commonly involved in snakebites of livestock. The eastern coral snake (*Micrurus fulvius*) and the Arizona coral snake (*Micruroides euryxanthus*) are two members of the Elapidae family indigenous to the United States, but they account for only about 3% of poisonous bites reported in human beings.<sup>9,26</sup>

Venom injected into prey is an aid to digestion and greatly reduces the time for complete digestion to occur in the snake. The amount of venom injected at a given time is under voluntary control, and larger amounts are injected into larger prey or when the snake strikes for defensive purposes. Not all bites

result in envenomation, and rattlesnakes are estimated to fail to inject venom in up to 20% of bites.<sup>9,26</sup>

Snake venom is a highly complex mixture of enzymes, lipids, biogenic amines, free amino acids, metal ions, proteins, and polypeptides. Most snake venoms contain up to 25 different fractions, yet many of them are not yet identified. Venom composition and toxic properties vary among *Crotalus* species and among individuals of the same species. Factors influencing venom composition include age, time from last feeding, and seasonal influences related to changes in feeding patterns or physiologic responses such as hibernation. The LD<sub>50</sub> in mice exposed to venom of *Crotalus* species ranges from 0.23 mg/kg for the Mojave rattlesnake (*Crotalus scutulatus*) to 3.77 mg/kg for the red diamond rattlesnake (*Crotalus ruber ruber*). The LD<sub>50</sub> for mice for the copperhead (*Agkistrodon contortrix*) and cottonmouth (*Agkistrodon piscivorus*) is 10.92 mg/kg and 4.17 mg/kg, respectively.<sup>26</sup> This large variation in dose and chemical composition of venom accounts for the extreme amount of variation in the physiologic responses of animals to these substances.

### CLINICAL SIGNS

Snakebites in horses are most common on or near the muzzle, but bites also may occur on the limbs or other parts of the body. The classic signs noted in most horses are acute onset of swelling and edema at the bite site. The muzzle and nasal passages may become swollen to the extent that respiration can become extremely labored, necessitating a tracheotomy. Epistaxis also may be apparent. Initially, fang marks may be evident, but they soon disappear with the onset of extensive swelling. Skin discoloration at the injection site is a common occurrence with many rattlesnakes but rarely occurs with copperhead and Mojave rattlesnake bites.<sup>9</sup> Varying degrees of necrosis of local tissue may occur, as well as secondary bacterial infections at the wound site. In the author's experience, bites involving the distal extremities of horses frequently have a prolonged convalescent period that may be accompanied by residual lameness.

Systemic manifestations of snake envenomation may be apparent when venom is injected intravascularly or perivascularly. In a retrospective study of rattlesnake venom poisoning in 32 horses, manifestations included fever, tachycardia, tachypnea, cardiac arrhythmia, hemolytic anemia, thrombocytopenia, hemorrhage, thrombosis of venipuncture sites, colic, diarrhea, and prehensile and masticatory dysfunction. Chronic problems included cardiac disease, pneumonia, lamiinitis, pharyngeal paralysis, and wound complications. The most common chronic problem observed in these horses was cardiac disease.<sup>27</sup> Labored respiration may result from pulmonary edema caused by passive congestion after vascular hypotension or precipitation of pulmonary emboli. Muscle fasciculation may be evident.<sup>9</sup> The venom of the Mojave rattlesnake produces respiratory paralysis that may result in death in human beings.<sup>26</sup> The overall mortality rate in 32 horses acutely affected with bites of prairie rattlesnake was 25%.<sup>27</sup>

The venom of coral snakes produces neurologic signs in affected human beings, with death occurring within 24 hours as a result of respiratory depression, hypotension, and cardiovascular collapse.<sup>26</sup> However, the coral snake requires prolonged contact (30 seconds or longer) to work the venom into the skin of its prey. Therefore it seems improbable that horses would become exposed to coral snake venom except under extremely unusual circumstances.

## PATHOPHYSIOLOGY

The venoms of Crotalidae are rich in enzymes. Proteases cause severe tissue damage by digesting tissue proteins and peptides, and hyaluronidase allows rapid spread of venom through tissue by hydrolyzing connective tissue hyaluronic acid. L-Amino acid oxidase, L-arginine ester hydrolases, and 5'-nucleotidase also may contribute to tissue destruction. Phospholipases A, B, C, and D hydrolyze lipids and cause hemolysis by destroying lecithin in the red blood cell membranes. They also disrupt neurotransmission at the presynaptic and postsynaptic junctions. Other enzymes present in crotalid venom include ribonuclease, deoxyribonuclease, transaminase, phosphomonoesterase, phosphodiesterase, ATPase, DNAase, alkaline phosphatase, acid phosphatase, and endonuclease.<sup>26</sup>

Crotalid venom contains a number of polypeptides in addition to the enzymes. These polypeptides are low-molecular-weight proteins that are 5 to 20 times more lethal than crude venom in animal models, and they do not have enzymatic activity. They are present in higher concentrations in cobra venom than in rattlesnake venom and are mainly responsible for blood dyscrasias and coagulopathies. Small peptides are partly responsible for the generation of disseminated intravascular coagulation, and a venom fraction of the timber rattlesnake (*Crotalus horridus horridus*) causes platelet aggregation with resultant thrombocytopenia. Additionally, the venoms of the Mojave and Southern Pacific rattlesnakes contain a direct cardiotoxin.<sup>26</sup>

Rattlesnake venom contains substances with anticoagulant, procoagulant, and plasminogen-induced fibrinolytic properties. The coagulopathy that occurs in a given instance varies and depends on the content of the various venom components and on the dose of venom injected. The anticoagulant activity of crotalid venom appears to result from reversible binding of venom to prothrombin. Thrombinlike enzymes produce hypofibrinogenemia and increased concentration of FDPs. They also are capable of directly converting fibrinogen to fibrin, which may result in excessive fibrin formation and rapid disseminated intravascular coagulation. The fibrinolytic characteristics of crotalid venom occur directly or indirectly through the activation of endogenous plasminogen.<sup>9,26</sup>

## DIAGNOSIS AND TREATMENT

Diagnosis of snakebite usually depends on clinical signs and accessibility to poisonous snakes. Laboratory abnormalities that may be present in affected horses include thrombocytopenia, hypofibrinogenemia, anemia, prolonged PT and PTT, hematuria, proteinuria, and myoglobinuria.<sup>9,26</sup>

Affected horses should be kept calm and quiet. Incision over the fang marks and suction are rarely indicated and probably of minimal value except in the immediate time frame of the bite, because the venom is absorbed almost immediately into the surrounding tissues. Tracheotomy is indicated in those horses that develop excessive edema and swelling of the head and external nares to the point that respiration becomes impaired. Topical cold therapy may have some beneficial effect if applied early and for short periods. Prolonged or excessive cold application, however, may enhance further tissue necrosis. Antivenom therapy commonly is used in instances of human snakebite but often is considered unnecessary in horses because of the low mortality rate, financial considerations, and availability of other therapies. An exception may be the horse or foal that is extremely valuable.

The clinician should initiate tetanus prophylaxis and systemic antibiotic therapy. Broad spectrum antimicrobial drugs should be used because gram positive and gram negative organisms are found in the mouth of North American pit vipers. The most common organisms isolated include *Proteus vulgaris*, *Escherichia coli*, *Corynebacterium* spp., *Streptococcus* spp., and Enterobacteriaceae.<sup>26</sup>

NSAIDs should not be used during the early stages of the bite wound because they may enhance the defects in primary hemostasis frequently induced by snake venom. NSAIDs may be used in the later stages of the disease to help reduce pain, swelling, and inflammation. Corticosteroids should be used with caution because they may diminish the clearance of FDPs from the peripheral vasculature by the reticuloendothelial system, and they may increase susceptibility to wound infection at the site. Corticosteroids may be beneficial, however, in treating severe hypotensive shock in young animals or in patients with intravenous envenomation. Heparin therapy also has been suggested to be helpful in instances of thrombus formation.<sup>9</sup>

Animals affected with systemic hypotension and cardiac dysrhythmias should be treated appropriately. Treatment may include the administration of intravenous fluids and plasma and the use of specific antiarrhythmic medications.

## FLUORIDE

Fluoride toxicosis in horses appears to be a rare event.<sup>28</sup> Although acute and chronic fluoride toxicosis have been described in various animals, chronic fluorosis appears more common. Common sources of fluoride in chronic fluorosis include forages subjected to airborne contamination from nearby industrial plants such as aluminum smelters, steel mills, or fertilizer plants that heat fluorine-containing materials and discharge fluorides; drinking water containing excessive fluoride; feed supplements and vitamin and mineral additives with high fluoride concentration; and vegetation grown on soils containing high fluoride levels.<sup>12</sup>

Animals normally ingest small amounts of fluoride throughout their lives, and it accumulates in the body as long as constant or increasing amounts are ingested. Chronic toxicosis can result from prolonged ingestion of sufficiently high levels. The long-term dietary tolerance for fluoride in the horse is reported to be 40 to 60 ppm dietary fluoride.

Fluoride is absorbed almost totally from the gastrointestinal tract. Once absorbed, approximately half is excreted rapidly in urine, with the remaining half being stored in bone and teeth. Fluoride accumulates in calcified tissues, but once exposure ceases, bone fluoride is depleted slowly over months to years.

## CLINICAL SIGNS

Chronic fluorosis in the horse is a rare event. In one suspected case the affected horse exhibited chronic weight loss of months' duration; poor growth; difficulty in mastication; and deformed, discolored, and absent deciduous incisors. The horse also was missing some deciduous premolars and molars.<sup>28</sup> Classic dental abnormalities reported in other species include mottled, hypoplastic enamel and brown discoloration with uneven wear of teeth.<sup>12</sup> Additional signs associated with chronic fluorosis in other animals include hyperostosis, enlargement and roughening of involved bones, intermittent lameness and generalized stiffness, dry and roughened hair

coat, and decreased weight and milk production.<sup>28</sup> Because of the insidious nature of chronic fluorosis, it is important to remember that a time lag may occur between ingestion of excessive fluoride and the appearance of clinical signs.

### **PATHOPHYSIOLOGY**

Excessive fluoride produces dental abnormalities by affecting the teeth during development. The primary effect of fluorine is thought to be a delaying and alteration of normal mineralization of the pre-enamel, predentine, and precementum. High fluoride levels appear to cause specific ameloblastic and odontoblastic damage. The matrix laid down by these damaged cells fails to accept minerals normally, resulting in faulty mineralization of the tooth bud. Once the tooth is formed fully, the ameloblasts have lost their constructive ability and the enamel lesions cannot be repaired. However, odontoblasts can produce secondary dentine to compensate for deficiencies brought about by excessive fluoride.<sup>12</sup> The brown to black discoloration of affected teeth results from oxidation of organic material in the teeth.

The pathogenesis of bone lesions associated with fluoride toxicosis is still undecided. One theory is that high fluoride levels lead to inadequate matrix and defective, irregular mineralization of bone. Another theory is that hydroxyl radicals in the hydroxyapatite crystal structure are replaced by fluoride ions, resulting in a decrease in crystal lattice dimensions. The pathologic results of skeletal fluorosis include dissociation of normal sequences of osteogenesis, production of abnormal bone, accelerated remodeling of bone, and occasional accelerated bone resorption.<sup>12</sup>

### **DIAGNOSIS AND TREATMENT**

Diagnosis of chronic fluorosis is based primarily on clinical findings and history of possible exposure to fluorides. Fluorosis usually is confirmed by analysis of skeletal or dental tissues for fluoride content and evaluation of fluoride concentration in urine. Water and feed consumed by the animals also should be analyzed for fluoride content.

Treatment of chronic fluorosis aims mainly at dietary restriction of fluoride-containing substances. Aluminum sulfate, aluminum chloride, calcium aluminate, calcium carbonate, and defluorinated phosphate have been used to reduce the toxic effects of fluoride, but no substance completely prevents the toxic effects of ingesting excessive amounts of fluorides.

## **ZINC**

Excessive exposure to dietary zinc can be a problem for young, growing horses. Sources of excessive zinc usually are soil and forage contamination from nearby smelters and pastures that were topdressed with zinc oxide.<sup>29,30</sup> Classic signs of copper deficiency associated with excessive zinc ingestion have been produced by experimental feeding of excessive zinc to young foals.<sup>31,32</sup> Skeletally mature horses do not appear to be susceptible to the effects of zinc-contaminated pastures.<sup>32</sup>

### **CLINICAL SIGNS**

Signs associated with zinc-induced copper deficiency include swelling at the physeal region of long bones, gradual onset of lameness and stiffness that may become so severe that affected animals are reluctant to rise from lateral recumbency, swollen joints resulting from synovial effusion, unthriftiness, and weight loss despite normal appetite.<sup>29-31</sup> Anemia also may develop in more chronically affected individuals.<sup>31</sup> The joint

swellings in affected horses are typical of those of osteochondrosis desiccans, and severe generalized osteochondrosis also develops in copper deficient horses.<sup>29,30,32</sup>

### **PATHOPHYSIOLOGY**

In horses this disease actually appears to be a manifestation of copper deficiency and the subsequent development of hypocupremia-induced articular cartilage disease.<sup>29,32</sup> Copper is an essential cofactor for lysyl oxidase, an enzyme involved in the formation of collagen cross-links. Copper deficiency interferes with collagen metabolism and results in production of weak connective tissue. This allows articular cartilage fractures and growth physeal fractures to occur in the zone of hypertrophic cells, producing the clinical syndrome of osteochondrosis desiccans.

The mechanism of zinc-induced copper deficiency is not totally understood. Experimentally, affected foals at necropsy had high hepatic copper content despite low serum copper concentration, suggesting that the hepatic copper was not readily available for production of ceruloplasmin or could not be mobilized rapidly enough for use by other tissues.<sup>32</sup> Excessive zinc stimulates production of metallothionein, an intestinal cell protein that binds to excessive zinc, copper, and other divalent metal ions and facilitates their excretion in bile, feces, and saliva. Copper has a higher affinity for metallothionein than does zinc, and increased production of metallothionein, with subsequent binding to copper, may lead to copper deficiency through increased copper excretion.<sup>33</sup>

### **DIAGNOSIS AND TREATMENT**

Once signs of osteochondrosis develop, the condition should be appropriately treated. Diagnosis of excessive zinc intake may be difficult in that zinc is excreted rapidly after absorption, and blood and tissue zinc concentrations tend to decline quickly to normal levels with cessation of intake. Liver, kidney, and serum zinc concentrations can be measured, but fecal samples collected from affected horses may be more suitable. Feed and water supplies also can be evaluated for zinc content.<sup>34</sup>

Treatment of affected horses aims to restore proper copper concentration in the diet and remove the source of excessive zinc. Diets containing 7.7 mg copper per kilogram and 250 mg zinc per kilogram of dry weight were sufficient to maintain normal serum copper and zinc concentrations and did not induce disease in treated foals. Diets containing 1000 mg/kg or greater of zinc caused hypocupremia and subsequent osteochondrosis desiccans when fed to foals over a period of several weeks.<sup>32</sup> Osteochondrosis desiccans is treated surgically.

## **SELENIUM**

Selenium toxicity in horses usually results from prolonged ingestion of plants containing excessive amounts of selenium. Intoxication can result from horses foraging on soil with high levels of selenium and ingesting selenium-accumulating plants growing on soils with minimal amounts of selenium.<sup>34-37</sup> Acute toxicosis also can occur through inadvertent overdosing of selenium supplements added to rations or given by parenteral injection.<sup>38</sup> The acute single oral toxic dosage of selenium given as sodium selenite is between 3.3 and 6 mg/kg for the horse.<sup>34,39</sup>

### **CLINICAL SIGNS**

Three different syndromes are attributed to selenium intoxication: acute toxicity and two chronic forms described as "blind staggers" and "alkali disease." Signs of acute toxicity develop

within 6 hours of ingestion and include sweating, diarrhea, tachycardia, tachypnea, mild pyrexia, lethargy, and mild to severe colic. Death may occur within 24 hours, and some horses exhibit a dumb attitude before death. Head pressing before death is suggested as a classic sign of acute selenosis.<sup>34,39</sup>

Chronic selenium intoxication described as blind staggers results from frequent ingestion of plants over weeks to months. Signs associated with this syndrome include aimless wandering or circling, muscle weakness, incoordination, respiratory difficulty, and decreased vision. In classic cases blindness eventually develops and is followed by paralysis and death.<sup>40</sup> Some have hypothesized that blind staggers is not due to selenium at all but is actually polioencephalomalacia associated with excess sulfur intake.

Alkali disease, the more common presentation of selenosis in horses, results from ingestion of seleniferous plants, and signs may develop weeks to months after exposure. Initially, lameness and swelling of the coronary band regions are apparent, along with anorexia and mild depression. These signs progress to transverse cracking of the hoof wall distal to the coronary band with associated lameness. The hooves eventually may be sloughed. Loss of hair from the mane and tail occurs because the hairs become brittle and are broken easily. Compromised reproductive and immune function also may develop in affected horses.<sup>35-38</sup>

### PATHOPHYSIOLOGY

Selenium is absorbed readily from the gastrointestinal tract, but organic forms of selenium generally are retained in greater amounts than are inorganic forms. Elimination occurs rapidly through urine, sweat, feces, and exhaled air. The clinician also must recognize hoof and hair as routes of excretion because excess selenium is deposited in these structures.<sup>38</sup> This latter fact has important diagnostic implications.

Selenium functions in a number of enzymatic and physiologic processes. The toxic effects of selenium have been associated with its affinity for reacting with sulfur-containing amino acid residues such as cystine that are incorporated synthetically into biologically active glycoproteins and polypeptides. As a result, various selenosulfides are formed as a substitute for disulfide bonds.<sup>41</sup>

### DIAGNOSIS AND TREATMENT

A presumptive diagnosis of selenium intoxication can be made on the basis of typical clinical signs and history of possible exposure to selenium iatrogenically in the form of selenium supplementation or through ingestion of appropriate plants. The clinician can attempt to make a definitive diagnosis by assaying blood, serum, hair, and hoof material for selenium content. In acute fatal selenosis serum selenium concentration may exceed 1 ppm.<sup>34,39</sup> A selenium concentration greater than 5 ppm in hair and hoof wall is considered diagnostic of selenosis.<sup>34,35,37</sup> It also is possible to measure selenium concentration in liver and kidney samples.

Treatment of affected horses involves removal of the selenium source, symptomatic treatment of lesions, and provision of good nursing care. Oral dosing of naphthalene at 4.5 g/day for 5 days, waiting 5 days, and then repeating the dose for an additional 5 days has been suggested for treatment of adult horses; however, this is not commonly done, and its efficacy is questionable.<sup>34,35</sup> Prevention of selenosis has been attempted by adding copper,<sup>38</sup> methionine,<sup>42</sup> or sodium arsenite<sup>34,35</sup> to the diet of at-risk animals.

## GANGRENOUS ERGOTISM (*CLAVICEPS PURPUREA*)

*Claviceps purpurea* is a fungal parasite that invades the developing ovary of the grass flower and cereal grains. This fungus commonly parasitizes rye, oats, wheat, and Kentucky bluegrass, which are associated most often with outbreaks of gangrenous ergotism. The fungus replaces the seed ovary with a dark brown to purple oblong body called a *sclerotium*. Sclerotia are slightly larger than the original whole grain seed, and their growth is promoted by warm, moist conditions. Horses rarely are affected by this condition, in part because of the distasteful nature of affected feedstuffs and because most fungal elements are removed during commercial grain processing procedures.<sup>12,13</sup>

### CLINICAL SIGNS

Signs of intoxication may become apparent if infected feeds are ingested over several days to weeks. Dry gangrene of the extremities is the classic sign associated with *C. purpurea* toxicosis and can affect the limbs, nose, ears, and tail. Early signs of toxicosis are lameness and cool extremities. The hindlimbs often are affected first, with swelling and tenderness in the fetlock area. The involved tissues become dark and discolored, and a transverse line of demarcation may occur between normal skin and the distal parts of the limb. Eventually, the hoof and associated bones and tissue may slough. This same sequence may involve the nose, ears, and tail. Gangrenous signs may be preceded by colic and constipation or diarrhea. Possible subacute effects include depression, partial anorexia, general unthriftiness, and increased pulse and respiratory rates.<sup>12,13</sup> Abortions also occur.

### PATHOPHYSIOLOGY

The major toxic alkaloids in ergot are a group of structurally similar ergopeptides. They are absorbed slowly and incompletely from the gastrointestinal tract, reaching peak plasma concentrations in approximately 2 hours. The liver is the primary site of metabolism, and approximately 90% of metabolites are excreted in bile. Small amounts of unmetabolized alkaloids are excreted in urine. The total concentration and proportions of alkaloids present in ergot sclerotia may vary with species and environmental conditions.<sup>12,13</sup>

Ergotamine, the most abundant of the alkaloids, is a polypeptide derivative of lysergic acid. The varied physiologic effects of ergot are caused primarily by mixtures of levoisomers of ergotamine, coupled with smaller amounts of acetylcholine, histamine, and tyramine.<sup>12</sup>

Ergotamine is a vasoactive substance that causes arterial and venous constriction. Ergotamine also may damage capillary endothelium. The combined effects of vasoconstriction and endothelial damage produce increased blood pressure, decreased blood flow through the extremities, vascular stasis, thrombosis, and eventually gangrene.<sup>12,13</sup>

The ergotoxine group of alkaloids produce  $\alpha$ -adrenergic blockade and antagonize 5-hydroxytryptamine. This produces an increase in blood pressure as a result of peripheral vasoconstriction, particularly in postcapillary vessels.<sup>12</sup>

### DIAGNOSIS AND TREATMENT

A tentative diagnosis of ergotism is based on clinical signs and exclusion of other disease processes. An experienced person can readily identify ergot sclerotia in grains. However, once

grinding or pelleting of feed has occurred, ergot can be recognized only by microscopic examination or chemical analysis for ergot alkaloids. Ergot alkaloids can be identified and quantitated by chromatographic methods, and a sample of the individual grain components should be obtained for analysis whenever possible.<sup>12</sup>

No specific treatment exists for gangrenous ergotism. The offending grain should be removed, and affected animals should be kept warm to avoid cold-induced vasoconstriction in the extremities. Supportive therapy in the form of antibiotics and analgesics may be indicated. The use of anti- $\alpha$ -adrenergic pharmaceuticals to effect vasodilation also may be helpful. Such agents might include acepromazine, isoxsuprine, phenoxybenzamine, and similar products.<sup>12,13</sup>

## TOXICOSES CAUSING SIGNS RELATING TO LIVER DISEASE OR DYSFUNCTION

### ☞ PLANTS

#### PYRROLIZIDINE ALKALOIDS

Pyrrrolizidine alkaloid toxicity results from consumption of plants that contain various pyrrrolizidine alkaloids. Horses can become intoxicated after ingesting fresh plants and dried plants incorporated into hay. As with many toxic plants, however, these plants are frequently unpalatable to most horses, although certain conditions may render them more appetizing. This toxicity is characterized by a chronic, progressive disorder manifested by signs of liver failure. The more common plants that cause toxicosis in horses include *Senecio jacobaea* (tansy ragwort), *Senecio vulgaris* (common groundsel), *Senecio longilobus* (groundsel), and *Cynoglossum officinale* (houndstongue).<sup>1,2</sup> Other plants that contain pyrrrolizidine alkaloids but are not commonly associated with clinical disease in horses include *Amsinckia intermedia* (fiddleneck tarweed), *Crotalaria* spp. (rattlebox), *Echium plantagineum* (Viper's bugloss), and *Heliotropium europaeum* (common heliotrope).

#### CLINICAL SIGNS

Signs of pyrrrolizidine alkaloid intoxication in horses are essentially those of liver failure. The most frequently noted signs include weight loss of weeks to months in duration, icterus, and behavioral abnormalities. The behavioral changes indicate hepatoencephalopathy and may include aimless pacing or wandering, ataxia, licking inanimate objects, blindness, head pressing, and uncharacteristic aggression. Convulsions and coma may precede death. Clinical signs of abnormal behavior usually are a terminal event in the disease process and typically have an acute onset.<sup>2,3</sup> Other signs less frequently reported include diarrhea, photosensitization of nonpigmented areas of skin, hemoglobinuria, and inspiratory dyspnea.<sup>2,4</sup> Abortion and poor exercise tolerance (reduced athletic performance) also have been observed in horses after ingestion of sublethal amounts.<sup>5</sup> Because toxicity of these plants is related to liver dysfunction, clinical signs of disease may not become apparent for weeks to months after ingestion.

#### PATHOPHYSIOLOGY

A number of pyrrrolizidine alkaloids are present in various plant species, and some plants may contain multiple alkaloids. These substances are absorbed from the gastrointestinal tract and carried to the liver, where they are metabolized by hepatic microsomal enzymes to pyrroles. These pyrroles then can cross-link double-stranded deoxyribonucleic acid (DNA) and bind to proteins and nucleic acid within hepatocytes.<sup>1,2</sup>

The cross-linking of DNA has an antimetabolic effect on hepatocytes. The hepatocytes are unable to divide and subsequently become megalocytes. As these cells die, they are replaced by fibrous tissue rather than normal hepatocytes. Binding of protein and nucleic acid results in inhibition of cytoplasmic protein synthesis. These changes may lead to more rapid death of hepatocytes and cause centrilobular necrosis. Eventually, liver function begins to fail because of progressive hepatocellular death and subsequent fibrosis.<sup>1,2</sup> As the disease progresses, generalized fibrosis develops. Once connective tissue bridges form between portal areas, the disease is fatal.<sup>1</sup>

Variation in the dosage and frequency of administration of alkaloids results in a wide spectrum of hepatic lesions. Acute toxicosis resulting from massive doses is more likely to produce centrilobular necrosis with hemorrhage; however, this type of exposure is extremely rare. Chronic doses tend to produce hepatocellular death in the portal areas, along with megalocytosis, fibrosis, biliary hyperplasia, and occlusion of hepatic veins.<sup>1,2</sup> Liver failure is thought to be ultimately responsible for the clinical signs observed in pyrrrolizidine alkaloid toxicosis.

The toxic dose of dried *Senecio* is estimated to be 5% of the body weight of the horse. This amount does not need to be ingested all at once, however, because the effects are cumulative. The total dose of alkaloids consumed determines the toxic effect, regardless of the amount of time in which the alkaloids were consumed.<sup>1,2</sup>

#### DIAGNOSIS AND TREATMENT

Most cases of pyrrrolizidine alkaloid toxicosis are diagnosed on the basis of history, compatible clinical signs, serum liver enzyme activities, and liver biopsy findings. When active hepatocellular damage is occurring early in the disease process, sorbitol dehydrogenase and LDH usually are elevated, but they often decline to normal values by the time the horse is showing clinical signs. Serum GGT, alkaline phosphatase, and AST activities tend to be elevated throughout the disease course. Serum concentration of bile acids also is reported to be elevated in affected horses. Serum bilirubin concentration tends to be elevated in later stages of the disease, and hypoglycemia and hypoalbuminemia rarely are seen except in cases of severe hepatic disease.<sup>1,2,4,5</sup>

Other diagnostic aids that may be useful from a diagnostic and prognostic standpoint include measurement of the ratio of branched-chain amino acids to aromatic amino acids in serum. The branched-chain amino acids isoleucine, leucine, and valine are catabolized primarily in muscle, and the aromatic amino acids phenylalanine and tyrosine are catabolized mainly in the liver. The ratio of the sums of these amino acids (branched-chain to aromatic) decreases progressively from normal in horses affected with pyrrrolizidine alkaloid toxicosis. If the ratio is below normal range and the horses are exposed continually to alkaloid-containing plants, they have a poor

chance of survival. Some affected horses also showed a dramatic decrease in this ratio just before death.<sup>6</sup> Liver biopsy findings of a triad of fibrosis, bile duct proliferation, and megalocytosis are highly suggestive of pyrrolizidine alkaloid toxicosis. Liver biopsy samples also can help in establishing prognosis because the presence of advanced or generalized hepatic fibrosis warrants a grave prognosis.<sup>1,2</sup>

Feed samples may be analyzed for pyrrolizidine alkaloid content, but the process is often time consuming and unnecessary.<sup>1</sup> Pyrrole testing of liver tissue can be helpful in confirming exposure to the plant in the early stages of the disease; however, this analysis is offered by only a few laboratories.

No specific treatment for pyrrolizidine alkaloid toxicity exists. Affected horses may survive if they are denied further exposure to alkaloid-containing plants and are fed a suitable diet. However, some horses still may show signs of liver disease even though they have not had exposure to the plant for some time. Specific treatment of acute and chronic liver failure is discussed elsewhere.

Prevention entails keeping horses away from pasture or feed contaminated with pyrrolizidine alkaloid-containing plants.

### **MUSHROOM (*AMANITA* spp.)**

One report describes fatal intoxication of a horse by ingestion of mushrooms (*Amanita* spp.).<sup>7</sup> Mushrooms apparently are unpalatable to livestock species, but the described horse also suffered from meningioangiomas, a rare benign tumor of the meninges and brain. The authors speculated that the presence of the tumor may have resulted in abnormal mentation and altered the normal eating behavior of the horse, resulting in mushroom consumption.

#### **CLINICAL SIGNS**

The described horse had acute onset of depression, head pressing, ataxia, and repeated recumbency with difficulty in rising. Before the onset of liver disease, many poisoned animals display signs of gastrointestinal distress. Clinical signs of shock, including hypothermia, poor capillary perfusion, and weak pulse, also were apparent. The horse was euthanized because of continued deterioration and lack of response to supportive therapy.

#### **PATHOPHYSIOLOGY**

Some species of *Amanita* mushrooms contain a number of biologically active cyclic peptides such as amatoxins, phallotoxins, phallolysin, and antaminide. Some of these peptides affect actin polymerization and cause hepatocytes to lose their cytoskeletal organization and cellular attachments, resulting in hepatocellular dissociation and necrosis. Amanitins are peptides that inhibit ribonucleic acid (RNA) polymerase II within the nucleus, thereby preventing DNA transcription and subsequent protein synthesis. The result is acute submassive hepatic necrosis, which was present in the described horse.

#### **DIAGNOSIS AND TREATMENT**

Diagnosis in the described horse was based on histologic findings of submassive hepatic necrosis, acute onset of clinical signs, and presence of partially digested mushrooms in stomach contents. No specific therapy is recommended, although prompt evacuation of the gastrointestinal tract coupled with supportive care would seem prudent. The quantity

of mushrooms ingested appears to be the primary prognostic indicator. If sufficient amounts of toxin are absorbed, the prognosis is grave. Hepatic coma often ensues in other species.

## **MISCELLANEOUS AGENTS**

### **IRON**

Iron toxicosis in horses is rare and can result from iatrogenic overdose of injected or oral products given to foals or from accidental consumption of iron-containing supplements. Supplemental iron is available in injectable and oral formulations, and presently more than 120 iron preparations are on the market.<sup>8</sup> Iron dextrin, iron polysaccharide, iron sorbitol, and ferric ammonium citrate are available injectable preparations. Oral formulations include iron salts such as ferrisulfate, citrate, and ammonium citrate; ferrous sulfate, chloride, glutamate, lactate, fumarate, and carbonate; and ferric phosphate with sodium citrate. Chelated iron compounds are about one fourth as toxic as other compounds. Some forms of iron are more bioavailable than others.

The toxicity of iron is least by the oral route, with intramuscular and intravenous routes being increasingly more toxic. Because most animals do not have a mechanism for iron excretion, the toxicity of iron depends on the amount of iron already present in the body.

#### **CLINICAL SIGNS**

Two syndromes of iron toxicosis in animals are reported. A peracute syndrome is represented by sudden death a few minutes to hours after injection. This syndrome may resemble an anaphylactic reaction, but the triggering mechanism is unknown. A subacute reaction characterized by progressive depression, icterus, and disorientation leading to coma and death seems to be the more typical syndrome seen in horses.<sup>8-10</sup>

#### **PATHOPHYSIOLOGY**

Experimentally, 5% to 10% of some forms of oral iron is absorbed in the small intestine, primarily from the duodenum and jejunum, by a rate-limited mucosal transfer system. The ferrous forms are absorbed to a greater extent than the ferric forms, but both can be absorbed if they are in the ionized state. Phosphates reduce the absorption of iron, and a high-sugar diet increases absorption. Once absorbed, iron is bound in serum by transferrin.<sup>8</sup>

Toxic doses of orally administered iron overwhelm the mechanism controlling absorption of iron from the intestine, resulting in massive iron absorption. Toxicity occurs when serum iron levels exceed the iron-binding capacity of transferrin. Free circulating iron then damages blood vessels, may cause erosion and ulceration of the stomach and intestine, causes hepatocellular necrosis and fatty degeneration of the myocardium, and can produce cerebral edema.<sup>8,11</sup> In horses hepatic failure appears to be the cause of death.<sup>9</sup>

At the cellular level, excessive iron causes extensive peroxidation of lipids in biologic membranes. A resulting decline in the ratio of unsaturated to saturated fatty acids leads to increased membrane rigidity, reduction of membrane potential, and increased permeability to various ions, leading to rupture of the membrane. The intracellular organelles adversely affected include the mitochondria and the lysosomal and sarcoplasmic membranes.<sup>12</sup> Elevated serum iron also inhibits the

thrombin-induced conversion of fibrinogen to fibrin, thereby adversely affecting coagulation and enhancing any hemorrhagic process.<sup>10</sup> Histologically, affected livers are characterized by small size and have prominent bile duct proliferation, periportal fibrosis, and hepatocellular necrosis.<sup>11</sup>

### DIAGNOSIS

Measurement of serum iron concentration is the best method of confirming a diagnosis of iron toxicity.<sup>8</sup> In addition, a history of iron administration coupled with clinical signs and laboratory evidence of hepatocellular damage and cardiovascular collapse is highly suggestive of toxicity.

Abnormal laboratory findings include prolonged PTT and PT, high concentrations of aromatic amino acids (tyrosine, phenylalanine, tryptophan, methionine), elevated plasma ammonia concentration, and increased activities of the liver-derived enzymes alkaline phosphatase and GGT. In addition, a high ratio of aromatic to branched-chain amino acids and an elevated total serum bilirubin content can be found.<sup>9</sup>

### TREATMENT

Treatment of peracute iron toxicosis usually is unrewarding. Once clinical signs become evident, major organ damage usually is present. No specific treatment for horses affected with iron toxicity is known. Treatment of affected dogs has included supportive therapy with glucose and norepinephrine and magnesium oxide given orally to help complex the ingested iron. Experimentally, a specific chelator of ferric iron, deferoxamine, has been used at 0.75 mg/kg/min intravenously to chelate the circulating iron in dogs. This drug should be administered slowly by intravenous drip because it can cause a sharp decline in blood pressure. Plasma extenders and intravenous fluids also have been used to counteract cardiovascular shock present in some dogs.<sup>8</sup>

In cases of human toxicosis, gastric lavage, chelating agents, and cathartics (sodium sulfate and magnesium sulfate) have been used. The use of oral bicarbonate solutions to decrease iron absorption is controversial, and activated charcoal is given orally to absorb the iron-deferoxamine complex, even though charcoal does not effectively bind free iron.<sup>11</sup>

The chelator of choice in human toxicosis is deferoxamine. Deferoxamine is administered intravenously for maximum effect; the drug has a plasma half-life of about 1 hour. Deferoxamine is detoxified by the liver, but the iron-deferoxamine complex is excreted by the kidneys.<sup>11</sup>

### AFLATOXIN

Aflatoxicosis is a rarely documented disorder of horses, as demonstrated by the paucity of clinical cases reported in the literature.<sup>13-15</sup> In reported instances toxicosis developed in horses being fed contaminated feedstuffs, but horses also have been affected experimentally by forced feeding of aflatoxin-contaminated material.<sup>16,17</sup>

Aflatoxins are toxic metabolites primarily produced by the fungi *Aspergillus flavus* and *Aspergillus parasiticus*. These molds are ubiquitous and normally can be found in stored feeds. The molds are not inherently toxigenic, but they can grow rapidly and produce large amounts of aflatoxin under environmental conditions of adequate temperature and humidity. Many feedstuffs can support the growth of these molds, but cereal grains, cottonseed meal and cake, and peanuts seem to be affected most commonly.<sup>18</sup>

These molds produce five major aflatoxins: B1 and B2, which fluoresce blue under long-wave ultraviolet light; G1 and G2, which fluoresce green; and M1 aflatoxin, which is present in milk. B1 is the most important of these because of its toxicity and its abundance under natural conditions.<sup>18</sup>

Aflatoxins are a group of polycyclic, unsaturated compounds that have a coumarin nucleus coupled to a reactive bifuran system and a pentenone or lactone. These toxins are insoluble in water and are heat resistant; they are absorbed rapidly from the gastrointestinal tract and bound to serum albumin. Most of the toxins are removed from the bloodstream in the liver, where aflatoxins bind to macromolecules such as DNA, endoplasmic steroid-binding sites, and certain enzymes within the hepatocytes. In the liver a variety of metabolites are produced at rates that vary among species. The metabolites may be lipid-soluble or water-soluble conjugates and are excreted in bile. At least some of the metabolites undergo an enterohepatic cycle of absorption and excretion. The aflatoxins and their metabolites are excreted in urine and feces, and complete elimination may take several days. The aflatoxins are not known to be stored in any particular tissue.<sup>18</sup>

Acute and chronic aflatoxicoses are reported in a variety of animal species, including human beings. However, clinical reports of equine disease are concerned primarily with acute intoxication. The acute oral LD<sub>50</sub> of aflatoxin B1 in horses is reported to be 2 mg/kg or greater. One author reported signs of toxic hepatopathy and gastrointestinal upset in horses that consumed feed containing 2 to 50 ppb of aflatoxin B1. Toxicity of aflatoxins also is reported to be enhanced by riboflavin; exposure to light; and a diet low in protein, choline, and vitamin B<sub>12</sub>.<sup>18</sup>

### CLINICAL SIGNS

Clinical signs associated with acute aflatoxicosis include anorexia, elevated temperature, increased heart and respiratory rates, ataxia, depression, lethargy, convulsions, icterus, colic and abdominal straining, bloody feces, and death. These signs were exhibited by horses experimentally intoxicated with aflatoxin at dosages of 2 to 5 mg/kg. Onset of signs began as early as 4 hours after dosing, and deaths occurred from 68 hours to 32 days after intoxication.<sup>14,16,17</sup> An additional sign observed in a naturally occurring instance of toxicosis was subcutaneous hemorrhages.<sup>14</sup>

The feed concentration of aflatoxin B1 necessary to cause signs of chronic aflatoxicosis in horses has not been established, and reports of chronic aflatoxicosis were not found in the literature. Signs of chronic aflatoxicosis in other species have included reduced feed efficiency, rough hair coats, anemia, anorexia, depression, mild jaundice, and occasionally abortion.<sup>18</sup> It should be noted that experimental trials have indicated that some horses refuse mold-contaminated grain and well-fleshed animals may be at lesser risk of developing aflatoxicosis than unthrifty animals.<sup>14,16</sup>

### PATHOPHYSIOLOGY

The hepatic cytotoxicity of aflatoxins is thought to be related to their binding to intracellular macromolecules. Aflatoxin B1 binds to nuclear DNA to inhibit RNA synthesis, which subsequently inhibits synthesis of intracellular enzymes and other proteins. Aflatoxin also binds to endoplasmic steroidal ribosome-binding sites, resulting in ribosomal disaggregation. Metabolites of aflatoxin B1 also can bind to cellular macromolecules, and most of the cytotoxicity of aflatoxin B1 appears to result from binding of certain of these metabolites rather than

from aflatoxin B1 itself. This impairment of protein synthesis and the related ability to mobilize fats is thought to cause the early lesions of hepatic necrosis and fatty degeneration of the liver in aflatoxicosis.<sup>8</sup>

The possibility of other mechanisms being responsible for the other signs and lesions noted with aflatoxicosis has been suggested. Aflatoxins are known to be carcinogenic, they can be immunosuppressive, and they also can inhibit synthesis of clotting proteins. The mechanisms whereby these changes take place have not been well described.<sup>18</sup>

### DIAGNOSIS AND TREATMENT

Definitive diagnosis of aflatoxicosis can be difficult because of the nonspecificity of many clinical signs and because the disease can mimic many other conditions. Experimentally intoxicated horses have elevations in serum concentrations of AST, alanine aminotransferase, GGT, iditol dehydrogenase, and arginase.<sup>14,16,17</sup> Other laboratory abnormalities include hypoglycemia, hyperlipidemia, lymphopenia, and elevated PT.<sup>13,14,17</sup>

Gross necropsy lesions typically consist of variable degrees of hepatic degeneration and necrosis, visceral petechial hemorrhages, and hemorrhagic enteritis.<sup>13,14,17</sup> Other lesions noted at necropsy include encephalomalacia of the cerebral hemispheres, myocardial degeneration, fatty infiltration of the kidney, and subcutaneous and intramuscular hemorrhage.<sup>13,14</sup> Histopathologic abnormalities may include fatty degeneration and necrosis of hepatocytes, bile duct hyperplasia, periportal fibrosis, and inflammatory cell infiltration into the liver. Renal lesions have included lipid accumulation in the tubular epithelial cells of the proximal tubules and protein precipitation in the tubular lumen.<sup>13,17</sup>

Although metabolites of *Aspergillus* species fluoresce under ultraviolet light, the presence of fluorescence in suspect feed samples is not pathognomonic for aflatoxin. Aflatoxin can be assayed definitively in feed samples by a variety of analytical methods.<sup>14</sup> It also is possible to quantitate aflatoxin in animal tissues, although this test is not routinely available through diagnostic laboratories.<sup>13,17</sup> Tissue residue testing can come up negative because of the long delay between time of exposure and demise of the patient. Mold culture is nondiagnostic.<sup>18</sup>

Treatment is largely symptomatic and must include removal of the offending feed material, if it still is being fed. An easily digested, low-fat diet containing appropriate protein has been recommended. Multiple vitamin supplementation might be beneficial, and treatment of specific organ dysfunction should be initiated. In acutely intoxicated horses orally administered charcoal has been recommended.<sup>18</sup> Prevention of the condition requires storing feeds in a suitable environment that discourages mold growth and the feeding of non-contaminated feedstuffs.

### TOXICOSES CAUSING SIGNS RELATING TO THE URINARY SYSTEM

Detection of renal disease can be difficult, regardless of cause. Whereas nephrotoxicity associated with equine administration of medications is well established and usually recognized, that linked to ingestion of plants is less commonly detected, which makes it more difficult to make a definitive diagnosis. Although heavy metals such as cadmium and mercury have

long been known for their nephrotoxic effects, clinical signs are nonspecific, and the diagnosis will be made only if the clinician performs diagnostic tests to specifically rule these problems in or out.

## PLANTS

### OXALATE TOXICOSIS

The most common source of oxalates for livestock is plants, particularly those of the Chenopodiaceae family. These plants contain varied amounts of soluble oxalates, usually in the form of sodium or potassium salts. However, because plants containing oxalates (Box 22-3) are generally unpalatable to horses, plant-associated oxalate intoxication is rare.

Of the plants listed in Box 22-3, *Halogeton* and *Sarcobatus* seem to be the primary offenders in range animals in the western United States.<sup>1</sup>

Because oxalates accumulate in the plants throughout the growing season, the incidence of toxicosis may be highest in the fall and winter months.<sup>2</sup> The oxalate content is highest in the leaves, with a lesser amount in seeds and a minimal amount present in the stems. The nonfatal toxic dosage of sodium oxalate for adult horses is approximately 200 g/day for 8 days.<sup>1</sup>

### CLINICAL SIGNS

Affected horses may begin to show signs of depression, mild to moderate colic, muscular weakness, and irregular gait 2 to 6 hours after ingestion. Weakness may proceed to lateral recumbency, unconsciousness, and death in 10 to 12 hours. Some animals may exhibit convulsions before succumbing.<sup>1</sup> The observed clinical signs of acute toxicity are typical of those of hypocalcemia.

### PATHOPHYSIOLOGY

Oxalates combine with serum calcium ions to form insoluble calcium oxalate. The result is a functional hypocalcemia in acute cases, with associated signs of altered behavior and neuromuscular abnormalities.

#### BOX 22-3

#### PLANTS THAT CONTAIN LARGE AMOUNTS OF SOLUBLE OXALATES

<i>Amaranthus</i> spp.	Pigweed
<i>Beta vulgaris</i>	Beet, mangold
<i>Chenopodium album</i>	Lambsquarters
<i>Halogeton glomeratus</i>	Halogeton
<i>Oxalis</i> spp.	Wood sorrel, soursob
<i>Portulaca oleracea</i>	Purslane
<i>Rheum rhaponticum</i>	Rhubarb
<i>Rumex</i> spp.	Sorrel, dock
<i>Salsola kali</i>	Russian thistle
<i>Sarcobatus vermiculatus</i>	Black greasewood

Chronic ingestion of oxalates can result in renal failure. Insoluble calcium oxalate crystals can lodge in the renal tubules, producing tubular blockage and necrosis. Oxalates also may crystallize in the vasculature and infiltrate blood vessel walls, producing necrosis and hemorrhage.<sup>1</sup>

### DIAGNOSIS AND TREATMENT

In instances of acute toxicosis, consistent clinicopathologic abnormalities include moderate to significant hypocalcemia and varied electrolyte alterations. In chronic toxicity urinalysis may reveal the presence of characteristic calcium oxalate crystals on microscopic examination. Impending renal failure also is characterized by increases in BUN and creatinine concentrations.<sup>1</sup>

Treatment usually is of little value once clinical signs have appeared. Calcium gluconate can be administered intravenously, but usually it provides only temporary relief of signs. Balanced electrolyte solutions are indicated to aid diuresis, and diuretics also may have benefit in the volume-loaded patient. Prevention primarily entails keeping horses from the plants by providing adequate suitable sources of feed.<sup>1</sup>

## SORGHUM

Ingestion of *Sorghum* species and certain hybrid Sudan grasses has been associated with the development of an ataxia-cystitis syndrome.<sup>3,4</sup> The toxicity occurs when horses graze the plants. More cases occur when the plant is young and rapidly growing, but mature and second-growth plants also have been incriminated. Horses being fed well-cured *Sorghum* species have not developed signs of toxicity. Occurrence of toxicity may increase during seasons of medium to high rainfall, but no cases have been recognized following the date of the first frost. Signs of toxicity may develop following a grazing period of 1 week to several months.<sup>3</sup>

### CLINICAL SIGNS

The primary clinical signs are those of posterior ataxia and urinary incontinence or cystitis. The neurologic signs usually develop first and begin as posterior ataxia and incoordination. Affected horses may sway from side to side if forced to move, and signs tend to worsen on backing the animal. Occasionally, the rearquarters may drop almost to the ground, and flaccid paralysis of the tail and the rear legs may develop within 24 hours of the onset of neurologic signs. Affected horses remain alert and afebrile and have a normal appetite and pulse and respiratory rates. Mares frequently exhibit continual opening and closing of the vulva and relaxation of the perineal muscles. Males typically have a relaxed and extended penis.<sup>3,4</sup>

Urinary incontinence exhibited by continual urine dribbling is prominent in both sexes, and urine scalding on dependent skin becomes pronounced. The urinary bladder typically is distended and atonic, resulting in moderate to severe cystitis. Urethritis and ureteritis also may develop, and in horses that die because of the disease, ascending pyelonephritis usually is the cause of death. Other clinical signs include abortion and birth of foals with arthrogryposis.<sup>3,4</sup>

### PATHOPHYSIOLOGY

The clinical signs result from axonal degeneration and demyelination of nerve fibers in the spinal cord, particularly in the lumbar and sacral segments. The toxic substance in *Sorghum* species responsible for causing this change is unknown. Most

*Sorghum* species are cyanogenic plants and contain various amounts of HCN. Exposure to multiple sublethal doses of HCN has been suggested to induce axonal degeneration and demyelination.<sup>3</sup> Another hypothesis is that sorghum plants contain lathrogenic precursors and that this toxicosis may be caused by the ingestion of lathrogenic nitriles present in rapidly growing plants.<sup>1,4</sup>

### DIAGNOSIS AND TREATMENT

Diagnosis of sorghum ataxia-cystitis is based primarily on appropriate clinical signs, history of grazing the plants, and exclusion of other known causes of posterior ataxia or paresis. No specific diagnostic tests are available. Cystitis and pyelonephritis are diagnosed by standard laboratory methods.

No specific treatment is available. The offending feed should be removed immediately. Once the feed is removed, affected horses usually show gradual improvement over several weeks to months, but complete recovery may not occur. Supportive and symptomatic therapy should include appropriate antibiotic treatment of bacterial urinary tract infections and topical treatment of urine scald dermatitis. Periodic manual decompression of the urinary bladder may be helpful. Catheterization and frequent aspiration of bladder contents may be necessary to aid resolution of cystitis.

## ☞ MISCELLANEOUS AGENTS

### VITAMINS D<sub>2</sub> AND D<sub>3</sub>

Horses are capable of meeting their requirement for vitamin D if they are exposed to sunlight or have access to sun-cured forages. Although dietary requirements for the horse have not been established, a maximum safe level of 44 IU per kg of body mass daily has been proposed for long-term feeding (>60 days).<sup>5</sup> Most cases of vitamin D intoxication are iatrogenic, resulting from overzealous use of vitamin supplements or improperly formulated vitamin D-supplemented feeds. Ingestion of *C. diurnum* (wild jasmine) also can result in vitamin D toxicosis because this plant contains a metabolically active glycoside of 1,25-dihydroxycholecalciferol (see the section on wild jasmine [*Cestrum diurnum*]).

Vitamins D<sub>2</sub> (ergocalciferol) and D<sub>3</sub> (cholecalciferol) are potentially toxic, but vitamin D<sub>3</sub> is much more active and results in more severe lesions with wider tissue distribution than does an equivalent dose of vitamin D<sub>2</sub>.<sup>6,7</sup> Other variables that may affect toxicosis include duration of treatment and route of administration. High concentrations of dietary calcium also might enhance the effects of excessive amounts of vitamin D. The effect of vitamin D supplementation is cumulative, and signs of toxicity may occur weeks after supplementation has begun.

### CLINICAL SIGNS

The clinical signs associated with vitamin D toxicosis are associated with impairment of the renal, cardiovascular, and musculoskeletal systems. Signs may include depression, anorexia, weakness, polyuria and polydipsia, cardiac murmurs and tachycardia, limb stiffness with impaired mobility, and recumbency. Calcification of tendons, ligaments, and other soft tissue structures may be palpable on physical examination.<sup>6</sup> Ultrasonographic examination of these structures also may demonstrate abnormal mineralization within the tissues.

The toxicity of excessive amounts of vitamin D<sub>3</sub> results from extensive dystrophic mineralization rather than from any inherent toxicity of vitamin D itself. Soft tissue sites most frequently affected include the kidneys, the endocardium and walls of large blood vessels, and tendons and ligaments.<sup>6,7</sup>

Laboratory findings associated with toxicosis vary with the organ system affected, but generally include persistent hypercalcemia and hyperphosphatemia, although the latter may not be especially pronounced. Serum calcium concentration may remain within a normal range in some horses. Other laboratory evidence of chronic renal failure may become evident with progression of toxicosis. A definitive diagnosis is made by measuring serum concentrations of vitamins D<sub>2</sub> and D<sub>3</sub> and 1,25-dihydroxycholecalciferol.<sup>7</sup>

## TREATMENT

Treatment of vitamin D intoxication should include removal of all exogenous sources of vitamin D. A cation chelator such as sodium phytate may be helpful in reducing intestinal absorption of calcium, but the efficacy of this product has not been determined. If necessary, symptomatic therapy for renal insufficiency and failure should be instituted. Recovery may take months in less severely affected horses,<sup>7</sup> but treatment usually is unrewarding if excessive mineralization has occurred.

## MENADIONE SODIUM BISULFITE (VITAMIN K<sub>3</sub>)

Vitamin K<sub>3</sub> is a reported cause of acute renal failure in horses, but the product has been withdrawn from the U.S. market. When the product was given at the manufacturer's recommended dosage of 2.2 to 11 mg/kg intravenously or intramuscularly, signs of toxicity became evident 6 to 48 hours after injection in affected horses.<sup>8</sup> Clinical signs included depression, anorexia, colic, hematuria, and stranguria. Azotemia, electrolyte abnormalities, proteinuria, and isosthenuria also were apparent. Pathologic lesions noted at necropsy were those of acute tubular necrosis. Interstitial fibrosis and chronic renal failure also were present in one horse.<sup>8</sup> Treatment of affected horses is symptomatic for acute or chronic renal failure.

## CADMIUM

Intoxication with cadmium rarely is reported in horses but has been seen in animals raised near smelting operations.<sup>9</sup> Environmental contamination of soil and forage by cadmium and zinc was the cause of excessive intake.

Affected horses exhibited signs of unthriftiness, lameness, and swollen joints. Some of these signs were attributed to excess zinc in the diet, but the horses also had pronounced osteoporosis and nephrocalcinosis, which along with proteinuria are typical findings of cadmium toxicosis in human beings.<sup>9</sup>

Serum concentrations of zinc and potassium were elevated in these horses, and the serum magnesium concentration was low in one foal. Sodium, calcium, chloride, and bicarbonate concentrations also were decreased. Extensive nephrocalcinosis was characterized by multifocal loss of cortical tubules, which were replaced by dense deposits of calcium phosphate crystals.

Cadmium induces changes in proximal renal tubular cells by an unknown mechanism. However, increased numbers

of lysosomes and mitochondrial swelling in the proximal tubular cells are early changes. Proteinuria usually is the first abnormality noted in human beings and laboratory animals. With continued chronic exposure, fibrosis and atrophy resulting from interstitial nephritis may ensue, leading to chronic renal failure.<sup>10</sup> Cadmium exposure can be confirmed by analyzing blood and various biologic tissues, including liver and kidney.

In human beings treatment essentially is supportive, with elimination of exposure to cadmium being imperative. Research data suggest a possible beneficial role of zinc, vitamin B complex, and nickel preparations, but their clinical efficacy is unproven.<sup>10</sup>

## MERCURY

Mercury exists in a variety of organic and inorganic forms. Both forms can be toxic to horses, but more recently reported cases involve acute toxicity resulting from inorganic mercury-containing blistering agents topically applied to skin.<sup>11,12</sup> Ingestion of feed or seed grain contaminated with organic mercurial seed preservatives has been a source of contamination in previous years.

Acute and chronic forms of toxicosis can occur in horses. The acute toxic dose of inorganic mercury in adults is 5 to 10 g.<sup>1</sup> Experimentally, chronic toxicity from inorganic mercury has been produced by ingestion of mercuric chloride, 0.8 mg/kg/day, over a 14-week period.<sup>13</sup> Chronic organic mercury toxicosis also has been produced experimentally by feeding methylmercury at 0.4 mg/kg/day for 10 weeks.<sup>14</sup>

## CLINICAL SIGNS

Signs associated with toxicity of the various mercurial compounds differ, but they all include some degree of renal dysfunction. Acute toxicity resulting from inorganic mercury can cause signs of acute renal failure, including oliguria and depression, and signs of gastrointestinal irritation. Ulcerative stomatitis, excessive salivation, colic, and diarrhea are common findings associated with gastrointestinal tract disturbances.<sup>11,12</sup> Chronic intoxication with inorganic mercury can result in signs of oral ulceration, reduced appetite and weight loss, alopecia, progressive respiratory difficulty, gradually increasing urine production, and terminal azotemia.<sup>13</sup> Signs reported with chronic organic mercury toxicity include development of neurologic dysfunction characterized by proprioceptive deficits, exudative dermatitis, reluctance to move, reduced appetite and weight loss, dullness, and renal changes exhibited by a steadily increasing BUN concentration and glucosuria.<sup>14</sup>

## PATHOPHYSIOLOGY

Inorganic mercury compounds are absorbed from the lungs and gastrointestinal tract and absorbed poorly through the skin. After ingestion and absorption, accumulation in the liver and particularly the kidney occurs. Some forms of organic mercury are degraded in the body to inorganic forms, which then also accumulate in the kidney before excretion.<sup>1</sup>

Inorganic mercury is concentrated to high levels within the proximal renal tubular cells. Metallothionein, a low-molecular-weight metal-binding protein is synthesized within 48 hours after exposure to heavy metals. This protein binds mercuric ions within the endoplasmic reticulum of the tubular

epithelial cells and then slowly releases mercury. This slow release of sequestered mercury can cause continuing damage to tubular cells after the source of mercury is removed.<sup>15</sup> Hence the development of mercury nephropathy appears to be a function of the amount of protein-bound mercury concentrated in the renal tubules. Bound mercury can persist in the kidneys for several weeks after exposure.<sup>250</sup> Acute toxicity results in massive tubular necrosis and acute renal failure, and chronic exposure may cause renal interstitial fibrosis leading to chronic renal failure.

Methylmercury can be biotransformed in the body to inorganic mercury, but methylmercury also accumulates in the brain to a much greater extent than do other forms of mercury.<sup>1</sup> The exact mechanism whereby methylmercury and other alkylmercurials damage the nervous system is not understood.<sup>14</sup>

At the cellular level mercury combines with sulfhydryl groups within cells. As a result, sulfhydryl enzyme systems essential to cellular metabolism and respiration are inhibited, resulting in cell death.

## DIAGNOSIS AND TREATMENT

Mercury intoxication is suspected when horses show compatible clinical signs and have a history of exposure. Laboratory abnormalities are similar to those of other causes of acute or chronic renal failure and irritative gastrointestinal diseases. Definitive diagnosis usually is based on measurement of mercury concentrations in blood, kidney, and liver.<sup>1</sup> Stomach and intestine samples also may be submitted for analysis in acute cases.

Treatment of mercury intoxication initially involves removal of the source. In acute toxicity evacuation of the bowel with a mild laxative may be helpful. The oral administration of 500 g of activated charcoal might help block absorption of mercury, but its efficacy has not been demonstrated. Dimercaprol (used to inactivate circulating mercury) can be given at a dosage of 3 mg/kg intramuscularly every 4 hours for the first 2 days, 4 times on the third day, and twice daily for the next 10 days until recovery is complete.<sup>11</sup> The clinician also should follow other principles of therapy for acute or chronic renal failure. Treatment of chronic mercury intoxication usually is unrewarding.

 respiratory, 311–322  
   African horse sickness virus, 320–321  
   emergency tracheostomy and, 322  
   equine adenoviruses, 319–320  
   equine herpesvirus type2, 316–317  
   equine herpesvirus type5, 317  
   equine herpesvirus types 1 and4, 314–316  
   equine herpesviruses, 313–314  
   equine influenza virus, 311–313  
   equine rhinitis viruses, 319  
   equine viral arteritis, 317–319  
   Hendra virus, 320  
   neonatal, 1341  
   tracheal disorders and, 321–322  
 spread in host of, 73–74, 74f  
 transmission of, through semen, 1104–1105  
 in vesicular eruptions, 718  
 virulence of, 73  
 virus life cycle and, 69–71, 71f  
 virus structure, taxonomy, and replication in, 68, 68f–70f  
 virus-cell interactions and, 71–72  
 Virologic latency, viral, 72  
 Virulence  
   bacterial infection and, 59  
   fungal infection and, 66  
   viral infection and, 73  
 Visceral pain, 234–235  
 Visual analog scale for pain assessment, 238–239, 239f  
 Vital HN, 218  
 Vitamin C, 1323  
 Vitamin D  
   in calcium regulation, 1284–1285  
   metabolism of, 1283  
   normal serum concentrations of, 1282t  
 Vitamin D<sub>2</sub> toxicity, 1410–1411  
 Vitamin D<sub>3</sub> toxicity, 1410–1411  
 Vitamin E  
   deficiency of  
     in dilated cardiomyopathy, 450  
     in equine degenerative myeloencephalopathy, 607, 608, 608f  
     in equine motor neuron disease, 521–522, 636, 637  
   musculoskeletal disorders and, 520–527  
   in nutritional myodegeneration, 520, 522–525  
   for foals, 1323  
   for high-risk pregnancies, 1313–1314, 1313t  
   role of in muscle function, 520–521  
   supplementation of  
     in equine degenerative myeloencephalopathy, 608, 609  
     in equine motor neuron disease, 637  
 Vitamin K deficiency, 761–762  
 Vitamin K<sub>3</sub> toxicity, 1411  
 Vitiligo of Arabian horses, 713–714, 714f  
 Volume of distribution (Vd) of drugs, 150–152, 151f–152f  
 clinical use of different values, 152, 153b  
 conditions that affect, 152–153  
 Volvulus  
   large intestinal, 879–880  
   small intestinal, 877–878  
 Von Willebrand's disease, 753, 758  
 Von Willebrand's factor (vWF), 750, 754, 756  
 V-Q mismatch. *See* Ventilation-perfusion (V-Q) mismatch.  
 VSDs. *See* Ventricular septal defects (VSDs).  
 Vulva, 1016–1017  
   hematomas of, postpartum, 1083  
 Vulvoplasty, Caslick, 1017  
 vWF. *See* Von Willebrand's factor (vWF).  
**W**  
 Walking  
   compulsive, 547  
   gait evaluation during, 550  
   normal, 551  
 Warbles, 708  
 Warfarin  
   toxic effects of, 762, 1390–1392  
   vitamin K deficiency and, 762  
 Warm shock, 249  
 Warts, 723  
 Wasp stings, hypersensitivity to, 691  
 Waste products, production and renal elimination of, 1150–1152, 1151b  
 Wasting disorders, 501b  
   in equine motor neuron disease, 635, 635f, 636  
 Water  
   excretion of, renal, 1161  
   intake of. *See* Polydipsia.  
   management of, for insect control, 692b  
   voluntary consumption of, 127t  
 Water balance  
   maintenance of, 127  
   renal regulation of, 1153–1155, 1153t  
 Water deprivation test, 1173–1174, 1174f  
   in polyuria and polydipsia, 129–130  
 Water diuresis in polyuria with secondary polydipsia, 128, 129b  
 Water-soluble carbohydrates, 208b, 212  
 Weakness, 138–139  
   dysphagia and, 106  
   gait evaluation and, 550  
 Weanlings  
   gastric ulcers in, 841–842, 842f  
   proliferative enteropathy in, 863  
 WEE. *See* Western equine encephalomyelitis (WEE).  
 Weight, changes in, 96, 97t  
 Weight loss  
   in chronic renal failure, 1191  
   in hepatic insufficiency, 949  
   in infective endocarditis, 443f  
 Weight management programs, 226–227  
 West Nile virus encephalitis, 630  
   clinical findings in, 631–632  
   diagnosis of, 632  
   equine protozoal myeloencephalitis versus, 614  
   pathologic findings in, 632–633  
   prevention of, 633  
   spinal ataxia and, 137  
   therapy in, 633  
 West Nile virus (WNV), 137  
 Western blot, 613  
 Western equine encephalomyelitis (WEE), 614, 624–628, 625f, 625t  
 Wet gangrene, 719–720  
 Wheal-and-flare reaction, 29  
 White blood cell count  
   in cellular immunity assessment, 34–37  
   cerebrospinal fluid and cytologic evaluation of, 555  
   normal values for, 556t  
   turbid, 555  
 White muscle disease. *See* Nutritional myodegeneration (NMD).  
 White snakeroot toxicity, 1389  
   musculoskeletal, 527  
 Whole blood transfusion, 253, 765–766  
 Wigger's cardiac cycle, 377, 378f  
 Wild jasmine toxicity, 1398–1399  
*Wolbachia*, 80  
 Wounds  
   botulism in, 642  
   oral, 829  
**X**  
 Xanthine oxidase in intestinal reperfusion injury, 798–799, 798t, 799f  
 Xanthochromia, cerebrospinal fluid, 555  
 XXterra for sarcoids, 711–712  
 Xylazine  
   for acute diarrhea, 873  
   for atopy, 694–695  
   for colic, 883t  
   for esophageal obstruction, 833  
   gastrointestinal ileus associated with, 803–804  
   head trauma and, 584  
   for hepatic insufficiency, 956  
   for pain management, 240t–241t, 242–243, 243t  
   for sedation  
     in cerebrospinal fluid collection, 553  
     in electromyography, 557  
   for seizures, 576  
**Y**  
 Yearlings, gastric ulcers in, 842  
 Yellow starthistle toxicity, 654, 1383–1384  
*Yersinia* species, 62  
 Yohimbine, 243  
 Yunnan Baiyao, 738  
**Z**  
 Z line of muscles, 488–489  
 Zero order reactions, 149, 149f  
 Zinc  
   deficiency of, 700  
   toxic effects of, 1404

# See detailed videos of diseases and procedures you read about!

More than 120 video clips on the **bound-in DVD** bring to life the symptoms and treatment of diseases covered in the text. These clips demonstrate problems and procedures related to the cardiovascular and neurologic systems for greater comprehension.

**This DVD includes:**

- **Video clips of different procedures** relating what you read to real-life examples of diseases and their treatment.
- **Audio-visual demonstrations** that familiarize you with all aspects of carrying out procedures.

***Start using your DVD now!***
