of soft tissue. Thus the practitioner should limit treatment to lesions less than 2 mm deep, such as corneal, scleral, or superficial conjunctival SCCs. Radiation is most appropriate as an adjunct therapy after surgical removal of a corneal or conjunctival SCC. When used appropriately, <sup>90</sup>Sr can achieve a nonrecurrence rate for SCC of 87.5% after 2 years.<sup>32</sup>

The use of interstitial radiotherapy for periocular SCC has been reported.<sup>29,32</sup> Radioactive gold seeds (<sup>198</sup>Au) were used to impart a medium-energy  $\gamma$ -ray (0.41 MeV) with a half-life of 93.3 hours for a total recommended dose of 5000 rad.<sup>29</sup> Success rates of 80% at 1 year and 70% at 2 years are reported.<sup>32</sup> Disadvantages of radioactive implants are their substantial cost, their limited availability, the risks associated with human exposure, and the licensing restrictions on their handling.<sup>29</sup> Secondary complications of interstitial radiation therapy include temporary corneal opacity, local necrosis, hair loss, damage to normal structures, and local depigmentation.<sup>29,32</sup> Although no retinal or lens changes have been reported after interstitial radiation treatment, the practitioner should consider the possibility of photoreceptor damage and cataractogenesis following radiation therapy.

Radiofrequency hyperthermia involves the passage of a radiofrequency (2 MHz) electric current between two electrodes. Tissue between these probes offers resistance, resulting in thermal energy being transferred to the tissue. Tissue temperature increases to 50° C in a 1-cm<sup>2</sup> area,<sup>29</sup> with malignant cells exhibiting a greater sensitivity to thermal energy than normal cells. The practitioner should not use topical radiofrequency hyperthermia as the only mode of treatment for tumors extending deeper than 3 mm or those greater than 4 to 5 cm in diameter. Superficial eyelid SCCs or corneal and conjunctival SCCs are most appropriate for treatment using radiofrequency hyperthermia. The practitioner should be careful not to overlap the fields of exposure, especially in corneal tumors, because this creates a risk of excessive necrosis of normal tissue.<sup>33</sup>

Cryosurgery using nitrous oxide (–80° C) or liquid nitrogen (–185° C) in a single freeze- or double freeze-thaw cycle results in tissue destruction. Cryodestruction is most often indicated for treatment of eyelid SCCs. Associated local depigmentation of skin and hair may occur in the treated area. The practitioner should use thermocouples, and tissue temperatures of –25° C are optimal.

Intralesional chemotherapy with cisplatin or bleomycin in an oil-water emulsion has been reported to result in regression of equine SCC. Treatment is the same as previously described for eyelid sarcoidosis. Of those horses with adnexal SCC treated with intralesional cisplatin, 65% to 93% were relapse free at 1 year.<sup>8,31</sup> A second study reported a success of 88% at 4 years.<sup>9</sup>

Regardless of the treatment used, frequent and continued follow-up examinations result in the greatest long-term success in managing ocular and periocular SCC. Recurrence may happen at the initial site of involvement and must be distinguished from granulation tissue associated with the previous treatment. In addition, the practitioner must monitor other sites and the opposite eye for the development of new SCC lesions.

## ☞ NASOLACRIMAL SYSTEM

The nasolacrimal system consists of the superior and inferior puncta and canaliculi, nasolacrimal sac, nasolacrimal duct, and nasal punctum located on the floor of the nasal

vestibule.<sup>34</sup> The nasolacrimal system serves to carry tears from the medial canthus of the eye to the nasal vestibule. Abnormalities of the nasolacrimal system result in epiphora, an overflow of tears, following an impairment in drainage of tears. Epiphora can be serous, mucoid, or mucopurulent and must be differentiated from reflex lacrimation resulting from ocular irritation or inflammation. Examination of the nasolacrimal system includes placement of fluorescein stain in the conjunctival cul-de-sac and observing its appearance at the nasal opening. The nasolacrimal system can be irrigated antegrade from the eyelid punctum or retrograde from the nasal punctum. The practitioner applies topical anesthetic (0.5% proparacaine) to the eye and places a 3.5F open-ended feline urinary catheter in the superior punctum. Sterile eye-wash or saline (10 to 20 ml) is used to irrigate the system, and fluid is observed passing out of first the inferior punctum and subsequently the nasal punctum. If performing retrograde irrigation from the nasal punctum, the practitioner uses a 5F or 6F urinary catheter and increases the volume of irrigating solution. Radiographic imaging of the nasolacrimal duct, dacryocystorhinography, can be performed using contrast material injected into the duct from the superior eyelid punctum.<sup>3,34</sup> Lateral and oblique radiographic views are best, and useful contrast materials include 60% barium sulfate (Novapaque, Picker Corp., Cleveland, Ohio) and 31% diatrizoate meglumine and diatrizoate sodium (Renovist II, Bristol-Myers Squibb, Princeton, N.J.). Indications for dacryocystorhinography include chronic epiphora, inability to irrigate the nasolacrimal duct, suspicion of a nasolacrimal foreign body, and evaluation of the nasolacrimal duct for congenital or acquired abnormalities. The nasolacrimal duct can also be imaged using a computed tomography (CT) scanner.

Abnormalities of the nasolacrimal system can be congenital or acquired. In the horse the most common congenital abnormality is atresia of the distal portion of the nasolacrimal duct and the nasal punctum, which results in mucoid epiphora at 3 to 4 months of age.<sup>3,35</sup> Additional congenital abnormalities include atresia of an eyelid punctum, abnormal placement of an eyelid punctum, and multiple nasal openings.<sup>3,16</sup> Whether these conditions are inherited is unknown. To correct an atretic nasal opening, the clinician passes a catheter from the inferior eyelid punctum to the level of the atresia. The clinician then palpates the end of the catheter in the nasal vestibule and makes an incision through the nasal mucosa overlying the catheter, exposing the catheter. The clinician then brings the tubing out the nasal opening and, along with the portion of tubing from the inferior punctum, sutures it to the skin of the face. The tubing is left in place for 3 to 4 weeks, and topical broad spectrum ophthalmic antibiotic solution is administered during this time.

Acquired conditions of the nasolacrimal system include dacryocystitis, foreign body obstruction, trauma, and involvement secondarily in neoplastic or inflammatory conditions of the medial canthus. Dacryocystitis appears as a mucopurulent ocular discharge without associated ocular inflammation. Dacryocystitis and foreign body obstructions are treated by nasolacrimal irrigation, as previously described, and bacterial and fungal culture with or without the aid of radiographic or CT evaluation. Topical broad spectrum ophthalmic antibiotic solution is administered after irrigation. Topical corticosteroids or systemic nonsteroidal anti-inflammatory drugs (NSAIDs) can also be used to help control swelling and inflammation.

Traumatic or other damage to the nasolacrimal duct is best repaired at the time of injury, and placement of a tube in the nasolacrimal duct for 3 to 4 weeks to maintain patency while healing occurs is recommended. Surgical repair of the nasolacrimal duct is a referral procedure and requires general anesthesia. If the nasolacrimal duct cannot be made patent, treatment is symptomatic therapy for the epiphora or surgical trephination (conjunctivorhinotomy) to create a new outflow pathway for the tears.

## ☞ CORNEA

### ANATOMY AND PHYSIOLOGY

The cornea consists of the epithelium, stroma, Descemet's membrane, and endothelium. The epithelium is 7 to 15 cells thick and is replaced every 7 to 10 days. The corneal endothelium is a monolayer of cells with little to no regenerative capacity. Damage to the endothelium is therefore of great significance, because complete repair is often not possible and results in permanent corneal edema. The cornea is transparent and avascular and is supplied with sensory nerves from the ophthalmic branch of the trigeminal nerve. The epithelium and anterior stroma are innervated richly with sensory nerves, whereas the middle and inner cornea is less well supplied. Nutrition and waste removal are carried out by the tear film, aqueous humor, and diffusion to and from the scleral and conjunctival blood vessels. The cornea is maintained in a state of deturgescence by the mechanical barrier and pump mechanisms of the epithelium and endothelium. Interference with these barriers results in corneal edema, with endothelial damage being the more significant. Chronic irritation of the cornea results in superficial vascularization, whereas inflammation of the anterior uvea results in deep corneal vascularization. Corneal pigmentation often follows vascularization. Cellular infiltration of the cornea occurs in neoplastic, infectious, and inflammatory disease. All of these processes can occur alone or in combination, resulting in an alteration of corneal transparency. In addition, scar formation and non-cellular infiltrates such as mineral and phospholipid deposits (corneal degeneration) alter corneal transparency. Establishing the cause of these changes and, if possible, eliminating the cause are essential.

### ULCERATIVE DISEASES

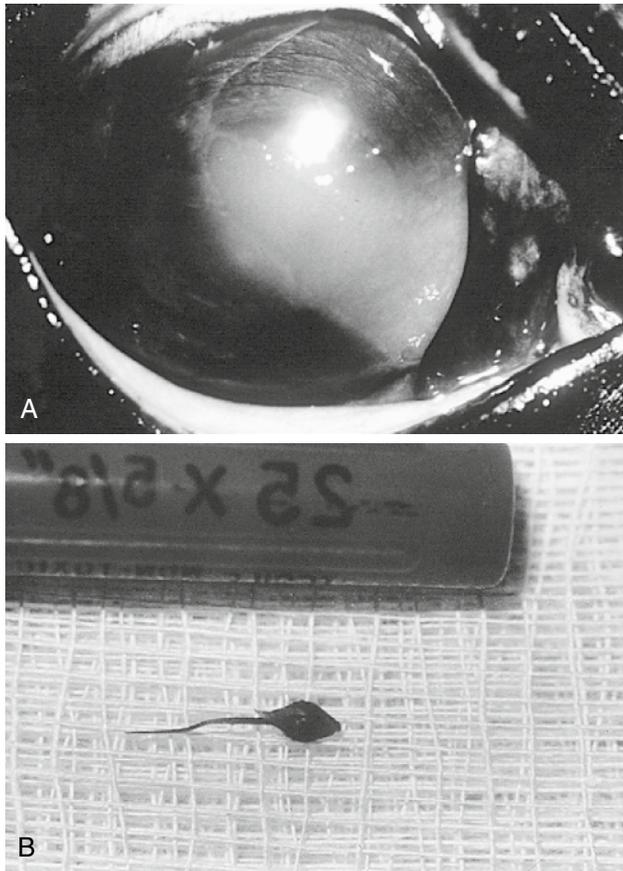

Corneal ulceration is perhaps the most frustrating and potentially devastating disease of the equine eye. Of all species commonly treated in veterinary ophthalmology, the cornea of the horse is the slowest to heal, is the most likely to become infected, and has the poorest prognosis for outcome. In addition, the size and temperament of the animal make frequent treatment difficult for owner and veterinarian. In most instances corneal ulceration results from an initial trauma, but secondary infection is common, especially in eyes treated with topical corticosteroids after ulceration.

### CLINICAL SIGNS AND DIAGNOSIS

A corneal ulcer is a break in the corneal epithelium. Clinically, ulceration results in lacrimation, blepharospasm, photophobia, conjunctival hyperemia, corneal edema, and possibly miosis and aqueous flare. The diagnosis of a corneal ulcer is based on these clinical signs and fluorescein staining

of the cornea. The underlying stroma retains the fluorescein stain and appears green. Before instilling any therapeutic or diagnostic agents in the eye, the veterinarian should submit bacterial and fungal culture samples from all corneal ulcers in the horse and should obtain culture samples from the margin of the ulcer. After obtaining culture samples and staining the cornea with fluorescein, the veterinarian applies topical anesthetic and obtains a scraping from the ulcer for cytologic examination. The cells are placed on a glass slide and stained to allow examination for bacteria, fungal hyphae, and cell type. Gram and Giemsa stains work well for examination. The presence of gram negative rods indicates the possibility of an infection with *Pseudomonas* spp., whereas cocci are suggestive of *Streptococcus* spp., a frequent and severe corneal pathogen. The presence of fungal hyphae is pathognomonic for mycotic keratitis, with *Aspergillus* spp. and *Fusarium* spp. being the most frequent corneal pathogens. Mixed bacterial and fungal infections are common.

A corneal ulcer is characterized according to size, depth, and the presence or absence of cellular infiltration. In addition, the veterinarian examines the anterior chamber for anterior uveitis. With all corneal ulcers, attempting to establish the cause of the ulceration and eliminate it is essential (Figure 17-7). The veterinarian examines the palpebral conjunctiva and bulbar surface of the nictitans for the presence of a foreign

**FIGURE 17-7** A, Chronic, superficial corneal ulcer. The shape and orientation of the corneal ulcer suggest a foreign body on the bulbar surface of the nictitans. B, Foreign body removed after examination of the bulbar surface of the nictitans.

body, evaluates the blink response and tear film, and obtains a complete history regarding trauma and previous medication. Topical corticosteroids should not be administered in the presence of a corneal ulcer, and a history of previous topical corticosteroid therapy increases the likelihood of infectious, especially fungal, keratitis.

Some specific types of corneal ulcers in the horse include indolent ulcers,<sup>36</sup> ulcers with eosinophilic cellular infiltrate,<sup>37</sup> collagenase and mycotic ulcers, and possibly viral ulcerative keratitis.<sup>3,16</sup>

### ROUTINE TREATMENT

Treatment of an uncomplicated corneal ulcer involves controlling pain and inflammation, eliminating or preventing infection, and preventing secondary complications (Table 17-3). Healing occurs by migration and mitosis of the adjacent epithelial cells and, depending on the size of the ulcer, should be complete in 2 to 6 days for an uncomplicated corneal ulcer. Complicated corneal ulcers are those that fail to heal in an appropriate time, are secondarily infected, have an ongoing source of irritation or reulceration, have a collagenase component, are associated with corneal vascularization, or are worsening despite appropriate treatment.

If miosis is evident, the clinician can administer topical atropine 1% to dilate the pupil, decrease the pain of anterior uveitis, and prevent posterior synechiae formation. Topical atropine is used as needed to dilate the pupil, but treatment frequency should not exceed 4 times daily. All topical ophthalmic medications are absorbed and have systemic effects, and topical atropine can result in colic following ileus. While administering topical atropine, the clinician should evaluate intestinal motility by auscultation, and the owner should observe for fresh fecal material in the stall every day. Systemic flunixin meglumine is indicated to suppress inflammation and control pain associated with a corneal ulcer, which in combination with topical atropine helps dilate the pupil.

Topical broad spectrum antibiotics such as neomycin-bacitracin-polymyxin B ophthalmic are the initial antibiotics of choice. Ointments are preferred for their ease of administration and prolonged corneal contact time. Frequency of administration varies according to severity of the disease. When topical antibiotics are used prophylactically for an uncomplicated corneal ulcer treatment, administration three or four times daily is sufficient, but in severe infectious keratitis, therapy might be hourly. If infection with *Pseudomonas* spp. is suspected, topical gentamicin, polymyxin B, tobramycin, or preferably ciprofloxacin or ofloxacin is indicated every 2 to 4 hours. Although gram positive organisms predominate initially in equine infectious keratitis, intensive topical antimicrobial therapy results in a significant shift to gram negative organisms and a change in susceptibility patterns.<sup>38,39</sup> Additional treatment varies according to the type and severity of the ulcer (see the section on complicated ulcerative diseases). Topical corticosteroids should not be administered to a horse with a corneal ulcer.

### COMPLICATED ULCERATIVE DISEASES

Complicated corneal ulcers are those that require treatment over and above routine ulcer management, are infected, exhibit chronicity or recurrence, are in imminent danger of perforation, or have a collagenase component (Figure 17-8). Secondary infection of a corneal ulcer is suggested by increasing pain, corneal edema, interstitial keratitis associated with an

increase in stromal inflammatory cells, corneal vascularization, purulent discharge, severe anterior uveitis, and stromal necrosis and liquefaction.

In many instances, complicated corneal ulcers require frequent and prolonged therapy, and some form of medication delivery system is indicated to ensure adequate treatment. Use of subpalpebral and nasolacrimal medication delivery systems has been described previously.<sup>40</sup> The author prefers to use the commercially available Mila lavage catheter (Mila International, Inc., Erlanger, KY.). When a lavage catheter is used, it should be kept clean and medication should be delivered to the eye slowly using air to push the medication through the tubing. Medication used with a subpalpebral lavage system must be in solution, not ointment. The volume of medication used at each treatment time should be 0.1

to 0.2 ml, and air must be used to deliver this medication to the eye. The use of irrigating solution to deliver the medication dilutes the medication. Once daily the system should be irrigated with sterile eyewash to ensure its patency and to rinse away mucus buildup.

Complications from a subpalpebral lavage system include trauma during tube placement, improper placement of the catheter or foot plate, irritation to the cornea from the tubing, and migration of the tubing. Observation of the medication reaching the cornea always is essential. Improper placement or migration of the tube may result in delivery of medication to the subcutaneous tissues and severe irritation. If corneal trauma occurs, the clinician must remove the tube and replace it or find an alternative means of medication. Many complicated corneal ulcers require a combination of surgical

and medical therapy to improve the likelihood of a successful outcome.

### INDOLENT CORNEAL ULCERATION

Indolent corneal ulcers are by definition chronic and superficial.<sup>36,41</sup> Indolent ulcers often have a rim of loose or detached epithelium at the margin, are associated with focal corneal edema and moderate discomfort, and elicit minimal corneal vascularization. As with all chronic corneal ulceration, the veterinarian must examine the eyelids, conjunctiva, and third eyelid thoroughly for the presence of foreign bodies, ectopic cilia, or other abnormality that might result in persistent ulceration.

The cause of indolent ulcers is suspected to be a failure in the attachment of the corneal epithelium to the underlying basement membrane. This attachment normally develops after epithelial migration and mitosis in the repair of a corneal ulcer. A basement membrane abnormality is suspected to be the underlying problem.

Treatment of indolent corneal ulcers includes removal of abnormal, loose epithelium and facilitation of epithelial attachment. After sedation, auriculopalpebral nerve block, and topical anesthesia, the veterinarian débrides the loose epithelial margins of the indolent ulcer to the point of normal attachment using a cotton swab or cilia forceps. A superficial linear keratotomy using a 25-gauge needle may facilitate healing in some instances but will also expose the corneal stroma and increase the potential for infectious keratitis. A linear keratotomy is performed using the beveled edge of the needle to create a series of superficial, parallel horizontal and vertical grooves in the cornea 0.5 to 1.0 mm apart that extend through the basement membrane and need be only deep enough to be visualized.

These areas serve as attachment sites for the migrating epithelium, shortening the healing time. Topical tetracycline has been shown to shorten time to healing for indolent ulcers in other species and is indicated every 6 to 8 hours. Tetracycline works not as an antimicrobial but as a matrix metalloproteinase inhibitor and anti-inflammatory. Topical, broad spectrum antibiotics are administered every 6 hours for prophylaxis, and if miosis is present, atropine 1% is used as needed to dilate the pupil. Systemic NSAIDs improve patient comfort. Topical soft contact lenses or hyperosmotics have been advocated for indolent corneal ulceration but are of no benefit in the author's opinion, and topical corticosteroids are contraindicated. A superficial keratectomy or

a conjunctival pedicle graft or both can be used for indolent ulcers that fail to respond to débridement and superficial linear keratotomy. Corneal sequestration is also possible in the horse and will appear as an indolent-like ulcer that fails to respond to therapy. A superficial keratectomy is indicated in the case of corneal sequestration.

### SUPERFICIAL PUNCTATE KERATITIS

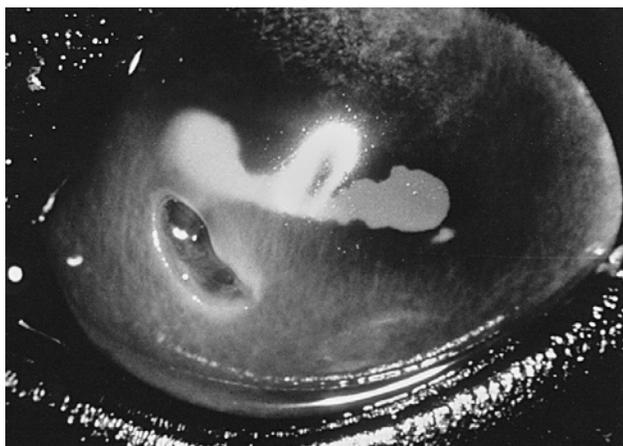

Superficial punctate keratitis is characterized by multifocal, lacelike epithelial to subepithelial corneal opacities, some of which may be fluorescein positive, with mild corneal edema. Blepharospasm may be evident, but many horses are asymptomatic. The cause is unknown, but viral agents, specifically equine herpesvirus type 1, onchocerciasis, and immune-mediated causes, have been proposed.<sup>5,13,16</sup>

Treatment recommendations vary and include topical antibiotic and corticosteroid application three to four times daily, topical cyclosporin A,<sup>46</sup> topical antiviral therapy, or a combination of these. Although the condition may respond to topical corticosteroids, recurrence is common, and extreme caution is essential when using topical corticosteroids. Topical ophthalmic antiviral agents (idoxuridine and trifluridine) or cyclosporin are administered every 6 to 8 hours and are the treatment of choice for most ophthalmologists.

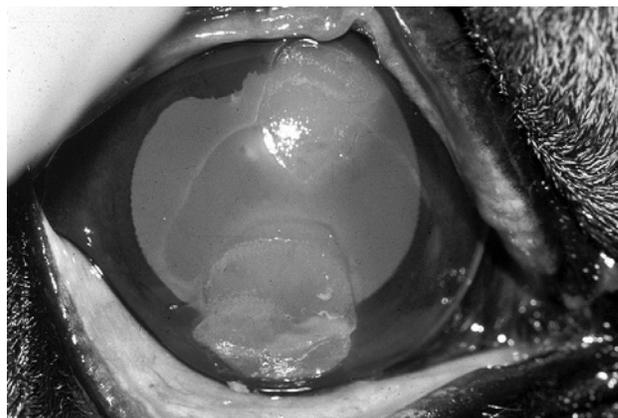

### EOSINOPHILIC KERATOCONJUNCTIVITIS

Presenting symptoms of eosinophilic keratitis include blepharospasm, chemosis, and conjunctivitis, but the hallmark feature is a yellow-white caseous plaque adhering to the limbal cornea with perilesional edema and corneal ulceration<sup>37,43</sup> (Figure 17-9). Similar caseous material may also be found adhering to areas of ulcerated conjunctiva. Cytologically, the caseous material is predominantly eosinophils with a few mast cells.<sup>37</sup> The lesion may be unilateral or bilateral, and more than one lesion may be present within an eye. The condition appears seasonally, presenting in the spring and summer. The diagnosis is based on clinical signs, season of the year, and cytologic examination.

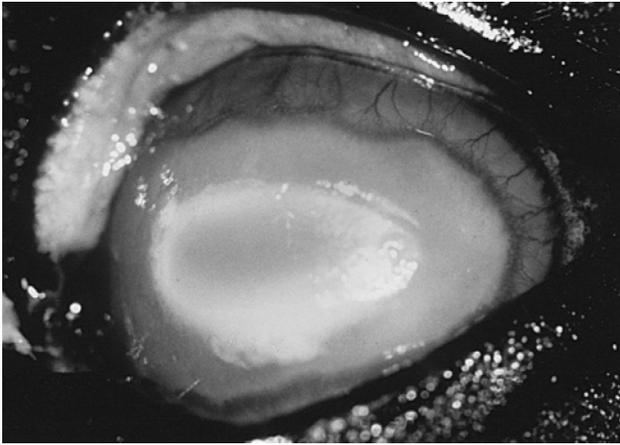

Untreated, eosinophilic keratoconjunctivitis is a chronic disease with healing by vascularization and scarring over several months. During this time secondary infection and acute exacerbation are possible. Treatment with topical corticosteroids has been described as reducing clinical signs, but mean time to resolution was 64 days, which is not significantly greater than without treatment.<sup>37</sup> In addition, secondary bacterial or

**FIGURE 17-8** Deep corneal ulcer and descemetocele with associated focal corneal edema and miosis.

**FIGURE 17-9** Two areas of ulcerative keratitis are present, each adjacent to the corneoscleral junction. Cytology revealed large numbers of eosinophils.

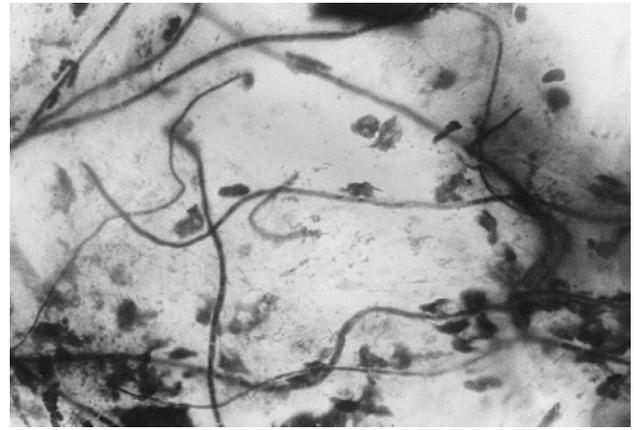

**FIGURE 17-10** Mycotic keratitis. Deep corneal vascularization, stromal edema, and cellular infiltration resulted from infection with *Aspergillus* spp.

fungal infectious keratitis is a risk with the use of topical corticosteroids. Topical iodoxamide 0.1% (Alomide, Alcon Laboratories) every 6 to 8 hours is the treatment of choice, along with fly control using fly masks. Superficial keratectomy also may be of benefit in resolving eosinophilic keratoconjunctivitis.

#### MYCOTIC KERATITIS

The clinician must consider all chronic corneal ulcers and ulcers that have been treated with topical corticosteroids as mycotic ulcers until proved otherwise. Keratomycosis is more common in the summer months and in warm climates.<sup>44</sup> Mycotic ulcers often have multifocal areas of cellular infiltrate and colonies of fungal organisms (Figure 17-10) that appear as white lesions deep in the corneal stroma adjacent to the ulcer and often appear 7 to 10 days after initial ulceration. These infiltrates are often fluorescein negative as the overlying epithelium heals, resulting in a corneal stromal abscess. Diagnosis of mycotic keratitis is based on history; clinical signs; cytologic examination; culture; and, if possible, histopathologic examination of a biopsy sample (Figure 17-11). Failure to see fungal elements on cytologic examination or culture does not rule out mycotic keratitis. The most common isolate for eyes with keratomycosis is *Aspergillus* spp.<sup>44</sup> *Fusarium* spp., *Penicillium* spp., and *Candida albicans* also are associated with keratomycosis. If the cause is in doubt, treating the horse for fungal infection is appropriate.

In eyes in which mycotic keratitis is suspected or documented, topical antifungals are indicated in addition to routine ulcer management. The only approved ophthalmic antifungal is natamycin 5% suspension (Natacyn, Alcon Laboratories), but it is costly and has limited efficacy. Although not approved for ophthalmic use, the imidazole antibiotics (miconazole, ketoconazole, fluconazole, voriconazole) may have the best efficacy for the treatment of keratomycosis.<sup>44</sup> Miconazole 1% can be compounded as a solution or ointment and administered every 2 to 4 hours topically for mycotic keratitis. An itraconazole–dimethyl sulfoxide ointment also has been used topically to treat keratomycosis.<sup>45</sup> In addition, dilute povidone-iodine solution is fungicidal and can be applied to the cornea with a cotton swab once every 1 to 2 days. Iodine is irritating to corneal and conjunctival tissues and should be irrigated from the conjunctival cul-de-sac after application. All topical antifungal medications have limited ability to

**FIGURE 17-11** Corneal cytologic sample from horse with a combined infection of *Aspergillus* spp. and *Streptococcus* spp. Filamentous hyphae and bacteria are present in the sample.

penetrate intact corneal epithelium, although miconazole is better than most. If the lesion is fluorescein negative, debriding the epithelium before medicating may be necessary (see the section on corneal stromal abscess). Topical antifungal medication must be administered for a minimum of 3 to 4 weeks along with concurrent routine topical and systemic corneal ulcer management. Dermal antifungal preparations are not appropriate for topical use in the eye, but human vaginal antifungal preparations may be administered as a last resort.

Recently, use of the systemic antimycotic agent fluconazole has been evaluated.<sup>46</sup> In the author's opinion, oral administration of fluconazole (Diflucan, Pfizer Roerig, New York, N.Y.) at 1 mg/kg every 12 hours for 14 days and then every 24 hours for 7 days is associated with significant improvement and resolution of early keratomycosis and corneal stromal abscessation after fungal infection. In addition, topical 1% voriconazole has been evaluated for use in horses, and the author's clinical experience suggests that this is the current topical antifungal of choice.<sup>47</sup>

Many mycotic corneal ulcers are managed best using a combination of surgical and medical management.<sup>16</sup> Surgical débridement in the form of a partial- or full-thickness keratectomy may help remove much or all of the infected corneal stroma, respectively; is performed under general anesthesia; and requires microsurgical instrumentation and magnification. For a partial-thickness keratectomy, the clinician may manage the resulting ulcer medically or, more appropriately, may suture a conjunctival pedicle graft<sup>3,48,49</sup> to the ulcer to aid in healing. The corneal vascularization provided by a conjunctival graft facilitates healing. One can perform a penetrating keratoplasty with a corneal transplant for deeper lesions<sup>50</sup> (see the section on corneal surgery). Most mycotic corneal ulcers and abscesses ultimately vascularize and scar to some degree, regardless of the treatment method. Topical corticosteroids have little if any effect on corneal scar formation and are not indicated, even after resolution of keratomycosis, because the possibility of sequestered organisms exists with subsequent exacerbation.

#### COLLAGENASE ULCERS

Keratomalacia, or corneal melting, results from host-derived collagenase (from neutrophils and keratocytes) and bacterial enzymes such as those produced by *Pseudomonas aeruginosa*

**FIGURE 17-12** Severe melting caused by collagenase ulcer following infection with *Pseudomonas aeruginosa*. Corneal malacia surrounds a large descemetocele.

or  $\beta$ -hemolytic *Streptococcus* spp.<sup>51</sup> Collagenase ulcers progress rapidly and can result in corneal perforation within 24 hours (Figure 17-12). Samples should be obtained for bacterial and fungal culture and cytologic examination. Cytologic examination must include Gram staining to examine for the presence of gram negative rods suggesting *Pseudomonas* spp. or gram positive cocci suggesting  $\beta$ -hemolytic *Streptococcus* spp. The topical antibiotics of choice for collagenase ulcers are ciprofloxacin (Ciloxan, Alcon Laboratories, Fort Worth, Tex.)<sup>38,51</sup> or ofloxacin (Ocuflox, Allergan Inc.) every 2 hours. Topical tetracycline every 4 to 6 hours or oral doxycycline may be of benefit because they inhibit matrix metalloproteinases that are activated in keratomalacia. Topical autologous serum may also inhibit corneal malacia and can be administered every 2 to 4 hours. Serum must be collected and handled in a sterile manner and replaced every 24 to 48 hours to prevent contamination. In addition, débridement of the malacic cornea and a conjunctival pedicle graft or penetrating keratoplasty often are indicated to repair the defect, aid in healing, and prevent corneal perforation.

### DESCEMETOCELE

Descemet's membrane is the basement membrane of the endothelium and the last barrier to corneal perforation. Descemet's membrane does not stain with fluorescein and appears as a clearing in the center of an otherwise edematous corneal ulcer (see Figure 17-8). As with all corneal ulcers in the horse, routine diagnostic procedures for a descemetocele include culture and cytologic examination. A descemetocele is a surgical emergency and likely requires referral to a veterinary ophthalmologist. Surgical management is designed to provide support to the weakened cornea, allowing blood vessels and fibroblasts to repair the damage. Support is achieved with a conjunctival graft or a lamellar or penetrating keratoplasty (see the section on corneal surgery). Routine treatment for a corneal ulcer follows surgery and is best delivered through a subpalpebral lavage system to avoid manipulation of the eyelids and corneal graft. The conjunctival graft may be débrided 6 to 8 weeks after surgery in an attempt to minimize scar formation by severing the blood supply to the graft tissue.

**FIGURE 17-13** Corneal perforation with associated hyphema and iris prolapse.

### CORNEAL PERFORATION AND LACERATION

Causes of corneal perforation include rupture of a deep corneal ulcer or descemetocele and sharp and blunt trauma. Depending on the cause of the perforation and severity of the damage, treatment involves primary repair, an intraocular prosthesis, or enucleation. If the horse is to be referred for consultation and treatment, self-trauma can be prevented during transportation by using cradles or other protective devices and sedation as required. The prognosis after a penetrating injury varies depending on the cause, size of the wound, location, depth of penetration, intraocular damage, and the presence or absence of infection or retained foreign objects. In general, perforating corneal wounds in the horse have a grave prognosis for vision and a guarded prognosis for cosmesis. Such wounds always are associated with secondary anterior uveitis, iris prolapse, and possible lens perforation and rupture (Figure 17-13). Sequelae to a corneal perforation include corneal scar, anterior and posterior synechiae, cataract, glaucoma, retinal detachment, phthisis bulbi, blindness, and loss of the eye.

Primary repair of a corneal perforation is a referral procedure. Treatment includes repairing the rent, re-establishing the anterior chamber, preventing infection, and decreasing inflammation and pain. Removal of a penetrating object is best done at the time of repair. Tetanus toxoid is administered before repair. The aqueous humor, along with any retained foreign objects, should be cultured for aerobic bacteria and fungi. If iris tissue protrudes but appears viable and minimally contaminated, it can be replaced; however, contaminated, nonviable iris is amputated using electrocautery to minimize hemorrhage. If electrocautery is not available, one can perform sharp excision and control the bleeding. Intracamerally administered epinephrine, 1:10,000, can help control intraoperative bleeding and also facilitates pupil dilation. One can use a viscoelastic agent such as sodium hyaluronate to tamponade vessels in addition to maintaining the anterior chamber and manipulating tissues. If the lens capsule has ruptured secondary to trauma, the lens should be removed; lens protein is antigenic and may stimulate severe anterior uveitis. If it is possible to appose wound margins, the cornea is repaired with partial-thickness, simple interrupted or continuous 7-0 to 8-0 absorbable sutures. The anterior chamber is reformed with a balanced

salt solution or, if this is unavailable, lactated Ringer's solution. Conjunctival grafts can be used to promote rapid corneal healing and vascularization and to provide support. If a portion of cornea is missing or the wound edges cannot be apposed, a corneal-scleral transposition or other type of graft procedure is required. After surgery, one administers topical broad spectrum antibiotics every 2 to 4 hours, uses topical atropine as needed, and administers systemic antibiotics and flunixin meglumine. Use of a subpalpebral lavage delivery system is indicated.

Blunt trauma, whether contusive, penetrating, or perforating, generally results in more severe ocular damage than injury from a sharp object<sup>5</sup> (Figure 17-14). In contrast to sharp perforating injuries, blunt trauma results in a rapid increase in IOP, an explosive rupture from the inside outward, and the expulsion of the intraocular contents. The resulting rent in the fibrous tunic is often large and irregular, and portions of the cornea or sclera may be lost. The typical wound is one that originates at the limbus, extending forward into the cornea and posterior into the sclera. If the posterior portion of the eye ruptures, the horse may show hyphema and decreased IOP and may require ocular ultrasound for accurate diagnosis.

Repair of these explosive ruptures is difficult, and the treatment of choice may be enucleation. If cosmetic repair is important, an intraocular silicone prosthesis may be used in some patients, provided enough tissue is left to close the fibrous tunic.<sup>3</sup> This procedure should be performed as soon as possible after injury. If the injury is chronic and atrophy of the globe has occurred, placement of an intraocular prosthesis is not possible. The only cosmetic alternative in these horses is an orbital prosthesis, which is expensive and time consuming and requires frequent maintenance on the part of the owner.<sup>3</sup>

### CORNEAL SURGERY

Surgery in the form of a superficial keratectomy, conjunctival graft, or corneal graft may be indicated in addition to aggressive medical therapy for many complicated corneal ulcers.<sup>53</sup> Corneal surgery requires general anesthesia to optimize the outcome.

A superficial keratectomy provides a biopsy for histopathologic examination, débrides and debulks damaged and infected corneal stroma, and provides a bed for transplanting

**FIGURE 17-14** Corneal perforation following blunt trauma. The lesion is explosive and expulsive with loss of intraocular contents. Enucleation is the treatment of choice.

and suturing a conjunctival or corneal graft. A No. 64 Beaver blade or Martinez corneal dissector is used first to outline the area to be excised and then to undermine and remove the affected area of cornea. In general, 50% to 70% of the corneal thickness can be removed, but excision of 50% or more is an indication to reinforce the remaining cornea with a conjunctival or corneal lamellar graft. The normal equine cornea is 1.0 to 1.5 mm thick and is thinnest centrally. The cornea increases in thickness with disease because of edema, cellular infiltration, vascularization, and scar formation.

Conjunctival grafts include advancement, hood, bridge, pedicle, and complete conjunctival grafts.<sup>48,49,52</sup> The author prefers to perform a conjunctival pedicle graft for most focal corneal ulcers and uses the other types for more extensive lesions.<sup>49</sup> Before placement of a conjunctival graft, débridement of the affected cornea by superficial keratectomy is indicated. The bulbar conjunctiva is mobilized, leaving an intact blood supply. One should attempt to appose conjunctival and corneal epithelium at the edge of the graft and to place 7-0 to 8-0 Vicryl (polyglactin 910) sutures two thirds deep into healthy cornea. A continuous suture pattern, simple or double, works best and is associated with less graft retraction and dehiscence than a simple interrupted suture pattern for equine conjunctival grafts. Conjunctival grafts adhere to the underlying exposed corneal stroma, providing the blood supply and cells required to repair and rebuild the damaged cornea. Opacification of the graft site occurs but is generally less than what would have occurred without surgery. Opacification can be minimized by trimming the graft and severing its blood supply 6 to 8 weeks after the initial surgery.

Autologous and homologous lamellar corneal grafts, corneal-scleral transposition, deep lamellar keratectomy, and penetrating keratoplasty are more involved techniques reserved for the most severe corneal ulcers or for perforating corneal lesions. These are described elsewhere and are referral procedures.<sup>53-55</sup>

In addition to cornea and conjunctiva, other grafting materials, such as equine amnion and porcine collagen, have been used with success for management of equine corneal disease.<sup>56</sup> Nictitating membrane or third eyelid flaps are of little or no benefit for managing complicated and infected equine corneal disease and are contraindicated in many instances.

### NONULCERATIVE DISEASES

Nonulcerative corneal diseases include corneal scar, corneal edema, stromal abscessation, cellular and noncellular infiltrates, immune keratitis, and nonulcerative keratouveitis.<sup>57</sup> Corneal scars are not painful, follow a history of corneal disease, and are associated with corneal vascularization. Topical corticosteroid therapy does not decrease corneal scarring significantly but does predispose the eye to infection and decreases healing in the event of a corneal ulcer. Tattooing of a corneal scar for ocular cosmesis is described<sup>3,16</sup> but not advised.

Cellular infiltration in the corneal stroma includes neoplastic and inflammatory cells. The most common corneal neoplasia is SCC (see the section on conjunctiva and third eyelid; see Figure 17-6). Corneal lymphosarcoma also occurs. Inflammatory cellular infiltration (neutrophils, lymphocytes, plasma cells, eosinophils) usually occurs in infectious keratitis (bacterial, mycotic) and is associated with corneal ulceration. However, a small, focal corneal ulcer can become infected and re-epithelialize, resulting in a corneal stromal abscess. In addition, inflammatory corneal infiltration occurs with equine

ocular onchocerciasis, immune keratitis, and nonulcerative keratouveitis.

Noncellular corneal infiltration or corneal degeneration is a sequela of previous corneal or limbal inflammation. Accumulations of mineral and phospholipids may remain within the corneal stroma after inflammation and appear as crystal-line infiltration. Such accumulations are rare, generally are not painful, and do not require treatment. In some instances they predispose the eye to corneal ulceration and can be removed with a superficial keratectomy.<sup>3</sup>

### CORNEAL EDEMA

Corneal edema, if not associated with a corneal ulcer (fluorescein negative), results from corneal endothelial damage. Blunt trauma to the globe can result in displacement of the corneal endothelium from the posterior surface of the cornea, which results in full-thickness, diffuse corneal edema and which may gravitate to the ventral cornea with time. In addition, diseases of the anterior uvea and aqueous humor, anterior uveitis and glaucoma, and anterior lens luxation can interfere with endothelial cell function, resulting in diffuse corneal edema. Although no specific treatment exists for corneal edema of endothelial origin, hyperosmotic agents such as sodium chloride 5% (Muro-128; Bausch and Lomb, Rochester, N.Y.) applied topically every 4 to 6 hours may decrease the severity of the edema and help prevent rupture of corneal bullae. In the author's opinion, this has only minimal efficacy. With time the corneal endothelium may reattach, or adjacent endothelial cells may hypertrophy, resulting in a decrease in corneal edema. While the edema is present, the cornea is compromised and at risk of ulceration. Topical corticosteroids are therefore contraindicated.

### NONULCERATIVE KERATOUVEITIS

A condition consisting of interstitial keratitis with peripheral corneal vascularization, edema, and cellular infiltrate and anterior uveitis (miosis, aqueous flare, iritis) has been described in five horses.<sup>57</sup> The pathogenesis of nonulcerative keratouveitis is unknown, but anterior uveitis has been suggested to follow interstitial keratitis, and an immune-mediated mechanism is believed to be involved. No infectious or neoplastic process is apparent. Histologically, nonulcerative keratouveitis is characterized by vascularization, fibroblasts, and inflammatory cells, predominantly lymphocytes. No infectious agents are visible on light or transmission electron microscopy.

Treatment is similar to that for equine recurrent uveitis and involves suppression of inflammation and control of ocular pain. Topical and subconjunctival corticosteroids, topical NSAIDs, topical cyclosporin A,<sup>42</sup> topical mydriatic cycloplegics, and systemic NSAIDs effectively control the signs, but some level of long-term maintenance therapy usually is required.

The differential diagnoses for nonulcerative keratouveitis include corneal stromal abscess, equine ocular onchocerciasis, and neoplasia.

### CORNEAL STROMAL ABSCESS

The usual cause of corneal stromal abscess formation is a focal, superficial corneal ulcer that allows opportunistic infection of the corneal stroma and then heals, trapping the microorganism. Topical antibiotic-corticosteroid therapy in eyes with corneal epithelial cell loss may predispose to stromal abscess formation.<sup>3,58,59</sup> The lesion results in discomfort apparent as photophobia, blepharospasm, and excessive lacrimation.

A chronic, yellow-white, corneal stromal infiltrate with associated corneal edema and deep corneal vascularization is present.<sup>58,59</sup> Anterior uveitis may be present. Fluorescein staining of the cornea is often negative. Diagnosis is based on clinical signs. A corneal scraping should be obtained from the lesion, after removal of the overlying corneal epithelium, and submitted for cytologic examination, bacterial culture and sensitivity, and fungal culture. Gram positive cocci (*Streptococcus* and *Staphylococcus* spp.) are the predominant organisms recovered,<sup>58</sup> but fungal stromal abscesses also occur. Differential diagnosis includes nonulcerative keratouveitis.

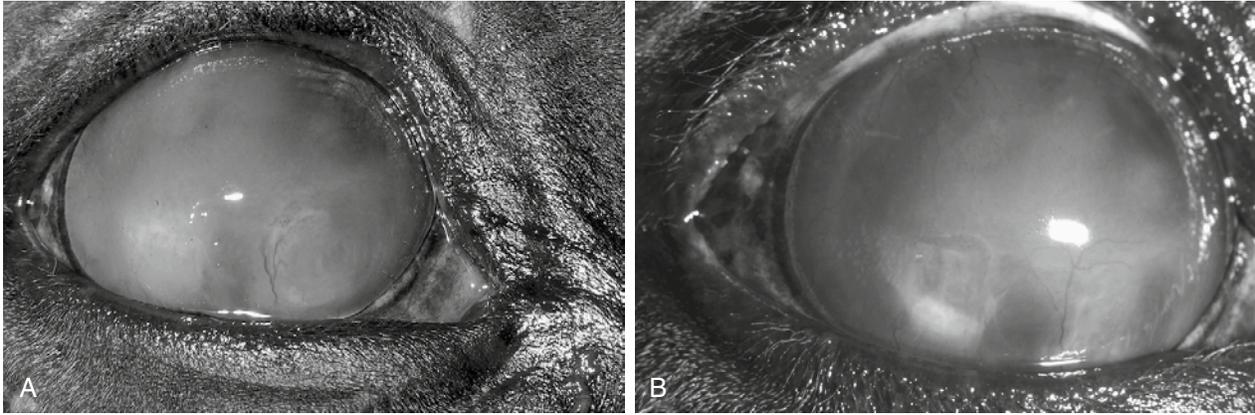

If the overlying epithelium is intact, one can remove it before initiating treatment to facilitate penetration of antibiotics. The fluoroquinolones, ciprofloxacin or ofloxacin, are the topical antibiotics of choice because they penetrate intact corneal epithelium; treatment every 4 hours is recommended pending culture and sensitivity results. In addition, some authors recommend subconjunctival injections of antibiotics.<sup>3,58</sup> If a mycotic stromal abscess is suspected, oral administration of fluconazole (Diflucan, Pfizer Roerig, New York, N.Y.) at 1 mg/kg every 12 hours for 14 days and then every 24 hours for 7 days is indicated.<sup>46</sup> Alternately, 1% voriconazole or an itraconazole-dimethyl sulfoxide ointment can be used topically.<sup>45</sup>

If anterior uveitis is present, topical atropine 1% is administered as needed to dilate the pupil, up to a maximum of 4 times a day. Systemic flunixin meglumine helps reduce ocular pain and secondary complications associated with inflammation. Topical corticosteroids are contraindicated. Resolution of the abscess requires 2 to 8 weeks, is associated with corneal vascularization, and results in corneal scar formation. In addition, the associated anterior uveitis may result in secondary intraocular complications.

A superficial keratectomy and conjunctival pedicle graft,<sup>59</sup> posterior lamellar keratoplasty,<sup>60</sup> or penetrating keratoplasty<sup>50,55,61</sup> is also appropriate and may result in a more rapid resolution and reduced corneal opacification than medical management alone. After performing a keratectomy, one should submit the excised corneal stroma for culture and cytologic or histopathologic examination, because the corneal stroma yields more diagnostic information than preoperative samples.<sup>59</sup>

### EQUINE OCULAR ONCHOCERCIASIS

*Onchocerca cervicalis* is a common equine parasite that has been implicated in conjunctivitis, peripheral keratitis, anterior uveitis, and peripapillary chorioretinitis. Corneal lesions result from *Onchocerca* microfilariae that migrate to and die in the corneal stroma and may incite an inflammatory response. The lesion begins peripherally at the temporal limbus but can extend axially. Interstitial keratitis, manifested as corneal edema, vascularization, and subepithelial focal corneal opacities, occurs and may be associated with temporal bulbar conjunctival vitiligo, conjunctivitis, and anterior uveitis. Diagnosis is based on history, clinical signs, and the presence of eosinophils on cytologic examination and microfilariae on conjunctival biopsy.<sup>62</sup> One can demonstrate microfilariae cytologically through a biopsy of temporal bulbar conjunctiva, placing the sample on a slide with warm saline and examining for the presence of motile microfilariae. The presence of microfilariae must be interpreted in conjunction with the clinical signs because microfilariae can be found in many horses without associated ocular disease.

**FIGURE 17-15** A, Presumed immune keratitis before treatment. B, The same eye 5 days after therapy with oral doxycycline.

Treatment includes suppression of ocular inflammation and microfilaricidal therapy (see Table 17-2). Topical corticosteroids and systemic phenylbutazone or flunixin meglumine control inflammation (see Table 17-3). If anterior uveitis is present, topical atropine 1% can be used as needed to dilate the pupil. Pretreatment with anti-inflammatory medications for 2 to 3 days before administration of microfilaricides is indicated to minimize the ocular response to the dying microfilariae.

#### BAND KERATOPATHY

Single or multiple linear streaks affecting one or both eyes in the horse have been described.<sup>63</sup> Histologically, these are areas of thinning of Descemet's membrane and may be congenital. The principle differential is a corneal stria following chronic glaucoma and enlargement of the globe with stretching of Descemet's membrane. Ophthalmic examination should reveal evidence of prior inflammation or glaucoma, and the clinician should assess vision and determine IOP.

#### OTHER KERATOPATHIES

In addition to the corneal diseases noted, there exists a keratitis that is presumed to be immune mediated. The keratitis presents with punctate to diffuse corneal involvement with mild to no discomfort. The cornea is fluorescein negative, and no concurrent uveitis is observed. There is often a yellow-green color to the corneal stroma (Figure 17-15). Biopsy to date has revealed lymphocytic-plasmacytic keratitis, with no organisms identified. The keratitis has responded to topical corticosteroids, cyclosporin A, and systemic doxycycline, with each horse varied in its response to the form of therapy selected. In addition, the keratitis often recurs when therapy is stopped.

### ☞ UVEA

#### ANATOMY

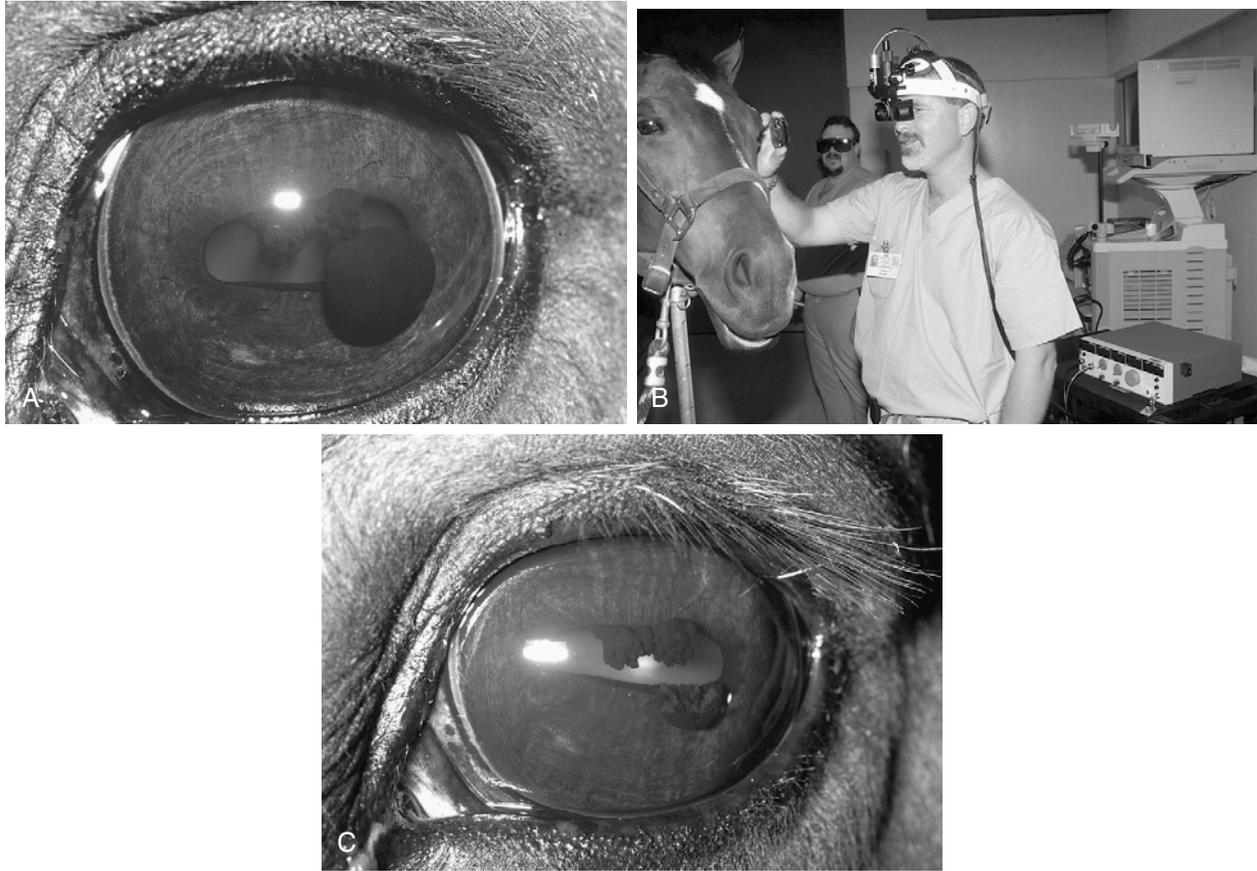

The uvea is the middle, vascular tunic of the eye and comprises the anterior portion, the iris and ciliary body, and the posterior choroid. Histologically, the uvea contains blood vessels; pigment cells; smooth muscle; and in the horse, a noncellular, fibrous tapetum in the choroid. The uvea is the primary site of the blood-ocular barrier, which has importance

in the formation of the aqueous humor, serves as a barrier to bloodborne materials, and is an immunologic barrier to the internal components of the eye. Inflammation disrupts this barrier (uveitis). Smooth muscles in the iris and ciliary body, under autonomic control, regulate pupil size and accommodate for near and far vision, respectively. In uveitis spasm of these muscles results in constriction of the pupil and pain, seen clinically as miosis and photophobia. The ciliary body is the source of aqueous humor, which supplies nutrition to the cornea and lens. Aqueous humor is produced by active and passive processes; its production is decreased by inflammation and by pharmacologic agents used in glaucoma therapy. The choroid supplies nutrition to the retina and also serves as a heat sink to protect the photoreceptors from the heat generated by light striking the retina. The tapetum, contained within the superior choroid, reflects light back across the retina, thereby maximizing the use of available light.

#### ABNORMALITIES OF THE PUPIL

The pupil of the horse is horizontally elliptic, with the dorsal and ventral margins having pigmented prominences termed *corpora nigra*. The pupillary light reflex in the horse is similar to that of other species with a direct and a consensual response. The afferent fibers of the pupillary light reflex are carried in cranial nerve II, and the efferent parasympathetic fibers are carried in cranial nerve III. Abnormalities in pupil response to a light stimulus result from afferent lesions involving the retina or optic nerve. Afferent abnormalities are associated with loss of vision in the affected eye. Efferent lesions are rare but include damage to cranial nerve III with an associated ventrolateral strabismus, abnormalities of the iris itself (as with synechiae), and glaucoma. It is important to differentiate excited horses with sympathetic override, weak light source, and improper examination technique from an abnormal pupillary light response.

Sympathetic nerve fibers supply the dilator muscles of the iris. These fibers travel in the spinal cord, emerge in the ventral nerve roots at first and second thoracic nerves, course through the thorax, run in association with the internal carotid artery, synapse at the cranial cervical sympathetic ganglion, and travel to the eye with the ocular arteries. Damage to the sympathetic fibers results in Horner's syndrome. Clinical signs include ptosis, miosis, enophthalmos, protrusion of the third eyelid, and sweating on the affected side of the face and neck.

**FIGURE 17-16** **A**, A heavily pigmented uveal cyst that is resulting in headshaking and shying behavior. **B**, Transcorneal laser ablation of the cyst is performed in the standing horse. **C**, The cyst immediately after laser ablation.

Treatment is directed toward the primary disease, if possible. In some horses the clinical signs of Horner's syndrome resolve without treatment.

### UVEAL CYSTS

Cysts of the anterior uvea (iris, corpora nigra, and ciliary body) have been reported in the horse.<sup>64,65</sup> The cysts are usually heavily pigmented and may not transilluminate, making a uveal melanoma the most likely differential diagnosis. Ocular ultrasonography reveals these as cystic structures and confirms the diagnosis.

Treatment is not required unless the cysts are numerous or impair sight. One can collapse the cyst; aspirate it by paracentesis; or disrupt it using laser energy delivered transcorneally if this technology is available.<sup>65</sup> Diode laser energy (810 nm) can be delivered to the cyst through the cornea using an indirect ophthalmoscope and a 20-D condensing lens. One performs the procedure on the standing horse and photocoagulates the cyst wall, shrinking the cyst and preventing recurrence (Figure 17-16).

### ANTERIOR SEGMENT DYSGENESIS

Anterior segment dysgenesis has been described in the Rocky Mountain Horse, Kentucky Mountain Saddle Horse, and Mountain Pleasure Horse breeds. The abnormalities associated

with this syndrome include macropalpebral fissure, megalo-cornea, ciliary body and peripheral retinal cysts, congenital miosis, iris stromal hypoplasia, iridocorneal angle abnormalities, cataract, retinal dysplasia, and retinal detachment.<sup>66</sup> The abnormalities appear linked to coat color, with the highest prevalence of abnormalities associated with chocolate coat and white mane and tail.

### UVEITIS

Uveitis is an inflammation of the iris and ciliary body (anterior) and choroid (posterior). Uveitis is a common manifestation of many ocular and systemic infectious and noninfectious diseases, and as such, an attempt to ascertain the cause is essential. Differentiating uveitis from other ophthalmic diseases resulting in a red and painful eye, such as glaucoma, corneal ulceration, and conjunctivitis, is also essential. Uveitis is reported as the leading cause of blindness in horses throughout the world.<sup>4,5,16</sup>

### CLINICAL SIGNS

Acute inflammation of the anterior uvea results in spasm of the iris and ciliary muscles, which is apparent clinically as miosis and photophobia, and a breakdown in the blood-ocular barrier (Box 17-2). The primary mediators of intraocular inflammation are prostaglandins. Eyelids and conjunctiva may be swollen and hyperemic in the acute phase of anterior uveitis.

## BOX 17-2

## SIGNS OF ACUTE AND CHRONIC UVEITIS

**Acute**

Miosis  
 Photophobia  
 Blepharospasm  
 Eyelid swelling  
 Aqueous flare  
 Corneal edema  
 Chorioretinitis  
 Keratitic precipitates  
 Hypopyon  
 Hypotony

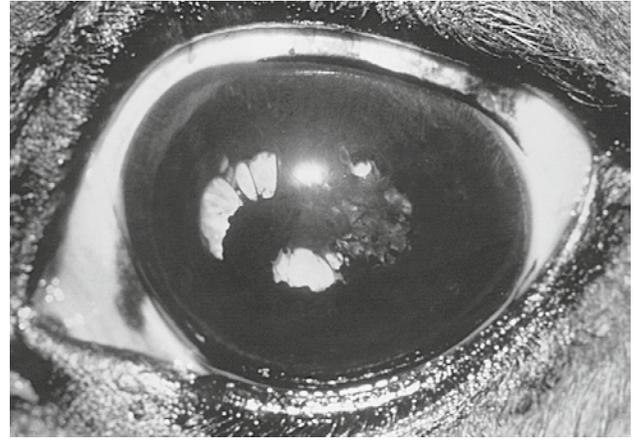

**Chronic**

Posterior synechiae  
 Cataract  
 Pigmentation of anterior lens capsule  
 Atrophy of corpora nigra  
 Glaucoma  
 Peripapillary depigmentation  
 Phthisis bulbi  
 Blindness  
 Lens luxation

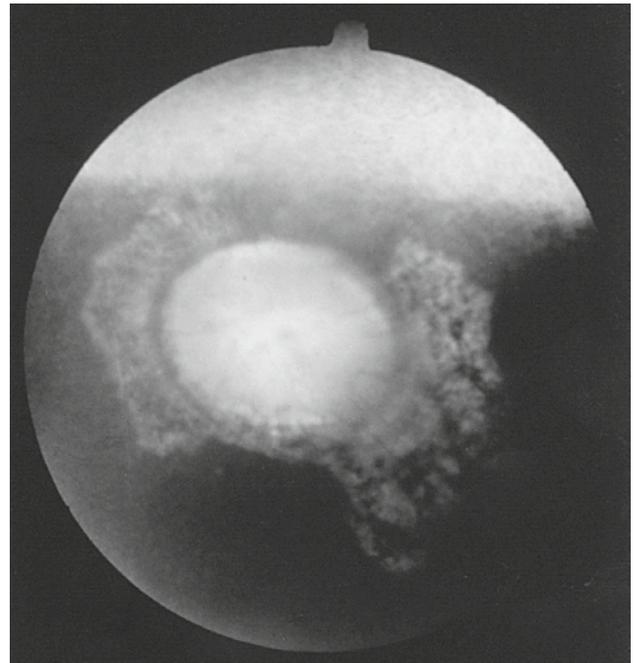

Protein and cells leak into the anterior chamber, resulting in aqueous flare, hypopyon, and keratitic precipitates. The cornea may show diffuse edema, and the IOP will be low in acute uveitis. Chronic inflammatory changes in the aqueous humor can result in secondary corneal endothelial and lens changes (e.g., corneal edema and cataract) and adhesions between the iris and adjacent lens or cornea, termed *synechiae* (Figure 17-17). The lens may stain a yellow color as a result of chronic serum leakage. The corpora nigra will atrophy with chronic uveitis, appearing abnormally small and smooth. Inflammation of the choroid, because of its close association with the retina, usually also involves the retina and is termed *chorioretinitis*. Chorioretinitis is diagnosed by direct or indirect ophthalmoscopy and results in retinal and subretinal transudate and exudate, retinal vascular changes, hemorrhage, retinal detachment, and retinal degeneration. The optic nerve may show hyperemia and later atrophy. Vitreal changes may be observed in association with posterior uveitis. This may include vitreous debris, cells, liquefaction, and yellow discoloration of the vitreous. Choroidal depigmentation and areas of repigmentation or pigment clumping may be present (Figure 17-18). Other chronic changes resulting from intraocular inflammation include secondary glaucoma, retinal detachment, blindness, and phthisis bulbi. The development of intraocular changes following uveitis is related directly to the duration and severity of the acute episode and is exacerbated by recurrent episodes of inflammation.

**CAUSES**

The causes of anterior and posterior uveitis include primary ophthalmic and systemic diseases.<sup>1</sup> Blunt or penetrating ocular trauma, intraocular neoplasia (primary or secondary), corneal ulceration, parasitic infiltration, and numerous systemic infectious diseases with associated septicemia, toxemia,

**FIGURE 17-17** Numerous posterior synechiae and a cataract occur following chronic anterior uveitis. The corpora nigra are adhered to the anterior lens and result in distortion of the pupil margin.

**FIGURE 17-18** Peripapillary depigmentation, a so-called butterfly lesion, associated with the chorioretinitis of equine recurrent uveitis.

immune-complex disease, and viremia are associated with uveitis. Of the systemic infectious diseases implicated in equine uveitis, infections of *Streptococcus equi* subsp. *equi* (strangles) and *Leptospira interrogans* serogroup *pomona*<sup>68,69</sup> and gram negative sepsis occur most commonly. In addition to a complete ophthalmic examination, evaluating the entire animal through a complete physical examination and appropriate laboratory testing is essential. A complete ophthalmic evaluation must include fluorescein staining of the cornea; penlight examination to evaluate pupil size, aqueous humor content, lens position, and transparency; and direct and consensual pupillary light responses. Direct (with or without indirect)

ophthalmoscopic examination of the fundus is also essential. Failure to perform these routine diagnostic tests results in misdiagnosis and incorrect therapy and may result in a failure to consider and examine for systemic disease, thereby placing the health of the animal in jeopardy.

Primary ophthalmic diseases that result in anterior uveitis include corneal ulceration, lens-induced uveitis, intraocular neoplasia, and direct ocular trauma. Corneal ulceration results in secondary anterior uveitis through a reflex pathway involving the ophthalmic branch of cranial nerve V. Fluorescein staining of the cornea therefore is indicated in eyes with anterior uveitis. The lens is considered to be an immune-privileged site and as such is capable of stimulating an inflammatory reaction. Lens protein is exposed by traumatic rupture of the lens capsule or during the degenerative process of a hypermature cataract undergoing liquefaction and leakage. Either of these processes can lead to anterior uveitis, with rupture of the lens resulting in the more severe inflammation and frequently secondary glaucoma. Uveitis resulting from direct ocular trauma may be associated with rupture of the fibrous tunic of the eye, hyphema, lens luxation, corneal endothelial damage, retinal detachment, or proptosis. A complete ophthalmic examination is essential. If the anterior and posterior segments of the eye are not completely visible, then an ocular ultrasound examination is indicated, specifically to evaluate the position of the lens and retina and to look for changes in the echogenicity of the vitreous humor. In addition to a complete ophthalmic evaluation, the entire animal should be examined for signs of trauma to other body systems. Fractures and soft tissue damage of the head and neck, thoracic and abdominal trauma, fractures of the limbs, and neurologic changes involving the central nervous system are potential complications associated with ocular trauma.

Systemic diseases resulting in anterior and posterior uveitis are numerous and include bacteremia, septicemia, disseminated mycoses, and the syndrome of equine recurrent uveitis. Infection with *Borrelia burgdorferi* has been reported to result in arthritis and panuveitis in a pony.<sup>69</sup> Foals with neonatal septicemia are especially prone to anterior and posterior uveitis. The uveitis in these foals is usually sterile. Systemic antimicrobial, topical and systemic anti-inflammatory, and topical atropine 1% therapy are the treatments of choice. Copious fibrin production may result from anterior uveitis, especially in young foals, and can result in posterior synechia and opacification of the lens capsule. Intracameral tissue plasminogen activator, 25 to 75  $\mu$ g administered in the first few days after fibrin formation, can result in complete lysis and resolution.

### EQUINE RECURRENT UVEITIS

Equine recurrent uveitis (ERU; also known as *moon blindness* or *periodic ophthalmia*) is the most common cause of blindness in horses, with Appaloosas at increased risk.<sup>68</sup> ERU is an immune-mediated disease with numerous initiating or exacerbating factors<sup>3,67,70</sup> (Box 17-3). The clinical signs of ERU are similar to those of other causes of uveitis, the distinguishing feature being its recurrent nature. The frequency and severity of each recurrence vary greatly. Even in times of clinical quiescence, inflammation is believed to continue at a subclinical level, resulting in further intraocular damage. Diagnosis is based on history and clinical examination. Although serologic evaluation for *Leptospira* spp., *Brucella* spp., or *Toxoplasma* and

Other

conjunctival biopsies to evaluate for the presence of *O. cervicalis* have been advocated,<sup>3</sup> the results of these tests rarely alter individual therapy, in part because of the chronicity of the disease and because the inciting cause may have begun years before development of uveitis.

Treatment of the individual horse is directed toward suppressing inflammation, controlling pain, and preventing sequelae. When the prevalence of ERU in a barn exceeds that which is normally expected, serologic testing and examination to attempt to determine the cause are indicated. Routine vaccination for *Leptospira* spp. is controversial and may be contraindicated in horses with active inflammation.

The prognosis for ERU varies according to the severity of uveitis, duration of episodes, response to treatment, and frequency of recurrence. Each episode results in some degree of intraocular damage, and damage to the corneal endothelium, lens, and retina is cumulative because repair of these tissues is difficult. In addition, damage often occurs at a subclinical level during the so-called inactive periods. Horses with evidence of previous uveitis, corneal edema, cataract, synechia, pigment on the anterior lens capsule, atrophy of the corpora nigra, and degeneration of retina and optic nerve should be considered ophthalmologically unsound. All animals that have had an episode of acute uveitis should be considered at risk to develop chronic recurrent uveitis. All animals with chronic recurrent uveitis have a guarded prognosis for long-term maintenance of normal vision, with blindness often the result.

### TREATMENT

The treatment of any uveitis, acute or chronic, involves specific therapy determined by the cause of the uveitis and nonspecific therapy designed to decrease inflammation, alleviate pain, and prevent further intraocular damage. The initiation of specific therapy depends on correctly identifying the cause, whether a primary ophthalmic disease or a systemic problem. Failure to control intraocular inflammation may lead to severe secondary ophthalmic complications such as glaucoma, synechia, cataract, retinal detachment, phthisis bulbi, and blindness.

Nonspecific therapy includes topical and systemic corticosteroids and NSAIDs to decrease inflammation and atropine to dilate the pupil and decrease the pain of ciliary muscle spasm. Selection of medication, frequency of treatment, and route of

administration depend on the cause and severity of the uveitis and whether the uveitis is anterior, posterior, or both.

Topical medications for treating anterior uveitis include atropine, corticosteroids, cyclosporin A, and NSAIDs. Topical atropine 1% is administered as needed to dilate the pupil, but generally not more than four times a day. The clinician should monitor intestinal motility because topical atropine can result in ileus and colic. Topical corticosteroids are useful, provided corneal ulceration is not present, as determined by fluorescein stain. Prednisolone acetate 1% ophthalmic is the corticosteroid of choice because it achieves the highest intraocular levels. Alternatively, dexamethasone 0.1% ophthalmic solution or 0.05% ointment may be used. Frequency of administration varies according to severity, with initial frequency being every 4 to 6 hours and subsequently decreased as the eye responds to therapy. Topical corticosteroid therapy should be continued for several weeks after resolution of clinical signs. In addition, subconjunctival corticosteroids have been advocated in severe cases of anterior uveitis<sup>3,16</sup> (see Table 17-3). Topical NSAIDs are available, but little information exists regarding their efficacy for treating ERU. The author's experience suggests some efficacy but significantly less clinical response than with topical corticosteroids. Topical NSAIDs can be used in horses with anterior uveitis and associated corneal ulceration with less risk than corticosteroids. Topical corticosteroids and NSAIDs have a synergistic effect and can be used in combination. Topical antibiotics are not required unless a corneal ulcer is present; corticosteroids then are contraindicated. Topical cyclosporin A 0.2% ointment (Optimmune, Schering-Plough, Kenilworth, New Jersey) may be efficacious for treating active uveitis and as a long-term treatment to decrease the frequency and severity of subsequent recurrences.<sup>42</sup> Unfortunately, although cyclosporine is the drug of choice, it has limited ability to penetrate the intact cornea and reach target tissues.

Systemic NSAIDs are used with topical therapy. Flunixin meglumine is the systemic NSAID of choice for acute ocular inflammation and can be used safely in the presence of corneal ulcer. Alternatively, phenylbutazone or aspirin can be used. Chronic oral administration of aspirin at 25 mg/kg every 24 to 48 hours has been advocated to decrease the frequency and severity of recurrent episodes of uveitis.<sup>3</sup> Horses with active uveitis should be confined in a darkened stall to decrease discomfort and limit exercise.

Recently, surgical management of ERU has been advocated. Surgeries include intravitreal or suprachoroidal placement of a sustained-release cyclosporine-impregnated device<sup>71-74</sup> or vitrectomy.<sup>75</sup> Implantation of a 4- $\mu$ g/day intravitreal cyclosporin A implant decreased the frequency and severity of recurrent uveitis episodes in 23 horses with a mean follow-up of 1 to 29 months (mean 10.5  $\pm$  SD 7.6 months).<sup>71,74</sup> Of the treated horses 18 of 23 (78.2%) had sight at the time of follow-up. Complications of the intravitreal cyclosporin A implant include glaucoma and retinal detachment, both of which may relate to ERU. Placement of a suprachoroidal implant is associated with less postsurgical complications than with the intravitreal device and is the current treatment of choice for many horses with ERU. Compared with suprachoroidal cyclosporin A implantation, pars plana vitrectomy is a more invasive surgery, requiring more instrumentation and expertise, and is often associated with significant postoperative vision-threatening complications. Pars plana vitrectomy does appear, however, to decrease the severity and frequency of ERU episodes.

## GLAUCOMA

Glaucoma is an elevation of IOP to a level incompatible with the health of the eye. Equine glaucoma is secondary in virtually all cases, typically resulting from ERU.<sup>76</sup> The reported normal IOP in the horse varies according to the technique used and whether sedation is used, with sedation resulting in a decrease in IOP. One should perform an auriculopalpebral nerve block before determining IOP in the horse. Normal values are reported to range between 15 to 25 mm Hg. Measurement of IOP in the horse presents a challenge in that indentation tonometers, such as the Schiøtz, are not well suited for use in the horse. Applanation tonometers, especially portable devices such as the Tonopen Vet, are best suited for determining equine IOP. In the author's practice determination of IOP is a routine part of a complete equine ophthalmic examination. Before determining IOP in the horse, one should remember that intravenous administration of xylazine significantly lowers the IOP.<sup>3</sup>

Although congenital glaucoma (megaloglobus) has been reported in the horse, secondary glaucoma resulting from anterior uveitis, especially ERU, is the most common cause of equine glaucoma.<sup>76</sup> The clinical signs of glaucoma in the horse are often more subtle than those in other species. Acute glaucoma may result in pain (photophobia, blepharospasm, lacrimation), corneal edema, linear corneal opacities (striae), mydriasis (provided uveitis or posterior synechiae are not present), and decreased menace response. The linear opacities in equine glaucoma often extend from limbus to limbus and are areas of thinning of Descemet's membrane.<sup>5</sup> Similar linear opacities also occur in normal horses, have been termed *band* or *linear keratopathy*, and are not significant. In chronic glaucoma corneal edema and corneal striae may be visible. Enlargement of the globe (buphthalmos), retinal degeneration, and blindness also occur.

Unfortunately, most horses with glaucomatous eyes do not receive treatment until late in the disease, resulting in a poor response to therapy. Medical treatment of acute glaucoma involves topical agents such as timolol maleate 0.5% (Timoptic; Merck and Co., West Point, Pa.), dorzolamide 2% (Trusopt, Merck), and the combination of these two drugs (Cosopt; Merck).<sup>77,78</sup> These drugs are administered alone or in combination two to three times daily in an effort to reduce IOP by increasing the outflow and decreasing production of aqueous humor. Of all the topical glaucoma agents, timolol maleate and dorzolamide are most effective in the horse, and the combination is more effective than administration of the two drugs concomitantly.<sup>77</sup> Because of the large percentage of uveoscleral outflow in the horse, careful use of topical atropine may actually reduce IOP in some eyes.<sup>79</sup> Use of atropine is controversial, however. Topical corticosteroids, systemic flunixin meglumine, or combined therapy is indicated to control any concomitant inflammation or pain. Failure of topical therapy to control acute glaucoma indicates the need for surgical intervention.

Surgery for the acute glaucoma patient includes transscleral cyclocryosurgery or cyclophotocoagulation using a Nd:YAG or diode laser.<sup>76,80-83</sup> Both procedures are designed to reduce the production of aqueous humor and decrease IOP. Cyclophotocoagulation has fewer intraocular side effects than cyclocryosurgery and is the surgical treatment of choice. In a retrospective evaluation of 27 horses treated by transscleral diode laser cyclophotocoagulation, adjunct medical therapy

was required for 90% of horses and vision was maintained in 64% with a mean follow-up of 33 months (7 to 69 months).<sup>76</sup> Surgical filtering procedures, designed to provide an alternative outflow pathway for aqueous humor, are generally unsuccessful in the horse.<sup>5</sup>

Treatment of chronic glaucoma is surgical and is designed to reduce discomfort. Enucleation or evisceration with insertion of an intraocular silicone prosthesis is the procedure of choice.<sup>84</sup>

## HYPHEMA

Hyphema is blood in the anterior chamber of the eye (see Figure 17-13). As is true of bleeding into other body cavities, blood in the anterior chamber of the eye does not usually clot. It is important to remember that not all hyphema results from ocular trauma. One must consider systemic diseases that result in clotting disorders or intraocular inflammation.

If the hyphema is complete and precludes the evaluation of intraocular structures, ocular ultrasound is indicated to assess the lens position, retina, and posterior eye wall. The greatest resolution in ocular ultrasound is achieved with a 10- to 20-MHz or, if unavailable, a 7.5-MHz probe. One places the probe directly on the cornea or images through the eyelid or an offset device. Provided no other intraocular damage is evident, hyphema will resolve, often without significant sequelae. If associated intraocular damage has occurred, potential sequelae include cataract, posterior synechiae, glaucoma, retinal detachment, and blindness (Figure 17-19).

When hyphema results from a traumatic event, concurrent anterior uveitis is usually present. Although hyphema usually does not require therapy, the associated anterior uveitis does. As previously discussed, anterior uveitis is treated with topical atropine and systemic flunixin meglumine. If no corneal ulcer is associated with the hyphema, topical corticosteroids also may be administered. Resolution of hyphema may require 7 to 21 days; to decrease the incidence of rebleeding, the horse should not be exercised during this time. Surgical intervention to remove the hyphema rarely, if ever, is indicated. When lysis of a clot is beneficial, intracameral injection of tissue

**FIGURE 17-19** Ocular ultrasonography using a 7.5-MHz probe. A retinal detachment is visible with the retina remaining attached at the optic nerve and ciliary body.

plasminogen activator (TPA; 25-75 µg; Activase, Genentech, Inc., South San Francisco, California) may be indicated.<sup>85</sup> Injection of TPA should not be performed until the cause of the hemorrhage is resolved and the vessel wall repair is complete, or rebleeding may occur. This generally happens 7 to 14 days after the initial bleeding episode.

## LENS

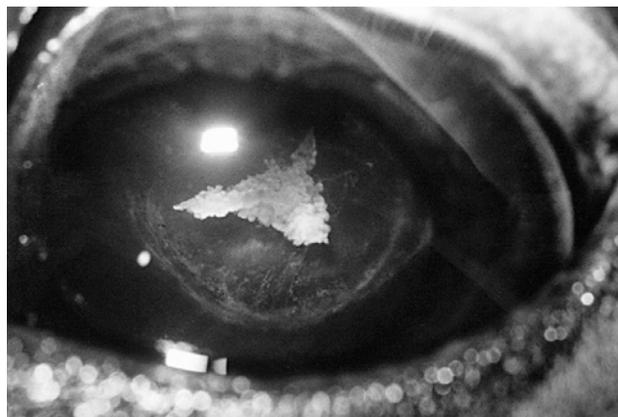

The lens originates from surface ectoderm and is a clear, avascular, biconvex structure suspended posterior to the iris by lenticular zonules arising from the ciliary body. The lens depends on the aqueous and vitreous humors to supply nutrition and remove waste products. The lens should be examined in a darkened environment after dilation of the pupil with tropicamide 1.0% (Mydracyl, Alcon Laboratories). Using a bright focal light source, one evaluates the lens for size, shape, location, and transparency. In addition, a new handheld, monocular slit lamp that attaches to an otoscope or ophthalmoscope handle is available (HSL-10) and provides magnification and an appreciation for depth and three-dimensional anatomy of the lens and anterior segment. Abnormalities of the lens include congenital malformations, cataract, and luxation.

## CONGENITAL

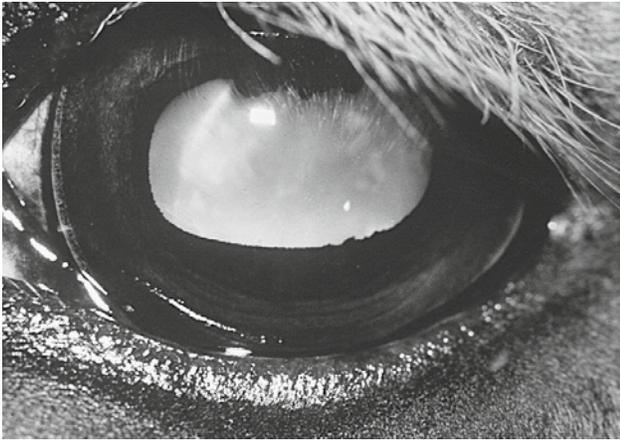

Congenital disorders of the lens, other than cataract, are rare. Abnormalities of size (aphakia, microphakia), shape (coloboma, spherophakia), and location (luxation) generally are associated with other ocular abnormalities, such as microphthalmos, retinal dysplasia, and retinal detachment. These abnormalities can be unilateral or bilateral and may or may not be inherited. Treatment usually is not required except for cataract and luxation. Breeding of affected animals is discouraged.

## CATARACTS

A cataract is any opacity, of any size, involving the lens or its capsule (Figures 17-20 and 17-21). Cataracts can be unilateral or bilateral and are classified according to location and degree of lens affected (Box 17-4). Classification helps determine the cause and likelihood of progression and helps the clinician follow progression. These terms are only descriptive and are

**FIGURE 17-20** An incipient posterior cortical cataract.

**FIGURE 17-21** A mature cataract.

#### BOX 17-4

##### CHARACTERIZATION OF CATARACTS

###### Location

- Capsular
- Subcapsular
- Cortical
- Equatorial
- Axial
- Nuclear
- Anterior/posterior

###### Severity

- Incipient: earliest form; small vacuoles
- Immature: most of lens affected; fundus visible
- Mature: entire lens affected; fundus not visible
- Hyper mature: liquefying lens fibers; leaking through lens capsule
- Morgagnian: entire cortex liquefied; nucleus settles ventrally

not mutually exclusive. For example, one such description might be an “anterior, cortical, axial, incipient cataract.” In general, anterior, cortical, and equatorial cataracts are more likely to progress than are nuclear and posterior cataracts. In addition, cataracts are classified on the basis of age of onset and, if possible, cause. Classification by age of onset includes congenital, juvenile, adult, and senile cataracts. Congenital cataracts are the most common congenital ocular anomaly in the horse, can be unilateral or bilateral, and may affect only the nuclear portion of the lens.<sup>86</sup> Juvenile and adult cataracts, although acquired, are still heritable.

Although many causes of cataracts exist in other species, most causes have not been documented in the horse. Potential causes of cataract formation include inherited, inflammatory, traumatic, metabolic, toxic, and nutritional abnormalities. Suspected inherited cataracts have been reported in several

breeds of horses (Belgian, Morgan) and are thought to occur in other breeds but are difficult to prove because of the small number of offspring produced. It is important to remember that inherited cataracts are not necessarily congenital and that not all congenital cataracts are inherited. In general, if the cause of a cataract cannot be determined and intraocular inflammation is not evident, breeding of the animal should be discouraged. The most common cause of cataract formation in the horse is ERU.

Treatment of cataracts, if required, is surgical. The decision to treat depends on the severity and cause of the cataract and the presence or absence of concomitant ocular disease. Cataracts that are unilateral or not sufficiently severe to interfere significantly with vision generally do not require treatment. Cataracts resulting from intraocular inflammation, such as those associated with ERU, may not be amenable to surgery. However, with the availability of a sustained-release cyclosporine-impregnated device,<sup>71-73</sup> cataract surgery can be performed with or without a partial vitrectomy and implantation of a cyclosporin A device. Treatment of cataracts associated with abnormalities of the retina, such as retinal detachment or degeneration, is not indicated. If the cataracts are bilateral, interfere with vision, and do not result from ERU or other intraocular inflammation, then the lens and its anterior capsule can be surgically removed. Before cataract surgery, retinal anatomy and function should be evaluated using ocular ultrasound and electroretinography. One should operate on foals with congenital cataracts early (<6 months) to prevent possible deprivation amblyopia. Surgery is best performed using phacoemulsification.<sup>5,87,88</sup> An artificial intraocular lens implant (IOL) is now available for horses. Cataract extraction without implantation of an IOL results in a significant degree of postoperative hyperopia (farsightedness).<sup>16</sup> Implantation of an IOL is designed to correct this postoperative refractive error and restore the horse to emmetropia. Although use of an IOL is common in other species, it is only recent in the horse, and there is not sufficient information to discuss intraoperative and postoperative complications. Cataract surgery is a referral procedure.

#### LUXATION

Lens luxation and subluxation can be congenital or acquired. Acquired lens luxation results from glaucoma and buphthalmos; trauma; or, most frequently, uveitis, especially ERU. Once luxated, the lens can be displaced anteriorly or posteriorly. A posteriorly luxated lens results in liquefaction of the vitreous from lens movement. The lens settles inferiorly, may or may not attach to the retina, and generally does not result in significant problems or require therapy. Anterior lens luxation results in anterior uveitis; trauma to the corneal endothelium, resulting in diffuse corneal edema; and obstruction of aqueous humor circulation, resulting in secondary glaucoma. Treatment of anterior lens luxation is surgical removal using an intracapsular extraction technique, provided the eye is visual. This is a referral procedure. In a blind, painful eye, enucleation or intrascleral prosthesis is the treatment of choice.

#### ☉ FUNDUS

The equine fundus is best examined in a darkened environment after mydriasis. Direct and indirect ophthalmoscopy are useful for examining the equine fundus, although direct

ophthalmoscopy is preferable for examining the optic nerve and retinal blood vessels. Examination should include evaluation of the tapetal and nontapetal fundus, retina, retinal blood vessels, and optic nerve. Variations in the normal equine fundus are common, and familiarity with these variations is essential.<sup>16,86,89,54</sup> The horse has a periangiitic retina (partially vascularized) with 30 to 60 small retinal vessels radiating from the margin of the optic disc. These vessels are visible for a distance of one to two disc diameters. The remainder of the equine retina is avascular, being supplied from the underlying choroidal blood vessels. The optic disc is situated in the nontapetal fundus, is oval, and is salmon-pink. The fundus is divided into tapetal and nontapetal regions. The tapetum is situated in the dorsal fundus and is responsible for the characteristic yellow-green of this portion of the fundus. Variations in tapetal color are related to coat color and include yellow, orange, and blue-green.<sup>16,86</sup> The tapetum of the horse is fibrous and penetrated by small choroidal vessels that appear as dark dots in the tapetum, termed the *stars of Winslow*. The ventral, nontapetal fundus is generally dark brown or black but can appear lighter or nonpigmented depending on coat color.<sup>16,86</sup>

Abnormalities of the posterior segment can be congenital or acquired. Abnormalities on fundic examination include changes in size, shape, and color of the optic nerve and retinal vessels; elevation or depression of the optic nerve; hemorrhage; changes in tapetal reflectivity (hyper-reflective and hyporeflective), and changes in pigmentation. Hyper-reflective abnormalities often indicate thinning or loss of retinal tissue. Hyporeflective changes can indicate an increase in tissue thickness resulting from cellular infiltrates, edema, or folding of the retina, as in retinal dysplasia. Inflammation can result in depigmentation and pigment clumping in the nontapetal fundus and hyperpigmentation in the tapetal fundus. Equine motor neuron disease has been described to result in a mosaic pattern of yellow-brown pigmentation in the tapetal fundus accompanied by a horizontal band of pigment at the tapetal-nontapetal junction.<sup>90</sup>

## RETINA

### CONGENITAL STATIONARY NIGHT BLINDNESS

Equine night blindness is a bilateral, congenital, nonprogressive retinal disease of Appaloosas. The degree of visual disturbance varies among horses, with mildly affected horses exhibiting signs only in dark conditions, whereas severely affected horses are totally blind in the dark, exhibit apprehension in daylight, and may have a bilateral dorsomedial strabismus and nystagmus.<sup>91</sup> The diagnosis is based on history, breed of horse, clinical signs, and maze testing in illuminated and darkened environments, but it must be confirmed by electroretinogram because the fundic examination in affected horses is normal. Electroretinography demonstrates an almost purely negative waveform in the scotopic (dark-adapted) response, characteristic of equine night blindness.<sup>91,92</sup> The results of the electroretinogram indicate an abnormality in signal transmission from the photoreceptor cells to the inner retina.<sup>91</sup> Although the inheritance of equine night blindness in the Appaloosa is not defined completely, the disease is suspected to be an autosomal recessive disease. No treatment is available.

### CHORIORETINITIS

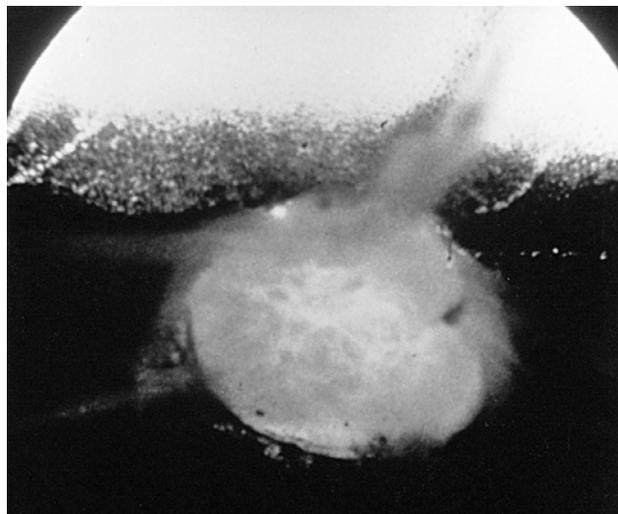

Inflammation of the retina and choroid in the horse most often results from ERU and may be associated with concomitant optic neuritis. In addition, the vascular nature of the choroid results in susceptibility to bloodborne disease, as with bacteremia, septicemia, and viremia, and most often occurs in foals with pneumonia, strangles (*Streptococcus equi* subsp. *equi*), and other severe infectious diseases. Inflammation of the anterior portions of the eye, anterior uveitis, often is associated with chorioretinitis. Treatment of chorioretinitis includes systemic therapy for the primary infectious disease, if present, and flunixin meglumine to decrease inflammation. Topical treatment is indicated only with anterior uveal involvement. The sequelae of chorioretinitis include retinal degeneration, retinal detachment, and optic nerve atrophy.

### RETINAL DETACHMENT

Retinal detachment can be congenital or acquired, partial or complete (Figure 17-22). Because the equine retina depends almost totally on the underlying choroid for its blood supply, detachment results in rapid and severe retinal degeneration. Common causes of retinal detachment in the horse include an inherited abnormality (associated with retinal dysplasia), ERU, and trauma. Congenital retinal detachment often is associated with other ocular abnormalities. Hyphema may be associated with traumatic detachment, requiring ocular ultrasonography for definitive diagnosis. Treatment is limited to controlling the inciting disease and use of systemic anti-inflammatory drugs.

### PHOTIC HEADSHAKING

A condition of headshaking induced by exposure to light and eliminated by blindfolding, darkened environment, and contact lenses has been reported in horses.<sup>93,94</sup> The problem usually occurs in the spring and summer; is exacerbated by exercise; and may be accompanied by sneezing, snorting, and nasal rubbing. Differential diagnoses for photic head shaking include middle ear disorders, ear mites, guttural pouch

**FIGURE 17-22** Gray folds of retina are visible overlying and adjacent to the optic nerve, indicating retinal detachment.

mycosis, other ocular disorders, and nasal and dental disease. Ophthalmic examination in these animals is normal. An optic-trigeminal response is hypothesized to occur with optic stimulation, resulting in referred stimulation in areas innervated by the trigeminal nerve.<sup>93</sup>

Treatment using cyproheptadine at 0.3 mg/kg (Sidmark Laboratories Inc., East Hanover, N.J.) orally every 12 hours has been effective in several horses.<sup>93,94</sup> Cyproheptadine is an antihistamine (histamine<sub>1</sub> blocker) and a serotonin antagonist and is hypothesized to work in photic headshaking by moderating the trigeminal nerve sensation, having a central effect on melatonin, or through anticholinergic activity.<sup>93</sup>

## EQUINE MOTOR NEURON DISEASE

Equine motor neuron disease results from a dietary deficiency in the antioxidant vitamin E (See Chapter 12).<sup>95,96</sup> Ceroid-lipofuscin subsequently accumulates in the retinal pigment epithelium.<sup>95</sup> With ophthalmoscopy, this appears as irregular, sometimes linear accumulations of pigment in the tapetal and nontapetal retina (Figure 17-23). The ophthalmoscopic findings, along with appropriate musculoskeletal signs, highly suggest a diagnosis of equine motor neuron disease.

## ☞ OPTIC NERVE

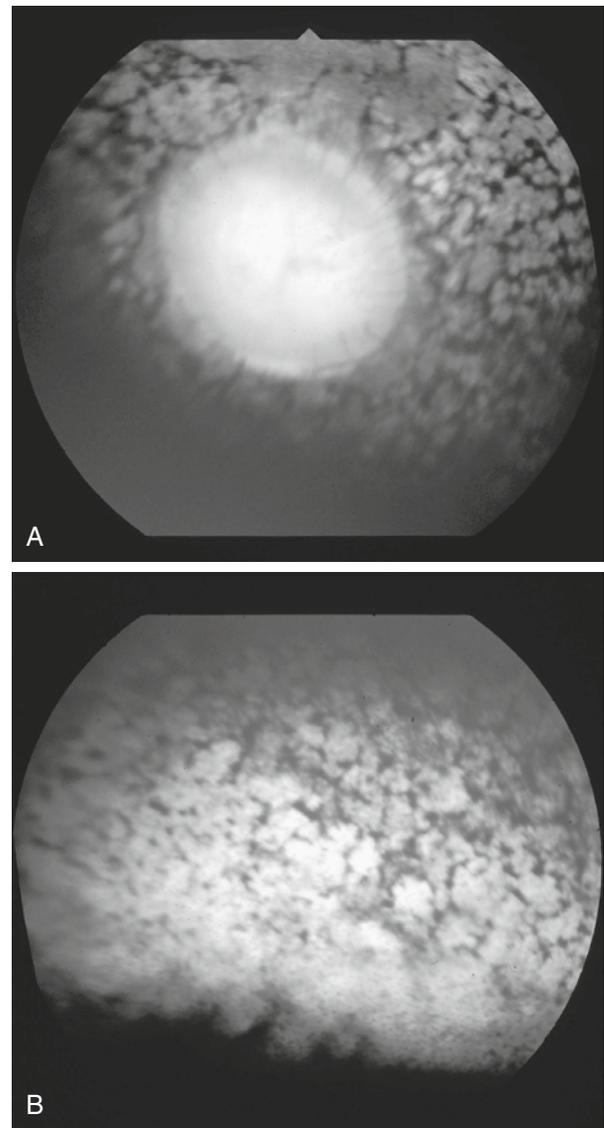

The equine optic nerve is oval, salmon-pink, and located in the nontapetal region of the fundus. Arterioles and venules (30 to 60) extend a short distance from the optic nerve into the surrounding peripapillary retina. On direct ophthalmoscopic examination the margin of the optic nerve is sharp and well defined, as are the retinal blood vessels. Often the nerve fiber layer of the retina is visible as linear white streaks radiating outward from the optic nerve. Congenital abnormalities of the optic nerve are rare and include coloboma and hypoplasia, which may occur alone or in association with other ocular congenital anomalies. Acquired abnormalities of the optic nerve may appear as indistinct margins, pallor, vascular attenuation, peripapillary depigmentation, edema, hemorrhage, or proliferative changes.

## OPTIC ATROPHY

Trauma to the head of the horse has been associated with acute unilateral or bilateral blindness resulting from optic nerve damage. The pupil in the affected eye is dilated, but the remainder of the ophthalmic examination may be normal initially. Occasionally, retinal hemorrhage and papilledema are present. Fundic examination 3 to 4 weeks after the traumatic episode reveals optic nerve pallor and absence of retinal blood vessels, indicating atrophy (Figure 17-24). The cause of this lesion is hypothesized to be stretching of the optic nerve with subsequent rupture of the optic nerve axons<sup>97</sup> or trauma from bony fractures adjacent to the optic nerve. A small number of these horses may benefit from systemic anti-inflammatory therapy in the acute phase. The prognosis, however, is guarded, and treatment usually is unrewarding. Optic nerve atrophy also is associated with ERU and results from chronic glaucoma.

## ISCHEMIC OPTIC NEUROPATHY

Ischemic optic neuropathy and resulting blindness are described as following treatment of guttural pouch mycosis by arterial occlusion (see Chapter 9). The horses are acutely blind,

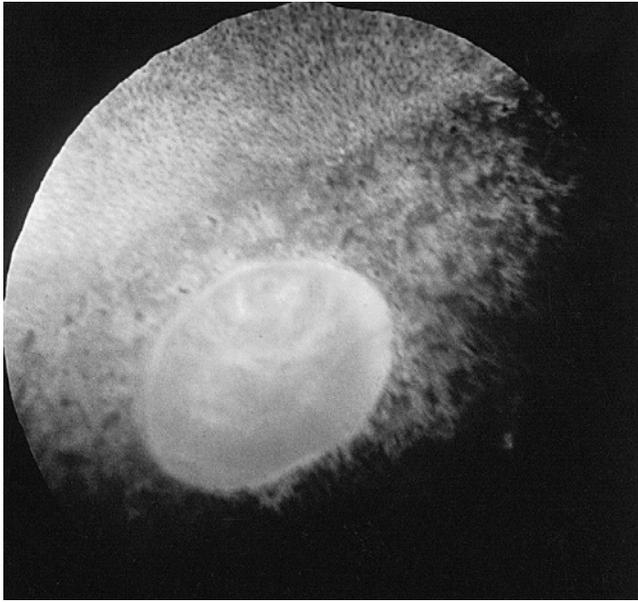

**FIGURE 17-23** **A**, The optic nerve and peripapillary region of horse affected with equine motor neuron disease. The linear accumulations of pigment are ceroid-lipofuscin in the retinal pigment epithelium. **B**, Similar lesions are visible in the dorsal tapetal retina.

with a fixed and dilated pupil on the affected side immediately after surgery. Blindness is thought to result from ischemia and infarction of the optic nerve and its associated fibers. The initial fundic examination is normal, with abnormalities first seen 3 days after surgery. Indistinct optic disc margins suggesting papilledema or papillitis and raised, white lesions involving the optic nerve are the initial changes.

## OPTIC NERVE HYPOPLASIA

Horses affected with optic nerve hypoplasia have visual impairment or blindness and slow to absent pupillary light reflexes.<sup>16,86</sup> The abnormality is congenital and can be unilateral or bilateral. Optic nerve hypoplasia may be associated with other ocular abnormalities, including cataracts, retinal detachment, and microphthalmos.<sup>86</sup> The optic disc appears

**FIGURE 17-24** Severe optic nerve atrophy associated with head trauma. The optic nerve is pale, with loss of peripapillary retinal blood vessels. The horse is blind in the affected eye.

small and pale, with fewer retinal vessels than normal. Clinically, optic nerve hypoplasia can resemble acquired optic nerve atrophy. A definitive diagnosis can be made on histologic examination. No treatment is indicated, and although the definitive cause is not known, owners should not use the affected horse and possibly the sire and dam for breeding.

Other abnormalities of the optic nerve include bilateral optic neuropathy and blindness following severe hemorrhage<sup>99</sup>; proliferative optic neuropathy, as in aged horses<sup>100</sup>; neoplasia of the optic nerve<sup>101</sup>; and optic neuritis, which may be associated with ERU.

## ORBIT

The horse has a complete bony orbital rim composed of the frontal, lacrimal, zygomatic, and temporal bones. The caudolateral and ventral walls of the equine orbit are fasciae. Abnormalities of the equine orbit usually result from trauma. The zygomatic arch and supraorbital process of the frontal bone and the medial orbital wall are most susceptible to injury. Damage to these areas can involve the supraorbital foramen and its associated nerve or the osseous portion of the nasolacrimal system, respectively.

The diagnosis of an orbital fracture is based on history, clinical signs, and radiographs. Radiographic evaluation of the equine orbit is technically difficult and often unrewarding. Oblique views, highlighting the area of greatest concern, usually are required. One must take care to evaluate the paranasal sinuses—the frontal, maxillary, and sphenopalatine—especially when subcutaneous emphysema is present.

Traumatic fractures of the orbit often are associated with concomitant injury of the globe and adnexa. Complete ophthalmic examination is essential and must include assessment of facial symmetry, vision (menace response, maze testing), pupillary light reflex, fluorescein staining for the presence of a corneal ulcer, examination of the anterior chamber for

hyphema and anterior uveitis, fundic examination evaluating the retina and optic nerve, assessment of globe and eyelid mobility, and nasolacrimal irrigation. Head trauma in the horse has been reported to result in acute blindness with fixed, dilated pupils resulting from optic nerve compression, stretching, or avulsion. In those eyes in which ocular damage precludes examination of the posterior segment, ocular ultrasound examination is advised.

Blunt trauma to the orbit can result in a breakdown of the fibrous orbital septum and subsequent herniation of orbital fat. Clinically, the condition is a nonpainful swelling that appears at the time of, or following, orbital trauma and is best treated surgically, removing or replacing the herniated portion of the orbital fat pad and attempting to repair the rent in the septum.

Traumatic proptosis is rare in the horse because of the complete bony orbital rim. If the globe protrudes, it indicates severe head trauma, and thorough physical and neurologic examinations are required. Provided the optic nerve and extraocular muscles are intact, an exophthalmic globe should be replaced, a procedure that requires general anesthesia. After replacing the globe, one performs a temporary tarsorrhaphy to protect the eye until the swelling subsides. Systemic antibiotics and anti-inflammatory drugs are indicated to control postoperative complications.

Treatment of orbital trauma in the acute phase includes systemic anti-inflammatory therapy; systemic antibiotics, especially if a paranasal sinus is involved; and cold compresses. The anti-inflammatory drug of choice is systemic flunixin meglumine. Local therapy is required to manage corneal exposure, ulceration, and anterior uveitis. If eyelid movement is impaired because of neurologic dysfunction or swelling of the eyelids, the cornea must be protected from exposure and desiccation by using a topical, sterile ophthalmic lubricant applied as frequently as possible or, in the more severe cases, by using a temporary tarsorrhaphy. Topical broad spectrum antibiotics are indicated in horses with corneal ulceration, and atropine relieves the discomfort associated with anterior uveitis.

Although facial and orbital fractures in horses often heal without surgery, they may do so in a manner that results in deformity and interferes with the normal function of the eye and adnexa. Therefore surgical correction may be indicated, especially in those fractures that are displaced. Fractures that extend into a paranasal sinus must be considered as open fractures because these sinuses contain resident bacterial and fungal flora. Early repair is associated with a more favorable cosmetic result because skull fractures consolidate rapidly, and the resulting fibrous callus may interfere with surgical reduction. Generous skin flaps in the surgical approach are advised because fractures are often more extensive than initially thought. Excessive periosteal dissection is not recommended because periosteum provides stability and blood supply to the damaged area.

Orbital neoplasia is rare and may result in exophthalmos, strabismus, and vision and pupil abnormalities. Skull radiographs, orbital ultrasound, cytologic examination of a fine-needle aspirate, and histopathologic examination are useful in confirming the diagnosis. SCC, lymphosarcoma, adenocarcinoma, medulloepithelioma, melanoma, and tumors of neuroendocrine origin have been described.<sup>102</sup> Differential diagnoses include trauma and orbital abscess and cellulitis. Because most horses do not receive treatment until late in the

course of disease, orbital exenteration is often the treatment of choice. If an orbital neuroendocrine tumor is suspected, caution should be exercised during enucleation and exenteration because extensive intraoperative hemorrhage is frequent.

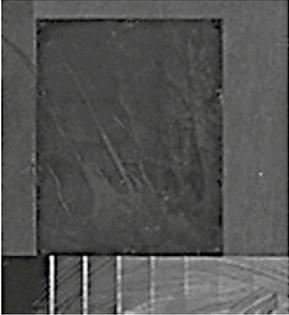

A technique for radical enucleation and exenteration with partial orbital rim resection, mesh skin expansion, and second intention healing has been described recently for extensive periocular tumors in horses.<sup>103</sup> This technique is indicated when skin is insufficient to complete a standard primary closure after surgical resection.

# DISORDERS OF THE REPRODUCTIVE TRACT

## CHAPTER 18

Grant Frazer

### REPRODUCTIVE ANATOMY AND PHYSIOLOGY OF THE NONPREGNANT MARE

Daniel C. Sharp, Michael B. Porter

Equine reproductive physiology deviates from other domestic and companion animal models, often providing open-minded practitioners and researchers with a lifetime of challenges or frustrations, depending on their approach. This chapter presents the authors' current understanding of equine reproductive physiology set against a backdrop of accepted dogma for other species as often as appropriate.

#### SEASONAL REPRODUCTIVE CYCLE

A dominant and often troublesome feature of equine reproduction is the adherence to an annual rhythm of reproductive competence and incompetence. The annual reproductive cycle of mares reflects an evolutionary strategy to maximize survival of foals by programming the breeding season so that it is attuned to gestation length. Thus mares, with approximately 11 months' gestation, begin to breed in the midspring so as to time parturition in midspring. Therefore the mechanisms best able to regulate timing of the annual reproductive cycle are long-term and highly reliable. Nutritional and environmental temperature changes do not fit that requirement well. The four main phases of the annual reproductive rhythm are discussed in the subsequent sections.

#### ANESTRUS

Anestrus usually occurs during the shortest days of winter and is characterized by reproductive incompetence in most mares. Measurements of hypothalamic gonadotropin-releasing hormone (Gn-RH)<sup>1-4</sup> indicate a low hypothalamic Gn-RH content and secretion rate during anestrus. Pituitary gonadotropin secretion consequently is reduced, with low or undetectable circulating concentrations of luteinizing hormone (LH) and follicle-stimulating hormone (FSH).<sup>5-7</sup> Although pituitary stores of FSH appear to be adequate throughout anestrus,<sup>8</sup> this is not the case with LH. The messenger ribonucleic acid (mRNA) encoding LH subunit production becomes undetectable in

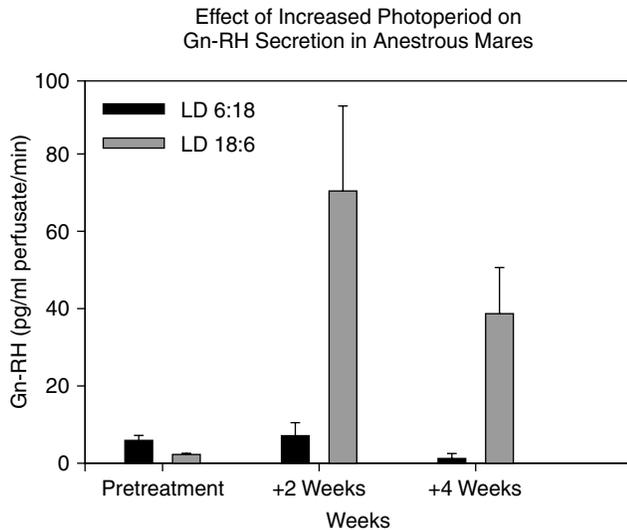

pituitary tissue during anestrus.<sup>9,10</sup> Thus pituitary gonadotropins (FSH and LH) are low during anestrus because of suppression of the releasing signal from the hypothalamus (Gn-RH), plus inactivation of the gene encoding LH synthesis in the pituitary. The result is, not surprisingly, loss of function of the ovaries. Ovarian activity, including follicular development and hormone production, is minimal, with few follicles greater than 5 mm in diameter and undetectable circulating concentrations of estradiol and progesterone.

As might be expected from this reduction in circulating hormones, sexual receptivity in mares during anestrus tends to be reduced or lacking altogether. Given the lack of circulating hormones, the passivity of mares in response to teasing not surprisingly is highest in winter.<sup>6</sup>

#### VERNAL (SPRINGTIME) TRANSITION

The vernal transition of the annual reproductive cycle, which begins sometime around the first of the calendar year, is the most troublesome commercially. The first event in transition—likely the initiating one—is an increase in hypothalamic Gn-RH observable within 1 week after the winter solstice<sup>2</sup> or 2 weeks after exposure to an artificially increased photoperiod several weeks before the solstice (Figure 18-1).<sup>11</sup> Whether the increase in hypothalamic Gn-RH represents a response to increasing day length, refractoriness to short day length, or some other factor remains unresolved.

Hart, Squires, Imel, et al.<sup>8</sup> reported that the increased Gn-RH secretion shortly after the winter solstice leads to increased FSH secretion from available pituitary stores but that LH levels remain low. Sherman, Wolfe, Farmerie et al.<sup>9</sup> explained this phenomenon, stating that the mRNA encoding LH subunit synthesis was undetectable in the winter and early spring. The third major event during the vernal transition, after hypothalamic Gn-RH secretion and subsequent release of pituitary FSH stores, is follicular development. During vernal transition the size and number of manually detectable follicles increases.<sup>12,13</sup> The follicular population changes from only two or three small follicles (5 to 10 mm in diameter) to six or more midsize follicles (15 to 25 mm), with the diameter of the largest follicle exceeding 35 to 40 mm.<sup>12</sup> A major problem early in the breeding season is that many of these large vernal transition follicles do not ovulate. In ponies an average  $3.5 \pm 0.7$  large ( $\geq 30$  mm) anovulatory follicles develop in sequence before the first ovulation of the year.<sup>6</sup> These anovulatory vernal transition

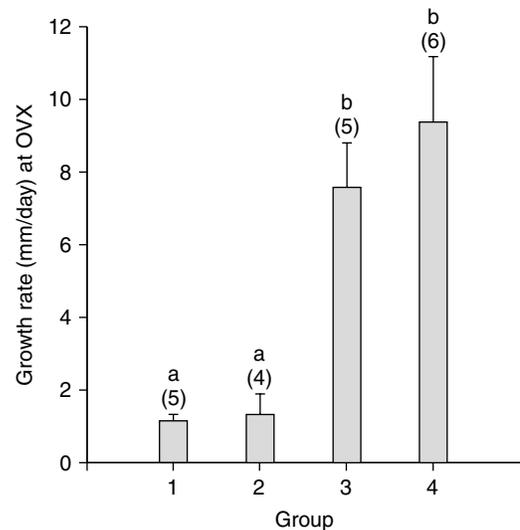

**FIGURE 18-1** Gonadotropin-releasing hormone (Gn-RH) secretion (picograms per milliliter per minute, LS means  $\pm$  SEM) as measured with push-pull perfusion of the pituitary in mares exposed to short photoperiod (LD 6:18,  $n = 4$ ) and in mares exposed to long photoperiod (LD 18:6,  $n = 4$ ) for 4 weeks. In the bars marked pretreatment, all mares had been exposed to LD 6:18. Subsequently, four mares were exposed to LD 18:6, and Gn-RH secretion was measured at 2-week intervals. Time of year the experiment was begun was December 1. Gn-RH was highly significantly elevated in mares after only 2 weeks of photostimulation.

follicles are the cause of high reproductive inefficiency during the springtime, and it is impossible to discern, by palpation or ultrasound, whether they will be ovulatory. Consequently, many mares are sent to the stallion inappropriately, which adds to the frustration and expense of breeding. Furthermore, mares with chronic failure of uterine clearance likely suffer most from such an inappropriate breeding, and the penalty to the breeder is often greater expense aimed at resolving uterine contamination.

The first several vernal transition follicles are different from fully functional follicles during the breeding season. Although they attain a diameter comparable with that of pre-ovulatory follicles of the breeding season ( $>30$  mm), they do so much more slowly. Careful tracking of follicles reveals that the first and second large follicle of the year grow at a rate of only 1 to 2 mm per day (Figure 18-2), compared with growth rates of about 10 mm per day for follicles that go on to ovulate.<sup>14</sup> Therefore one may assess the potential functional status of springtime follicles by frequently monitoring their growth.

The slower growth rate of vernal transition follicles reflects other metabolic deficiencies, including poor vascularity compared with that of ovulatory follicles and significantly smaller granulosa cell content.<sup>15</sup> The poor granulosa cell investment of early vernal transition follicles is significant in that the granulosa cell layer contributes substantially to the steroidogenic capabilities of the follicle. Thus steroid production by the early vernal transition follicles is limited. The follicles do not produce estradiol, as monitored by peripheral blood, follicular fluid, or in vitro production rate. Estradiol concentration is low or undetectable in peripheral plasma until 5 or 6 days before the first ovulation of the year.<sup>7,14,16</sup> One can measure

**FIGURE 18-2** Growth rate (millimeters per day) of follicles during vernal transition. Groups represent mares at first, second, third, and fourth follicle of the year. (From Tucker KE, Cleaver BD, Sharp DC: Does resumption of follicular estradiol synthesis during vernal transition in mares involve a shift in steroidogenic pathways? *Biol Reprod* (suppl 1) 48:188, 1993.)

circulating estradiol to discriminate between nonfunctional and functional (ovulatory) follicles.

When one of the sequential vernal transitional follicles acquires steroidogenic capability, the circulating estradiol increases significantly 5 to 6 days before the first ovulation of the year. The average date for the first ovulation of the year is consistent from year to year, and variance among mares in a population is low. Data collected from as far north as 43 degrees north latitude to as far south as 18 degrees north latitude have indicated an onset of the breeding season (date of first ovulation of the year) to be around the first week of April in mares and the second week of May for pony mares that have not been exposed to artificial lighting. Once the first ovulation of the year has occurred, vernal transition is completed and regular polyestrous cycles occur throughout the late spring and summer in unbred mares.

Renewed LH synthesis and secretion, also manifested by a large surge 5 to 6 days before the first ovulation of the year, is associated with the rise in estradiol. Sharp, Grubaugh, Davis et al.,<sup>17</sup> and Cleaver and Sharp<sup>18</sup> have demonstrated that administration of estrogen advances this secretion of LH in mares during early vernal transition, and Sharp, Wolfe, Cleaver et al.<sup>10</sup> further demonstrated that estrogen administration to ovariectomized mares at the same time of year stimulated the mRNA encoding for the LH  $\alpha$  and  $\beta$  subunits. In other words, estrogen administration was associated with activation of the LH gene. However, as Freedman, Garcia, and Ginther<sup>5</sup> and Peltier, Robinson, and Sharp<sup>7</sup> have demonstrated, the increase in peripheral LH occurs at approximately the same time in mares with and without ovaries. Thus the role of estrogen in bringing about the resurgence of LH synthesis and secretion remains unclear. Furthermore, one must resist the temptation to use estrogen to hasten LH synthesis in mares during the early vernal transition because of the negative effects of estrogen on FSH secretion. The clinician may initiate LH synthesis only to find that it inhibits follicular development.

## BREEDING SEASON

The next section discusses the breeding season in detail. The breeding season is characterized by regularly recurring cycles of estrus and diestrus throughout the summer, unless pregnancy occurs.

## AUTUMNAL TRANSITION

The transition from reproductive competence in the breeding season to reproductive quiescence characteristic of anestrus is perhaps the least understood part of the annual seasonal reproductive cycle in mares. The period of reproductive decline has a much greater variance during the fall than does the period of reproductive renewal in the spring. The variance is understandable from the evolutionary aspect, because mares likely faced little pressure to reproduce in the fall because their offspring would face more difficult survival at foaling the next year. Although this is an oversimplification, the autumnal transition may be characterized simply as the gradual loss of gonadotropic support for ovarian function, resulting in reduced follicular development. The final act of the autumnal transition may be development of a large preovulatory follicle that fails to ovulate.<sup>19</sup>

## ☞ MORPHOLOGIC BEHAVIORAL AND HORMONAL CHANGES OF THE ESTROUS CYCLE

### ESTRUS

Estrus, defined by receptivity of the mare to a stallion, is characterized by profound changes in the ovaries as follicles develop and in the uterus, cervix, and vagina as the developing follicles begin producing estrogen and by the occurrence of a prolonged surge or increase in LH.

### BEHAVIOR

Understanding estrous behavior, as monitored by teasing with a stallion, is an important foundation to any breeding program. The word *estrus*, coined by Walter Heape,<sup>20</sup> is thought to come from the Greek word *Oestridae*, a genus of the gadfly, because locomotor activity of many female ungulates increases during estrus. Estrous behavior is associated temporally with increasing estrogen concentrations peripherally but also may be associated with the concomitant decline in progesterone levels. Support for the idea that estrogen may not be essential for estrous behavior comes from observations of estrous display in mares with inactive ovaries and from ovariectomized mares during anestrus.<sup>21</sup> The displays of estrous mares reflect a wide range of behaviors and extents, however, and successful breeding farms often owe their success in part to careful monitoring and record keeping for each mare. Among the signs observed during estrus are elevation of the tail in the presence of the stallion, eversion of the vulvar lips to expose the clitoris (“winking”), squatting with rotation of the pelvis, urination, and remaining calm (i.e., not moving away) in the immediate presence of a stallion. Recording behavioral signs tends to take the decision making out of the watching process and potentially provides a more precise record of progress through the estrous cycle.

## OVARIAN MORPHOLOGY

Morphologic changes during estrus can be used to monitor the progress toward ovulation. The equine ovary is structurally different from that of other species in that the cortical elements containing the primordial follicles are located centrally in the ovary instead of peripherally, as in all other species that have been studied so far. This central position of potential ovulatory follicles presents a dilemma in that ovulation cannot occur at the site of follicle development. Most of the surface of the equine ovary is covered with mesothelium, which apparently does not allow the tissue remodeling required for rupture of the follicle. Instead, ovulation in the mare always occurs at a specific site, called the “ovulation fossa,” which is located ventrally on the ovary. The bean shape of the equine ovary creates a recessed fossa area in which germinal epithelium is located. This inside-out structure of the mare’s ovary likely contributes to some of the unusual aspects of the equine estrous cycle, including the period of prolonged estrus, the large preovulatory follicle size, and the prolonged increase in LH that precedes ovulation. A logical assumption is that the structure of the ovary led to co-evolution of a hypothalamic-pituitary axis that was able to present gonadotropins over a prolonged duration. The ovarian structure requires extensive tissue remodeling for a developing follicle to reach the restricted area of the fossa where it can ovulate. The extended gonadotropin secretion seems likely to be an important part of the tissue remodeling process that precedes rupture of the follicle. Administration of Gn-RH analog to stimulate endogenous LH release, or human chorionic gonadotropin (hCG; LH activity), results in increased levels of tissue remodeling enzymes in the follicle within 24 hours.<sup>22</sup> This prolonged process presents challenges to the breeder or veterinary practitioner who is attempting to schedule breeding at a time appropriate to the expected ovulation.

## TUBULAR REPRODUCTIVE TRACT

Perhaps the two most prominent changes in the equine tubular reproductive tract are the appearance of the external portion of the cervix and the pattern of intrauterine edema as monitored with ultrasound. The vaginal portion of the cervix exhibits cyclic changes that reflect the rise and fall of estrogens and progesterone. During estrus the cervix becomes relaxed and droops toward the ventral floor of the anterior fornix, whereas in diestrus, under the influence of progesterone, the external cervical folds become more rigid and buttonlike, or “tight and white” in the vernacular. One can appreciate these changes by visual examination with a vaginal speculum.

Changes in intrauterine edema are evident, as monitored by ultrasound imaging, in the pattern of fluid (edema) present in the endometrial folds during estrus (Figure 18-3). The appearance of edema often is used to indicate estrus, but an important note is that the relationship between edema and ovulation is inverse. Edema is maximal several days before ovulation and then begins to dissipate. Ovulation occurs 3 to 4 days after peak edema scores are exhibited and the edema pattern is in the process of dissipation.<sup>23</sup> Because estrogen stimulates edema rapidly (within 6 hours), the presence of edema appears to be a useful indicator of estrogen secretion. However, dissipation of the edema is an active process, requiring the presence of ovaries, and likely involves progesterone as well. Far more intriguing, then, is the question of the mechanism of dissipation of edema. What is the purpose of edema

**FIGURE 18-3** **A**, Portion of uterine horn showing edema score of 1 (relatively homogeneous pattern with little evidence of fluid). **B**, Portion of uterine horn showing edema score of 4 (marked heterogeneity with clear evidence of fluid-filled lacunae).

in the first place if an active process exists for its dissolution before ovulation?

### HORMONES

Estrus in mares is characterized by increasing estrogen and a prolonged elevation in LH. The prolonged elevation of LH,<sup>24</sup> often reaching peak concentrations after ovulation, may reflect the need for extensive tissue remodeling of the ovaries for ovulation to occur. Estradiol reaches peak concentrations of greater than 30 to 40 pg/ml 2 to 3 days before ovulation. Evidence exists for a positive feedback effect of estradiol on LH,<sup>25</sup> but evidence also suggests that LH rises spontaneously after corpus luteum (CL) regression and the loss of progesterone negative feedback. This raises the question of whether estrogen positive feedback is necessary for the ovulatory increase in LH or whether it merely serves to enhance the default situation of elevated LH in the absence of progesterone.

### DIESTRUS

Diestrus is essentially the polar opposite of estrus from the behavioral standpoint.

### BEHAVIOR

Mares generally exhibit little or no interest in the approach of a stallion, and this often is manifested by violent demonstrations (e.g., kicking, switching of the tail, flattening of the ears, vocalizing) in a teasing situation. Rising progesterone concentrations are thought to play a role in the sexual nonreceptivity of mares. Although not critically determined, the sexually negative behavior of mares is widely assumed to be associated with progesterone concentrations greater than 1 ng/ml. Progesterone concentrations increase quickly after ovulation, reaching 1 ng/ml by 24 to 48 hours after ovulation, which coincides with the expected onset of diestrus.

### OVARIAN MORPHOLOGY

The primary feature of ovarian morphology in diestrus is the presence of a CL within the ovary. Because of the inside-out structure of the ovary and the restriction of ovulation to the

ovulation fossa, the CL remains almost entirely within the ovary and provides little evidence of its presence by transrectal palpation, which is not the case with ruminants. The advent of ultrasound imaging has improved diagnostic capabilities by enabling practitioners to visualize the CL.

### HORMONES

Diestrus is dominated by elevated progesterone, with its negative feedback effect on LH secretion.

## ☞ POSTPARTUM PERIOD

Immediately after expulsion of the fetus, the equine uterus begins the process of involution, and this continues for several days after passage of the placenta. During this time detection of fluid within the uterine lumen by ultrasound is not abnormal. However, the uterine fluid (lochia) and debris should dissipate 7 to 10 days after parturition in preparation for “foal heat” in the mare.<sup>26</sup> One should not detect fluid by ultrasound 10 to 14 days postpartum, and the uterus should be restored to nearly prepregnancy condition within 3 to 4 weeks.

*Foal heat* is defined as the first period of sexual receptivity after parturition and usually begins 7 to 9 days after foaling.<sup>27</sup> The first ovulation after foaling occurs on average at 9 days after foaling. Depending on the efficiency of uterine involution, the fertility of this foal heat varies. If significant fluid is present within the uterus at foal heat, breeding the mare is not recommended. In addition, studies regarding the effect of season on first postpartum ovulation suggest that mares that foal in January and February tend to have longer intervals from foaling to the first fertile ovulation than mares that foal in late spring.<sup>28</sup> After the foal heat most mares have a 30-day heat that occurs approximately 21 days after the foal heat and may represent a more fertile estrous cycle.

In addition to the effects of season, a condition known as *lactational anestrus* may develop immediately after foaling. In some cases the condition may persist until weaning (4 to 6 months). Determining whether the lactational anestrus results from the foal nursing or the time of year (seasonal) is important. Limited studies have been performed in

which foals were removed from mares at varying time points after parturition. Research indicates that removal of the foal hastens the onset of estrus. Foal removal has been associated with elevated LH concentrations and increased ovarian follicle diameter.<sup>29</sup>

## MARE BREEDING SOUNDNESS EXAMINATION

*Nigel R. Perkins, John B. Chopin*

Breeding soundness examination (BSE) of the mare may be performed for a variety of reasons, including prepurchase or prebreeding examinations to confirm the absence of detectable abnormalities involving the genital tract and examination of subfertile mares after unsuccessful breeding or tentative identification of a potential problem associated with the genital tract. Procedures that should be performed in all BSEs include perineal examination, rectal palpation, ultrasonography, vaginoscopy, and digital vaginal examination. Additional procedures may be considered depending on patient signalment, history, and initial findings of each individual.

### IDENTIFICATION

Detailed identification of the mare is very important. The recording of acquired brands, tattoos, and detection of a microchip should all be considered to supplement the physical description or photographs.

### SIGNALMENT AND HISTORY

History and signalment may suggest possible problems and guide the diagnostic approach (Table 18-1). The use of drugs during an athletic career can affect the horse's breeding future. The use of anabolic steroids can change behavior and external genitalia. There might also be a downregulating effect on the hypothalamic-pituitary-gonadal axis that has to reverse over time. The use of an anti-GnRH vaccine (Equity; Pfizer Animal Health, West Ryde, Australia) is an effective way to inhibit estrus behavior in fillies. Unfortunately a number of fillies have had prolonged ovarian inactivity into their breeding career.<sup>1</sup> The author had one cytogenetically normal mare that was retired from breeding with four seasons of ovarian inactivity after the use of the vaccine.

Breeding history should include detailed information from the immediate past, including information on the standard of breeding management and facilities. It is also valuable, though more difficult, to obtain historical information on the mare's entire breeding career.

### BEHAVIOR

The season of the year should be considered when assessing behavior in the mare.<sup>2</sup> Assessing the mare's response to the teaser while in estrus is important for future breeding use. Shy or aggressive behavior toward the teaser by the mare while in physiological estrus might limit natural breeding options.

TABLE 18-1

#### Details of Information to be Gathered During History Taking

History	Comments
General health	Vaccination, deworming, foot care, dental care, nutritional history, systemic diseases, and management
Athletic	Level of activity, age at which athletic career ended, any known drug usage
Cycling	Length of estrus, expression of estrus, interovulatory interval
Breeding	Number of cycles bred, breeds per cycle, natural or artificial insemination, fertility of stallion, age at which the mare was last bred
Pregnancies	Number of diagnosed pregnancies and outcomes
Foaling	Any history of dystocia, type of management
Prior reproductive examinations	Diagnoses, treatment, management
Prior reproductive surgeries	Nature of surgery, date performed and outcome
Drug use during breeding season	Ovulation induction, estrous cycle manipulation

### GENERAL PHYSICAL EXAMINATION

General observation of the mare while loose and being led to the stocks will allow assessment of behavior and preliminary assessment of condition and conformation. A brief general physical examination should be performed to ensure that the mare has no detectable condition that could interfere with an ability to conceive or carry a foal to term. The practitioner should inspect the mammary glands visually and with digital palpation for evidence of abnormalities such as mastitis, fibrosis, and neoplasia. In general, excessive body condition will not interfere with reproductive potential, whereas poor body condition may.

### RESTRAINT

The mare must be adequately restrained before examination. What constitutes adequate restraint will depend on the nature of the mare, the skill and experience of the handler and veterinarian, procedures being performed, and the physical facilities available. Particular care must be exercised when performing a BSE on mares with little prior exposure to procedures such as transrectal palpation. Stocks should be used for restraint during a BSE. The primary function of stocks is to prevent the mare moving forward or to the side during the examination.

Chemical restraint is an effective and safe method in most cases for BSE procedures, particularly in those that are either less well tolerated or more prolonged. Chemical restraint may cause some degree of relaxation of the perineal region

and alter assessment of vulval conformation in some cases. If possible, examination of vulval conformation should be made before sedation.

## EXAMINATION OF EXTERNAL GENITALIA

The perineal region is inspected for indications of vulval discharge and gross abnormalities of the anogenital region. Vulval discharge or urine scalding of the inner thighs may suggest genital infection, urine pooling, or urinary incontinence. Clitoral enlargement may indicate prior exposure to androgens or progestagens or an intersex condition. Normal vulval lips are vertical, have good tone, and are in close apposition. The practitioner should gently part the vulval lips to determine if air is readily aspirated into the vagina. If there is poor vulval apposition or ready aspiration of air, then the mare may be prone to pneumovagina and at increased risk of ascending vaginitis.

Vulval integrity is important in the formation of an effective seal against contamination of the genital tract with air, urine, feces, and potential pathogens.<sup>3</sup> Vulval conformation is assessed by digital palpation adjacent to the vulval lips to locate the caudal bony pelvic brim. Pascoe's description of a Caslick index has been modified to produce a simple assessment technique for vulval conformation:<sup>4</sup>

- VC (vulval conformation) good: No Caslick is required. Dorsal commissure of the vulva is less than 4 cm above the bony pelvic brim, and vulval lips are within 10 degrees of vertical and form an effective seal.
- VC marginal: Caslick may be required. Dorsal commissure of the vulva is 4 to 7 cm above the bony pelvic brim, vulval lips are within 10 to 20 degrees of vertical, vulval lips are still forming an effective seal.
- VC poor: Caslick or some other corrective procedure is definitely required. Dorsal commissure of vulva is 5 to 9 cm or more above the bony pelvic brim, vulval lips are 30 degrees or more in front of vertical, and the vulval seal is less than effective.

## TRANSRECTAL PALPATION AND ULTRASOUND EXAMINATION OF THE GENITAL TRACT

It is absolutely imperative that the nonpregnant status of the mare be confirmed before any procedure is performed that could threaten a pregnancy, even if the history suggests that she is not pregnant. Transrectal palpation of the genital tract is associated with some risk of rectal mucosal trauma and potentially laceration. The risk increases if excessive force is used, if palpation continues in the presence of pneumorectum, and if the mare strains excessively. Mild sedation to relieve the anxiety of the animal, especially with mares that are not accustomed to the experience, may be accomplished with an  $\alpha$ -2 agonist (e.g., xylazine) with or without an opioid (e.g., butorphanol). Administration of N-butylscopolamine by intravenous injection several minutes before the examination may also help prevent straining, but it may interfere with assessment of uterine tone.

Palpation of the genital tract requires a methodical approach. The author usually locates the uterus and palpates structures in the following sequence: right uterine horn, right ovary, right uterine horn, left uterine horn, left ovary, left

uterine horn, uterine body, cervix. Cervical size and consistency are assessed by pressing the cervix down against the pelvic floor. Cervical relaxation can most effectively be measured on a sliding scale, from 0% relaxed (i.e., tightly closed, tubular cervix) to 100% relaxed (i.e., indistinguishable from adjacent uterus).<sup>5</sup>

It is important to purposefully assess anatomic structures other than the genital tract as part of the palpation examination, including pelvis, intestines, lymph nodes, and bladder. Note the presence of soft tissue or bony changes that may narrow the luminal diameter of the pelvis. Possible causes include vaginal lacerations, hematoma, abscessation, neoplasia, and pelvic fracture.

Ultrasound examination should be considered a routine part of a reproductive tract examination. Ultrasound examination allows the use of electronic calipers for measuring structures and allows assessment of tissue and fluid characteristics. Table 18-2 presents comparative information on the application of palpation and ultrasound for assessing various genital tract structures.

TABLE 18-2

### Application of Transrectal Palpation and Ultrasound of the Genital Tract for Assessing Various Parameters

Organ	Structure	Detail of assessment	Technique
Ovary	Ovary	Size, shape, presence of ovulation fossa	P, US
		Echotexture of contents	US
		Consistency of tissue	P
	Corpus haemorrhagicum	Presence	P, US
		Corpus luteum	Presence or absence, size, shape, echotexture
	Uterus	Follicles	Size
Shape, wall thickness and echotexture, echotexture of contents			US
Uterus		Turgidity	P
		Diameter, shape, tone, wall thickness, endometrial folds, luminal fluid (larger amounts)	P, US
Cervix	Cervix	Wall echotexture, endometrial folds, luminal fluid volume and echotexture	US
		Length, width, depth	P, US
	Vagina and vestibule	Echotexture	US
Relaxation		P	
Vagina and vestibule	Vagina and vestibule	Fluid accumulation, gas (air) accumulation	P, US

P, Transrectal palpation; US, ultrasound.

The same basic approach is used for ultrasound examination as described previously for rectal examination. While holding a linear transrectal ultrasound probe, the practitioner extends the fingers beyond the ventral surface of the probe to assist in locating genital tract structures and to palpate uterine horns for assessing uterine tone. The uterine body is initially identified as a landmark by sweeping the probe from side to side in the anterior pelvis. The uterine body is then followed cranially to the bifurcation and the probe then swept out toward the right uterine horn and right ovary. Structures are examined in the same order as for palpation alone: right horn, right ovary, right horn, left horn, left ovary, left horn, uterine body, and cervix. As the probe is withdrawn into the pelvic cavity, the uterine body is examined by moving the probe from side to side.

A simple recording system should be used with defined abbreviations. This ensures that records can be understood at a later date and facilitates a common approach for use by multiple attending veterinarians. Uterine horn diameter should be measured about one third of the distance from the bifurcation, and uterine tone is recorded with presence of dilation and fluid. Endometrial folds can be assessed by gently palpating the uterus between fingers and thumb. The practitioner should assess the dimensions and shape of each ovary and ensure that the ovulation fossa is detectable (loss of ovulation fossa can be an early indicator of distortion of the normal ovarian shape caused by neoplasia). All follicles larger than about 15 mm in diameter are recorded individually, and smaller follicles are recorded as multiple small follicles. Loss of turgidity is recorded for preovulatory follicles (softness being a possible indicator of impending ovulation).

## DIAGNOSIS OF OVARIAN PATHOLOGY

Abnormal ovarian enlargement should be suspected if an ovary is greater than 10 cm in diameter and the increased size cannot be attributed to recent ovulation or a follicle and persists for more than a month.<sup>5,6</sup> Large ovaries may be associated with physiologic causes (e.g., persistent follicles, hematoma, multiple CLs) or pathologic processes (e.g., neoplasia, abscess).

Neoplasia more commonly affects one ovary, although it can affect both, and typically results in a variable degree of alteration in ovarian size, shape, and consistency. There appears to be no consistent pattern in the change affecting a neoplastic ovary, with the exception of teratomas in which the diagnosis may be based on detection of germ tissues, including cartilage, hair, and bone. Other neoplasias may present as single large cystic or multicystic structures or even solid tissue. In many cases the diagnosis of ovarian neoplasia is based on persistent unilateral ovarian enlargement with obliteration of the ovulation fossa and an inactive or normally functioning contralateral ovary.<sup>7,8</sup> There might be a history of aberrant ovarian activity before the development of the tumor.<sup>9</sup> A granulosa cell tumor may produce varying levels of testosterone, estrogen, and inhibin<sup>9,10</sup> but rarely produce progesterone. The measurement of  $\alpha$ -inhibin might be more accurate for diagnosis than measuring  $\alpha\beta_A$ -inhibin.<sup>11</sup>

Functional ovarian tumors such as granulosa-theca cell tumor (GTCT) may manifest as masculinization of appearance and behavior and increased plasma inhibin and testosterone concentrations.<sup>12</sup> The ultrasonographic appearance of the GTCT is characteristic, varying from uniformly dense to cystic.<sup>13,14</sup>

Anovulatory follicles often grow to an unusually large size and fill with blood, organizing into a structure with the ultrasonographic appearance of a hematoma that gradually recedes over time. Some of these structures appear to develop a thick rim of tissue resembling luteal tissue, with the mare entering a diestrus-like state. Others do not develop a thick rim of tissue, and the structure may appear to be inert. There is a lack of consensus regarding terminology, with some authors distinguishing anovulatory hemorrhagic follicles (no luteinization) from luteinized unruptured follicles (development of luteal rim). Others suggest that the two structures are variations of the same condition.<sup>15</sup> The condition appears to be more common in mares approaching winter anestrus and in pregnant mares under the influence of equine chorionic gonadotropin. Anovulatory follicles occur in 8% of all estrous cycles<sup>16</sup> but in 5% of estrous cycles in the early ovulatory season and 20% of estrous cycles in the late ovulatory season.<sup>17</sup> The ultrasonographic appearances of ovulatory and anovulatory follicles are largely the same.

Failure of the normal process of luteolysis may result in prolonged luteal maintenance. Diagnosis depends on confirmation of nonpregnant status and the presence of a CL for a period longer than the normal diestrus length. This condition, termed *pseudopregnancy*, must be differentiated from cases in which a mare is ovulating between examinations and exhibiting an apparently persistent CL. Luteolysis depends on prostaglandin (PG) release from the uterus,<sup>18-20</sup> which in turn might depend on a uterine clock being set for PG release. An ovulation during diestrus does not always set this clock, and the resultant CL can last for more than 2 months.<sup>19,20</sup> Other reasons for failure of luteolysis include release of PG when the CL is still immature and unable to respond to PG (before 6 days of age), failure of PG to be released at the proper time, and insignificant release of PG from the endometrium in mares with degenerative endometritis.<sup>21</sup>

Small cystic structures may be palpated or visualized ultrasonographically, adjacent to the ovary. These are typically incidental findings assumed to be cystic remnants of the mesonephric tubules and ducts. It is possible that these structures could interfere with gamete transport if they obstruct normal function of the ovarian bursa and infundibulum.

Very small and inactive ovaries may be secondary to seasonal anestrus, reproductive senescence in old mares, pituitary gland dysfunction, severe malnutrition, administration of anabolic steroids, administration of anti-GnRH vaccine, or congenital infertility resulting from sex chromosome abnormalities.<sup>1,22</sup> Sex chromosome abnormalities are often associated with hypoplasia or segmental aplasia of the tubular tract. Karyotyping may be used to further investigate such mares. Chromosomal abnormalities have also been reported from subfertile mares that have foaled previously and have no detectable abnormalities of the genital tract. In light of this fact, karyotyping may be considered in mares in which routine diagnostic procedures fail to explain subfertility.

Individuals with 63,X karyotype tend to be small in stature, phenotypically female, with small uterus and ovaries, and no sexual behavior.<sup>23-26</sup> However, some might show irregular estrus behavior, and the uterus palpably and histologically can be within normal limits.<sup>24,27</sup> Plasma estrogen levels are low and plasma LH levels are normal to high.<sup>24</sup> Sex reversal is a disorder that occurs in horses and can have a variety of abnormalities.<sup>28</sup> The two most common forms of sex reversal are mare phenotype with male karyotype 64,XY and male

phenotype with female karyotype 64,XX. There can be a wide phenotype variation with both conditions.<sup>29,30</sup>

X trisomy is relatively rare in the horse. The mare is infertile; shows estrus behavior and normal external genitalia; and is phenotypically female, with small, thin walled uterus and small hypoplastic ovaries.<sup>23,25,31,32</sup>

Mosaics and chimeras occur when the individual has more than one cell line with different chromosomal makeups. 63,X/64,XX mosaics are phenotypically female; the uterus varies in development, but ovaries may be small and nonfunctional. These horses may show estrus behaviour, an endometrial biopsy reveals glandular hypoplasia, and the clitoris may be enlarged.<sup>23-25,26,33</sup>

## DIAGNOSIS OF UTERINE PATHOLOGY

### ENDOMETRITIS

Ultrasonography is very useful for evaluating presence, quantity, and echotexture of uterine luminal fluid. Fluid echotexture is correlated with the amount of debris or white blood cell infiltration into the fluid and is more common in older mares.<sup>34</sup> Table 18-3 presents a grading system for recording uterine fluid echotexture.<sup>35</sup> The presence of grade I, II, or III fluid during any stage of the cycle indicates endometritis. The presence of fluid in diestrus results in a lower pregnancy rate and a higher embryo loss rate,<sup>36</sup> presumably caused by high levels of PGF<sub>2a</sub> in the fluid from the neutrophils.<sup>37</sup> The presence of more than 2 cm of fluid in the lumen during estrus, the presence of fluid during diestrus, and fluid 72 hours after insemination are strong indicators of mare susceptibility to endometritis.<sup>38</sup> Table 18-4 presents a grading system for recording the volume of intrauterine fluid.

TABLE 18-3

Classification System for Recording Uterine Fluid Echotexture		
Grade	Ultrasound Appearance	Gross Appearance
I	White (hyperechoic)	Thick and creamy
II	Light gray	Milky
III	Black with white specks	Obvious sediment in fluid
IV	Black (anechoic)	Clear fluid

TABLE 18-4

Grading System for Recording Volume of Intrauterine Fluid		
Classification	Maximum Fluid Depth (mm)	Gross Description
VS (very small)	1 to 2	Barely detectable
S (small)	1 to 5	Often focal
M (moderate)	5 to 20	Obvious fluid
L (large)	>20	Immediately apparent

Complete absence of detectable uterine luminal fluid during estrus is associated with absence of cytologic inflammation in 99% of cases.<sup>39</sup> The significance of clear (grade IV) luminal fluid is less clear. Small or very small volumes of clear fluid during estrus are likely to be normal, particularly if present during early estrus before complete cervical relaxation and maximal uterine drainage. Large volumes of clear fluid during estrus, fluid that persists into late estrus, or smaller volumes during early diestrus suggest an increased predisposition to endometritis and reduced pregnancy rates compared with mares without fluid.<sup>39-41</sup> Luminal fluid visible more than 12 to 20 hours after breeding indicates mating-induced endometritis.<sup>22,42</sup> This condition has recently been reported in 10% to 15% of mares being bred on a commercial Thoroughbred stud farm.<sup>43</sup>

Discrete hyperchogenic reflections seen in the uterine lumen on ultrasonographic examination indicate air. Pneumouterus may be seen in normal mares soon after uterine treatment, insemination, or breeding but should not be seen more than hours after breeding or treatment. The presence of pneumouterus at times other than soon after breeding or uterine therapy indicates loss of integrity of physical barriers to contamination (vulva, vestibulovaginal sphincter, and cervix).

### ENDOMETRIAL CYSTS

Circumscribed, discrete collections of clear fluid within the uterine lumen indicate endometrial cysts or a conceptus. Cysts may occur on the endometrial surface or within the endometrium. Cysts may be single, discrete structures closely resembling a conceptus or complex, compartmentalized structures with irregular borders. Cysts that protrude into or occlude the uterine lumen may reduce fertility by interfering with embryo mobility and maternal recognition of pregnancy.<sup>36,44,45</sup> Cysts within the endometrium may interfere with gland function.

Properties of an early conceptus that can be used to distinguish it from a cyst include the following: movement between days 10 through 16 post ovulation; spherical, symmetric appearance; rate of growth (cysts are assumed to grow little if at all); and appearance of the embryo proper after about day 20. In addition, there are palpable changes in the tract that are consistent with early pregnancy (e.g., increased uterine tone and closed, elongated cervix) that would not be expected to occur in a nonpregnant mare with endometrial or lymphatic cysts. Any association between cysts and reduced fertility remains unclear.<sup>46</sup> Large cysts or large numbers of cysts may interfere with embryonic movement, maternal recognition of pregnancy, and early placentation. Extensive glandular cystic change may also adversely affect uterine gland function and compromise establishment or normal development of pregnancy.

### PYOMETRA

Pyometra is a chronic condition with mucoid or mucopurulent material within the uterine lumen, with or without cervical occlusion. The condition is not dependent on the presence of a CL, as it usually is in other species, and does not typically result in any systemic signs of illness. Pyometra may be mistaken for pregnancy on palpation as a result of fluid distention of the uterus but can be diagnosed effectively with ultrasound.<sup>47</sup>

## ADHESIONS

Adhesions and scarring involving the endometrium may result from infusion of irritating solutions into the uterus and perhaps as a result of trauma associated with dystocia and its correction. Luminal adhesions involving the cervix have similar initiating causes. The role of chronic endometritis or iatrogenic causes such as mechanical curettage in uterine or cervical adhesions is less clear. Adhesions may reduce fertility by interfering with function of the uterotubal junction or with embryo movement and maternal recognition of pregnancy.<sup>45</sup>

Occlusive adhesions may result in accumulation of fluid in the proximal portions of the tubular tract, and this may be detected on palpation or ultrasound examination of the tract. More commonly, adhesions are detected during hysteroscopy.

Focal uterine lesions may respond well to surgical removal using a biopsy instrument or laser surgical equipment guided by hysteroscopy.<sup>48</sup> If the lesions are extensive or affecting the deeper layers of the endometrium, then the prognosis may be poor and treatment not warranted. Cervical adhesions are commonly managed by manual disruption and then repeated application of topical ointment containing antibiotic and steroid in an attempt to prevent recurrence. In many horses, cervical adhesions tend to recur once treatment stops.

## VENTRAL UTERINE SACCULATION

Ventral sacculation is associated with a loss of normal muscular contractile activity in the uterine wall, with the uterine wall forming sacculations ventrally at the base of one or both uterine horns. The condition is more common in older, multiparous mares and may indicate increased risk of endometritis caused by loss of the normal contractile mechanisms responsible for expelling uterine luminal fluid. This may also be linked to mares that have a more ventral oriented uterus. When the uterocervical angle is more ventral than horizontal, the mare is more prone to fluid accumulation because of a reduced ability to clear fluid.<sup>49</sup>

## HYGIENE FOR VAGINAL PROCEDURES

Good hygienic practice is essential in performing any vaginal procedure and particularly those procedures that involve penetration of the cervix. This is perhaps the simplest and most fundamental principle of good reproductive practice. The practitioner should bandage the proximal portion of the tail or enclose it in a plastic sleeve and tie it to the mare's neck with a quick release knot; alternatively, an assistant may hold it out of the way. The perineal region should then be washed with water and detergent and rinsed thoroughly, preferably with a spray nozzle attached to a hose to deliver a constant supply of fresh clean water. The practitioner should then wipe just inside the vulval lips with damp cotton to remove any contaminating material; this is particularly important for mares with sloping vulval lips or if a rectal examination has just been performed. The presence of fecal matter in the dorsal vestibular area without a history of any invasive procedures indicates a failure of the vulvovestibular seal.

Use of sterile, plastic sleeves for vaginal procedures is ideal. A practical alternative used by the author is to keep, in a dust-free area, a zipper storage bag (e.g., Ziploc) containing clean plastic sleeves to be used for vaginal procedures only. A new

sleeve is taken out carefully by grasping it only at the open end, or each sleeve is turned inside out immediately before putting it on to minimize the risk of contamination. Tearing off the fingers from a plastic sleeve and putting on a sterile, surgical glove can increase sensitivity and also facilitate cleanliness. Sterile lubricant and equipment should be used. The practitioner should be meticulous to prevent contamination of either equipment or sleeves and gloves during any procedure.

## VAGINAL SPECULUM EXAMINATION

A sterile, lubricated speculum is inserted into the vestibule in a slightly dorsal direction to avoid the urethral opening and pushed through the vulvovestibular sphincter, with sphincter integrity assessed as the speculum is inserted. Because they reduce the risk of iatrogenic infection, single-use, sterile, disposable specula are preferred over metal caslick specula for routine examinations. In some cases, a self-retaining metal caslick speculum may provide better visualization of the caudal vagina and vestibule.

Vaginoscopy is useful for detection of vaginal hyperemia, suppurative exudates, persistent hymen, urine pooling, varicose veins, vaginal trauma, rectovaginal defects, and cervical defects. Although examination with a vaginal speculum may be performed at any stage of the cycle, inspection of mares suspected of pooling urine is best performed during estrus because estrogenic relaxation of the genital tract and perineal region is maximal at this time.<sup>50</sup> Vaginal speculum examination is an important component of the BSE but should not be considered a routine procedure to be performed repeatedly in normal mares.

The timing of the vaginal examination in relation to the rectal examination is also important. Careful cleaning of the perineum is required if the vaginal examination follows the rectal examination. However, this slight disadvantage is offset by the advantage of doing the rectal ultrasound examination first to assess pneumovagina and pneumouterus. The presence of air in the vagina and uterus is difficult to interpret after a vaginal examination. However, if air is present before a vaginal examination, it may indicate vulvovestibular seal dysfunction. Repeated vaginoscopy may be associated with an increased risk of iatrogenic vaginitis and persistent infection. As a result, the author prefers to perform routine assessment of cervical relaxation by transrectal palpation.

## MANUAL EXAMINATION OF THE VAGINA AND CERVIX

Examination of the genital tract is incomplete without manual exploration of the vagina and cervix. The major benefit in this procedure is detection of cervical defects. Once the hand is inserted into the anterior vagina, the forefinger is placed into the cervical lumen and the thumb in the vaginal fornix. The hand is then rotated and the entire circumference of the cervix palpated between finger and thumb to feel for disruption in the cervix resulting from lacerations or damage to submucosal layers that might interfere with the ability of the cervix to close effectively. Cervical disruption is significant only if it prevents the cervix from forming an effective seal during diestrus and pregnancy. A partial tear involving the external os of the cervix may not require treatment if the cervix can still maintain an effective seal. For this reason, assessment of the severity of cervical disruption should be performed when

the mare is in diestrus.<sup>51</sup> Alternatively, the diestrus tone can be duplicated by the administration of progesterone or progestagen for a few days to close the cervix.

Care should be taken while performing a manual examination of the vagina and cervix to take time to palpate the vaginal surface for problems such as rectovaginal fistulas, vaginal lacerations, and perivaginal hematoma or abscess formation. The examiner should also consider the length and diameter of the cervical canal in relation to the estrous stage of the mare. A tortuous canal might impair drainage. The older maiden mare, typically older than 10 years of age, can have a long, narrow cervix that is difficult to open and has poor drainage of uterine fluid.

## ENDOMETRIAL CULTURE AND CYTOLOGY

The practitioner must not perform any procedure that involves penetrating the cervix of a mare unless the nonpregnant status of the mare has been confirmed by transrectal palpation, either alone or in combination with ultrasonography.

A variety of instruments and techniques have been described for culturing the genital tract. The lack of consistency in methodology has almost certainly contributed to the lack of consensus regarding the role and interpretation of genital tract cultures. Interestingly, in a group of mares infected with *Klebsiella*, the normal uterine swab was less sensitive at detecting infection (27/60) than use of a tampon (55/60).<sup>52</sup> A gynecologic brush was superior to a cotton swab or aspiration in the detection of endometritis. The cotton swab often produced a false-negative result.<sup>53</sup> In the author's experience, aspiration or analysis of a small volume saline lavage can sometimes yield more information than a cotton swab. Sterile digital sampling of the endometrium has been described as a quick stallside test for cytology.<sup>54</sup> Care should be taken not to collect neutrophils from caudal areas of the reproductive tract and interpret that as endometritis.

Cultures may be taken from multiple sites in the genital tract, including endometrium, cervix, vagina, clitoral fossa, and clitoral sinuses. The isolation of bacteria from the anterior vagina is associated with reduced fertility.<sup>55</sup> Genital tract culture performed to investigate possible endometritis or as part of a BSE should be taken from the endometrial lumen and not from the vagina or cervix. Endometrial culture should be performed before any other invasive procedure in a BSE to reduce the risk of inadvertent contamination of the uterine lumen before taking the culture sample.

A guarded culture rod should be used to minimize the risk of contamination with material from sites other than the uterine lumen.<sup>56</sup> Single- or double-guarded culture rods may be used. It is also possible to take an endometrial culture from a uterine biopsy sample as long as the culture sample is taken in a sterile manner and before placing the tissue into fixative. There is a lack of consensus on the optimal time of the cycle for obtaining endometrial culture and cytology samples. Some experts recommend performing endometrial cultures on the first or second day of estrus, when uterine secretions are increasing and the flushing action of the uterus is just beginning.<sup>57,58</sup>

Mares with endometritis have been reported to accumulate free luminal fluid in late diestrus, and this represents an alternative time for endometrial culture.<sup>36</sup> The practitioner should carry the guarded culture rod into the vagina and through the cervix beside one finger. The rod is then passed cranial to the

finger, into the endometrial lumen, and the culture tip pushed through the guard and rolled against the endometrial surface for 30 to 60 seconds. The culture tip is withdrawn into the rod before withdrawing the culture rod to prevent contamination during removal from the genital tract.

The sample should be transferred onto the final growing medium immediately after the sample is obtained to allow quantification of colony numbers as an indication of severity of infection. When possible, quantification of colony growth should be performed because heavy growth after 24 to 48 hours' incubation is more meaningful than a few scattered colonies. If immediate plating is not possible, transfer the culture tip in a sterile manner into appropriate transport medium. Use of transport medium allows proliferation of some species and possibly reduced growth of others, so colony counts are not interpretable.

Interpretation of endometrial culture results is difficult. False-positive and false-negative results are common. Several recommendations can be made to minimize the likelihood of an erroneous interpretation. Culture results should be interpreted in conjunction with results of concurrent endometrial cytologic examination. In addition, the practitioner should consider whether the organisms recovered represent pure or mixed growth and whether growth can be considered heavy or light. Acute endometritis is more commonly associated with mixed bacterial growth on culture than pure growth.<sup>59</sup>

A wide range of organisms have been isolated from horses with acute endometritis. A combination of positive culture and evidence of inflammation on endometrial cytology is sufficient to diagnose endometritis and identify the organisms recovered as the causative agents. A positive bacterial culture in the absence of any cytologic evidence of inflammation is considered likely to be due to contamination during the culture procedure and does not indicate endometritis.

In the absence of cytologic evidence, it is particularly difficult to interpret culture results. Recovery of relatively pure or heavy cultures of the following organisms may be considered indicative of endometritis:  $\beta$ -hemolytic streptococci, hemolytic *Escherichia coli*, *Pseudomonas* spp., *Klebsiella* spp., and *Candida* spp.<sup>60,61</sup> Recovery of other organisms without concurrent cytologic information should be viewed with more suspicion.

Endometrial cytology is used by some practitioners as a rapid screening test for detection of endometrial inflammation in mares at the beginning of the breeding season or before breeding. When it was first described in the mare,<sup>62</sup> the detection of neutrophils was correlated with positive bacteriologic findings. When no or low numbers of neutrophils were detected, bacteriologic findings were more often negative.<sup>62</sup> Mares with cytologic evidence of inflammation had lower 28-day pregnancy rates than mares with normal cytologic results, irrespective of culture results. Day 28 pregnancy rates were also lower in mares that had bacteria isolated from their uterus even if cytologic results were normal.<sup>63</sup>

Numerous techniques have been described for collecting cytologic samples. The approach used by the author is simple, rapid, and feasible in busy clinical practice. A guarded culture rod with a snap-on cap (Kalayjian: Kalayjian Industries Inc., Long Beach, California) is used to collect a culture sample. The swab tip is withdrawn back into the sheath and the rod rolled against the endometrium to collect fluid and cells in the cap. After the rod is withdrawn from the mare, the cap can be cut off and tapped against a slide to make the smear from the small drop of fluid.<sup>64</sup> The smear is dried and stained using any

commercial staining kit (e.g., Diff-Quik; (American Scientific Products, McGaw Park, Ill.). If no endometrial cells are seen on an initial inspection of the slide, the sample may not have been collected from the uterus and another sample should be taken. The presence of polymorphonucleocytes (PMNs) is generally believed to indicate bacterial endometritis, but the most appropriate methodology for quantifying PMNs remains subject to debate. Suggestions for criteria to diagnose endometrial inflammation include observation of more than 1 or 2 PMNs in five high-power microscope fields (400×) or more than 1 PMN per 10 endometrial cells in more than one area of the slide.<sup>65,66</sup> In most mares with endometritis, there are large numbers of PMNs evident on cytologic evaluation.

## ENDOMETRIAL BIOPSY

Preparation for endometrial biopsy is the same as for culture or cytology. Diestral samples are generally preferred over estral samples because physiologic changes in the endometrium during estrus make the slides more difficult to interpret.<sup>67,68</sup> However, samples may be taken at any stage of the cycle as long as the information on the stage of cycle is provided and the person reading the slide has experience in assessing equine biopsy slides. In the absence of clinically detectable pathology involving the uterus, a single endometrial biopsy sample is representative of the entire endometrium.<sup>69</sup> However, another study found that even in clinically normal mares endometrial biopsy scores varied with the site selected.<sup>70</sup>

The sterile mare biopsy instrument is introduced into the uterine lumen guided by one hand placed in the vagina. The tip of the biopsy forceps might necessitate assistance through the cervix, especially with a biopsy procedure performed during diestrus. The traditional technique involves withdrawing the hand from the vagina and inserting it into the rectum. The instrument is directed to a specific site within the uterus, generally the base of one horn. The instrument is then turned on its side and the jaws gently opened. A portion of endometrium is pressed between the jaws using the index finger within the rectum and the jaws closed to remove the tissue sample.

A simpler vaginal technique is useful for collecting biopsy samples when there is no need to sample from a specific site.<sup>67,68,71</sup> The instrument is introduced into the uterine lumen, and the hand is left in the vagina with the index finger in the cervical lumen. The tip of the instrument is advanced about 2 to 3 cm into the uterine lumen with the jaws closed. The jaws are opened and the instrument advanced an additional 1 to 2 cm. The instrument can then be deviated slightly to one side and the jaws closed to collect a sample. The sample is taken from the cranial uterine body close to the bifurcation. This approach has the advantage of being quick and simple. It allows the operator to return for a second sample immediately if the first sample is too small, whereas the rectovaginal technique often results in gross contamination of the instrument and vulva during the procedure, making a second sample impossible unless the mare is cleaned again and a second sterile instrument is available.

The specimen is removed from the biopsy basket using a small-gauge needle and transferred to fixative solution, preferably Bouin's fixative or 10% buffered formalin. Samples placed into Bouin's fixative should be transferred to 10% formalin or 80% ethanol after 12 to 24 hours for optimal retention of cell detail and tissue integrity.<sup>64</sup>

There is a strong case to be made for clinicians to read slides from their own cases. Although expert assessment by a trained pathologist may better reflect histologic tissue changes, the clinician is in the best position to interpret histologic change in light of clinical and historical information about the mare. Training and practice will allow the clinician to detect most of the common pathologic changes seen in biopsy samples, although expert help should be sought if needed. The examination process should be methodical. The clinician must ensure that cellular characteristics are consistent with the stage of estrous cycle. Pathologic changes include inflammation, fibrosis, cystic glandular distention, and lymphatic stasis. Increasing numbers of inflammatory cells in the lamina propria indicate inflammation. Acute inflammation is associated with PMNs and an increased likelihood of positive endometrial culture. Increasing numbers of PMNs and their presence in deeper layers of the lamina propria indicate more severe inflammation. Chronic inflammatory change includes lymphocytes, plasma cells, eosinophils, and mast cells.

Endometrial fibrosis is a permanent degenerative change occurring around glands (fibrotic nests) or gland branches and also adjacent to the basement membrane of the luminal epithelium. Fibrosis often forms in concentric layers around gland branches or glands, and the number of layers of fibrosis is related to the severity of the degenerative change.<sup>72</sup> Fibrosis may be localized or diffuse, and the more widespread or severe the change, the more adverse the effect on gland function and fertility. These degenerative changes appear to be closely associated with age rather than parity.<sup>34,73-75</sup> Severe degenerative endometrial fibrosis can occur in the older maiden mare that has not had the challenges of pregnancy and exposure to semen.<sup>74,75</sup>

Cystic gland distention may be seen in normal mares during anestrus. When diagnosed in mares during the breeding season, it is considered a pathologic change and is associated with reduced fertility. Glandular fibrosis may also be associated with cystic distention of the affected glands. Extensive fibrosis interferes with uterine gland function and may result in early embryonic death.<sup>76</sup>

Endometrial atrophy is associated with an extremely poor breeding prognosis.<sup>67,68</sup> Large empty spaces on the biopsy slide must be interpreted with caution, because they may be artifacts associated with sample processing. If the spaces appear to be lined with an endothelial cell layer, this indicates lymphatic stasis. Widespread lymphatic stasis may be associated with reduced contractile capability within the uterus, a doughy feel to the uterus on transrectal palpation, and reduced fertility.<sup>64</sup>

Assessment of severity and distribution of pathologic changes allow the sample to be classified into one of four diagnostic and prognostic levels based on a modified version of the original three-level system proposed by Kenney.<sup>72,77</sup>

Category I: No significant changes in the endometrium and no treatment required; expected foaling rate of 80% to 90%.

Category IIA: Slight to moderate inflammatory change. Scattered fibrotic change may consist of either fibrosis around individual gland branches or fewer than two fibrotic nests per high-power field. There is moderate cystic glandular distention or extensive lymphatic stasis. If two or more of these changes are present in the same sample, the sample is classified as IIB. Expected foaling rates are 50% to 80%.

Category IIB: Inflammatory change is widespread and moderately severe. There is widespread fibrotic change or up to four fibrotic nests per high-power microscope field. Widespread, severe cystic glandular distention or lymphatic

stasis is evident. If two or more of these changes are present, the sample is classified as III. Expected foaling rates are 10% to 50%.

Category III: The mare exhibits widespread, severe changes that are likely to be permanent and has an expected foaling rate of less than 10%.

Use of paired biopsy samples taken at the initial diagnostic workup and again 4 weeks after completion of treatment appears to improve the usefulness of the biopsy as a prognostic indicator of a mare's fertility.<sup>74,75</sup> Mares that were classified as grade III pretreatment and that improved to grade II after treatment achieved a foaling rate of 40%, whereas mares that were still grade III after treatment had a 0% foaling rate. This is likely to be a result of improvement in reversible pathologic changes.<sup>74,75</sup> This approach allows effective use of the grade III categorization on the follow-up biopsy to justify recommending that such mares be culled from the breeding program.

### UTERINE ENDOSCOPIC EXAMINATION: HYSTEROSCOPY

Hysteroscopy allows direct visual inspection of the uterine lumen through a flexible fiberoptic endoscope. Hysteroscopy is indicated when other diagnostic procedures do not detect a cause for subfertility or to further examine a mare with a suspected uterine luminal lesion.<sup>78,79</sup>

Sedation is a useful restraint aid because the procedure is associated with mild discomfort. The perineum is prepared as for other vaginal or uterine procedures, and a sterilized endoscope is inserted in the vagina and manipulated through the cervix and into the uterus. The cervical lumen is then occluded, either by inserting 1 or 2 fingers into the cervix alongside the endoscope or by gently holding the external os of the cervix around the endoscope. The uterine lumen is distended with saline or water infused through a flexible catheter held adjacent to the endoscope or with air delivered through the endoscope. Endometrial folds should be assessed while the uterus is being distended because they flatten out and become difficult to distinguish in the fully distended uterus. The endoscope is then manipulated through the uterine lumen, allowing visualization of the entire endometrial surface, including the tips of the uterine horns and the two oviductal ostia. Hysteroscopy allows direct visualization of a variety of abnormal changes, including inflammation, polyps or neoplasia, cysts, adhesions, and severe scarring or fibrotic change. It can also aid in various procedures, including guided retrieval of foreign bodies and laser surgical management of conditions such as endometrial cysts or adhesions.

Excessive distention of the uterus may cause discomfort and an elevated heart rate and should be avoided.<sup>80</sup> Mares subjected to hysteroscopy appear to be at risk of developing subsequent endometritis.<sup>80</sup> Care should be taken to sterilize the equipment before use; the author suggests that mares be examined during the subsequent estrus period to check for evidence of endometritis.

### ☞ HORMONAL ASSAYS

In the nonpregnant mare serum or plasma samples may be collected for measurement of a variety of reproductive hormone concentrations, including progesterone, estrogens, testosterone, inhibin, and gonadotropins. Other conditions that may have effects on cyclicity and fertility include abnormalities

involving the thyroid and adrenal glands and pituitary pars intermedia dysfunction.

Progesterone is produced by ovarian luteal tissue. Serum progesterone concentrations are low during estrus and begin to rise 12 to 24 hours after ovulation, peaking between days 5 to 10 after ovulation.<sup>81,82</sup> Progesterone assays in nonpregnant mares can be used to assist in determining the stage of the cycle and to confirm that ovulation has occurred. They are also used as an indirect method of pregnancy diagnosis, but false-positive results are common.

Progesterone is necessary for pregnancy maintenance, and primary luteal insufficiency has been linked to pregnancy loss.<sup>40,83,84</sup> Low levels of progesterone are associated with increased pregnancy loss, and higher levels of progesterone are associated with successful pregnancies in mares that habitually aborted twins.<sup>85</sup> Older mares appear to require a higher level of progesterone to maintain pregnancy.<sup>59</sup> Progesterone levels on day 7 were significantly lower in mares with periovulatory intrauterine fluid accumulation and significantly lower in mares that underwent embryonic loss.<sup>40</sup> The presence of luminal fluid in diestrus was associated with a lower progesterone level and increased embryonic loss, indicating endometritis as a cause for lower progesterone levels.<sup>36</sup>

Some researchers recommend that progesterone concentration in peripheral blood of pregnant mares be above 2.5 to 4 ng/ml for normal pregnancy maintenance.<sup>86</sup> Single samples of peripheral blood concentrations are difficult to interpret because repeated sampling of normal pregnant mares has shown that blood levels vary widely over short periods of time.<sup>81,82</sup>

Thyroid gland dysfunction has been linked to subfertility in mares with recommendations to measure total serum thyroxine (T4) or thyroxine response to administration of thyroid-stimulating hormone (TSH). Thyroxine is significantly affected by season and reproductive status.<sup>87,88</sup> Thyroxine is seasonally regulated when mares are kept on a constant energy balance out of season.<sup>89</sup> Although thyroidectomy of pony mares did not have any adverse effect on reproductive performance,<sup>90</sup> mares that continued to cycle out of season had higher levels of thyroxine than anestrus mares.<sup>88,91</sup> Mares with low thyroxine levels were more likely to enter anestrus after parturition.<sup>88</sup> There was no association between thyroxine level and pregnancy rate 15 to 16 days after ovulation.<sup>92,93</sup>

Ovarian neoplasia, particularly GTCTs, may be associated with increased production of testosterone and inhibin by the affected ovary. Serum inhibin concentration is elevated in approximately 90% of mares with a GTCT, and testosterone in about 50% to 60% of cases.<sup>94</sup> Functional GTCT cases almost invariably have a nonfunctional contralateral ovary and are anovulatory. Therefore a serum sample demonstrating high inhibin or testosterone and low progesterone concentrations is consistent with ovarian neoplasia. Normal ranges in nonpregnant mares for inhibin and testosterone are 0.1 to 0.7 ng/ml and less than 45 pg/ml, respectively.<sup>12,94</sup>

Horses with pituitary pars intermedia dysfunction often exhibit variable degrees of hirsutism with a range of other systemic signs. Diagnosis and treatment of this disorder are discussed in Chapter 20.

Measurement of estrogen concentration in blood, urine, feces, milk, and saliva has been used for monitoring the estrous cycle,<sup>95</sup> determining pregnancy status,<sup>96-98</sup> and monitoring fetal viability.<sup>99</sup> Peripheral blood estrogens may be either unconjugated or conjugated (bound to sulfates), and

different forms of estrogens are found in the mare, particularly during pregnancy. Conjugated estrogens generally exist in the circulation at much higher concentrations than unconjugated forms, and measuring either estrone sulfate or total conjugated estrogens appears to offer the most use for the aforementioned indications mentioned. A dramatic increase in peripheral blood estrone sulfate concentrations occurs in pregnant mares after day 60 of pregnancy, whereas in fecal assays this increase may take up to 150 days to occur.<sup>100,101</sup> A rapid decline of estrone sulfate concentration in a pregnant mare may indicate loss of fetal viability.<sup>99</sup>

Equine chorionic gonadotropin (eCG) is a hormone produced from the formation of endometrial cups at around day 36 of gestation. It has a luteinizing effect on follicles to create accessory CLs to help maintain pregnancy until the placenta is fully formed. These follicles often luteinize without ovulating.<sup>102</sup> Pregnancy loss after day 35 can sometimes be associated with negative blood eCG, and the failure of endometrial cup formation is presumed to play an essential role in pregnancy maintenance. Pregnancy loss after day 35 may be associated with a positive eCG measurement, and affected mares often do not cycle properly because follicles fail to ovulate and luteinize. When ovulation does occur, the pregnancy rate is low, presumably because of a low-grade endometritis resulting from the presence of endometrial cups. The endometrial cups have a life span of about 100 days and are therefore nonfunctional after about 150 days gestation.<sup>102</sup> However, there have been reports of the prolonged survival of endometrial cups after abortion.<sup>103,104</sup> The endometrial cups lasted an average of 18 months but could last up to 30 months. This has implications into the next breeding season, and mares showing aberrant ovarian activity should be investigated for the possibility of persistent endometrial cups.

Measurement of serum or plasma concentrations of GnRH, gonadotropins (FSH and LH), and steroids appears to offer promise in the diagnostic assessment of the hypothalamic-pituitary-ovarian axis. The anterior pituitary gland produces FSH in response to GnRH release.<sup>105,106</sup> FSH is released in a bimodal pattern with peaks (35 ng/ml) in early and late diestrus. There are two major waves of follicular growth coincident with the two surges of FSH.<sup>107</sup> FSH starts to rise 4 to 5 days before an ovarian follicular wave. The peak of FSH is 3 days before the emergence of the wave, which then plateaus for 5 days.

GnRH release from the hypothalamus stimulates LH release from the pituitary gland,<sup>108</sup> although there is an association between releases of oxytocin in estrous mares and LH release, which suggests that repeated sexual stimulation might also increase LH and advance ovulation.<sup>109</sup> LH concentrations are low during the midluteal phase (5 ng/ml) but rise a few days before estrus after progesterone decreases (<1 ng/ml) because of luteolysis. LH peaks (45 ng/ml) during estrus at ovulation and returns to midluteal levels over a few days.<sup>107</sup>

Several issues must be addressed before such methodologies become either available or useful. Little information is available regarding the existence of abnormalities in the hypothalamic-pituitary-ovarian axis and either their relationship with subfertility or their detection by measurement of hormone concentrations. Assessment of the production and release of either GnRH or FSH and LH presents practical difficulties because this may require cannulation of the pituitary venous sinuses.<sup>110</sup> In addition, these hormones are released in a pulsatile manner, with pulse frequency and amplitude influencing function.<sup>111,112</sup> Finally, there are varying isoforms

with differing bioactivity that may be difficult to distinguish on enzyme-linked immunosorbent assay (ELISA) or radioimmunoassay (RIA).<sup>111,112</sup>

Leptin is a protein synthesized by adipose (fat) tissue.<sup>113-115</sup> Leptin acts as negative feedback to brain centers to control obesity (satiety centers) in times of nutritional abundance.<sup>113,114,116</sup> During starvation reduced leptin levels cause changes in reproductive endocrinology that limit reproductive activity.<sup>117</sup> Short-term feed restriction (for 24 hours) significantly decreases leptin levels in mares but does not affect reproductive hormones.<sup>118</sup> There might be a seasonal influence on leptin levels because mares in good body condition experience a general decline in leptin concentrations during winter. The decline is not as great as that observed in mares in poor body condition, and the mares in good body condition continue to have estrous cycles through winter.<sup>119</sup>

Currently, measurement of these and other hormones of the central nervous system appears to be restricted to research applications. Measuring these products may offer considerable benefits in the future, but additional research and development are required before it can be of use to field practitioners.

## MARE REPRODUCTIVE PATHOLOGY

*Carlos R.F. Pinto, Dale L. Paccamonti*

### ☞ VULVA

The integrity of the vulvar lips and their anatomic relation to the perineal area and anus are essential components of a mare's fertility because they provide the first barrier to contamination between the external environment and the uterus. The endocrine patterns associated with each stage of the estrous cycle and pregnancy can influence the disposition of the vulva, affecting vulvar length and tone. In general, the vulva should have at least two thirds of its length below the pelvic brim, the slope of the vulva in relation to the vertical axis should not be greater than 10 degrees, and the vulvar lips should have an even and firm apposition. Absence (natural or acquired) of a normal perineal conformation can facilitate the entry of air (pneumovagina), feces, and potential pathogens into the reproductive tract, which jeopardizes the fertility of the mare.

### BODY WEIGHT

Severe loss of body condition, as experienced by some pregnant mares not adequately supplemented during the winter, results in a sunken anus and an increased slope of the vulva. An apparently normal perineal conformation noted in mares in good body condition may become less than adequate if loss of body weight is extreme. Contamination of the vagina with feces during mid to late gestation may lead to ascending bacterial placentitis, one of the leading causes of abortion and neonatal septicemia in the United States.<sup>1</sup>

### PARITY AND AGE

Aging of the mare associated with repeated foaling can cause stretching and loss of tone of the perineal muscles that allow the vulva to form a barrier to external contamination and entry of air into the vagina. Injury to the mare during foaling

aggravates this condition, resulting in loss of vulvar tone and apposition of the labia. Mares undergoing episiotomy also may have permanent damage to vulvar structures.

### CASLICK VULVOPLASTY

Surgical closure of the dorsal part of the vulvar labia is intended to correct poor perineal conformation. By decreasing the length of the vulvar cleft, one decreases entry of air and potential pathogens into the vagina in a mare otherwise susceptible to pneumovagina, fecal contamination, and associated complications. It has been reported that Caslick-operated mares with poor perineal conformation that successfully foal should be resutured immediately after parturition to minimize the chances of uterine contamination and consequent endometritis. This preventive measure is believed to contribute to adequate pregnancy rates and maintenance of pregnancy until term.<sup>2</sup>

This procedure, however, is overused in mares in which such intervention is not warranted. Paradoxically, a mare with successful Caslick surgeries may experience considerable loss of vulvar tissue, thus generating an abnormal perineal conformation.

Another indirect complication associated with the Caslick vulvoplasty is the increased incidence of vulvar lacerations and dystocias in mares in which the vulva was not opened before foaling. Regardless of the originating cause, the Caslick operation is used to correct first-degree perineal laceration affecting only the perineal skin and vulvar mucosa. Second-degree (laceration of deeper tissues of the perineal body) and third-degree (a defect resulting in communication of the ventral rectum with the dorsal vagina) lacerations require more elaborate reconstructive surgery to correct.<sup>3</sup> As a rule, any corrective surgery of the perineal body and vulva should be delayed until inflammation and edema of the involved tissues have resolved. Mares with third-degree rectovestibular laceration invariably develop endometritis, but endometrial biopsy of mares affected with third-degree laceration have shown a rapid endometrial response to surgical repair of the laceration; mares can be artificially inseminated by 2 weeks after surgery.<sup>4</sup>

### EQUINE COITAL EXANTHEMA

Equine coital exanthema is a venereal disease caused by equine herpesvirus type 3. Mares infected with equine coital exanthema develop pustules and ulcers in the vulvar mucosa and perineal area. Once the lesions start to heal (usually by 14 days after the onset of clinical signs), characteristic depigmented areas in the vulvar labia and perineal skin are visible.<sup>5</sup> Similarly to other herpesvirus-induced diseases, lifelong infection is the rule. Recrudescence may occur after stimuli such as stress, systemic disease, or trauma to the genital area. No specific treatment is recommended, other than disinfection of pustules and ulcers to prevent secondary bacterial infections during the acute phase. Natural service should be avoided while active lesions are present to prevent transmission of the disease. One can artificially inseminate affected mares during the symptomatic stage of the disease or wait until 6 weeks after complete healing of equine coital exanthema-associated lesions before natural service.

### NEOPLASIA

Melanoma is the most common disease affecting the vulva, affecting 80% to 100% of adult gray horses and, less frequently, aging horses of other colors. Common sites for melanoma

include the anus, perineum, and vulva. No effective treatment is available for melanomas; however, oral treatment with cimetidine (a histamine<sub>2</sub> antagonist) has been reported with variable success to result in partial or complete regression of melanocytic nodules.<sup>6</sup> Squamous cell carcinomas are less common than melanomas.

### CLITORIS

The clitoris is enclosed in the clitoral fossa in the ventral part of the vulva but is rhythmically exposed after urination or teasing (winking) as a result of contractions of the vulvar constrictor muscle. The clitoris has several sinuses that contain a natural smegma. Whereas the lateral sinuses are shallow, the median sinuses are sufficiently deep to allow the growth of bacteria. The anatomy of the clitoris in the mare is particularly important because the clitoris is an important reservoir for the bacterium *Taylorella equigenitalis* in mares affected with contagious equine metritis. The disease is highly contagious, and the organism can be harbored in the clitoral fossa and sinuses (especially the median sinuses) for prolonged periods. To test a mare for contagious equine metritis, the practitioner should swab the median clitoral sinuses and then seed an Amies charcoal medium to be transported (preferably kept at 4° C) to a diagnostic laboratory.

Even in contagious equine metritis-free areas, it is important to remember that the clitoral sinuses may function as nidi for uterine infection, especially infection that was iatrogenically induced during diagnostic procedures of the reproductive tract or artificial insemination. Careful asepsis of the perineal and vulvar area, including the clitoral fossa, with a mild disinfectant before any invasive procedures are performed minimizes the risk of introducing potential pathogens into the uterus.

Congenital anomalies of the external genitalia occur in intersex animals that may have underdeveloped vulvar labia associated with an abnormally enlarged clitoris. Treating prepubertal mares with anabolic steroids may lead to enlargement of the clitoris, resulting in a partially and permanently exteriorized clitoris.

### VAGINA

The vestibule is the area that separates the vulva and clitoris from the vagina proper. At the cranial border of the vestibule, where it meets the vagina, lies the vaginovevibular fold. This folded mucous membrane acts as the second and most important<sup>7</sup> physical barrier between the uterus and the external environment. In young horses the hymen is usually a weak membranous extension of the vaginovevibular fold. Occasionally, a persistent hymen may be present in a maiden mare. A manual examination of the vagina is usually sufficient to rupture the persistent hymen. Some mares with a persistent hymen may accumulate fluid in the vagina proper and uterus (mucometra). Once the persistent hymen is disrupted, evacuation of the fluid is uneventful.

### PNEUMOVAGINA

Listening for an inrush of air into the vagina when one gently parts the vulvar labia can test the adequacy of the vaginovevibular fold as a physical barrier to external contaminants. A positive test (noticeable sound of air rushing in to the vagina)

indicates that the vestibular fold is not properly restricting the vagina proper from the outside environment.

Improper functioning of the first barrier (vulva) and second barrier (vaginovestibular fold) may lead to the constant or frequent entry of air into the vagina. The condition may be exacerbated during estrus, when the perineal body is more relaxed than in other stages of the estrous cycle. Accumulation of small amounts of a frothy fluid in the cranial vagina may indicate pneumovagina, as may the presence of air in the uterus (pneumouterus) that is visible as hyperechoic particles between the endometrial folds during ultrasonographic examination.

In mares with severe alteration of the perineal conformation, vulvar closure using Caslick vulvoplasty may not correct the problem, and surgical reconstruction of the perineal body (perineoplasty) is recommended.

### UROVAGINA

*Urovagina*, also known as *vesicovaginal reflux* or *urine pooling*, refers to the presence of urine in the cranial vagina and possibly in the uterus. As with pneumovagina, mares with marginal perineal conformation may be predisposed to accumulate urine in the vagina during estrus, when reproductive organs and the perineal body are relaxed. In older mares with splanchnoptosis, the reflux of urine into the genital tract may be permanent. Urovagina can cause vaginitis, cervicitis, and endometritis, which ultimately result in infertility. Perineoplasty and urethral extension are common surgical procedures to correct this condition.

### VARICOSE VEINS

During estrus and especially during pregnancy, varicose veins may develop in older mares. Varicose veins can be present in any part of the vagina; however, they often are found in the vaginovestibular area. Bleeding may occur after natural service or spontaneously during mid to late gestation. Occasionally, a persistent hemorrhage results in considerable blood loss; however, the condition usually subsides with the end of pregnancy. Cautery or ligation of varicose veins is warranted if hemorrhage is persistent or frequent.

### NEOPLASIA

Vaginal neoplasms are not common in mares. Leiomyomas and squamous cell carcinoma have been reported.

### VAGINITIS

Minor tears, lacerations, and hematomas are common findings in the vaginas of mares after foaling. Medical treatment generally is not needed, and most mares do not show complications in the postpartum period. If more serious trauma occurs, the mare may develop vaginitis. Mares with extensive vaginitis or a large hematoma may show signs of pain and refuse to stand quietly to nurse the foal. Vaginal abscesses can develop when a vaginal laceration becomes infected. Clinical signs caused by swelling from a hematoma or abscess include stranguria and straining to defecate. Treatment with antibiotics and anti-inflammatory drugs is warranted when extensive vaginitis or abscesses are found in the vagina. An abscess impinging on the urethra or interfering with defecation may

require drainage. Occasionally, vaginal trauma may result in adhesions that can interfere with uterine drainage.

### RECTOVAGINAL FISTULAS

During parturition the foot of the foal may be directed toward the dorsal vagina or ventral rectum and if unattended may cause a third-degree perineal laceration. However, if the dystocia is corrected in time, the damage may be limited to a first- or second-degree rectovaginal tear or rectovaginal fistula. Surgical correction of the anatomic defect is necessary to restore fertility.

### BREEDING TRAUMA

Vaginal lacerations may occur during natural service when the stallion is disproportionately large compared with the mare. Depending on the location of the tear in relation to the peritoneal reflection, a vaginal tear may communicate with the peritoneal cavity, likely resulting in peritonitis, or may be retroperitoneal. Treatment includes broad spectrum antibiotics, anti-inflammatory drugs, and tetanus prophylaxis. Peritoneal lavage may be beneficial if the tear communicates with the peritoneal cavity. A breeding roll positioned under the tail of the mare and dorsal to the penis of the stallion prevents the stallion from inserting the full length of its penis into the vagina and consequently helps prevent mating-induced trauma.

### ☞ CERVIX

The cervix is the last of the three physical barriers protecting the uterus from the external environment. Cyclic hormonal changes dictate the tonicity of the cervix. During estrus the cervix is relaxed and open. High concentrations of progesterone during diestrus or pregnancy cause the cervix to be tubular, firm, and tightly closed. These changes are readily palpable rectally. Moreover, a vaginal examination during estrus reveals the cervix positioned low in the cranial vagina and relaxed and easily dilated, allowing access to the uterus. During diestrus or pregnancy, a vaginal examination reveals a tightly closed cervical os, which is pale and positioned high off the floor of the vagina.

### CERVICITIS

Inflammation of the cervix often accompanies vaginitis or endometritis. Cervicitis usually occurs in the postpartum period, especially after a dystocia. Severe cervicitis associated with metritis also may occur in mares infected with organisms such as *T. equigenitalis* that cause copious purulent discharge.<sup>8</sup> Infusion of certain chemicals (e.g., chlorhexidine, strong iodine solutions) into the uterus to treat endometritis may irritate not only the endometrium but also the cervix and vaginal mucosa. If the practitioner intends to use such solutions, vaginal speculum examinations to assess the condition of the cervix are warranted between treatments.

### TRAUMA

Although cervical lacerations can occur during natural service, these lesions are usually small and resolve without major consequences. Occasionally, maiden mares are found in estrus with

a tightly closed cervix, which might suffer laceration during natural service, especially if the stallion is disproportionately larger than the mare. However, these tears are usually small and heal without further treatment. Most serious lacerations occur during parturition. They may result from normal parturition, or they may be iatrogenic, occurring during intervention to correct a dystocia by mutation or fetotomy. Although one should examine the cervix digitally after a difficult foaling or dystocia, especially if a fetotomy procedure is involved, the extent and severity of a cervical laceration are best evaluated once the cervical lesion is healed. The competency of the cervix should be evaluated during diestrus or when the mare is under the influence of exogenous progestagens so that its ability to close tightly can be verified. One can more easily diagnose transluminal adhesions and anatomic defects by digital examination of the cervix rather than by vaginoscopy. Because surgical correction is difficult and not always rewarding, the practitioner should take a biopsy sample of the uterus to assess the mare's ability to maintain a pregnancy before attempting surgical correction of a cervical laceration.

## POLYPS OR CYSTS

Occasionally, pedunculated cystlike structures are apparent on visual or manual examination of the cervix. These structures are attached to the cervical os or emanate from the cervical lumen and protrude into the vagina or uterine body. Although their cause is unknown, they do appear to be associated with infertility, and removal by laser or ligation is recommended.

## ☞ UTERUS

### VENTRAL SACCULATIONS

Aside from changes associated with pregnancy, other pathologic conditions cause focal enlargements in the ventral portion of the uterus. These uterine changes usually are associated with increased age and parity and invariably are found at the base of one or both of the uterine horns, where pregnancies usually are established. Inexperienced palpators may mistake these enlargements for a pregnancy, especially if they do not use ultrasonography to confirm their palpation findings. Mechanisms contributing to formation of ventral uterine enlargements have been identified, including but not limited to endometrial atrophy, focal myometrial atonia, and lymphatic lacunae.<sup>9</sup> Furthermore, in older and multiparous mares the uterus may tilt ventrally in relation to the pelvic brim (uterine splanchnoptosis). Mares with ventral sacculations and uterine splanchnoptosis have a higher incidence of delayed uterine clearance than normal mares.<sup>10</sup>

### ENDOMETRIOSIS

*Endometrosis* was once known as *chronic infiltrative endometritis* and currently refers to the presence of fibrosis in the stromal and periglandular compartments. The degree of endometrosis is associated closely with the ability of a mare to establish and maintain a healthful pregnancy until term. Parity and age contribute to degenerative changes occurring in the endometria of mares.<sup>11</sup>

Fibrotic changes may occur around the endometrial glands and in association with the basement membrane in the stratum compactum. The amount and pattern of distribution of

the fibrotic tissue has been classified descriptively as slight, one to three layers of periglandular fibrosis; moderate, 4 to 10 layers; and severe, more than 10 layers of periglandular fibrosis.<sup>12</sup> Cystic glandular dilation is another manifestation of endometrosis. Periglandular fibrosis, glandular epithelial hypertrophy, or inadequate lymphatic drainage may lead to dilation of the endometrial glands.

Other degenerative alterations in the endometrium that lead to endometrosis include lymphatic lacunae and angiosis.<sup>11,13</sup> Lymphatic lacunae are histopathologic indications of lymphangiectasia. Angiosis (a vascular pathologic condition) is associated with aging and parity, especially in uteri with ventral sacculations and associated venous congestion, which are pathogenic factors for angiosis.<sup>13</sup> No treatments exist for these anatomic and vascular degenerative changes in the uterus. Mares with lymphatic lacunae and disseminated uterine angiosis are at risk for infertility caused by delayed uterine clearance and persistent mating-induced endometritis.<sup>11,13</sup>

Pregnancy loss attributed to endometrial fibrosis more commonly manifests during the embryonic period. The secretion of histotroph by the endometrium is critical for proper embryonic development. The area of the endometrium in immediate contact with the conceptus has been shown to undergo specific changes in glandular density on days 16 through 30 of gestation, a period during which embryonic loss is commonly diagnosed in mares with endometrosis.<sup>14</sup> If pregnancy continues to progress beyond the initial 30 days of gestation, abortion during the early fetal period may still occur if uterine fibrosis interferes with implantation of the placenta. Microcotyledonary attachments begin to develop by 80 to 120 days of gestation.<sup>15</sup> Ultrastructural evaluation of the placenta in mares with chronic degenerative endometritis (endometrosis) has shown a delay in microcotyledon development and a reduction in the number of microcotyledons and villi per surface area. Endometrial atrophy may not result in abortion but can influence fetal growth. Fetal weights in mares with degenerative endometritis were lower than in normal mares.<sup>16</sup> Evidence of endometrial atrophy may be evident on inspection of the placenta after delivery.<sup>17</sup>

### ENDOMETRITIS

Whereas endometriosis reflects chronic structural changes associated with age and parity, endometritis encompasses endometrial changes associated with acute or chronic inflammation. These changes are modulated by the action of a local immune system and influenced by the hormonal milieu. A transient endometritis normally occurs in all mares that were mated naturally or artificially inseminated. Mares mount an inflammatory reaction in response to the presence of semen in the uterus, but this apparently normal inflammatory response subsides (histologically) within 2 to 3 days. Detection of intra-uterine fluid by ultrasonography per rectum 24 hours after mating suggests delayed clearance. Persistent mating-induced endometritis is a clinical entity that has been recognized as a major cause of infertility in mares.

### ENDOMETRIAL BIOPSY

An endometrial biopsy often is considered a routine part of a complete BSE. Because an endometrial biopsy can aid in predicting the chances of a mare carrying a foal to term, one should consider the information provided by a biopsy before

purchasing the horse or undertaking reproductive surgery such as repair of a cervical tear. Biopsies sometimes provide information that is useful in the diagnosis of infertility and may provide a basis for treatment. One must realize, however, that an endometrial biopsy alone is not the only, nor usually the most important, piece of information and must be considered in light of other information obtained from the history and reproductive examination.

Generally, a biopsy specimen is taken from a site at the base of one of the uterine horns. When procuring a biopsy, the practitioner should take care not to obtain tissue from a site near the internal cervical os. Glands are less dense near the cervix, making a biopsy obtained from that area less representative of the uterus and more difficult to interpret. Moreover, accidentally taking a biopsy sample from the cervix can result in adhesions.

A single biopsy long has been considered to be representative of the entire uterus; however, studies have shown that variation by as much as an entire category may exist among sites.<sup>18</sup> Therefore one first should perform a thorough examination by palpation and ultrasonography to determine whether any areas of the uterus appear to be abnormal. If one detects an abnormal area, one should obtain biopsy samples from the abnormal and the normal areas. Repeated or multiple biopsies do not significantly affect fertility. A mare may become pregnant when bred just a few days after taking of a biopsy specimen.<sup>19</sup>

Because the cervix is dilated easily, biopsy samples may be taken at any time during the year or during any stage of the estrous cycle. Some clinicians prefer to obtain a biopsy sample during diestrus, when the endometrial glands are under the influence of progesterone, whereas others recommend taking the sample during estrus because of the ease in passing the instrument through the cervix. One must relay all pertinent history, including the estrous stage during which the biopsy sample was obtained, to the pathologist reading the sample. Periglandular fibrosis may appear worse in biopsy samples taken during anestrus because of the sparseness of glands. In addition, biopsy samples taken during anestrus or transition may have evidence of increased inflammation because the cervix has been in a relaxed state for a prolonged period as a result of the absence of progesterone.

Endometrial biopsies are classified into four categories (I, IIA, IIB, III).<sup>20</sup> A mare with a category I biopsy has an essentially normal endometrium. The likelihood of the mare becoming pregnant and carrying a foal to term, estimated at 80% to 90%, depends more on broodmare management than on the inherent fertility of the mare. Mares with a category III biopsy have severe pathologic changes in the endometrium and an estimated 10% chance of carrying a foal to term even with good breeding management. Most mares are classified as a category IIA or IIB with an estimated 50% to 80% and 10% to 50% chance, respectively, of carrying a foal to term, reflecting a combination of management practices and the inherent fertility of the mare.

The pathologist usually provides a complete histopathologic description, but it is beneficial if the practitioner reviews the biopsy slide because this can be helpful in developing a therapeutic plan for the mare. The clinician's primary concern is the severity and distribution of inflammation and the presence of degenerative changes such as periglandular fibrosis, angiogenesis, and lymphatic lacunae (enlarged and dilated lymphatics). Degenerative changes carry a worse prognosis than

inflammatory changes because they are considered to be permanent and progressive. No effective treatment for these conditions has been identified. The cause of such degenerative conditions is not known but widely presumed to be caused by repeated insults to the uterus. These conditions are more common in older mares.<sup>11</sup> Dilated lymphatics often indicate a uterine clearance problem. However, the practitioner can diagnose delayed clearance more reliably by ultrasonographic examination in the postmating period.

Although biopsy can reveal the presence of an inflammatory condition, other methods (e.g., examination of perineal conformation) are necessary to reveal the reason that the condition is present, and a culture is needed to identify the particular pathogen. A repeat biopsy after appropriate therapy may provide insight regarding the extent to which treatment was successful and aid in determining a prognosis for future fertility.<sup>21</sup>

## ENDOMETRIAL CYSTS

Endometrial cysts often are cited as a cause of infertility; however, a clear cause-and-effect relationship has not been established. The proportion of mares with endometrial cysts increases with age. Mares older than 11 years of age are more than 4 times as likely to have endometrial cysts as are younger mares, and most mares older than 17 years of age have endometrial cysts. Reports that associate endometrial cysts with a lower pregnancy rate or increased embryonic loss fail to account for the effect of advancing age. When one controls for confounding effects such as parity and age, the assumption that cysts are causing infertility is not supportable. When confounding factors were accounted for in the analysis of nearly 300 mares, endometrial cysts did not have a statistically significant effect on establishing or maintaining pregnancy, although the time of initial pregnancy diagnosis was not controlled strictly.<sup>22</sup> Another report by a different group of researchers who did control the time of pregnancy diagnosis similarly found no difference in pregnancy loss between mares with cysts and those without, although mares with endometrial cysts tended to have a lower day-40 pregnancy rate. The effect of cysts on fertility appeared to be quantitative because an effect was not evident until a mare had numerous cysts or the cysts were large. However, even then the effect of endometrial cysts on fertility was much less than that with delayed uterine clearance or intrauterine fluid accumulation. A quantitative effect of endometrial cysts could be caused by interference with embryonic mobility. A well-known fact is that the equine embryo undergoes a period of mobility after entering the uterus, finally becoming fixed in place at approximately 16 or 17 days of gestation. If mobility is restricted during this period and the embryo is not permitted to come into contact with a sufficient portion of the endometrium, maternal recognition of pregnancy may not occur, resulting in luteolysis and embryonic loss.

Rather than viewing endometrial cysts as a cause of infertility, one should consider them as an indication of underlying pathologic changes in the uterus. Endometrial cysts are of lymphatic origin, and their occurrence may be associated with a disruption of lymphatic function.

Endometrial cysts are best diagnosed with ultrasonography. Cysts are identified as hypoechoic, immovable structures with a clear border, as opposed to intraluminal fluid, which is movable and has a less distinct shape or border. Endometrial

cysts are usually multiple and most commonly found at the base of the uterine horns. Cysts may change in size and number between estrus and pregnancy.

Endometrial cysts can complicate a diagnosis of early pregnancy. An endometrial cyst is often similar in size and appearance to an early conceptus. Cysts that appear spherical often are shown to have a more irregular shape if the ultrasound probe can be reoriented in relation to the cyst. To make the diagnosis of early pregnancy easier and more reliable, the practitioner should record the size and location of endometrial cysts using a diagram or by storing ultrasonographic images during a prebreeding examination. Even so, it may be necessary to repeat the pregnancy examination or delay confirmation in some mares with endometrial cysts. In most cases of endometrial cysts, no treatment is necessary other than recording their size and location for future reference during pregnancy examination. However, if the cysts are sufficient in size or number such that they pose a potential threat to embryonic migration, treatment can be aimed at facilitating establishment of pregnancy by providing exogenous progesteragen.

Progestagens, usually in the form of altrenogest (0.044 mg/kg/day, administered orally), can maintain pregnancy even when the signal for maternal recognition of pregnancy is lacking. Numerous studies have shown the ability of altrenogest to maintain pregnancy after luteolysis or in ovariectomized mares. It is important to note that if progesteragen therapy is deemed necessary, the correct dose and frequency of administration are required, or the effort is wasted. For example, once-weekly injections of progesterone in oil or once-a-month administration of medroxyprogesterone are insufficient to maintain pregnancy and therefore would not be beneficial in mares with large or numerous endometrial cysts.

Alternatively, endometrial cysts may be removed surgically. Laser surgery is an ideal method if the equipment is available. Ligation and transection of the stalk of pedunculated cysts is an alternative. Merely puncturing and draining the cyst or incising its wall does not provide long-term remission.

### **TRANSLUMINAL ADHESIONS**

Severe infectious or chemically induced (e.g., after intrauterine infusion of irritating chemicals) endometritis may induce the formation of transluminal adhesions in the uterus. These lesions are asymptomatic and found during hysteroscopy. Uterine adhesions may cause the retention of endometrial secretions, resulting in mucometra or pyometra. Early embryonic motility, a phenomenon paramount for maternal recognition in horses, may be impaired by intraluminal adhesions. Treatment modalities include manual disruption of intraluminal adhesions or ablation by way of laser surgery.

### **PYOMETRA**

Pyometra is an accumulation of purulent exudate in the uterus. Unlike cows, mares with pyometra do not necessarily have a persistent CL, and many may cycle normally. A cervical anatomic defect that prevents the clearance of fluid from the uterus may predispose mares to pyometra. However, this condition also can affect mares without an apparent anatomic defect in the reproductive tract. One can diagnose pyometra readily by transrectal ultrasonography when intraluminal fluid with moderate echogenicity is visible in the uterus. Because most mares with pyometra are brought to the veterinarian's

attention at an advanced stage, degenerative changes such as endometrial atrophy may preclude mares from returning to normal fertility after treatment. A biopsy sample of the uterus should be examined before treatment to determine the prognosis for potential fertility. Although medical evacuation of the uterus may be attempted, hysterectomy is an option for mares refractory to treatment or with advanced degeneration of the endometrium (severe endometrosis).

### **NEOPLASIA**

Uterine neoplasms are uncommon in mares. Leiomyomas, often referred to as *fibroids*, are benign mesenchymal neoplasms derived from smooth muscle and often are associated with the presence of fibrous tissue. Leiomyoma is the most common neoplasm affecting the uteri of mares; if the neoplasm is small, reproductive failure does not necessarily result. Leiomyosarcoma, lymphosarcoma, and adenocarcinoma are rare malignant neoplasms affecting mares.

Neoplasms affecting the equine uterus are usually discovered during rectal palpation and transrectal ultrasonography in broodmares during the breeding season. If a uterine neoplasm is suspected, the clinician should perform uterine endoscopy and take a biopsy sample of the tissue for final diagnosis. Surgical excision of neoplasms is indicated when extensive hemorrhage and endometritis are present or when the presence of the neoplasia would be incompatible with establishing a pregnancy. Prognosis for future fertility is reduced, but pregnancy has been reported in mares with partial hysterectomy.<sup>23</sup>

### **UTERINE LACERATIONS**

Uterine lacerations can occur during unattended or assisted parturition. Rectal and vaginal palpation and abdominocentesis aid in diagnosis.<sup>24</sup> Adhesions involving the serosal surface of the uterus may occur after cesarean section or uterine tears. No effective treatment, other than attempted surgical excision, exists once the adhesions form. Therefore the veterinarian should take steps to minimize the likelihood of adhesion formation, including daily palpation of the uterus after cesarean section.

### **UTERINE ARTERY RUPTURE**

Age and parity are contributing factors for mares at risk for uterine artery rupture.<sup>25</sup> Uterine vessels undergo extensive dynamic remodeling during pregnancy and the postpartum period, and this is thought to contribute to progressive degenerative vascular changes. If a mare survives an acute episode of rupture of the uterine artery, antimicrobial therapy is indicated to prevent the hematoma from becoming an abscess. Monitoring the mucous membranes and pulse for 30 minutes after foaling is indicated if the parturition was induced or assisted by a veterinarian and especially when an intervention to correct a dystocia is performed.<sup>27</sup> In mares that survive a ruptured uterine artery, fertility is not altered, but mares may suffer fatal hemorrhage during the subsequent parturition.

### **☞ UTERINE TUBES**

The function of uterine tubes is essential for normal fertility. The passage of equine embryos throughout the uterine tube is longer than for other domestic species, which underlines the importance of the tubal environment for normal fertility.

Mares are also unique in that unfertilized oocytes are retained in the uterine tubes and are not transported to the uterus. The mechanism accounting for this phenomenon (selective transport of fertilized versus unfertilized oocytes) has not yet been elucidated fully, but it appears to involve secretion of PGE<sub>2</sub>. A healthy uterine tube responds to embryonic signals, resulting in proper timing of tubal transport. Diagnosis of pathologic conditions in the uterine tubes is difficult and often occurs only in postmortem examinations.

Postmortem examination of reproductive tracts revealed that salpingitis was common in mares; 37% had infundibulitis, 21% had ampullitis, and 9% had isthmitis. In that study 50% of mares were more than 15 years old, and 85% were older than 11 years of age. The infundibulum generally was found adhered to the uterus, mesovarium, or ovary. The incidence of adhesions on the right side was significantly higher than on the left side.<sup>28</sup>

Postmortem analysis of uterine tubes has suggested that tubal patency is not a major problem in mares. Oviductal obstructions are less common in the mare than in the cow, although masses of collagen have been found in the oviducts of young maiden mares and pregnant mares and were observed more often in mares more than 7 years old.<sup>29</sup> An examination of 700 postmortem specimens, primarily from mares older than 11 years of age, found that almost all oviducts were patent, although more than 40% had adhesions involving the infundibula.<sup>28</sup> Only one uterine tube was found to be occluded among 1248 pairs of uterine tubes that were flushed post mortem.<sup>28,30</sup> Based on these findings, diagnostic procedures to determine the patency of uterine tube in mares with unexplained infertility are not warranted.

## OVARY

The presence of an enlarged ovary in a mare may be normal or an indication of a pathologic ovarian condition. Consideration of the various possibilities and careful diagnostic procedures are necessary so that normal ovaries are not surgically removed. A thorough history, including changes in behavior, estrous cycle characteristics, sexual behavior, and the last observed estrus, is important to consider. Ultrasonography, palpation, and hormonal assays are helpful in reaching an accurate diagnosis. In some mares sequential examinations are beneficial in determining changes in the size of ovaries or various structures on an ovary.

Discovery of an enlarged ovary may be an incidental finding during a normal reproductive examination or may be stimulated by specific clinical signs. Behavioral changes or signs of colic in a mare warrant examination of the reproductive tract, with special attention to the ovaries. Mares with a history of infertility often are suspected of having abnormalities of the ovaries and deserve a thorough examination before surgical removal of an enlarged ovary. The clinician must consider various factors, such as season and pregnancy status, when interpreting a finding of ovarian enlargement. Large ovaries may be normal during the transitional periods in the spring and fall and are expected during certain stages of gestation.

## NEOPLASIA

Granulosa-theca cell tumors are the most common tumors of the reproductive tract in mares. They are benign sex-cord tumors that can occur in mares of any age and also have been

reported in foals and pregnant mares. Although the granulosa and the theca interna cell layers may be involved, the granulosa cell layer most commonly is affected.

Behavioral changes are common in mares with granulosa cell tumors. Behavior may be stallionlike, or persistent estrus or anestrus may occur, depending on the steroid production of the tumor. In other cases of granulosa cell tumors, behavior may be unchanged yet the mare may be showing signs of abdominal discomfort, lameness, or anemia or other signs seemingly unrelated to the reproductive system. Stallionlike behavior is the most commonly reported behavioral change observed, possibly because the change from previous behavior is obvious to the owner and causes an increased challenge in handling the mare. In one report of 63 mares diagnosed with granulosa cell tumors, 20 exhibited anestrus, 14 were in persistent estrus, and 29 showed stallionlike behavior. Stallionlike behavior usually is associated with elevated serum testosterone. However, persistent estrus has not been correlated with elevated estrogen.

On rectal palpation the affected ovary is enlarged, whereas the contralateral ovary is typically small and inactive. Atrophy of the contralateral ovary can be misleading during winter anestrus, when ovaries are typically small and inactive. Atrophy of the contralateral ovary is not absolute. Although unusual, granulosa cell tumors have been reported in pregnant mares and in cyclic mares with a functional contralateral ovary and even in both ovaries.<sup>31</sup> The enlarged ovary may be smooth or knobby, hard or soft, and may feel as if multiple follicles are present. Typically, one cannot palpate the ovulation fossa on the enlarged ovary, although with any greatly enlarged ovary, the fossa may be difficult or impossible to palpate. Although uncommon, the occurrence of bilateral granulosa cell tumors have been reported.<sup>31,32</sup> In one report a mare developed a granulosa cell tumor in the contralateral ovary 4.5 years after the initially affected ovary was surgically removed.<sup>32</sup> Ultrasonographic evaluation often shows the classic multiloculated appearance. However, sometimes the tumor may appear solid or with larger cystlike hypoechoic areas.<sup>33</sup> Although ultrasonography is a useful adjunct, it may not yield a definitive diagnosis in many cases. The ultrasonographic image of granulosa cell tumors can be similar to that of other ovarian abnormalities, especially ovarian hematomas. A variety of reported appearances make diagnosis based solely on ultrasonography impossible in many instances.

Mares with granulosa cell tumors may have elevated concentrations of estrogen or testosterone, but progesterone is almost always less than 1 ng/ml. Measurement of estradiol is of limited value. Although testosterone often is elevated in mares with granulosa cell tumors exhibiting stallionlike behavior, testosterone is within normal limits in 10% to 50% of cases. Testosterone in normal cycling mares is approximately 45 pg/ml and often is greater than 100 pg/ml in mares with stallionlike behavior. McCue reported that only 54% of mares with granulosa cell tumors had elevated testosterone, yet 87% had elevated inhibin, leading to the conclusion that inhibin is a better indicator of the disease.<sup>34</sup> Inhibin suppresses FSH, which leads to a decline in follicular growth, thus explaining the profound negative feedback effect on the contralateral ovary.

Overall, the prognosis for life and reproductive function in a mare with a granulosa cell tumor is good. Depending on the time of year when the ovary is removed, the individual mare, and the length of time the tumor has been present, resumption of ovarian activity usually occurs 83 to 392 days

after surgery, with a mean of 209 days. If the intended use of the mare is solely as a broodmare, a reproductive examination, including a uterine biopsy, is recommended before surgery.

Teratomas, although uncommon, are the second most common ovarian tumors. They contain at least two, if not all three, germinal layers. Most teratomas found in mares are benign. They usually contain hair and also may contain bone, teeth, and neural tissue. Teratomas are usually an incidental finding because most are small and do not often cause significant ovarian enlargement. However, on occasion, large teratomas develop that result in ovarian enlargement. Teratomas do not affect the estrous cycle and therefore lack obvious outward clinical signs.

Serous cystadenomas are neoplasms of epithelial origin usually found in older mares. These tumors do not metastasize. Although they have been found in mares with high plasma testosterone,<sup>35</sup> behavioral changes are not characteristic. The contralateral ovary is not affected, continues to have normal activity, and does not atrophy; and affected mares continue to cycle. On the affected ovary the ovulation fossa is not obliterated and is palpable.

Dysgerminomas are highly malignant tumors also of germ cell origin. They metastasize rapidly to the abdominal and thoracic cavities and are considered the counterpart of the testicular seminoma. Because of their nature, dysgerminomas can affect other organ systems, and cases have been reported of associated hypertrophic pulmonary osteoarthropathy.<sup>36</sup> Clinical signs on presentation therefore often are unrelated to the reproductive system. These tumors carry a poor prognosis.

## OVARIAN ABSCESS

Ovarian abscesses often are attributed to procedures involving puncture of the ovary, such as biopsy or follicle aspiration. As assisted reproductive techniques became more successful and therefore more popular, the incidence of ovarian abscesses was thought likely to increase. However, this has not proved to be the case. Moreover, not all ovarian abscesses can be attributed to iatrogenic causes. Ovarian abscesses have been reported in mares that have had no such procedures performed on them. In these cases they are likely caused by the hematogenous spread of bacteria or may be associated with strongyle migration.

Affected mares may be febrile and anorectic with an elevated white blood cell count. On ultrasonographic examination the enlarged ovary typically has a thick-walled, fluid-filled structure. The fluid is usually hyperechoic. Medical management with long-term antibiotic therapy has been successful in treating these cases. Surgical removal of the affected ovary is an alternative treatment, but one must take care that the abscess does not rupture in the abdominal cavity.

## OVARIAN TORSION

Ovarian torsion, a condition not uncommon in women, has been reported in a mare with a large GTCT that was showing signs of abdominal discomfort.<sup>37</sup> Ovarian torsion might be suspected in mares with known ovarian enlargement if sudden signs of abdominal pain develop.

## NON-NEOPLASTIC OVARIAN ENLARGEMENT

An ovarian hematoma forms as hemorrhage occurs into the previous follicular lumen after ovulation. On occasion this hemorrhage can be excessive, possibly because of an

anticoagulant in follicular fluid. Hematomas can be large, up to 20 cm in diameter or more. They are able to produce progesterone and do not affect the estrous cycle. Although the ovulation fossa is still present, palpating it can be difficult if the hematoma is large. The ultrasonographic appearance varies, causing confusion with a granulosa cell tumor. Large, fluid-filled cavities may be observed, or the hematoma may have a more solid appearance, sometimes with fibrin strands. A trait that is sometimes useful in differentiating a hematoma from a granulosa cell tumor is the responsiveness to PG. Hematomas that are at least 5 or 6 days old often respond to PG by decreasing in size because of the luteolytic effect. Granulosa cell tumors do not respond to PG treatment with any change in size, shape, or ultrasonographic appearance. Because the follicle wall still undergoes luteinization despite the presence of the hematoma, cyclicity remains unaltered; thus normal fertility is not compromised. However, because of the presence of a hematoma, the enlargement of the ovary may persist for several estrous cycles even though the life span of the luteal tissue is normal. Because this structure is a postovulatory phenomenon, the oocyte has been released and the mare may become pregnant if she is mated.

Anovulatory follicles most commonly occur in mares near the end of the breeding season as they go through the autumn transition. These follicles grow to an unusually large size (70 to 100 mm) yet fail to ovulate. Instead, they fill with blood and develop a gelatinous consistency. A thick (compared with a normal follicle) wall commonly forms. The follicles become firmer and then regress over time, usually disappearing within a month. With ultrasonography free-floating echogenic spots are evident in the antrum of the follicle; these increase in number as the follicle grows. When the follicle stops growing, the contents become organized, with an echogenic appearance and fibrin strands. Formation of luteal tissue around the periphery of the anovulatory follicle is usually minimal in a true autumnal follicle that occurs at the end of the season. The cause of anovulatory follicles is unknown, although they are hypothesized to be caused by changes in the hormonal status of the mare that occur with autumn transition. This hypothesis does not explain the occasional occurrence of anovulatory follicles during the breeding season, however. Luteinized anovulatory follicles, although unusual during the ovulatory season, most often occur in older mares and may be associated with senility. Their response to PG varies.

During certain periods of gestation, ovarian enlargement is normal and should be expected. Ovarian enlargement is associated with increased follicular activity and subsequent ovulation (secondary CLs) or anovulatory luteinization (accessory CLs). An increase in follicular growth begins before day 20 of gestation. New CLs form at approximately day 40 of gestation. Corpora hemorrhagica and hemorrhagic follicles commonly occur from day 40 to day 60. Mares bred early in the season have greater follicular activity during the first 4 months of gestation than mares bred after July.

During the spring, as mares undergo transition from winter anestrus to the normal ovulatory season, they undergo periods of prolonged anovulatory follicular development. These periods are characterized by the development of numerous follicles, at times large, on either ovary or usually both ovaries. The follicles may persist for varying lengths of time and then regress, and new follicles develop. This period lasts for a variable time depending on the mare, photoperiod, and other undetermined factors. The ovaries can be large during

this time and may be mistakenly called *cystic*. No treatment is necessary, although a combination of progesterone and estrogen often is used to suppress follicular activity in an attempt to hasten the onset of ovulation and normal cyclicity. The transition period ends with the first ovulation of the season, after which follicular activity and ovarian size return to normal.

Small and inactive ovaries normally are found in mares in deep anestrus, prepubertal mares, and pregnant mares in the last third of gestation when, curiously, the fetal gonads are larger than the ovaries of the dam. Mares subject to severe malnutrition, mares of advanced age, mares treated with anabolic steroids, and mares with chromosomal alterations leading to gonadal dysgenesis may have abnormally small and inactive ovaries.

## ENDOMETRITIS AND UTERINE THERAPY

Nigel R. Perkins, John B. Chopin

Endometritis is a major problem facing stud veterinarians attempting to maximize per-cycle conception and foaling rates. An improved understanding of the pathogenesis of endometritis has resulted in more effective methods to minimize the impact on fertility. Endometritis has been categorized into persistent mating-induced endometritis, chronic infectious endometritis, chronic degenerative endometritis, and sexually transmitted diseases.<sup>1-3</sup>

Failure of mechanical clearance of fluid, debris, and inflammatory by-products from the uterine lumen is recognized as the major predisposing factor associated with development of infectious endometritis.<sup>4-6</sup> Spermatozoa incite a leucocytic response leading to endometritis<sup>7</sup> 4 to 24 hours after insemination.<sup>8</sup> Significant endometritis is still present 48 hours after either artificial insemination or natural mating, even in mares of normal fertility.<sup>9</sup> Seminal plasma plays an important role in downregulating of endometrial inflammatory reaction to spermatozoa after mating,<sup>10,11</sup> and its removal from the inseminate might cause the reaction to worsen. Seminal plasma does not prevent neutrophil chemotaxis<sup>12</sup> but appears to prevent neutrophils from binding to spermatozoa.<sup>13,14</sup>

Diagnosis of infectious endometritis is based on one or more of the following: ultrasound detection of echogenic uterine luminal fluid and acute inflammatory change on endometrial cytology or biopsy in conjunction with a positive endometrial culture. The condition may be suspected in mares with cervical, vaginal, or vulval discharge during estrus. Diagnosis of chronic degenerative endometritis is mainly based on observation of fibrotic changes in endometrial biopsy samples and is most commonly a condition of older mares. Mares may have a history of failing to conceive over successive cycles or seasons, recurrent or chronic endometritis, and pregnancy loss before 60 days.

Sexually transmitted diseases include contagious equine metritis (CEM; *T. equigenitalis*), *Pseudomonas aeruginosa*, and *Klebsiella pneumoniae*. Susceptible mares bred to a CEM-shedding stallion will usually show shortened interovulatory intervals with a copious mucopurulent genital tract discharge associated with vaginitis, cervicitis, and endometritis.<sup>15-17</sup>

Diagnosis depends on recovery of the causative organism from culture samples obtained from the uterus, cervix, clitoral fossa, and clitoral sinuses.<sup>18</sup> The organism is difficult to culture and requires careful sampling, specific transport media, chilling during shipment, and appropriate incubation environment in a laboratory skilled at microbiologic procedures.<sup>19</sup> *P. aeruginosa* and *K. pneumoniae* are present in most equine breeding populations as occasional genital tract pathogens with the capability to be sexually transmitted. Diagnosis and treatment in the mare are as for other causes of infectious endometritis. Mares should be withheld from natural breeding until the infection is eliminated. The choice of uterine therapies for endometritis should be based on the same fundamental principles as for pharmacotherapy in other body systems. The anticipated therapeutic benefit should outweigh the potential risks associated with both the disease and the treatment being applied. Historical use of a particular treatment does not justify continued use unless it is accompanied by clear evidence documenting efficacy and safety. Many of the therapies described in this section are based on empirical evidence alone.

Drug preparations must be relatively nonirritating if they are to be used in the genital tract of the mare. Almost any substance, including physiologic saline, will induce an inflammatory response when introduced into the uterus of the mare.<sup>20</sup> This is particularly important when treatment is performed around the time of breeding because an inflammatory response that is severe and persists for longer than 5 days after ovulation is likely to interfere with embryo survival once the embryo enters the uterine lumen at about day 6 after ovulation.

## ANTIBIOTICS

The use of antibiotics in the treatment and prevention of endometritis is largely based on empirical evidence. One early review showed no effect on the foaling rate with the use of intrauterine antibiotics.<sup>21</sup> A more recent study of a large number of mares showed a significant increase in fertility when antibiotics were used.<sup>22</sup> There appear to be relatively few pharmacokinetic studies on which to base recommendations regarding choice of drug, route, dose rate, and frequency of administration. Table 18-5 provides recommended doses for various preparations commonly infused into the uterus of the mare.

## INTRAUTERINE VERSUS SYSTEMIC ANTIBIOTIC THERAPY

Antibiotics that have been recommended as possible systemic treatments for equine endometritis include amikacin sulfate, ampicillin trihydrate, gentamicin sulfate, procaine penicillin, and trimethoprim in combination with sulfadiazine. The use of a single dose of intrauterine antibiotics leads to levels in the reproductive tract that were higher at 12 and 24 hours than a single dose administered intravenously or intramuscularly.<sup>23</sup> After intrauterine administration, antibiotic levels peak in the tissue 1 hour after infusion and then decline steadily over 24 hours.<sup>24</sup> Systemic dosages, routes, and frequency of administration usually follow published guidelines for administration of these drugs for other conditions.<sup>25</sup>

Several advantages have been hypothesized to be associated with systemic antibiotic therapy as opposed to intrauterine infusion. Parenteral administration eliminates the risk of

TABLE 18-5

Recommended Doses of Intrauterine Drugs		
Drug	Dose	Comment
Amikacin sulfate	1 to 2 g	Gram negative
Ampicillin	1 to 3 g	
Carbenicillin	2 to 6 g	<i>Pseudomonas</i>
Ceftiofur	1 g	Broad spectrum
Gentamicin sulfate	0.5 to 2 g	Excellent, gram negative
Kanamycin sulfate	1 to 2 g	<i>E. coli</i> , toxic to sperm
Neomycin	3 to 4 g	
Nitrofurazones	50 to 60 ml	Questionable efficacy
Oxytetracycline	1 to 5 g	Use povidone-based products only
Penicillin (Na or K salt)	5,000,000 IU	Streptococci
Penicillin G procaine	3 to 6,000,000 IU	Streptococci
Polymixin B	40,000 to 1,000,000 IU	
Ticarcillin	1 to 6 g	Streptococci, <i>E. coli</i> , <i>Pseudomonas</i> , poor against <i>Klebsiella</i>
Trimethoprim/sulfadiazine	120 mg	
<b>COMBINATIONS</b>		
Neomycin	1 g	
Polymixin B	40,000 IU	
Furaltadone	600 mg	
Penicillin (Na or K salt)	3 to 5,000,000 IU	
Neomycin	2 g	
Penicillin G procaine	3,000,000 IU	
Gentamicin sulfate	0.5 to 2 g	
Penicillin G procaine	3 to 6,000,000 IU	
<b>ANTIFUNGAL THERAPIES</b>		
Nystatin	250,000 to 1,000,000 IU	Mix with sterile water; precipitates in saline
Amphotericin B	200 to 250 mg	
Clotrimazole	300 to 600 mg	Every 2 to 3 days for 12 days
Clotrimazole	500 mg cream	Daily infusion for 1 week
Vinegar	2% solution	20 ml wine vinegar in 1l saline
Povidone-iodine	1 to 2 % solution	
<b>IRRITANTS</b>		
Chlorhexidine	1 to 2 % of stock solution	
DMSO	5% solution	Infuse 50 to 100 ml
EDTA-Tris	1.2 g EDTA plus 6.05 g Tris per 1 water	Titrate to pH 8.0 with glacial acetic acid; infuse, then wait 3 hr, then infuse antibiotic
Hydrogen peroxide	1:4 dilution with saline	
Kerosene	50 ml	Avoid reflux through cervix
Povidone-iodine	0.05% solution	
Saline	Variable volume	Consider warming to 45° to 50° C
Streptococcal cell free filtrate		

Adapted from Perkins N: Equine reproductive pharmacology, *Vet Clin North Am: Equine Pract* 15: 687–704, 1999.  
DMSO, dimethyl sulfoxide; EDTA, ethylenediamine tetraacetic acid.

bacterial contamination of the reproductive tract, which is associated with repeated intrauterine infusions. Uterine tissue concentrations of ampicillin and enrofloxacin are reported to be higher than serum concentrations after systemic administration of the drugs by intravenous and oral routes.<sup>26,27</sup> Some drugs may be associated with an adverse local tissue reaction when administered into the uterine lumen and yet not have any adverse effect on uterine tissue when administered systemically. For example, intrauterine infusion of enrofloxacin has been linked to uterine pathology, including adhesion formation. Enrofloxacin has been associated with cartilage and skeletal damage in young, growing horses as well as joint effusion and mild cartilage lesions in adult horses after systemic use.<sup>27</sup> Nonetheless, mares receiving oral enrofloxacin (5 mg/kg b.i.d. for 21 days) had endometrial tissue concentrations higher than those observed in serum and all tissue levels of drug exceeded minimum inhibitory concentration (MIC) levels for common equine pathogens. Further work is required before this product can be recommended as a treatment for endometritis. Little documentation exists regarding the efficacy of systemic therapy in the treatment of endometritis. Some researchers have suggested that systemic therapy be considered when deeper layers of the uterus are infected or inflamed, as in the case of postpartum metritis.<sup>1,20</sup> The author routinely uses systemic antibiotic therapy only in mares that show systemic signs of illness associated with the reproductive tract. Most uterine infections in the mare are limited to the lumen and the superficial endometrium. Local uterine therapy by way of uterine infusion is favored in the treatment of such conditions because it is considered likely to result in high antibiotic levels within the lumen and superficial layers of the endometrium. In addition, uterine infusion of antibiotic is considered likely to be more economical than systemic therapy because doses and administration frequency are often lower than those used systemically.

### CHOICE OF ANTIBIOTIC

Factors to consider in the choice of antibiotic to use in the uterus include types of organisms isolated, antibiotic-sensitivity patterns of isolated organisms, and potential efficacy of the drug in the uterus. Antibiotic selection should be as specific as possible and based on microbiologic isolation of the etiologic organisms by uterine culture, followed by sensitivity testing.<sup>28</sup> The use of broad spectrum antibiotics in the absence of culture and sensitivity results is discouraged insofar as such indiscriminate use of antibiotics is likely to increase the risk of bacterial resistance and superinfection with different bacterial strains, fungi, or yeast.<sup>20,29</sup> Methicillin-resistant *Staphylococcus aureus* was isolated from several mares from one farm in Japan. The source of the infection was a cutaneous lesion on a stallion.<sup>30</sup> Fungi and yeast did not become more prevalent as causes of endometritis until the widespread use of intrauterine antibiotics in the mid-1950s.<sup>29</sup>

The use of antibiotic combinations is also discouraged because of the risk of incompatibilities resulting in reduced efficacy. An example is the suggested inactivation that is thought to occur when  $\beta$ -lactam antibiotics such as penicillin are combined with aminoglycosides such as gentamicin.<sup>31</sup> However, some experts argue that the first choice of antibiotic for intrauterine use should be a broad spectrum combination of drugs aimed at successfully treating all components of the mixed aerobic and anaerobic infections that commonly occur.<sup>32</sup> When

culture and sensitivity results are not available, the choice of drug should be based on the expected bacterial organisms and their predicted antibiotic susceptibility patterns.<sup>31</sup>

Virtually any bacterial species could be isolated from acute endometritis, although certain bacterial isolates are considered to be more likely than others. Several studies have reported that between 70% and 80% of acute aerobic endometritis cases were associated with *Streptococcus zooepidemicus*, *E. coli*, *P. aeruginosa*, and *K. pneumoniae*.<sup>31,33-35</sup> Large-scale data from routine endometrial cultures in the U.K. appear to show a slightly different pattern of bacterial involvement.<sup>25</sup> Of 3414 isolates associated with cytologic evidence of endometritis, 38% were recovered in pure culture and 62% in mixed culture.<sup>25</sup> Streptococci were more likely to be isolated when there was clinical signs of endometritis, whereas *E. coli* was more likely when mares were presented for repeat breeding.<sup>37</sup> The role of anaerobic bacteria in endometritis remains unclear. One study has reported that 18 of 71 (25%) cases in which endometrial cytology and culture were positive grew an anaerobe only on culture. The most common anaerobe recovered was *Bacteroides fragilis*.<sup>38</sup> Others have suggested that anaerobes are unlikely to play a significant role in endometritis.<sup>39</sup> No single antimicrobial therapy is effective against all of the commonly isolated uterine pathogens.  $\beta$ -Lactam antibiotics (penicillins and cephalosporins) are very effective against streptococci. Synthetic penicillins such as ampicillin and ticarcillin are also effective against many strains of *E. coli* and *P. aeruginosa*. Aminoglycosides are used primarily in the treatment of gram negative organisms. Bacterial sensitivity patterns are often variable, particularly for gram negative organisms, and accurate prediction of sensitivity patterns is impossible in many cases.<sup>31</sup>

The difficulties described in identification of the etiologic agent in cases of endometritis, prediction of antibiotic sensitivities, and the time constraints of a short breeding season mean that in most cases broad spectrum antibiotics are used as a first-choice treatment. In many cases a broad spectrum of activity is achieved by using combinations of drugs. Commonly used broad spectrum antibiotics include ticarcillin-clavulanic acid, ampicillin, and drug combinations such as penicillin-aminoglycoside and penicillin-furaltadone-neomycin-polymixin B (Utrin Wash, Univet Ltd., Wedgewood Road, Bicester, U.K.). Recently, ceftiofur sodium (1 g by intrauterine administration daily for 3 successive days) was used in clinical trials as a broad spectrum intrauterine treatment for equine endometritis and was considered to be an effective and safe alternative to the combination of penicillin, neomycin, polymixin B, and furaltadone.<sup>32</sup>

### ANTIBIOTIC FORMULATION, TREATMENT FREQUENCY, AND VOLUME

There is little evidence on which to base recommendations regarding dosage, formulation, volume of drug infused, diluent, and frequency of treatment. Dose regimens should be based on MIC data in conjunction with pharmacokinetic studies of drug disposition after intrauterine administration. In the absence of any data, it appears that dosages are based on the recommended parenteral dosage for the drug in question. In many cases the dose rate recommended for intrauterine use is lower than the systemic dose. Sometimes this is based on clinical evidence, and in others it appears to be more a response to convenience or cost. Use of a 2-g dose of amikacin sulfate administered by intrauterine infusion was reported to

be associated with a higher cure rate than 0.5- or 1-g doses in mares experimentally inoculated with *K. pneumoniae*.<sup>40</sup> There was little difference in endometrial or uterine luminal amikacin concentrations in mares after infusion of 2 g versus 3 g, and both infusion doses resulted in endometrial levels within assumed therapeutic ranges for a 24-hour period.<sup>24</sup> This information suggests that the infusion dose of amikacin should be 2 g.

Intrauterine treatments are commonly performed every day or every second day for 3 to 7 days. Treatment is usually performed during estrus, largely because uterine defense mechanisms are more effective during estrus than diestrus. Treatments may proceed for 2 to 4 days after ovulation, provided the infused preparation results in little endometrial irritation. Once-daily treatment with 3 g ampicillin maintains uterine levels above MIC for common equine uterine pathogens for the entire 24-hour period between treatments.<sup>41</sup> Although frequency of treatment should be based on the length of time that the antibiotic remains active and above estimated MIC within the uterus, the fact remains that the standard daily or every-other-day treatments are likely to be based on convenience and practicality rather than science. It may not be necessary to maintain antibiotic levels above MIC for the entire time interval between successive treatments. Exposure of bacteria to large doses of antibiotic for brief periods of time reportedly increases the susceptibility of bacteria to leucocyte killing.<sup>42</sup> This may explain the success of a convenience-based treatment protocol that might not maintain antibiotic levels above MIC for the entire intertreatment interval. The volume of fluid infused into a mare's uterus with each treatment ranges between 30 and 250 ml. In most cases a sufficient volume of fluid should be used to obtain complete uterine coverage when infused.<sup>28,34,43</sup> The capacity of a typical nonpregnant mare's uterus is about 35 ml, whereas an older mare's uterus may hold 60 to 150 ml.<sup>28,34</sup>

Infusion of fluid volumes ranging between 30 to 250 ml may not result in uniform distribution of fluid within the uterine lumen. The majority of infused fluid pools in the uterine body and at the body-horn junctions.<sup>44</sup> Most cervical reflux was observed 10 to 15 minutes after infusion, which is consistent with endogenous oxytocin or PGF<sub>2</sub>- $\alpha$ -stimulated uterine contractions. Larger volumes were more likely to result in reflux through the cervix. It appears likely that some of the benefit from infusing antibiotic into the uterus in volumes large enough to encourage cervical reflux is actually due to a lavage effect rather than a direct antibacterial effect.

Insoluble or irritant preparations are not recommended because they can cause chronic endometritis.<sup>45</sup> Drugs for uterine infusion are commonly diluted in either saline, balanced electrolyte solutions, or water for injection. Acidic drugs such as gentamicin and amikacin may be buffered by mixing equal volumes of antibiotic and 7.5% sodium bicarbonate before infusion into the uterus.<sup>25</sup> The choice of diluent may influence the pharmacokinetics of some drugs. Infusion of gentamicin into the uterus of cattle was followed by systemic absorption of more than 60% of the dose when the gentamicin was diluted in water, versus less than 20% of the dose when diluted with saline.<sup>46</sup> Procaine penicillin is discouraged for intrauterine administration owing to an early study based on hysteroscopy in which the endometrium was reported to be visibly covered with a white, chalky material, thought to be antibiotic, after infusion of ampicillin. The material was visible 3, 7, and 14 days after infusion.<sup>47</sup> Nonetheless, procaine

penicillin is widely used as an intrauterine infusion and is commonly mixed with aminoglycosides, particularly gentamicin and neomycin. The use of procaine penicillin in the equine uterus requires additional investigation.

## ☪ ANTIFUNGAL PREPARATIONS

Dilute povidone iodine or 2% vinegar (20 ml white vinegar in 1000 ml saline) has been proposed as an intrauterine therapy for fungal endometritis. A variety of antifungal medications have also been used as intrauterine treatments,<sup>48</sup> some of which are presented in Table 18-5. There appears to be little or no data on which to base recommendations regarding sensitivity patterns, dose rates, or frequency of treatment. Fungal endometritis has been reported as being difficult to treat, although this perception may be due in part to the use of ineffective or inappropriate treatments.<sup>48,49</sup>

A report using an instillation of 540 mg of lufenuron in 60 ml of saline after uterine lavage reported success of removal of fungal infection in 4 mares.<sup>50</sup>

## ☪ ANTISEPTICS AND IRRITANTS

Antiseptic or irritant therapy has commonly been recommended for mares in which a diagnosis of endometritis has been made but no specific etiologic agent isolated or for aged, subfertile mares with distinct degenerative changes on endometrial biopsy. Irritants have been used to reduce the size of the uterus and increase uterine tone. Antibiotics are not useful in this manner unless they are irritating. In addition, irritants may decrease fluid viscosity within the uterus to aid in its expulsion. Irritant therapy has also been credited with stimulating a severe, acute inflammatory response within the endometrium, which may help resolve the chronic monocytic inflammation commonly associated with degenerative endometritis or endometrosis. Mechanical curettage has similar effects, although the technique is difficult because of the bicornuate nature of the equine uterus. The typical endometrial response to infusion of an irritant is a nonspecific inflammatory reaction with hyperemia and neutrophil influx. This is followed by a slower infiltration of mononuclear cells that peaks between 4 and 7 days after treatment. The duration of inflammation and the extent of tissue damage varies considerably among individual animals receiving the same treatment. Irritant therapy nonspecifically activates endometrial glands.<sup>51</sup> Excessive irritation of the endometrium, associated with too harsh or concentrated a solution, may result in worsening of the degenerative condition and even in adhesion formation. Threlfall has stated that chlorhexidine solution has a propensity to cause endometrial adhesions and severe reactions and should not be used within the uterus.<sup>43</sup> Recently, anecdotal evidence suggests that enrofloxacin administered as a uterine infusion in mares may be highly irritating, resulting in a severe inflammatory reaction with serosanguineous uterine fluid containing fibrin tags.

### POVIDONE IODINE

Dilute povidone iodine solution is a commonly recommended intrauterine treatment because of its irritant, bactericidal, and fungicidal properties. Bactericidal activity of povidone-iodine is maintained in vitro down to concentrations of 0.01 to 0.005%, whereas more than 0.2% povidone iodine has been

claimed to inhibit neutrophil migration.<sup>52</sup> Stock povidone-iodine solution, used in practices to disinfect surgical sites, is described as a solution containing 10% povidone iodine, equivalent to 1% available iodine.

Discussions regarding the safety of dilute povidone-iodine solutions in the mare exemplify the need for critical information on the uterine effects of all potential irritant therapies. Earlier studies found severe inflammatory responses in the endometrium after infusions of 2% or more povidone-iodine.<sup>53,54</sup> A similar study reported severe prolonged irritation of the endometrium after infusion of 1% povidone-iodine solution, with mares still showing evidence of inflammation at the conclusion of the study, 30 days after infusion.<sup>55</sup> Other researchers have reported resolution of inflammation on uterine biopsy within 6 days of uterine infusion of 0.05% povidone-iodine solution.<sup>20</sup> In addition, infusion of 1 L of 0.05% povidone-iodine into the uterus 4 hours after breeding had no adverse effect on pregnancy rates.<sup>56</sup> Recently, Bracher reported that infusion of 0.05% povidone-iodine solution into the uterus (alone or in combination with either dimethyl sulfoxide [DMSO] or collagenase) induced adhesions, ulceration of the endometrium, and severe stromal fibrosis and gland degeneration in three of five treated mares.<sup>51</sup> Individual mares may be hypersensitive to povidone-iodine solution. Asbury and Lyle<sup>25</sup> have suggested that if any signs of discomfort or irritation, either on clinical observation or examination with a vaginal speculum, are observed after povidone-iodine infusion genital tract should be flushed with saline and povidone-iodine therapy should be discontinued. The author suggests that povidone iodine solutions be avoided or used with caution until further information is available regarding its safety as a uterine therapy.

## HYDROGEN PEROXIDE

Hydrogen peroxide acts as an irritant and has been recommended as an alternative approach for treating intrauterine infections caused by *P. aeruginosa*. Hydrogen peroxide is an oxidizing agent that readily breaks down to release oxygen and water, accompanied by effervescence. It should be used only in mares during estrus.<sup>57</sup>

## TRIS-EDTA

Intrauterine infusion of Tris-ethylenediamine tetraacetic acid (EDTA) results in a degree of inflammation similar to that observed after saline infusion.<sup>58</sup> Tris-EDTA may have a potentiating effect on the antimicrobial activity of a variety of antibiotic and antibacterial solutions.<sup>59</sup> It may have direct antibacterial effects in some cases; in others it may cause a reduction in the MIC for some organisms in association with particular antibiotics, including penicillin, oxytetracycline, and gentamicin.

## CHLORHEXIDINE GLUCONATE

Chlorhexidine is a strong irritant with the potential to cause intrauterine adhesions and therefore has been disregarded for potential uterine therapy.<sup>43</sup> Pony mares tolerate uterine infusions of 0.25% chlorhexidine gluconate (Hibitane; Schering-Plough Animal Health, Upper Hutt, New Zealand; dilution of stock solution of 20% v:v BP in water) with little evidence of irritation on vaginal inspection, whereas dilutions

of 0.5%, 1%, and 2% caused severe irritation in a number of mares treated.<sup>60</sup> A solution containing 100 µg/ml chlorhexidine gluconate exceeds the MIC for *Streptococcus equi* subsp. *zoepidemicus*, *P. aeruginosa*, *K. pneumoniae*, *Actinobacillus equuli*, and *Candida albicans*.<sup>61</sup> Infusion of this solution in a 200-ml volume on 3 successive days during estrus had no adverse effect on pregnancy rate when mares were given PGF<sub>2</sub>-α 8 to 9 days after ovulation and bred at the successive estrus.<sup>62</sup> More research is needed regarding the safety and efficacy of chlorhexidine as a uterine therapy.

## DIMETHYL SULFOXIDE

Dimethyl sulfide causes an inflammatory response after intrauterine infusion.<sup>51</sup> Intrauterine DMSO may decrease endometrial biopsy classification scores by 1 or more points largely because of the reduction of periglandular fibrosis,<sup>57</sup> although others have reported that DMSO did not have any fibrolytic effect.<sup>51,63</sup> One mare in a treatment group receiving concentrated DMSO subsequently was found to have developed transluminal adhesions.<sup>51</sup> A clinical trial involving uterine infusion of DMSO into subfertile mares failed to detect any improvement in fertility after DMSO infusion.<sup>57</sup>

## KEROSENE

Kerosene has been used as an irritant therapy in the equine uterus for many years.<sup>64</sup> Recently, an experimental comparison evaluated the uterine response in subfertile mares to infusions of kerosene, dilute povidone-iodine, DMSO, and collagenase. The uterine response to kerosene, collagenase, and DMSO was similar, resembling that seen after mechanical curettage. Gross and histologic evidence of inflammation resolved within 14 to 21 days of infusion. Kerosene-treated mares differed from other treatment groups in having improved gland activity on uterine biopsy and higher pregnancy rates after breeding. Nine of 11 (82%) mares conceived, and 5 of 11 (45%) subsequently foaled. Bracher concluded that the increase in secretory activity of the glands observed after intrauterine infusion of kerosene was a major factor in achieving the higher conception and foaling rates.

The standard approach for infusing kerosene involves infusing 50 ml of commercial-grade kerosene into the uterine lumen during diestrus. Diestrus is preferred because the closed cervix is more likely to prevent reflux of kerosene into the vagina with resulting inflammation.<sup>57</sup> Alternatively, infusions during estrus should be followed by digital occlusion of the cervix for a short time to prevent vaginal reflux.

## SALINE

Saline is very useful as a means of flushing or mechanically removing fluid and debris from the uterus as well as stimulating the uterus to contract and expel contents. It irritates the endometrium and causes migration of PMN into the uterine lumen. Warmed saline results in rapid and transient enhancement of uterine tone in mares with atonic or atrophic uteri. Saline flushes on day 6 after ovulation result in luteolysis through endometrial PGF release.<sup>25,43</sup>

The use of saline to flush the uterus 4 to 6 hours after insemination might result in increased fertility compared with lavage at 18 to 20 hours after insemination. Unfortunately, low treatment numbers did not allow a significant result.<sup>65</sup> Lavage

with lactated Ringer's solution can be performed immediately before insemination without affecting fertility provided that most of the fluid is removed first.<sup>66</sup>

## ☉ PLASMA

Plasma may be beneficial in mares with chronic and chronic-active endometritis by providing immunoglobulins and complement, both important components in opsonization of bacteria within the uterus.<sup>67-69</sup> Suppression of uterine neutrophil function in susceptible mares is likely to be a result of the accumulation of fluid, debris, and bacteria that occurs secondary to an underlying failure of uterine mechanical clearance.<sup>70</sup> Treatment and prevention are therefore better aimed at aiding clearance than infusing plasma. This hypothesis is supported by studies failing to demonstrate any beneficial effect of plasma in susceptible mares.<sup>71</sup>

The use of plasma alone reduced inflammation but did not inhibit bacterial growth.<sup>2</sup> Pascoe recently described a large field study involving the routine postbreeding use of plasma in conjunction with antibiotics. A significant improvement in pregnancy rate was seen when plasma was infused into barren and lactating mares but not in maiden mares.<sup>72</sup> It is possible that plasma may be beneficial in foaling mares or in mares that do not have a mechanical clearance problem. Further work is needed to determine factors that may influence the effect of plasma in the uterus of the mare.

Autologous plasma is believed to be preferable to heterologous plasma because of the risk of hypersensitivity, anaphylaxis, or transfusion illness after heterologous plasma infusion. However, many mares have received heterologous plasma without experiencing any problems. Preparation of plasma requires aseptic withdrawal of venous blood into a heparin-based anticoagulant (typically 5-10 units heparin per ml of blood).<sup>1</sup> Because complement rapidly degrades at room temperature, separation of plasma should be rapid. Gravity sedimentation is acceptable but should be performed under refrigeration. Once separated, plasma should be infused immediately or stored frozen in 100-ml aliquots ready for thawing and infusion. Thawing must be performed in warm water or in a microwave on a low setting. Thawing at too high a temperature will result in denaturation of protein and loss of immunoglobulin activity. In field conditions preparation of plasma is invariably performed under conditions that are less than ideal. The author always combines field-derived plasma with broad spectrum antibiotic as a uterine infusion to minimize the risk of inadvertently introducing infectious organisms when infusing plasma.

## ☉ UTEROTONICS

The importance of mechanical clearance of the uterus in resistance to bacterial infections has been clearly documented.<sup>2,6,70,73,74</sup> The inability to physically clear contaminating material from the uterus within a short period is believed to be the major factor resulting in mares being susceptible to chronic and recurrent uterine bacterial infection.<sup>1</sup> Some affected mares show decreased contractility of longitudinal muscles and decreased available intracellular calcium,<sup>75</sup> possibly as a result of a contractile defect in the myometrium of susceptible mares.<sup>76</sup> In addition, in the uterine fluid and endometrium of susceptible mares, there is a higher concentration of nitric oxide, which relaxes smooth muscle and will inhibit mechanical clearance.<sup>77,78</sup>

Treatments that help the uterus to physically clear bacteria, fluid, and associated inflammatory by-products and debris from the uterine lumen are critical to the effective treatment and prevention of infectious endometritis. Uterine lavage is very effective at removing material from the uterine lumen.

Pharmacologic therapies that induce uterine contractions include oxytocin and PGF<sub>2</sub>-α and analogs.<sup>79</sup> The use of oxytocin improved fertility,<sup>22,80</sup> especially when combined with antibiotics.<sup>22</sup>

PGF<sub>2</sub>-α or cloprostenol administered by intramuscular injection causes an increase in intrauterine pressure within 10 minutes, with contractions lasting for about 5 hours. Oxytocin produces a response within 60 seconds of intravenous administration, but contractions last only 40 to 60 minutes. Recently, investigators concluded that oxytocin was more effective than PG in clearing the uterus of colloid.<sup>73</sup> The same study also concluded that cloprostenol was more effective than PG or fenprostalene, although all mares treated with PG analogs had an increased clearance of radiocolloids.<sup>73</sup>

Cloprostenol has also been recommended in favor of dinoprost in mares that have lymphatic stasis. Lymphatics drain particulate matter from the uterine lumen and reabsorb the intramural fluid that accumulates within the uterine wall during estrus.<sup>74,81</sup> Lymphatics drain dorsally into the vessels in the broad ligament and then into the iliac and aortic lymph nodes. Lymphatic vessels do not contain smooth muscle and therefore must rely on uterine contractions to push fluid dorsally within lymph vessels.<sup>74</sup>

PGs should not be administered more than 48 hours after ovulation to minimize the risk of inducing luteal regression. There was a reduction in progesterone production and pregnancy rate after the use of cloprostenol, but not oxytocin,<sup>82</sup> 24 hours after ovulation.

Concurrent medications may interfere with uterine clearance in susceptible mares. Phenylbutazone and acepromazine administration interfere with the clearance of uterine radiocolloid in susceptible mares. The effect is reversed with the administration of oxytocin.<sup>74</sup> Xylazine may be a preferable to acepromazine as a sedative for susceptible mares in the breeding shed because xylazine causes an increase in uterine pressure. In the event that mares receive either acepromazine or phenylbutazone around the time of breeding, consideration should be given to concurrent administration of oxytocin to assist in uterine clearance.

Intrauterine oxytocin administration increases intrauterine pressure but not as much as intramuscular or intravenous administration.<sup>83</sup> Preliminary studies involving the intrauterine administration of 10-mg doses of dinoprost suggest that it is effective at inducing uterine contractility.<sup>2,84</sup> The use of oxytocin and PG (or analogs) as aids for uterine clearance remains empirical. Doses of 10 to 25 IU oxytocin have been used to aid mechanical evacuation of the uterus. Little information exists regarding the most effective dose, route of administration, and frequency of administration. There is also a lack of information on the safety of these products when used around the time of breeding, although both products are commonly used during estrus, both before and after breeding. In addition, there is relatively little information on practical methods of identifying mares with delayed uterine clearance that is suitable for application in the field. The presence of ultrasonographically detectable uterine fluid appears to be an indicator of reduced clearance, particularly if it persists for more than 6 to 12 hours after mating.<sup>3</sup>

## ☞ UTERINE LAVAGE

Uterine lavage is a traditional and highly effective method of removing fluid and associated debris from the lumen of the uterus. Uterine lavage is commonly performed both before and after breeding and is often combined with infusion of antibiotic, antiseptic, or other materials (e.g., plasma).<sup>43</sup> In addition, lavage is commonly applied in the early postpartum mare for the treatment of retained placenta, metritis, or both. Emptying the uterus of fluid before antibiotic infusion is likely to improve the efficacy of uterine antibiotic therapy by removing foreign material and inflammatory products from the lumen. This is likely to be more important for aminoglycoside and polymixin antibiotics, which bind to purulent material.<sup>20</sup>

Saline induces an inflammatory response within the uterus. Infusion of acidic saline resulted in an immediate release of endogenous PGF, whereas infusion of pH-neutral saline does not.<sup>85</sup> Heating lavage fluid to 45° to 50° C results in a rapid and transient increase in uterine contractility.<sup>43</sup>

Uterine lavage is normally performed with a Foley catheter or embryo transfer catheter with a large balloon cuff (75 ml). Fluid is infused until the uterus is distended (500 to 1000 ml), removed under gravity flow, and collected into a vessel to allow measurement of lavage and recovered volumes; the appearance of the recovered fluid is then assessed. The opacity of the recovered fluid is an indicator of the degree of inflammation present within the uterus and helps the clinician decide whether additional flushing is necessary. Lavage should be repeated until the recovered fluid is clear. There are no controlled studies documenting the efficacy of lavage as a treatment modality for endometritis.

## ☞ ALTERNATIVE TREATMENTS

The use of lectins to bind to *Streptococcus* and prevent it from binding to the endometrium was somewhat successful with D-galNAc and D-(+)-mannose. However, it required exposure of the lectin to the bacteria before its introduction to the uterine environment.<sup>86,87</sup>

Corticosteroid treatment of endometritis in mares has yielded contradictory results. Administration of dexamethasone (40 µg/kg) for 3 days while mares received concurrent progesterone therapy resulted in worse disease symptoms than those observed in control mares or mares receiving dexamethasone and antibiotics.<sup>88</sup> However, in a separate study mares receiving prednisolone had no difference in response to therapy than normal mares. Mares with a history of endometritis had decreased uterine fluid that was clearer and had a lower cell count after insemination with frozen semen compared with untreated mares. The pregnancy rate in the treated barren mares was greater than in untreated barren mares.<sup>89</sup>

Immunizing mares against *S. equi* subsp. *zoepidemicus* reduced infection and inflammation when the uterus was experimentally infected with the same bacteria.<sup>90</sup> The use of an immunostimulant made from *Propionibacterium acnes* reduced the cytologic diagnosis of endometritis on subsequent estruses.<sup>91,92</sup> The conception rate was good, but unfortunately the control mares that still had a high level of endometritis were not bred as controls.<sup>92</sup> Another study found a reduction in the diagnosis of endometritis with the use of *P. acnes* injection, and mares were more likely to get pregnant after treatment.<sup>93</sup>

When susceptible mares with experimental endometritis were treated with fresh, frozen, or lysed leucocytes, they were

able to clear bacteria significantly more quickly than the control mares.<sup>94</sup>

There is anecdotal evidence that magnesium sulfate may benefit some mares with endometritis. No fertility data have been published, but the few mares that were examined after being infused with 1 L of saline with 128 g of magnesium sulfate showed no evidence of permanent damage.<sup>95,96</sup>

When the mare is exposed to auditory and visual stimulus from the stallion or teaser male, there is a release of oxytocin and an increase in myometrial contractions.<sup>97</sup> The authors have used this with mares that show an adverse reaction to, or are dangerous with, repeated oxytocin injections. The mare can be run alongside the teaser male for the period of time that oxytocin release is needed, provided that the fences are sound and safe. In the authors' opinion, the stance that the mare adopts when she is teasing, wherein the caudal aspect of the pelvis tilts ventrally, might help in posturally draining the reproductive tract.

## ☞ CONCLUSION

Successful treatment of acute or chronic infectious endometritis is based on elimination of the etiologic organism, reduction of any accompanying inflammation, correction of anatomic defects, and prevention of recurrence. Predisposing anatomic causes of endometritis such as poor vulval conformation, cervical or rectovestibular lacerations, and urine pooling must be corrected surgically before the application of therapies aimed at resolving endometritis. The most common routine procedure performed on broodmares is Caslick surgery. More extensive surgical procedures should be performed during the nonbreeding season to allow the mare time to recover before breeding.

The approach to uterine therapy depends on the diagnosis and presenting clinical signs. Infectious endometritis is managed by elimination of fluid and debris from the uterine lumen by lavage and administration of uterotonic agents followed by uterine infusion of a topical treatment (e.g., antibiotic, antifungal, antiseptic). Choice of uterine therapy, formulation, dose, volume infused, diluent, and treatment frequency must be determined after consideration of individual patient information. It is necessary to lavage the uterus on subsequent treatment visits only if the uterine lumen continues to accumulate fluid or if the lavage is being performed to stimulate uterine contractility.

Many treatments have been suggested for chronic degenerative endometritis (endometrosis), but consistently favorable results have not been reported. Mechanical and chemical curettage or irritant therapy are commonly employed in mares with this condition.

Topical treatment of the uterus must be accompanied by strict attention to hygiene. Attention must be paid to management principles if successful resolution of endometritis is to be accompanied by a reduction in the risk of recurrence and an optimal opportunity for pregnancy to be achieved.<sup>20</sup>

An area in which important advances have been made in the past several years is in our understanding and management of postmating endometritis. A transient and physiologic endometritis occurs after breeding because of the intrauterine deposition of semen.<sup>1</sup> In normal, fertile (resistant) mares, this transient inflammation resolves within 36 hours after mating. Contamination and inflammation of the uterus after breeding must be resolved before the embryo enters the uterine lumen

at approximately 6 days after ovulation in the pregnant mare. Impaired physical clearance of bacteria, fluid, and inflammatory products is considered the primary factor responsible for susceptibility to persistent infectious endometritis.<sup>1</sup> Mares should be examined in early estrus using ultrasonography to evaluate the presence and echotexture of uterine luminal fluid. The presence of large volumes of echogenic fluid indicates acute endometritis, and it may be preferable to treat such mares aggressively through the estrus period and short cycle them to aim for breeding on the successive estrus. Large volumes of anechoic fluid in early estrus can be removed using uterine lavage with saline, followed by injection of oxytocin to prevent fluid accumulation recurring. Small to moderate volumes of fluid may be managed by oxytocin alone. It is useful to examine mares 20 minutes after administration of oxytocin to ensure that uterine fluid has been expelled. In some cases manual dilation of the cervix is needed to facilitate effective expulsion of fluid. Intrauterine infusion of antibiotic may be used in early estrus in an attempt to eliminate endometritis or reduce the risk of endometritis before breeding. Any product used for uterine lavage or instillation in the prebreeding or postbreeding estrous period should have minimal irritating effect on the endometrium. Physiologic saline, Dulbecco's phosphate buffered saline, or lactated Ringers' solution are believed to be associated with a reduced inflammatory response compared with water. Antibiotics should be chosen with care and antiseptics or irritants not used at all in this period. Ultrasound examinations may be continued through estrus right up to immediately before breeding, with the goal being to eliminate fluid from the lumen of the uterus before breeding.

There is general agreement that mares should be bred only once to minimize contamination of the uterus and genital tract. The use of ovulation induction agents such as hCG or synthetic GnRH should be considered routine for susceptible mares because they greatly improve the likelihood of a single breeding per ovulatory cycle. It is normal practice to aim for a single breeding in the period from 24 hours before ovulation to 12 hours after ovulation. Depending on stallion fertility, mares may be bred as early as 48 to 72 hours before ovulation without reduction in fertility. Recently, Pycocock proposed that susceptible mares be bred only once, at least 24 hours before ovulation and perhaps earlier, assuming suitable stallion fertility.<sup>98</sup> This ensures that any contamination associated with breeding occurs at a time when circulating estrogen concentrations are maximal, progesterone concentrations are minimal, uterine defense mechanisms and physical drainage should be optimal, and there is more time available after breeding to implement uterine therapy before progesterone rises and the cervix begins to close after ovulation.

If breeding by artificial insemination, semen extender containing antibiotic should be added to the ejaculate and the extended semen allowed to stand undisturbed for a minimum of 15 minutes to allow elimination of possible pathogens from the ejaculate. Antibiotic-containing semen extender may be infused into the uterus of the mare immediately before natural breeding in an attempt to obtain a similar effect. Susceptible mares should be examined by ultrasound as early as 4 hours after breeding and preferably before 12 hours, again to check for accumulation of fluid.<sup>56</sup> This ensures that uterine fluid can be eliminated using lavage, uterotonics, or a combination of these treatments before the development of an inflammatory response or proliferation of potentially pathogenic organisms.

Uterine infusion with broad spectrum antibiotics is performed about 20 minutes after administration of uterotonic. Pycocock suggests using a small volume infusion (30 ml) for the postbreeding treatment because susceptible mares are expected to have clearance problems.<sup>98</sup>

Administration of oxytocin can be continued and the mare examined the following day to ensure that uterine fluid is not accumulating. If fluid is still present, the treatment approach (lavage, uterotonic, and infusion) can be repeated. Intrauterine treatment should not be continued past day 3 after ovulation in order to minimize the risk of endometrial inflammation persisting past day 5 or 6, when an embryo may be expected to be entering the uterus. Uterotonics should not be administered past day 2 after ovulation because the cervix is generally starting to close and uterine drainage is then inhibited. PGs should be used with care after ovulation because of the added risk of possible induction of luteal regression. The use of a single postbreeding uterine infusion of broad spectrum antibiotic in combination with uterotonic administration results in higher pregnancy rates in field trials than either antibiotic or uterotonic alone.<sup>99</sup>

The combination of prebreeding and very early postbreeding estral management, with the use of oxytocin, has greatly improved our ability to prepare an optimal uterine environment, both for breeding and for establishment of early pregnancy. Anecdotal reports support the use of systemic antibiotics and nonsteroidal anti-inflammatory drugs in susceptible mares after breeding as a possible way to reduce the risk of establishment of endometritis and endometrial PG release.<sup>100,101</sup> Such therapies remain unproven.

## HORMONAL MANIPULATION OF THE MARE

*Elizabeth Metcalf*

Veterinarians attempt to alter the physiology or behavior of the mare through the administration of exogenous hormones. This chapter examines the effects of hormonal preparations administered to mares in an attempt to enhance their reproductive efficiency.

## ☾ VERNAL TRANSITION

As day length increases, nonpregnant mares gradually emerge from a state of ovarian quiescence to regular cyclicity. Through activation of the hypothalamic-pineal-pituitary-ovarian axis, mares begin to show clinical signs of a prolonged estrous period followed at last by the first ovulation of the season. The first section of this chapter, Reproductive Anatomy and Physiology of the Nonpregnant Mare, presents more precise physiologic events of this period.

Many hormonal regimens aimed at shortening the interval to first ovulation have been examined. Increasing the exposure of a mare to light from 6 A.M. to 10 P.M. has proved a potent and effective means of shortening the time to first ovulation of the season. In an attempt to more effectively hasten the interval using exogenous hormonal manipulation, researchers have examined other preparations, including melatonin,<sup>1</sup> progestins<sup>2</sup> (plus estrogens),<sup>3</sup> and dopamine antagonists such as domperidone,<sup>4-6</sup> sulpiride,<sup>6</sup> and perphenazine.<sup>7</sup>

Although all regimens are effective at shortening the interval to first ovulation, none were more effective than progesterone alone.<sup>6</sup> Intravaginal pessaries impregnated with progesterone also have been successful in induction of cyclicity in anestrus mares.<sup>8</sup> The provision of good nutrition, especially in aged mares, may hasten the onset of the first ovulation,<sup>9</sup> possibly by involving hormones that are associated with digestive metabolism. Once a mare has entered the period of transitional estrus in the spring and has developed a 25-mm follicle, intramuscular administration of 12.5 mg eFSH (Bioniche) twice daily significantly hastens the time to first ovulation compared with untreated control mares (22.4 versus 10.9 days,  $P < 0.05$ ) and increases the number of embryos recovered in treated mares.<sup>10</sup>

## ☞ SYNCHRONIZING THE ESTROUS CYCLE

In the attempt to optimize breeding efficiency, the ability to predict estrus and ovulation becomes an important management tool. Although mares show variability in their response to hormonal treatment, the concept of fixed-timed insemination, or “appointment breeding” has proved successful in equine reproduction. The objective of most attempts to manipulate the timing of the estrous cycle of the mare is synchronization of a group of mares (e.g., in an embryo transfer program) or, more commonly, strategic management of insemination with shipped or frozen semen.

To manipulate the estrous cycle of the mare with some precision, one must understand the basic endocrine events of the normal 21- to 22-day cycle of the mare.<sup>11</sup> The day of ovulation is considered to be day 0 and is preceded by a period of estrogen domination (5 to 7 days). The high estrogen levels are responsible for the signs of behavioral estrus and the palpably decreased tone of the uterus and cervix. Under the influence of estrogen priming, a cascade of preovulatory events occurs in the hypothalamic-pituitary axis, culminating in a sharp increase in (LH) blood levels that ultimately results in ovulation. The diestrous phase is dominated by progesterone secretion from the resultant CL. This diestrous phase lasts 14 to 16 days. In the absence of maternal recognition of a pregnancy, endometrial prostaglandin  $F_2\text{-}\alpha$  ( $\text{PGF}_2\text{-}\alpha$ ) surges—possibly stimulated by, or at least coordinated with, oxytocin—cause luteolysis and regression of the CL. Concomitant with the decline in progesterone, estrogen levels begin to rise as a new cohort of follicles develops.

Most hormone regimens used to synchronize estrus are aimed at manipulating the luteal phase of the cycle. Perhaps the simplest method of synchronizing the cycle of a mare is through the use of synthetic preparations of  $\text{PGF}_2\text{-}\alpha$ , which effectively and reliably shortens the cycle of the mare if used after the CL is well formed—after day 5 or 6 of the cycle. The mare returns to estrus within 3 to 5 days after administration of  $\text{PGF}_2\text{-}\alpha$  and subsequent regression of the CL. Depending on the structures present on the ovary at the time of administration, the mare ovulates approximately 7 days later.<sup>12</sup> Although administration of  $\text{PGF}_2\text{-}\alpha$  before day 5 is usually ineffective in returning a mare to estrus, treatment of mares with a  $\text{PGF}_2\text{-}\alpha$  analog on day 0 (ovulation) or day 1 has a negative effect on the developing CL. Not only is the size and echogenicity of the CL reduced, but a transient yet also significant suppression in progesterone levels occurs. Most important, pregnancy rates may be lower in treated mares.<sup>1,13,14</sup>

A number of  $\text{PGF}_2\text{-}\alpha$  preparations have been used successfully for luteolysis in the mare; some are associated with undesirable side effects, including profuse sweating, anxiety, diarrhea, and signs of colic. The severity of the side effects depends on the dose and preparation of  $\text{PGF}_2\text{-}\alpha$ . A two-dose regimen at a much lower dose (0.5 mg  $\text{PGF}_2\text{-}\alpha$ ) is equally effective in inducing luteolysis as a higher single dose (50 mg  $\text{PGF}_2\text{-}\alpha$ ) but devoid of adverse effects.<sup>15</sup> Similarly, a single dose of 25  $\mu\text{g}$  cloprostenol (Estrumate; Bayer Corp., Shawnee, Kan.),  $\frac{1}{10}$  of the previously recommended dose, is effective in inducing luteolysis and does not cause the adverse side effects.<sup>16</sup>

Treatment with progestins represents one of the oldest and most reliable means of synchronizing estrus in the mare, especially when coupled with appropriate light exposure and  $\text{PGF}_2\text{-}\alpha$  administration. Progestins simulate the diestrous period of the estrous cycle. Repositol progesterone, progesterone in oil (Sigma Chemical Co., St. Louis, Mo.), or oral progestin compounds (altrenogest [Regumate, Intervet Inc. Millsboro, Del.]) are effective in suppressing estrous behavior but not necessarily follicular development or ovulation. Combining progesterone with estradiol 17B (called *P+* or *P+E*) may be administered daily or as a 10-day repositol injection that will effectively suppress both estrus behavior and the formation of follicles. Treatment with these preparations is only effective, however, in synchronizing mares that are transitioning into regular cyclicity or cycling regularly; treatment is not effective in mares that remain in seasonal anestrus. Therefore examining the reproductive tract of the mare by transrectal palpation and ultrasound before initiating treatment is prudent. Ovaries in anestrus mares feel smooth, firm, and small on palpation. Their follicles are small, usually less than 10 mm in size on the ultrasound examination. Conversely, mares that are ready to begin regular cycles or are cycling regularly have larger, irregular-shaped ovaries of variable firmness, with multiple follicles greater than 10 mm in diameter, the presence of a CL, or both.

The oral progestin preparation altrenogest is perhaps still the most popular progestin compound for use in mares. Altrenogest is easy to administer, is not painful, and has few adverse effects. Fillies born to mares treated with altrenogest may reach puberty earlier than fillies from untreated mares and rarely are born with transiently enlarged clitorides. Injectable preparations of repositol altrenogest may be effective in suppressing estrus behavior but have not been thoroughly investigated for their ability to effectively synchronize estrus.

All progestin preparations should be used with caution in mares that are susceptible to delayed uterine clearance or uterine infections, for several reasons. Progestins increase the tone of the cervix, and their use may inhibit the physical clearance of fluid. Progestins also have been associated with lower immunoglobulin levels (especially IgG) in the uterus.<sup>17</sup> The combination of these adverse effects ultimately can lead to delayed uterine clearance, endometritis, pyometra, and other conditions.

When synchronizing mares, one should administer progestins for a minimum of 10 days in cycling mares and 14 days in transitional mares. On the last day of progestin treatment, a  $\text{PGF}_2\text{-}\alpha$  injection may be administered to lyse any remaining CLs. As in treatment with PGs alone, the mare should come into heat 3 to 5 days after the last treatment and ovulate an average of 7 days after treatment, depending on the structures present on the ovary at the end of treatment.

## INDUCING OVULATION

A number of agents that shorten the interval to ovulation in the mare have been used to induce ovulation. The most effective agents possess LH activity with varying degrees of FSH activity. Human chorionic gonadotrophin (Chroulon, Intervet), with its potent LH-like activity, is currently the least expensive and perhaps the most popular agent used for the induction of ovulation. Given intramuscularly, intravenously, or subcutaneously, hCG has been reported to be effective at doses ranging between 1000 to 5000 IU.<sup>18</sup>

Use of hCG in the mare has some limitations. First, with its repeated use, antibody development may occur.<sup>19,20</sup> Secondly, mare owners often complain about the apparent pain associated with administration of some hCG products. Finally, the reliability of hCG in its ability to hasten the interval to ovulation, especially in the older or compromised mare, has been questioned. Regardless of its potential disadvantages, hCG remains a popular, inexpensive, and effective means of inducing ovulation in most mares.

Synthetic GnRH analogs also have proved to be effective in inducing ovulation (deslorelin acetate [Ovuplant, Fort Dodge, Canada]; and buserelin [Buserelin, Intervet; neither is commercially available in the United States]).<sup>21,22,23</sup> The use of these agents may delay return to estrus by 1 or 2 days if the mare fails to conceive, but removal of the implant a few days after insertion can ameliorate this delay.<sup>23</sup> Injectable deslorelin is available through compounding companies in the U.S. The general impression of practitioners is that because these GnRH analogs are more reliable in inducing ovulation, especially in mares that are more prone to ovulation failure (e.g., older mares, mares in vernal transition, mares concomitantly treated with PG-inhibiting agents such as many anti-inflammatory drugs). Lastly, recombinant LH (rLH), administered at a dose of 750 µg, is an effective ovulation induction agent in the mare<sup>24</sup> and should be commercially available soon. Although the window of ovulation may not be as precisely synchronized as it is with deslorelin, rLH does not induce antibody production with repeated use.<sup>24</sup>

Ovulation induction agents are reliable and effective only if given at the appropriate time during estrus. If endometrial folds are apparent on the ultrasound examination and a dominant softening follicle is present, usually greater than 30 mm in diameter, then hCG, deslorelin acetate, and buserelin are expected to induce ovulation in an average of 36, 41 to 48,<sup>18</sup> and 24 to 48<sup>22</sup> hours, respectively, after administration. Samper reported that 98% of mares with maximal endometrial edema given hCG or deslorelin consistently ovulated within 48 hours of administration.<sup>25</sup> Most remarkably, most mares to which Ovuplant has been administered at the proper time, ovulate 38 plus or minus 2 hours later,<sup>26</sup> truly allowing appointment breeding.

## SYNCHRONIZING ESTRUS AND OVULATION

Progestins can be used with estradiol-17-β to obtain greater synchrony in mares. Although not commercially available, biodegradable microspheres impregnated with progesterone (1.25 g) and estradiol (100 mg) also have been used to synchronize the estrous cycle of the mare<sup>27-29</sup>; they appear to suppress follicular development and ovulation. However, these drugs have been replaced to some extent by intravaginal devices

(CIDR-B, InterAg, Hamilton, New Zealand) that contain progesterone; estradiol (10 mg) is administered at the time of insertion. Administration of a PGF<sub>2</sub>-α analog is advised at the time of insert removal (12 to 14 days). Finally, an ovulation induction agent is administered when the dominant follicle reaches a size of 35 mm. This regimen nicely synchronizes ovulation and estrus<sup>30</sup>; however, neither these intravaginal devices nor the encapsulated microspheres currently are licensed for use in horses.

## DELAYING ESTRUS AND OVULATION

Although most hormonal regimens act to hasten the interval to estrus and ovulation, there are occasional managerial reasons to delay estrus. Altrenogest was designed to prevent show mares from exhibiting estrous behavior, and it has proved to be effective in this regard, suppressing signs of estrus in 95% of mares that were given a daily dose of 0.044 mg/kg for 3 days.<sup>31</sup> In an attempt to find a more economic and less time-consuming means of suppressing estrous behavior in mares, progestin-estradiol implants (Synovex, Syntex Animal Health, Des Moines, Iowa) licensed for food animals have been investigated in mares. Although some mare owners report an improvement in the behavior of the mare, scientific reports have been less supportive of their use. McCue et al.<sup>32</sup> found that mares treated with these implants, even at 20 times the usual dose, did not show suppression of estrous behavior and cyclicity. Vanderwall et al.<sup>33</sup> have examined the effect of oxytocin on luteolysis. Mares that received oxytocin (60 IU twice daily intramuscularly) on days 7 through 14 after ovulation demonstrated prolonged luteal function up to 30 days after ovulation, suggesting that oxytocin administration may offer a means of long-term suppression of estrus.

Immunization against gonadotrophin releasing factor (GnRF) is another effective means of estrus suppression in the mare. Mares vaccinated twice, 4 weeks apart, with a GnRF vaccine (Equity; Pfizer Animal Health, Sydney) did not return to estrus during that breeding season but returned to cyclicity the next year. Foaling rates were not significantly different than for control mares.<sup>34</sup> The vaccine is not yet commercially available worldwide.

Theoretically, if the LH surge has not occurred yet, oral progestin treatment should inhibit LH and delay ovulation. Altrenogest at label dose or double the label dose is effective in delaying ovulation compared with control mares as long as an ovulation induction agent has not been administered.<sup>35</sup> Intraluminal fluid retention, possibly caused by increased cervical tone, has been observed in some mares. Although this application is promising, results should be interpreted with caution because treated mares had lower pregnancy rates (although the difference was not statistically significant).

Delaying the interval to first ovulation of recently foaled mares results in higher pregnancy rates for the first heat cycle. Although the natural foal heat of a mare may be highly fertile, many early pregnancies are lost, likely because of an adverse uterine environment. To optimize the maintenance of those early pregnancies and yet still increase the reproductive efficiency of the mare by breeding her back as soon as possible, delay of the first postpartum interval to ovulation using a combination of progesterone and estradiol-17β (E2-17B; Sigma) in oil is beneficial. In an attempt to increase the fertility of foal heat breeding, Sexton and Bristol<sup>36</sup> reported that this protocol successfully delays the postpartum interval to first ovulation,

thereby increasing the period of time for uterine involution and pregnancy rate.

## ☞ SUPEROVULATION

In an effort to increase the number of offspring produced in the lifetime of a mare or in any given season, researchers have investigated numerous means of superovulating mares. Overall, attempts at reliable superovulation in mares have not been as successful as those in the food animal industry. An increased number of ovulations and embryos have been minimal. The administration of porcine FSH preparations is ineffective in mares, except at cost-prohibitive doses.<sup>37</sup> Stimulation of endogenous FSH secretion by indirect and direct immunization against inhibin has not resulted in a superovulatory response in mares.<sup>38</sup> The administration of equine pituitary extract preparations in research trials only increases the number of embryos recovered from 0.5 per cycle to 2.2 per cycle.<sup>39,40</sup> Promising results have been achieved with the use of equine FSH (eFSH) (Box 18-1). Treatment of cycling mares with eFSH in early diestrus (12.5 mg, administered twice daily) increased the pregnancy rate compared with untreated control mares (1.8 versus 0.6, respectively).<sup>41</sup> In another study, wherein Welsh et al. incorporated a "coast" period into the above experimental design, the ovulation and embryo recovery rate were  $3.8 \pm 1.2$  ovulations and  $1.7 \pm 1.4$  embryos, respectively.<sup>42</sup>

Follicular stimulation through the use of eFSH has also been effective in the management of postpartum anestrus mares. In one study,<sup>43</sup> eFSH was administered to five mares with a history of lactational anestrus. After 5 to 10 days of twice-daily injections of 6.25 mg eFSH, all mares developed a preovulatory follicle, ovulated in response to hCG, and conceived.<sup>43</sup>

The efficacy of eFSH in stimulating early follicular development as well as shortening the interval to first ovulation during the spring transition has been evaluated. Administration of twice-daily injections of 12.5 mg eFSH resulted in ovulation in 80% of transitional mares. Multiple ovulations

were induced in 40% of treated mares. The interval to first ovulation was  $7.6 \pm 2.4$  days in treated mares versus  $39.5 \pm 17.2$  days in control mares.<sup>44</sup>

Unfortunately, the continued commercial availability of purified eFSH is limited. Recombinant FSH (reFSH) stimulates follicular activity in the mare and may replace purified eFSH as it becomes commercially available.<sup>45</sup>

## ☞ TEASER MARES

For semen to be collected from most stallions, breeding facilities require at least one mare exhibiting behavioral estrus. Some stallions appear to prefer a particular mare or a certain color of mare, and therefore a variety of mares in heat is sometimes desirable for good libido. Thus the use of exogenous hormone regulation to encourage a mare to display signs of estrous behavior often becomes necessary.

One strategy for ensuring the availability of a teaser mare is to have a rotating supply of mares that are constantly short-cycled with  $\text{PGF}_2\text{-}\alpha$  analogs. If the mare is injected with  $\text{PGF}_2\text{-}\alpha$  5 days after the cessation of behavioral estrus, in theory she will return to heat in a few days because the mature CL on her ovary will be lysed by the injection. Ideally, a minimum of two teaser mares suffices for this program. An additional benefit is that the fertility of the mare is unaffected by the PGs.

Administration of estrogen compounds causes some mares to exhibit estrous behavior. Estradiol cypionate (ECP, Upjohn), a long-acting estrogen, and estradiol-17 $\beta$ , a shorter-acting estrogen, have been investigated; the results of administration of either compound vary, especially over time and in particular with estradiol cypionate. The estrogen compounds are far more effective in ovariectomized mares than in intact mares because even the smallest amount of progesterin secretion from the ovary inhibits signs of behavioral estrus. Interestingly, ovariectomized mares often demonstrate low-grade signs of heat even in the absence of exogenous hormonal administration. Theoretically, these signs are caused by the absence of ovarian progesterone and the continued secretion of estrogens from other sources, particularly the adrenal glands. Moreover, even the smallest amounts of circulating estrogens are postulated to cause some mares to show constant signs of estrus in the presence of a stallion. The long-term response of ovariectomized mares to exogenous estradiol-17 $\beta$  or estradiol cypionate has not been reliable, especially with administration of these hormones in increasing amounts and frequency. The hormones appear to reach a threshold at which the clinical response is contrary to the signs expected, and treated mares actually may show increased aggressiveness to stallions. Low doses (1 mg intramuscularly) of estradiol cypionate, administered every 2 to 3 weeks, appear to be most effective in preserving the ovariectomized teaser mares for many years of service. Old, anestrus mares often function as ideal teaser mares for some stallions. In the absence of functional ovarian secretion, the low levels of circulating estrogens may cause a mare to exhibit signs of estrous behavior continually. Unfortunately, a number of stallions appear uninterested in these old mares despite their overt display of heat.

## ☞ MAINTENANCE OF PREGNANCY

Although the precise mechanism is unclear, progesterone supplementation in the form of injectable or oral preparations often is used to maintain pregnancy at all stages

### BOX 18-1

#### RECOMMENDED PROTOCOL FOR SUPEROVULATION IN MARES USING EFSH

1. Determine the day of ovulation.
2. Monitor follicular development in early diestrus.
3. Begin eFSH therapy (12.5 mg IM twice daily) when the largest follicle is 22 to 25 mm in diameter.
4. Administer cloprostenol (259  $\mu\text{g}$  IM) on the second day of eFSH therapy
5. Discontinue eFSH treatment when follicle(s) are greater than 32 to 35 mm in diameter.
6. Administer hCG (2500 IU) to induce ovulation.
7. Breed or inseminate according to standard procedure.

eFSH, Equine follicle stimulating hormone; IM, intramuscular. Adapted from McCue PM, LeBlanc MM, Squires EL: eFSH in clinical equine practice. *Theriogenology* 68: 429-433, 2007.

of gestation. Early pregnancy maintenance in the mare requires the function first of the primary CL (approximately 45 days) and then of the accessory CL (45 to 90 days or more). Regardless, some mares appear to require progesterone supplementation during this period; otherwise, they lose the pregnancy. Hormonal assays can sometimes be misleading because progesterin levels in these mares may appear well within the normal range for mares that do not appear to require supplementation.

Some mares appear to require progesterone supplementation for maintenance of pregnancy in the later stages of gestation as well. Altrenogest may be effective in preserving the pregnancy in a compromised mare. In an experiment that examined the maintenance of pregnancy in mares suffering from experimentally induced endotoxemia, mares treated with oral altrenogest administered at twice the recommended dosage (0.088 mg/kg/day) suffered significantly fewer pregnancy losses than untreated mares.<sup>46</sup> Interestingly, in mares suffering from experimentally induced placentitis, a significant change in progesterone profiles was associated with fetal-placental compromise and pregnancy loss.<sup>47</sup> Separate studies demonstrate that the addition of oral altrenogest (0.088 mg/kg/day) to antibiotic treatment in mares with placentitis significantly reduces pregnancy loss.<sup>48,49</sup>

Rates of pregnancy loss appear higher in the Miniature Horse mare (25%)<sup>50</sup> than reported in larger breeds (<10%).<sup>51</sup> Moreover, unlike reports of studies on larger breeds, most pregnancy loss in the Miniature Horse mare occurs during late term.<sup>50</sup> Thus many Miniature Horse mares receive supplemental progesterone for the duration of their pregnancy. Some researchers speculate that placental insufficiency may contribute to the increased loss of pregnancy in this breed because the size of the foal often is larger with respect to its dam than in the larger breeds of horses.

## ☉ DELAYED UTERINE CLEARANCE

Mating-induced endometritis is regarded as a normal transient physiologic event in the mare in response to sperm deposited in the uterus.<sup>52</sup> However, some mares are susceptible to delayed uterine clearance (DUC), especially older, multiparous mares in which the uterus lies well beneath the pelvic brim.<sup>53</sup> Small intramuscular or intravenous doses of oxytocin after warm saline lavage of the uterus have been especially beneficial in these susceptible mares.<sup>54,55</sup> The response to oxytocin appears to be greatest with administration just before ovulation.<sup>56,57</sup> Routine administration of exogenous oxytocin to mares immediately after insemination does not improve pregnancy rates.<sup>58</sup> Those mares with DUC in which intraluminal fluid remains or recurs despite multiple small doses of oxytocin may respond to carbetocin, a long-acting oxytocin analog. The duration of action of carbetocin is more than threefold longer than oxytocin.<sup>59</sup> In mares that appear to be unresponsive to tocolytic therapy, PGF<sub>2</sub>- $\alpha$  analogs that exert a more sustained effect on uterine myometrial activity than oxytocin may promote uterine evacuation and enhanced lymphatic drainage.<sup>60</sup> The effect of periovulatory administration of PGF<sub>2</sub>- $\alpha$  analogs on pregnancy rates has been controversial in the mare. The results from one study found that 250  $\mu$ g cloprostenol administered by intramuscular injection to mares on the day of ovulation resulted in lower pregnancy rates.<sup>13</sup> In contrast, Nie et al. reported that pregnancy rates are not affected by the administration of 20 IU oxytocin or 250  $\mu$ g

cloprostenol every 6 hours after ovulation if treated before the second day after ovulation.<sup>61</sup>

## ☉ CERVICAL DILATION

One of the most frustrating conditions encountered when breeding mares is failure of cervical dilation during estrus. On transrectal palpation the cervix may feel toned instead of soft, as it should during estrus just before ovulation. Because previous damage to the cervix and the subsequent formation of adhesions can present a similar and confusing picture of failure of cervical relaxation, a thorough visual and manual cervical examination is prudent. In maiden mares inserting a finger through the cervix to act as a guide for the insemination pipette is often difficult. Although this condition does not prevent artificial insemination, it can prevent not only penetration of the cervix by the penis of the stallion but also the normal evacuation of fluid in the hours after breeding, thereby setting the stage for DUC and persistent endometritis. Although not objectively studied, this condition appears to affect older maiden mares more commonly. However, even normal maiden mares may not have the same degree of cervical relaxation during estrus that is typical of pluriparous mares. A synthetic PGE<sub>1</sub> analog, misoprostol (Cytotec; Searle Corp., Chicago, Ill.), has been used successfully in women for cervical dilation. This compound has not yet been evaluated objectively in horses and currently is not approved for veterinary use. However, many clinicians have seen some encouraging results, simply by covering the external cervix with PGE<sub>1</sub> cream several hours before cervical dilation is desired. If only PGE<sub>1</sub> tablets are available, practitioners have crushed 1 to 2 tablets (200  $\mu$ g) and mixed them with a small amount of sterile lubricant before application. Digital insertion of a tablet into the external cervical os may be effective as well. Occasionally, veterinarians have used this preparation combined with other parturition induction agents when attempting to terminate a pregnancy prematurely. Again, only anecdotal reports of efficacy currently exist.

## ☉ OVIDUCTAL AND UTERINE CONTRACTION

The early embryo secretes PGE<sub>2</sub>, which is believed to play a role in the contractility of smooth muscle of the oviduct and to promote propulsion of the embryo through the oviduct.<sup>62</sup> PGE<sub>2</sub> is also secreted during the high mobility phase of the embryo and is suspected to stimulate uterine contraction and enhance uterine tone.<sup>63</sup> Laparoscopic application of PGE<sub>2</sub> along the serosal surface of the oviduct can modify embryo transport. Interestingly, not only is embryo transport hastened, but also unfertilized oocytes that are rarely recovered in the mare are transported to the uterus.<sup>64</sup>

The addition of PGE<sub>2</sub> to semen just before artificial insemination has increased pregnancy rates in mares bred with fertile semen but not with subfertile semen.<sup>65</sup> These results are disappointing because the addition of PGE<sub>2</sub> to semen is associated with higher fertility rates in other species.<sup>66,67</sup> The role of PGE<sub>2</sub> at the uterotubal junction (UTJ) of the mare has been speculated to affect spermatozoal selection. It was once believed that this selection at the UTJ was based on sperm morphology; however, motility of the spermatozoa may play a larger role in this selection process than initially suspected. Selection is an area of research that deserves continuing attention.

## BREEDING MANAGEMENT TO OPTIMIZE PREGNANCY RATES

Elizabeth Metcalf

In the past foals were born only as a result of natural field breeding, but innovations in modern horse breeding, both an art and a science, have kept pace with advances in reproduction. Foals are now born as a result of more advanced procedures that include artificial insemination, oocyte transfer, embryo transfer, embryo splitting, intracytoplasmic sperm injection, gender selection, and cloning from a single cell. Furthermore, through improvements in cryogenic techniques, gametes and embryos may be preserved indefinitely. Veterinarians and scientists function primarily as facilitators of these processes that serve to preserve and perpetuate valuable genetic lines. The following sections examine the procedures currently used in equine private practice to facilitate the insemination of horses.

Although increasing the number of pregnancies produced per mare in a given year is possible through the techniques of embryo and oocyte transfer, pregnancy rates per cycle have not improved significantly from field breeding to artificial insemination. In the past decade many changes have been implemented in breeding facilities and include (but are not limited to) the housing of mares and stallions, the methods used for teasing mares and stallions, the design of the breeding shed, stallion and mare handling techniques, promoting appropriate behavior in the breeding shed, the processing of stallion semen, and the management of the mare population.

In an attempt to mimic the physical and physiologic events that occur in nature, breeders must understand not only equine behavior but also the processes of intromission, ejaculation, and eventually fertilization of the oocyte.

Although natural and artificial insemination of the mare entail deposition of semen within the uterus of the mare, natural service invokes several physiologic processes that are absent in artificial insemination.<sup>1</sup> When the penis of the stallion enters the vagina of the mare, several rhythmic pelvic thrusts occur before ejaculation directly into the uterine body. Not only does this action cause rapid vasodilation of blood vessels that supply the corpus spongiosum penis, resulting in the characteristic “bellling” of the glans penis, but also it stimulates strong uterine contractions that in turn propel the deposited sperm toward the oviductal papillae of the mare. The engorged glans penis also may function as a physical barrier to prevent the immediate backflow of semen during ejaculation. Detumescence of the penis follows ejaculation, and the mare moves forward, out from under the stallion. This sequence of events may occur many times on a given day under natural conditions.

Fertilization of the oocyte in the mare takes place in the ampulla of the oviduct. Before this, the spermatozoa must undergo capacitation and the acrosome reaction, a complex series of events that results in remodeling of the sperm plasma membrane and release of specific enzymes that enable the sperm to penetrate the oocyte. Although capacitated sperm can be recovered from the uterus of the mare, uncapacitated sperm<sup>2,3</sup> are selected<sup>4</sup> to reside in the isthmus of the oviduct until the oocyte is present. Spermatozoa actually bind to oviductal epithelial cells, a process that appears to be enhanced

in estrous mares but not in diestrous mares.<sup>5</sup> Abnormalities of this process may contribute to the subfertility of the mare or the stallion.

Mares with poor fertility have fewer sperm residing in the storage sites of the oviduct.<sup>6</sup> Stallions with poor fertility may have spermatozoa with inherent damage that prevents them from being selected to reside in the oviduct. The effect of this damage is more likely to be caused by poor binding capacity than poor motility or reduced sperm transport.<sup>3</sup> Spermatozoa survive in oviductal cell culture for at least 6 days,<sup>7</sup> which supports the report of a mare that became pregnant after a single mating 7 days before ovulation<sup>8</sup> and the study by Woods, Bergfelt, and Ginther<sup>9</sup> in which mares were bred successfully more than 6 days before ovulation. Conversely, an oocyte is viable in the oviduct for only a short time, perhaps as little as 12 hours,<sup>10</sup> as indicated by the low pregnancy rates of mares bred more than 12 hours after ovulation.<sup>9,11,12</sup> Capacitated spermatozoa therefore must be available for successful fertilization.

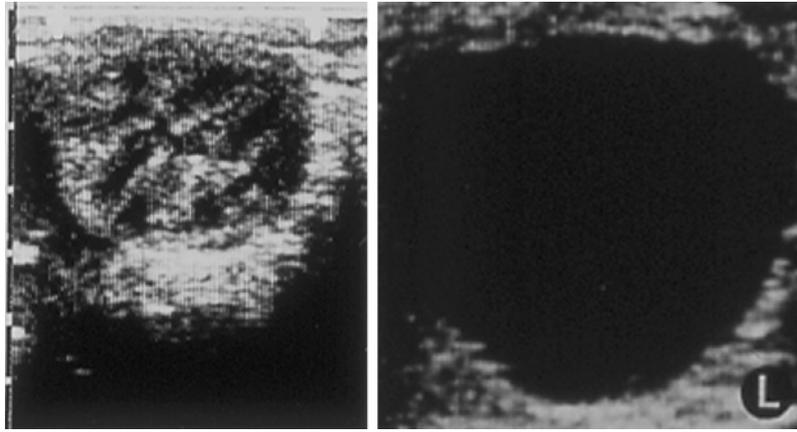

Before any type of insemination, the assessment of fertility of the mare and stallion is advisable. Many tests are available that evaluate the fertility of stallion semen, but the most informative measure is the per cycle conception or foaling rate. Although no single *in vitro* laboratory test correlates precisely with stallion fertility, stallions with semen that demonstrates a high percentage of morphologically normal, progressively motile spermatozoa with little reduction in motility over the first 24 hours of storage often prove to have better fertility than those with semen that lacks these attributes. The stability of chromatin structure is also correlated with stallion fertility, and therefore sperm chromatin structure assays may help in predicting fertility or diagnosing infertility. Other *in vitro* means of predicting stallion fertility include flow cytometric analysis of sperm membranes, cellular organelles, and viability; computer-assisted motility analysis; membrane “stress” tests; glass wool–Sephadex bead filtration; binding and penetration assays; and antisperm antibody assays (see discussion elsewhere in this chapter). These advanced tests are commercially available at several university teaching hospitals.

The fertility of the mare should also be evaluated. Too often the mare is selected as a broodmare candidate simply because of her availability. A BSE based on the age, history, and parity of the mare should be performed. The BSE may range from a rectal and ultrasonographic examination of the reproductive tract to a cytologic testing, culture, and biopsy of the endometrium to a videoendoscopic examination of the endometrium. Inclusion of an ultrasound examination at every rectal examination not only enhances the continual education of the veterinarian but also aids in the detection of many unpalpable changes. Most important, ultrasound examination ultimately enhances breeding efficiency and pregnancy rates by taking advantage of the most sophisticated tools available.

## ☞ PREPARATION OF THE MARE FOR BREEDING

The ultimate goal of insemination is to provide semen in a time frame that coordinates the availability of capacitated spermatozoa with the arrival of the transported oocyte within the oviduct of the mare. Therefore the timing of insemination with ovulation is critical.

Mares in heat require daily examination. During the estrous phase of the heat cycle, the practitioner performs an ultrasound examination of the reproductive tract, which

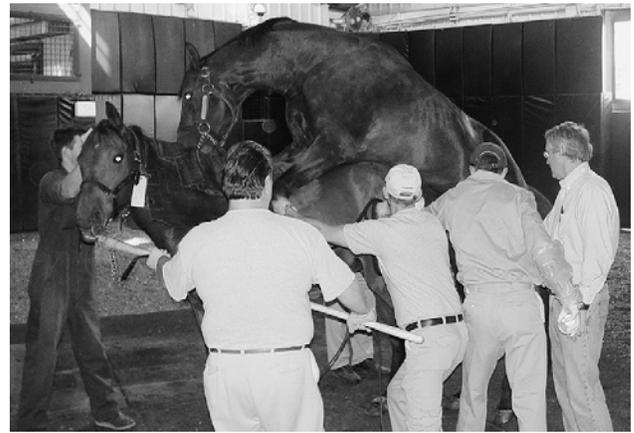

**FIGURE 18-4** The appearance of a dominant, growing, softening follicle (*right*) and the classic spoke-wheel pattern of endometrial edema (*left*) indicate pending ovulation. (From Ginther OJ: *Reproductive biology of the mare*, ed 2, Cross Plains, Wisconsin, 1992, Equiservices.)

complements the results of the rectal examination. The appearance of a dominant, growing follicle and the classic spoke-wheel pattern of endometrial edema, which may be evaluated and quantified subjectively<sup>13,14</sup> and objectively,<sup>15</sup> indicates pending ovulation (Figure 18-4). The ultrasound examination also may demonstrate the presence of echogenic particles within the follicle and increasing echogenicity of its wall, both of which indicate impending ovulation within the next 24 hours.<sup>16</sup> Detection of a decrease in follicular pressure by measuring transrectal tonometry indicates pending ovulation.<sup>17</sup> Although the duration of heat in the mare may vary, most mares ovulate near the end of this estrous phase.<sup>18</sup> Follicular edema is less apparent on ultrasound examination just before ovulation. Because the timing of insemination with ovulation is so critical, the presence or absence of this edema can be a powerful tool to optimize pregnancy rates through the control of ovulation timing.

A number of agents are available that effectively shorten the interval to ovulation.<sup>19-23</sup> These agents include hCG, GnRH analogs (see the previous discussion of hormonal manipulation in this chapter), and rLH. These induction agents are reliable and effective if administered at the appropriate time during estrus. If endometrial folds are observed on the ultrasound examination and a dominant softening follicle is present, usually greater than 30 mm in diameter, one can expect hCG, deslorelin acetate (Ovuplant, 2.2 mg; Fort Dodge, Canada), and buserelin (Buserelin; Intervet, Millsboro, Del. [not commercially available in the United States]) to hasten ovulation on an average of 36,<sup>19</sup> 41 to 48,<sup>19</sup> and 24 to 48<sup>13,20,24</sup> hours, respectively, after administration. However, some disadvantages are associated with the use of an implanted pellet of deslorelin acetate. In mares implanted with deslorelin acetate, the interestrus interval may be prolonged on an average of 2 days because of a diestrus inhibition of pituitary FSH secretion.<sup>25</sup> Removal of the implant 2 days after administration appears to prevent the delay in return to estrus.

## ☉ PASTURE BREEDING

Successful pasture breeding requires an understanding of equine social structure. Every time a new member is introduced to the herd, disruption of the social strata and a reorganization

**FIGURE 18-5** Breeding in-hand often requires more personnel to ensure safety of the horses and handlers.

of the ranking occur. Theoretically, optimal field breeding management aims for a closed herd to minimize stress and enhance breeding efficiency.

Under field conditions mares in heat approach the stallion for teasing. If interested, a stallion may mount a mare numerous times with or without an erection; with or without copulation; and, most interesting, with or without ejaculation. This behavior rarely is sanctioned in breeding facilities because it often leads to undesirable behavior in breeding stock.

## ☉ BREEDING IN HAND

Many breeding facilities continue to breed their stallions in hand, especially if the stallions belong to registries that do not allow registration of foals produced by artificial insemination. One perceived advantage to this management practice is that it may require fewer personnel or less time to breed the mare and therefore is less costly. However, this is not usually the case, for in-hand breeding poses far more risk to the mare, stallion, and handlers and therefore requires more personnel to ensure the safety of all involved (Figure 18-5). In-hand breeding also may require far more preparation of the mare

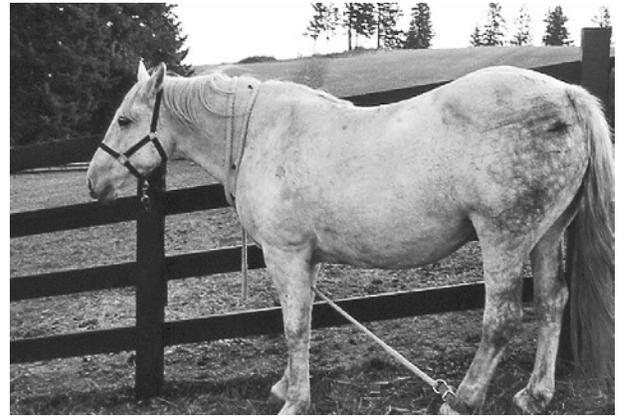

**FIGURE 18-6** Padded boots cover the rear hooves of a mare to prevent injury to the stallion during breeding or semen collection.

than artificial insemination, especially in the application of restraining devices or removal of the foal for breeding.

If breeding in hand, good communication among involved personnel is paramount to ensuring the safety of the horses. First, one prepares the mare in heat for natural cover by wrapping her tail to prevent laceration of the stallion's penis by the hair during breeding and washes her perineum with a mild soap, rinses it well, and dries it with a clean paper towel. One may apply a leather harness to her crest to allow the stallion to hold on to the mare securely without biting her during breeding. To protect the stallion from being kicked by the mare, padded hoof boots may be applied to the rear hooves (Figure 18-6) or hobbles may be fastened to the rear legs of the mare.

Desirable hobble attributes include comfort, ease of application, ease of removal (ensuring a quick release if needed), and simplicity so that the stallion cannot become entangled in the ropes or straps. Perhaps the simplest, safest, and most effective hobble design consists of two pieces of soft cotton rope that fit many different mares (Figure 18-7). The first cotton loop slips loosely around the neck of the mare to rest against the point of both shoulders. The second portion is a longer cotton rope attached to a padded leather anklet designed to fit snugly around the rear pastern of the mare. One straps the anklet around the left rear pastern, brings the left rear leg well under the body of the mare, pulls the rope gently between the front legs of the mare, and ties a quick-release knot just below the point of the shoulder on the left side. Additional restraint devices may be employed. A twitch may be applied just minutes before the stallion arrives, or the mare may be sedated. These additional restraints may inhibit the desired response, however, and the mare may fail to show signs of heat in response to the stallion.

All personnel stand on the left side of the horses, thereby allowing the horses to move unencumbered to the right if necessary. The mare handler steadies the mare as the stallion mounts and breeds her. The stallion handler is perhaps at the most risk during in-hand breeding (or semen collection) and therefore may direct the cover. Neither size nor strength is necessary in a stallion handler; rather a calm, firm, knowledgeable

**FIGURE 18-7** A simple yet effective hobble.

person fares the best in the breeding shed. The quality of the ejaculate often reflects the expertise of the stallion handler.

After ejaculation a variable latency period occurs until the stallion begins to dismount. In field breeding the mare initiates the dismount by moving away from the stallion. Patience and ingenuity are needed during in-hand breeding because theoretically the restrained mare cannot move. Because of the possibility that a mare may kick during the dismount, the heads of both horses are turned to the left simultaneously, causing their hind ends to move to the right and thereby creating an adequate space between them. If a dismount semen sample is required, expediency and experience are necessary to obtain it between the end of ejaculation and the dismount.

## ☞ ARTIFICIAL INSEMINATION

Most equine breed registries, with the notable exception of the Jockey Club, not only sanction but also encourage the use of artificial insemination. The advantages to breeding horses by artificial insemination are numerous and range from increasing the safety of horses and their handlers to enhancing the value of the stallion by increasing the number of offspring produced yearly (Box 18-2). Use of frozen semen for insemination has additional advantages (Box 18-3). Although cryopreserved semen is an attractive alternative for many reasons, it also can require more intensive mare management and sometimes results in lower pregnancy rates.

In an attempt to mimic the events of natural mating and yet ensure minimal contamination of the reproductive tract of the mare during artificial insemination, the following techniques have been described.<sup>27</sup> The mare should be restrained properly, preferably in stocks to protect the inseminator. Other devices, such as a twitch, have been used effectively for restraint but are usually unnecessary. If chemical restraint is warranted, the use of  $\alpha$ -agonists such as xylazine may be preferable to other agents because of their effect on contractility of the uterus while it is under the influence of estrogen, particularly in mares exhibiting DUC after insemination.<sup>28</sup> One bandages the tail of the mare, ties the tail so that it is not in contact with the vulva and perineum, washes the vulva well with liquid soap, and rinses the vulva thoroughly with water. The washing is repeated at least three times until the area appears to be free of any debris. The vulva and perineal area are then dried with a clean paper towel.

If cooled semen is being used, it is not necessary to warm it after removal from the storage container. If frozen semen is being used, it should be thawed in a water bath before insemination. Frozen semen is stored in liquid nitrogen at  $-196^{\circ}\text{C}$  until ready for use, at which time the inseminator must follow the thawing and insemination instructions that accompany the frozen semen. Thawing protocols at high temperatures ( $50^{\circ}$  to  $75^{\circ}\text{C}$ ) require closer adherence to exact immersion times than do low temperatures ( $37^{\circ}\text{C}$ ). Depending on the cryopreservation techniques and sperm concentration per straw, a breeding dose may consist of a single straw (0.5 to 5.0 ml) or multiple straws.

The inseminator dons a sterile sleeve and grasps a sterile insemination pipette between thumb and palm to protect the tip in a sterile environment. If using 0.5-ml straws of frozen-thawed semen, the inseminator may use a sterile insemination gun instead of the pipette. Nonspermicidal sterile lubricant

is applied sparingly to the sleeve covering the forefinger. Although labeled as nonspermicidal, some sterile lubricants have still been found to be detrimental to sperm motility and velocity.<sup>26</sup> The product Pre-Seed Equine™ (INGFertility Valleyford, Wash.) has been found to be less detrimental to stallion spermatozoa than Priority Care (First Priority, Elgin, Ill.), MiniLube™ (Minitube, Verona, Wis.), or EquiLube (Boehringer Ingelheim, St. Joseph, Mo.). Prepared semen should be contained in a nonspermicidal syringe and protected in the nonsterile hand from adverse environmental conditions such as ultraviolet light, cold, heat, and air.

The inseminator inserts the sleeved hand, continuing to protect the tip of the insemination pipette, through the lips of the vulva and into the vaginal vault and inserts one or two fingers through the cervical os. The finger (or fingers) then acts as a guide for advancement of the insemination pipette through the cervix approximately 1 cm into the uterus of the mare. If the advancement of the pipette has not encountered resistance once in the uterus, the inseminator can advance it carefully and gently into the desired uterine horn (usually ipsilateral to the developing follicle). This advancement is not always possible because of the amount of endometrial edema and folding, and the inseminator must take extreme care not to damage the endometrium. Once the pipette is satisfactorily in place, the inseminator depresses the plunger of the syringe and deposits the semen in the uterus. If resistance is encountered when depressing the plunger, the tip of the pipette may be obstructed by the endometrium and may require repositioning. A small amount of air may be introduced to clear the pipette. Massage of the vaginal vault during withdrawal of the inseminator's hand may stimulate uterine contraction and aid in propulsion of spermatozoa to the uterotubal junction.

#### BOX 18-2

##### ADVANTAGES OF ARTIFICIAL INSEMINATION USING COOLED SEMEN

- Allows many mares to be bred with a single ejaculate
- Prevents overuse of the stallion
- Enables mare owners to breed to any stallion regardless of distance, especially with cryopreserved semen
- Enhances and encourages genetic variability and hybrid vigor
- Controls management of the difficult breeder
- Reduces the chances of spread of infectious disease, venereal and systemic
- Reduces possibility of injury to mare and stallion
- Eliminates transportation and boarding expenses of the mare
- Allows evaluation of semen quality at each insemination
- Allows advance shipment of cryopreserved semen and increased availability
- May result in less variability in semen quality because of central processing station

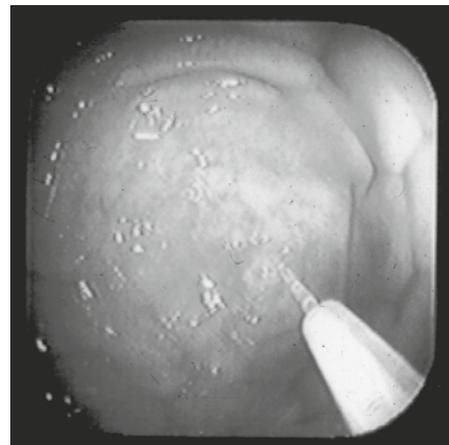

#### BOX 18-3

##### ADDITIONAL ADVANTAGES TO USING CRYOPRESERVED SEMEN FOR INSEMINATION

- Ability to breed any stallion in the world, regardless of distance
- Ability to ship the semen well in advance of breeding so that it is available when needed
- Preservation of stallion genetics for many years
- Insurance against unavailability, injury, or death of the stallion
- Less variability of semen quality

## SEMEN DEPOSITION

Although pregnancy rates appear to be independent of semen volume,<sup>29</sup> minute volumes and numbers of motile spermatozoa (as low as  $1 \times 10^6$  motile sperm) deposited at the uterotubal junction (Figure 18-8) or within the oviduct have shown promising pregnancy results.<sup>30-32</sup> Furthermore, deep uterine insemination may enhance pregnancy rates under conditions of low sperm availability.<sup>26</sup> With the procedure described by

**FIGURE 18-8** Through hysteroscopic insemination less than 0.25 ml of semen is deposited on the oviductal papilla. (Courtesy EL Squires, Colorado State University, Fort Collins, Col.)

**FIGURE 18-9** Specialized pipette for deep horn insemination. (Courtesy Minitube of America, Verona, Wis.)

Rigby,<sup>33</sup> the inseminator first passes the insemination pipette transcervically into the uterine body and then directs it into the uterine horn ipsilateral to the dominant follicle. Through transrectal manipulation the pipette is guided into the uterine horn by gently threading the uterus around the pipette. Specialized pipettes with palpable bulbs at the distal end have been designed for deep horn insemination in the mare (Figure 18-9). Because of the degree of edema of the mare endometrium during estrus, the inseminator must be careful not to damage the endometrium when using this technique.

## ☞ OPTIMIZING PREGNANCY RATES

Insemination of mares with a minimum insemination dose of  $500 \times 10^6$  progressively motile spermatozoa every other day has long been accepted as a means to maximize pregnancy rates.<sup>34</sup> Some stallions with apparently superior fertility may provide maximum pregnancy rates at much lower dosages. As with bulls, the minimal insemination dose for optimizing pregnancy rate appears highly male dependent.<sup>35</sup> However, as is not the case with bulls, no evidence currently suggests that increasing the insemination dose can compensate for morphologic defects in stallion sperm. Fortunately, the number of spermatozoa in a single ejaculate from a normal stallion far exceeds this dose, provided that the stallion is not suffering from overuse. Therefore, depending on the intensity of management, most breeding operations using in-hand breeding aim to cover mares shortly before ovulation or, if the stallion is not breeding other mares, every 48 hours while the mare is in standing heat. To prevent overuse of the stallion and to enhance pregnancy rates, mares should be examined with transrectal palpations and ultrasound at least every other day and should be bred when ovulation is expected within 24 to 48 hours. Postovulation breeding, although sometimes successful, more often is associated with embryos of inferior quality.<sup>10,36-38</sup>

In a breeding program that uses artificial insemination, the fertility of most stallion semen is greatest on the farm,

followed by that of shipped cooled semen, with frozen semen being least fertile.<sup>34</sup> Exceptions to this rule invariably occur. Because the fertility of semen appears to be stallion dependent, good breeding management requires an awareness of the minimal insemination dose necessary to maximize pregnancy rates for each stallion. The aim in a cooled-semen insemination protocol is to provide a minimum insemination dose ( $500 \times 10^6$  progressively motile sperm) to be inseminated every other day before ovulation. The semen must be extended to 25 to  $50 \times 10^6$  motile sperm per milliliter to achieve maximal pregnancy rates.<sup>39</sup> With highly fertile stallions, the minimum insemination dose necessary for optimal pregnancy rates may be much lower.

In an artificial insemination program that uses cooled shipped semen, often more than a single dose of semen is sent. Controversy exists regarding the fate of the unused doses: Should they remain in storage at  $4^\circ\text{C}$ , or should they be inseminated immediately into the mare? Supporters of the Equitainer (Hamilton-Thorne Research Inc., Danvers, Mass.) hypothesis argue that the sperm storage sites in the oviduct of the mare are filled with the first insemination and do not need to be replenished for at least 24 hours<sup>40</sup>; therefore using the mare as the incubator for the second dose is wasteful because the excess spermatozoa will be expelled. Those in favor of the mare as the optimal reservoir believe that although the motility of the second dose of semen fares well in the Equitainer, it does not necessarily reflect the fertility of this dose and therefore the sperm fare better in the mare.<sup>41</sup> The studies that have addressed this argument have used few stallions in the experimental design or have failed to take into account the interval from insemination to ovulation. In the study presented by Love et al.,<sup>42</sup> maintaining the fertility of the sperm when cooled at  $5^\circ\text{C}$  may yet again be stallion dependent; stallions with poor fertility appear to have more chromatin damage with cooling than stallions with good fertility. The most convincing evidence for sequential breedings arises in a studies by Heiskanen et al.<sup>43,44</sup> These researchers found that mares bred with semen stored at  $5^\circ\text{C}$  for up to 40 and 80 hours have pregnancy rates of 87% and 65%, respectively, thus demonstrating acceptable pregnancy rates with stored semen. Still, the optimal means for preserving the fertility of extra doses of semen remains a controversial subject, and the answer is not entirely clear, perhaps because the fertility varies among individual stallions and mares.

Occasionally, a suboptimal dose of semen arrives: the semen may be extended improperly, the sperm numbers may be low, or the motility or morphology may be poor. If the total volume of semen is not so great that it is expelled through the cervix on insemination, one should make every attempt to inseminate an optimal dose of semen for pregnancy. If the volume is too great, the semen may be centrifuged, but this may jeopardize the motility of the spermatozoa. Therefore reinseminating the mare 6 to 12 hours after the first insemination with a second dose is perhaps best in an attempt to cover her with an optimal dose over 24 hours.

Pregnancy rates with transported cooled semen are reported to range from less than 20% to greater than 80%.<sup>45,46</sup> Although dependent on the fertility of the mare and stallion, the extreme variability of the fertility rate often is due to other management factors, such as handling and management of the stallion, handling and management of the semen, extension of the semen, shipment of the semen, number of motile spermatozoa inseminated, management of the mare,

preparation of the mare for breeding, insemination technique, handling of the semen during insemination, and postinsemination management of the mare. Therefore pregnancy rates reflect not only the fertility of the horses but also the expertise and conscientiousness of the personnel involved in this endeavor.

With cooled semen, insemination of mares within 24 hours before ovulation is recommended to allow ample time for capacitation of the spermatozoa and transport to the oviduct. If ovulation fails to occur in the expected time frame, reinsemination every 24 to 48 hours with at least  $500 \times 10^6$  progressively motile spermatozoa should optimize pregnancy rates. However, repeated inoculation of the uterus with rebreeding can cause problems in mares that are susceptible to endometritis or DUC.

Pregnancy rates with frozen-thawed semen also demonstrate a wide range of success.<sup>45</sup> Cryopreserved semen from most stallions generally is believed to result in lower fertility rates than cooled semen, but this is not always the case. Frozen-thawed semen probably does not maintain viability within the mare as long as fresh or fresh-cooled semen.<sup>47</sup> This short viability may be due to the capacitation-like changes associated with frozen-thawed sperm.<sup>7</sup> Fewer spermatozoa are found bound to the oviduct of the mare after insemination with frozen-thawed semen. If indeed a selective mechanism exists for sperm-binding capacity within the oviduct and that sperm must be noncapacitated, irreversible damage during the process of freezing and thawing may cause spermatozoa to lose this binding ability.<sup>47</sup>

Per cycle pregnancy rates of 25% to 45% are typical<sup>48-50</sup> when breeding every 24 hours or after ovulation; high pregnancy rates (>70% per cycle) have been achieved with appointment breeding that includes preovulation and postovulation timed inseminations.<sup>48-52</sup> Predicting ovulation can be challenging, and management of mares to be inseminated with frozen semen is time consuming; however, timely treatment with an ovulation induction agent can ease management greatly. Not only do these agents reliably shorten the interval to ovulation, but also the window of ovulation is so small that far fewer examinations of the mare are necessary for success. Their use can curtail, if not eliminate, late-night breeding. Inseminations can be performed either at 24 and 40 hours or 36 and 44 hours after ovulation induction, with ovulation occurring between inseminations. This protocol allows insemination at specific times and eliminates more frequent examinations of the mare to determine if the mare has ovulated, and the single

TABLE 18-6

Comparison of Field Fertility of Fresh and Frozen-Thawed Semen		
	Cooled	Frozen
Number of stallions	16	100
Number of mares	850	641
First cycle conception rate (%)	59.4	51.3
Seasonal pregnancy rate	74.7	71.9

Data from Loomis PR: The equine frozen semen industry, *Anim Reprod Sci* 68:191–200, 2001.

dose is then inseminated. The results of a recent retrospective study in which 876 mares were bred with frozen-thawed semen from 106 stallions revealed no significant difference in first-cycle pregnancy rates, seasonal pregnancy rates, or number of cycles per pregnancy between cooled and frozen semen shipped from one facility to a large number of mare owners (Table 18-6).<sup>53</sup> In this study inseminators were instructed to breed the mares with the frozen-thawed semen before and after ovulation and close to ovulation. In this instance management and selection of the stallions were optimal, and the stud farm was involved closely (through instruction and communication) with selection and insemination of the mares. Therefore management and selection of breeding stock may assume even greater importance when breeding with frozen semen.

The number of morphologically normal, progressively motile sperm (PMS) that yields optimal pregnancy rates with frozen-thawed semen is likely to be stallion and management dependent (Table 18-7). Vidament<sup>54</sup> examined more than 30,000 mare inseminations in the French National Stud and concluded that mares should be inseminated with a minimum of  $750 \times 10^6$  total frozen-thawed sperm per cycle; doses consisting of a lower total number of total sperm were associated with lower per cycle pregnancy rates. Based on these results, this figure has been adopted and is currently recommended by the World Breeding Federation of Sporthorses. The number of motile frozen-thawed spermatozoa also affects pregnancy rates.<sup>55</sup> Per cycle pregnancy rates were significantly higher when the insemination dose of frozen-thawed semen was increased from  $137-210 \times 10^6$  to  $222-333 \times 10^6$  PMS (44% versus 73% respectively).<sup>56</sup> Significant differences in per cycle pregnancy rates were observed based on the insemination dose of frozen-thawed PMS; mares bred with  $600-800 \times 10^6$  PMS had significantly higher per cycle pregnancy rates than mares bred with other doses.<sup>52</sup>

## ☞ FUTURE TECHNIQUES

Procedures that were once considered to be advanced reproductive technology have become a routine part of many equine reproduction practices. These procedures include embryo transfer, gamete intrafallopian transfer, and cryopreservation

TABLE 18-7

### The Relationship Between Number of Progressively Motile Sperm (Frozen-Thawed) and per Cycle Pregnancy Rate

Total number PMS	Pregnant	Open	% Pregnant
<200	12	10	54.5 <sup>a</sup>
200-400	66	28	70.2 <sup>a</sup>
400-600	30	20	60 <sup>a</sup>

of spermatozoa and oocytes, to name a few. These techniques offer the possibility of preserving valuable lines that otherwise might be lost in breeding stock.

## EQUINE EMBRYO TRANSFER

*Elizabeth Metcalf*

Unlike the stallion, the mare is limited in the number of offspring that she can produce in her lifetime. Embryo transfer offers a means for enhancing production of offspring from mares of superior genetic lines or that are incapable of carrying a foal to term. More specifically, this procedure offers the following advantages:

1. Embryo transfer allows a mare to remain in competition while still producing valuable offspring.
2. Embryo transfer allows production of offspring from mares suffering from pathologic conditions of the uterus severe enough to prevent carrying a foal to term.
3. Embryo transfer allows production of offspring from mares suffering from systemic illness that prevents them from carrying a foal to term.
4. Embryo transfer allows for production of offspring from mares with musculoskeletal disease in which their health may be jeopardized by carrying a pregnancy to term or delivering a foal (e.g., fractured pelvis or hip, severe arthritis).
5. Embryo transfer prevents risk of postfoaling complications in the valuable mare or older mare at risk.
6. Embryo transfer allows more than a single offspring to be born within a given year.
7. Immature (2-year-old) mares unable to carry a foal to term are capable of producing embryos that have a good survival rate in mature recipient mares.
8. In breed registries in which the value of the offspring often depends on a determined date of birth, embryo transfer allows mares that foal late in the season to produce an embryo for that year and yet also be prepared to be bred early on the subsequent season because they have been left open.
9. The procedure has proved invaluable in many research projects comparing effects on twins that arise from embryo splitting or double ovulation.

As breed registries have permitted registration of the foals produced by embryo transfer, the technique rapidly has become a routine procedure offered in many equine private practices. Although most practices do not maintain a herd of recipient mares and most small-scale mare owners do not provide enough recipients, the procedure of flushing embryos from donor mares and shipping the embryos to recipient mares at a distant location has grown in popularity. Still, despite the numerous advantages to transferring embryos, the procedure is an expensive endeavor that may cost in veterinary and mare care alone more than \$10,000.<sup>1</sup> Coupled with the stud fee, these offspring, assuming the procedure is successful, are indeed valuable.

## ☞ FACTORS AFFECTING SUCCESS RATES

Three major factors affect success rates in an embryo transfer program: the fertility of the mares (donor and recipient), the fertility of the semen, and the expertise of all technical and

veterinary personnel. Best management practices optimize all three factors for success. All horses involved should receive a BSE, the extent of which depends on the age, history, and parity of the mares and the reproductive history of the stallion.

## FERTILITY OF THE DONOR MARE

The ideal candidate for a donor mare in an embryo transfer program is a 3- to 10-year-old, healthy, reproductively sound mare. Foss, Wirth, Schlitz et al.<sup>2</sup> reported high embryo recovery rates in show mares (84.2%) followed by an acceptable rate in multiparous, nonbarren mares (59.7%). However, mares with a history of infertility showed a significantly lower embryo recovery rate (30%). Unfortunately, the value of many mares is not realized until they are older, when superior performance of their offspring has been exhibited. The age of the mare appears to play a major role in fertility<sup>3</sup>; early loss of pregnancy is a common and frustrating problem encountered in older mares. Investigation into the causes of this age-associated infertility has led researchers to examine changes that occur in the reproductive tracts of aging mares: the uterine environment, the uterine tube environment, and ovarian function.

The numbers and quality of oocytes differ greatly between young and aged mares.<sup>4</sup> Oocytes from older mares (i.e., >20 years) have significantly more morphologic anomalies.<sup>5</sup> The clinical impression of many practitioners is that delayed development occurs in embryos obtained from older mares.<sup>4,6</sup> In evaluations of equine embryo quality and viability, not only have young mares (<10 years old) been reported to produce more embryos, but also the embryos that are recovered from them are of significantly superior quality compared with embryos from older mares.<sup>7-9</sup> Embryos are graded on the basis of morphologic characteristics and size (grade 1, excellent; grade 4, poor).<sup>10</sup> Transfer of grade 1 embryos results in significantly higher 50-day pregnancy rates (70% to 80%) than transfer of grade 4 embryos (30% to 40%).<sup>9</sup> Transferred embryos classified as grades 1 and 2 demonstrate significantly higher pregnancy rates than grade 3 embryos.<sup>10</sup> Embryo loss between 12 and 50 days of gestation was significantly greater with grade 2 embryos than with grade 1 embryos.<sup>11</sup>

Because the number of blastocysts recovered from the oviductal lumen 2 days after ovulation does not vary according to the age of the mare,<sup>6,11</sup> fertilization and early cleavage steps may not be the limiting factors in production of embryos in older mares. However, pregnancy rates at 4 days demonstrate a significant difference depending on mare age.<sup>6,12</sup> Although age-associated degenerative and inflammatory changes to the endometrium and its associated blood vessels are well documented and in some cases may contribute to lower foaling rates in old mares, the defect that causes early embryonic losses appears to occur before the mature blastocyst can be found within the uterus.<sup>13</sup> Early (2-day) pregnancy rates are not different depending on the age of the mare,<sup>12</sup> but 3-day pregnancy rates are decreased significantly in aged mares.<sup>14</sup> Day 4 embryos collected from the uterine tubes of old mares and transferred to the uteruses of young normal mares show significantly lower survival rates.<sup>15</sup>

Apparently, older mares require superior nutritional support, particularly during the vernal transition period to hasten the interval to ovulation.<sup>16-19</sup> Follicular development is prolonged in older mares, especially as they approach ovarian senescence.<sup>20,21</sup> The most common cause of early pregnancy

loss in older mares appears to be an intrinsic defect within the oocyte itself or in the physiologic events that occur before the formation of a day 3 embryo. Other factors, such as failure of maternal recognition of pregnancy, immune-mediated causes, chromosomal aberrations, reaction to stress, nutrition, hormonal insufficiencies, and postovulatory insemination may play a role in early pregnancy loss and delayed embryonic development.<sup>22</sup>

### **FERTILITY OF THE RECIPIENT MARE**

A young, healthy, reproductively sound mare is the ideal candidate to act as an embryo recipient. Factors that further enhance success rates in the recipients include good nutrition, good general health care, minimal stress, and hormonal synchrony with the donor mare. Ideally, the recipient mare should ovulate during a period from 1 day (+1) before to as many as 6 days after (–6) the donor mare to optimize pregnancy rates.<sup>23,24</sup> Carnevale, Ramirez, Squires et al.<sup>11</sup> have reported that embryo loss rates are significantly higher in recipient mares that ovulate 7 days or more (–7) after the donor mare. The administration of PGF<sub>2</sub>-α alone or with progestin compounds promotes synchrony between the ovulations of the donor and recipient mares.<sup>25</sup> Ovulation induction agents such as hCG or deslorelin may further enhance desired synchrony.

To eliminate the need for synchrony, many researchers have used ovariectomized recipient mares that have been treated with progestins alone or a combination of progestins and estrogen.<sup>26-28</sup> Although McKinnon, Squires, Carnevale et al.<sup>28</sup> found that pregnancy rates were similar between ovariectomized, progesterone-supplemented mares and synchronized recipients, results in the field have been unreliable using ovariectomized recipients, perhaps because ovariectomized mares that remain open for a season appear to be less optimal candidates for subsequent recipient seasons. From an economic standpoint, ovariectomized mares also require upward of 120 days of progestin supplementation.<sup>29</sup> Researchers also have evaluated the suitability of hormone-treated mares in the beginning of the transitional period as embryo recipients, but pregnancy rates are often not as high as those in recipients that are cycling regularly.<sup>11</sup>

Uterine tone at day 5 after recipient ovulation represents a useful predictive indicator of success in transfer. Recipient mares with good uterine tone 5 days after ovulation had significantly higher pregnancy rates at day 50 than mares with poor to fair uterine tone.<sup>11</sup> McCue, Vanderwall, Keith et al.<sup>30</sup> have shown that mares that qualify as recipients on the basis of uterine tone have significantly higher progesterone concentrations at day 5 than mares who failed to qualify. This finding is consistent with another study reported by Sevinga, Schukken, Hesselink et al.<sup>31</sup> that found that the size of the CL and progesterone production are higher at day 8 or 9 after ovulation in pregnant mares compared with nonpregnant mares.

Although veterinarians generally agree that the parturient mare determines the size of the foal at birth, research has demonstrated that choosing a recipient pony mare to deliver the foal of a donor Warmblood mare is unwise.<sup>32</sup> Allen<sup>33</sup> has demonstrated that the size of the recipient mare does affect the adult size of the offspring. Wilsher and Allen<sup>34</sup> split equine embryos and transferred these identical twins into recipient mares of varying heights. Although the donor mare appeared to determine the size of the foal at birth, the height of the adult horse appeared to depend on the size of the recipient

mare. Therefore choosing donor and recipient mares of similar size is recommended.

### **FERTILITY OF THE SEMEN**

The quality of semen affects the success rate of embryo recovery.<sup>35</sup> In general, the best results are obtained when the mare is inseminated with semen collected on the farm (or is bred under natural cover), followed by semen that is cooled and shipped to arrive within 24 hours of collection, followed by frozen semen.<sup>25</sup> High pregnancy rates have been demonstrated when the mares are inseminated before and after ovulation during a 12-hour period.<sup>36</sup> Results from an embryo transfer program in a private practice over a 2-year period of evaluation support this discrepancy in fertility based on the type of semen, with fresh, chilled, and frozen semen resulting in embryo recovery rates of 55%, 44%, and 32%, respectively.<sup>24</sup>

### **EXPERTISE OF THE VETERINARIAN**

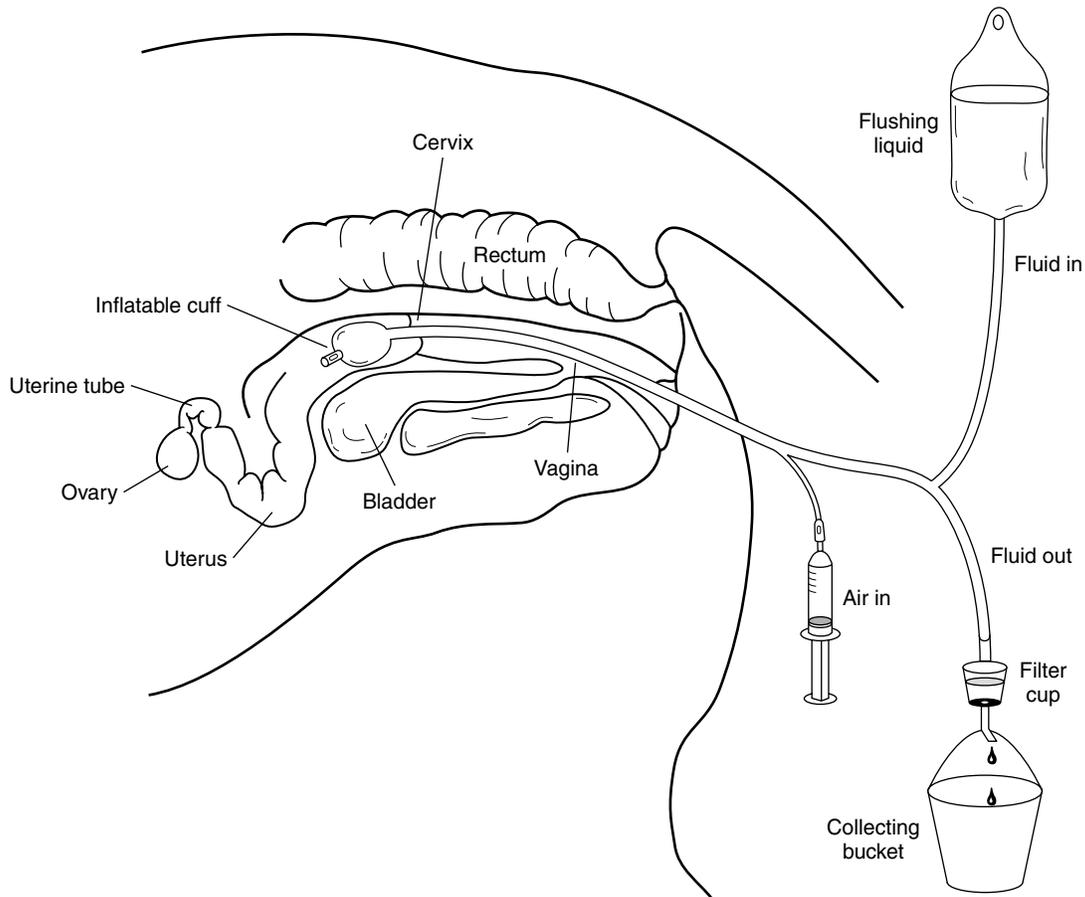

The veterinarian's role is not only to determine the optimal time for breeding but also to recognize abnormalities as they arise. Abnormalities such as DUC<sup>37</sup> or hemorrhagic follicles can be detrimental to successful embryo recovery. The veterinarian also should be experienced in embryo recovery and transfer techniques to achieve the most successful pregnancy rates. Owners must have realistic expectations before embarking on this expensive endeavor. They must realize that even with a young, fertile mare bred with fertile semen and under the care of an experienced veterinarian, the best embryo recovery rates are only 70% to 80%. If semen shipped cooled or frozen is used, then the success rates are often lower.<sup>38</sup>

### **PROCEDURE FOR EMBRYO RECOVERY**

Most embryo flushes are attempted on days 7 or 8, with the day that the donor ovulated designated as day 0. Day 0 is the first day that a corpus hemorrhagicum is visible on transrectal ultrasound examination, assuming that the mare has been examined at least daily. If the mare is examined more frequently, as is often the case when breeding with frozen semen, day 0 is still determined by the first appearance of the corpus hemorrhagicum. Occasionally, another question of ovulation may arise because of the presence of a hemorrhagic follicle; these anomalies occur more often in transitional and older mares. In these cases ovulation generally is believed not to have occurred.<sup>39</sup>

The developing embryo enters the uterus after day 5 at the morula or early blastocyst stage.<sup>40</sup> Enormous growth of the blastocyst and rapid expansion of the inner cavity, the blastocoele, occur during the next few days. Most embryos destined for transfer are flushed as expanded blastocysts (day 7 or 8) because they appear to optimize transfer pregnancy rates.<sup>24,41,42</sup>

One lavages the uterus of the donor serially with liters of Dulbecco's phosphate buffered saline or synthetic oviductal fluid warmed to 37° C (Figure 18-10). Antimicrobial agents and 1% fetal calf serum (FCS; Hyclone Laboratories, Logan, Utah) may be added to the lavage medium. Although many Foley-type catheters have been used for the lavage, a large-bore (8.0 mm) sterile silicone catheter (80 cm; Bivona ET flushing catheter; Western Veterinary Supply, Grapevine, Tex.) with

**FIGURE 18-10** Embryo flushing: the inflated catheter seals the cervix. (Courtesy T. Ayres, Aurora, Ore.)

an inflatable cuff is often ideal for most donors presented in practice. The uteruses of some older or multiparous mares may require more than a single liter of fluid to distend the uterus. Likewise, the smaller uteruses of maiden mares may take less than 1 L for maximum distention. This often can be determined by the ease of fluid flow into the uterus. One evacuates the uterus by gravity flow and passes the recovered fluid through a sterile recovery cup lined with a 0.75- $\mu\text{m}$  filter (Harvet, Spring Valley, Wisconsin). It is important to ensure that the cup does not run dry; a certain amount of fluid must remain in this cup at all times to bathe the embryo. Even though most embryos are recovered in the first flush, this procedure must be repeated two or three more times, with the recovered fluid measured on each flush so that most of the fluid has been recovered by the time that the procedure is complete. One performs transrectal massage of the uterus for the last two flushes, ensuring recovery of all fluid introduced into the uterus.

Once in the laboratory, the contents of the cup are swirled and then poured into search dishes that have been maintained at 37° C. The cup is rinsed with 20 ml of the remaining Dulbecco's phosphate buffered saline solution, which is then decanted into the search dishes. Using a stereoscopic microscope, usually at 15 $\times$  magnification, one methodically searches for the embryo. After finding it, one evaluates the embryo at higher magnification for age, size, and morphology and then washes it three times in lavage medium with 10% FCS in preparation for shipping or transfer. Antimicrobial agents often are added to this medium as well.

## EMBRYO TRANSFER INTO THE RECIPIENT MARE

Surgical and nonsurgical techniques have been used successfully to transfer mare embryos. For many years surgical transfer by way of a standing flank laparotomy demonstrated the most favorable pregnancy rates. However, this procedure is more expensive, labor intensive, and time consuming for the veterinarian, and it poses a higher risk to the recipient mare. Over the past few years, nonsurgical transfer has been reported to achieve similar, if not superior, pregnancy rates for many clinicians.<sup>2,38,43</sup> This success rate appears to depend on the experience and expertise of the veterinarian performing the transfer.

One loads the embryo into a sterile 0.25-ml or 0.50-ml straw using a ureteral catheter adapter (Cook Urological, Spencer, Indiana) attached to a tuberculin syringe. The size of the straw depends on the size of the embryo. To ensure the midstraw location of the embryo at all times before transfer, one first loads the straw with lavage medium (10% FCS), then with an air pocket, then with medium (10% FCS) containing the embryo, then with another air pocket, and followed at last by medium (10% FCS). For nonsurgical transfer, the first fluid section must penetrate the wick of the straw to prevent loss of the contents of the straw by gravity. This sequence not only allows verification of the location of the embryo but also reduces the amount of fluid inoculated into the uterus of the mare on transfer.

The straw is loaded into a sterile insemination gun. Although several commercially available guns have been designed to fit the different sizes of straws, some veterinarians prefer to use a stainless steel reusable gun, and others prefer an intrauterine pipette for transfer of large embryos. Manipulation of the cervix or inoculation of the uterus during transfer long has been considered detrimental to a successful pregnancy. This invasion of the reproductive tract of a diestrus recipient mare also has been suspected potentially to lead to eventual regression of the CL through the release of PG, oxytocin, or both. Thus one must take many steps to preserve the CL and thus the transferred pregnancy.

Although studies have shown that no benefit accrues from treating the recipient mare with altrenogest (Regumate, Intervet Inc., Millsboro, Delaware) or flunixin meglumine (Banamine, Schering-Plough Animal Health, Union, N.J.), many practitioners continue to administer these drugs to mares before transfer of the embryo. Some also use a single intramuscular dose of procaine penicillin (Aquacillin, Vedco, St. Joseph, Missouri) for its antibiotic action, whereas others administer dexamethasone (Dexaject SP; Burns Veterinary Supply, Rockville Center, N.Y.) for its anti-inflammatory effects, terbutaline (Franck's Veterinary Pharmacy, Des Moines, Iowa) for its tocolytic action on the uterus, and propantheline bromide (Franck's) for transient relaxation of the rectum.<sup>2</sup>

Unfortunately, scientific data validating the merits of these therapies are lacking. Sedation of the recipient mare depends on her temperament and degree of discomfort during the procedure. Work by LeBlanc, DeLille, Cadario et al.<sup>44</sup> suggests that tranquilization using an  $\alpha_2$ -agonist such as domosedan may cause less stimulation of uterine contraction because the uterus of the recipient mare is under the influence of progesterone from the CL. When  $\alpha_2$ -adrenoceptors predominate, they inhibit contractions.

One secures the loaded, sterile embryo transfer gun, perhaps shielded by a sterile outer guard sleeve, in the palm with the thumb; then applies a small amount of sterile lubricant; and inserts the hand and gun transvaginally. One digitally palpates the external cervical os and passes just the tip of the gun gently through the guard sleeve and then the remainder of the cervix. At this point, many prefer to deposit the embryo in the uterine body. If the veterinarian is planning to deposit the embryo in the uterine horn instead, he or she then inserts a well-lubricated arm into the rectum of the recipient, locates and grasps the uterine horn, and gently threads the tip of the gun into the uterine horn. Next, the veterinarian slowly depresses the plunger, releasing the embryo from the straw as the gun is withdrawn. Because of equine embryo mobility, into which horn the embryo is deposited does not matter.

Surgical transfer of an embryo is performed on a sedated recipient mare aseptically prepared for a routine flank incision. An inverted L or line block over the paralumbar fossa is generally used for local anesthesia. The surgeon exteriorizes the uterine horn of the mare and makes a small puncture with a cutting-edge suture needle. The surgeon then enlarges the hole slightly with iris forceps and inserts the sterile straw containing the embryo through the hole into the uterine lumen to deposit the embryo. The surgeon places the uterine horn back into the abdomen and then repairs the incision with a routine three-layer closure.

A developing embryonic vesicle can be detected by transrectal ultrasound examination as early as 5 days after transfer. If the embryonic vesicle is not visible at this time, the

mare must be rechecked every 48 hours at least through day 16. Carnevale, Ramirez, Squires et al.<sup>11</sup> have shown that the presence or absence of an embryonic vesicle at 5 days is an important predictor of pregnancy loss by 50 days. Recipient mares in which the embryonic vesicle is large enough to be seen on the first pregnancy examination (usually 5 days) have fewer embryonic deaths than mares in which the vesicle is not seen until subsequent examinations. Ginther, Bergfelt, Leith et al.<sup>45</sup> support this theory; they also found that undersized embryonic vesicles are associated with a higher rate of pregnancy loss.

## SHIPPING EMBRYOS

Carney, Squires, Cook et al.<sup>46</sup> have shown that no significant differences occur in pregnancy rates between mares that have embryos transferred immediately after collection and mares that receive cooled, transported embryos. The expense of maintaining open recipient mares is considerable, and a number of commercial recipient herds are now available to practitioners. Because most of these commercial herds have limited numbers of mares, having contracts signed and mares reserved early in the breeding season is important.

Preparing the embryo for shipping is uncomplicated. Most embryos in the United States are shipped in Ham's F-10 (Sigma Chemical Co., St. Louis, Mo.) medium buffered to an optimal pH with a mixture of 5% carbon dioxide, 5% oxygen, and 90% nitrogen gas.<sup>47</sup> The final preparation of the medium contains 10% FCS (filtered through a Millipore filter) and antimicrobial agents (usually a combination of penicillin and streptomycin). Although most larger commercial operations send the buffered medium on ice to the practitioner the day before the embryo flush, this transport medium is simple for the practitioner to make in the clinic, provided that a tank of the appropriate gas mixture is on hand.

Several other media are available for embryo transport that eliminate the need for the gas buffer of Ham's F-10, which is necessary to maintain the correct pH for embryo transport. Moussa, Duchamp, Bruyas et al.<sup>48</sup> reported that two commercially available embryo holding media (Emcare Holding Solution [ICP, Auckland, New Zealand] and ViGro [AB Technology, Pullman, Wash.]) appear to have an effect on embryo viability similar to the gas-buffered Ham's F-10 for 24-hour cooled storage of embryos. However, this study did not examine pregnancy rates after transfer. Fleury, Fleury, and Landim-Alvarenga<sup>49</sup> recently reported that using hydroxyethyl-piperazine ethane-sulfonate (HEPES)-buffered Ham's F-10 (with 0.4% bovine serum albumin [BSA]) for temporary storage of embryos gave 15-day pregnancy rates of greater than 75% in recipient mares. This medium also eliminates the need for incubation with the gases. In this experiment embryos were stored at ambient temperature, between 15° and 24° C, thereby eliminating the need for cooling as well.

The washed embryo is transferred using a sterile 0.25- or 0.5-ml straw to a 6-ml snap-top tube containing the transport medium. One tightly closes the top and places the tube in a larger tube (50-ml centrifuge tube) also filled with transport medium. One then places both tubes into an isothermalizer cup (37° C) and places that into an Equitainer (Hamilton-Thorne Research Inc., Danvers, Mass.) for shipment.

Some commercial operations with recipient herds prefer that the embryos be transported by commercial airlines in an attempt to minimize the time that the embryo spends

outside of the uterus of the mare. Others believe that commercial transport companies that deliver the embryo within 24 hours are acceptable and that pregnancy rates do not differ between 12-hour and 24-hour shipment.<sup>50</sup> Foss<sup>24</sup> has shown that pregnancy rates do not differ between embryos transported by airlines and those transported by courier services. The largest factor in choosing the means of transportation is reliability of service. Whatever means of transporting the embryo that is ultimately chosen, the imperative is to ensure that the paperwork is filled out correctly and that the shipment is insured.

## THE PREGNANT MARE

Grant S. Frazer

### ☞ PHYSIOLOGY OF GESTATION

#### MATERNAL RECOGNITION OF PREGNANCY

The zygote begins its journey down the oviduct once the oocyte has been fertilized, reaching the uterine horn by day 6.<sup>1,2</sup> Detailed descriptions of the early development of the equine embryo have been published and are beyond the scope of this text.<sup>3,4</sup> Early embryonic development in the horse is characterized by the formation of an unusual acellular glycoprotein “capsule” between the trophoctoderm and the overlying zona pellucida. This structure is first detected between days 6 and 7 after ovulation and completely envelops the spherical conceptus until as late as day 23 of gestation.<sup>5</sup> Although the term *embryo* is used routinely to describe the early conceptus, it is important to understand that what is generally being discussed is the embryonic vesicle as well as the embryo itself. These two structures will ultimately develop into the fetal membranes and fetus, respectively. Embryonic development has progressed sufficiently by day 40 of gestation that the term *fetus* is used thereafter.<sup>4</sup>

The longitudinal arrangement of the endometrial folds may favor mobility of the spherical equine embryo.<sup>4</sup> After entering the tip of the uterine horn on day 6, the embryo moves down toward the body by day 8.<sup>6,7</sup> The intrauterine mobility phase continues until days 15 through 17, and during this period the embryo may move between horns 10 to 20 times each day.<sup>2,4,7-9</sup> If the pregnancy is to be maintained, the embryo must send a signal to the endometrium and prevent the cyclic release of the uterine luteolysin (PGF<sub>2</sub>-α).<sup>10</sup> An embryo-derived factor is the most likely cause for the suppression of PGF<sub>2</sub>-α release and interruption of the oxytocin–PGF<sub>2</sub>-α interaction in mares during early pregnancy.<sup>11,12</sup> The mobility of the spherical equine conceptus is critical for blockage of luteolysin.<sup>3</sup> This is why large uterine cysts may cause pregnancy loss.<sup>13-15</sup> If the enlarging vesicle can not pass by a cyst, it may be unable to come into contact with all endometrial surfaces and thus inhibit PGF<sub>2</sub>-α production.<sup>16</sup> Yet another unique feature of equine reproduction is the fact that the luteolysin is delivered to the ovary systemically.<sup>17</sup> Such delivery contrasts with the local countercurrent, utero-ovarian route in domestic ruminants in which intimate contact occurs between the ovarian artery and utero-ovarian vein.<sup>18</sup> The embryo typically becomes fixed at the base of one of the uterine horns, with the embryonic pole of the vesicle opposite the mesometrial

attachment (antimesometrial).<sup>19</sup> An early vascular indicator of the future position of the embryo proper consists of a colored spot in the Doppler image of the endometrium, close to the wall of the embryonic pole. This finding may prove useful when differentiating between a cyst and a vesicle before the embryo proper becomes visible on the ultrasound image.<sup>19,20</sup> In postpartum mares the embryo usually becomes fixed in the more involuted horn.<sup>21-23</sup>

#### PLACENTATION

The trophoblast cells of the early embryo are destined to form the absorptive placental contact with the endometrium.<sup>4</sup> The mare has a rather unique nondeciduate, epitheliochorial, diffuse, microcotyledonary placenta.<sup>3,24-30</sup> The entire maternal surface of the fetal membranes becomes covered with delicate microvilli (diffuse), which interdigitate with the proliferating luminal epithelial cells to form intricately branched microcotyledons.<sup>25,26,28</sup> The interdigitation tends to be deeper at the tip of the nongravid horn, and this may help explain the higher incidence of fetal membrane retention in that horn.<sup>31</sup> In a normal pregnancy the noninvasive allantochorion extends slowly to fill the uterus by days 80 through 85, and its microcotyledonary architecture, which provides both hemotrophic and histotrophic nutrition for the growing fetus, is not fully established until days 120 through 140.<sup>2,28,32,33</sup> During the second half of gestation, most of the mitotic activity is confined to the periphery of the microcotyledons, which are still growing.<sup>33-36</sup> Constant supplies of the principal vasculogenic and angiogenic factor (vascular endothelial growth factor) and its two main receptor molecules are available on both the maternal and fetal sides of the placental barrier throughout gestation in the mare. They are presumed to facilitate the continuing development of the extensive fetal and maternal capillary networks that are such prominent features within the microplacentomes of the diffuse, epitheliochorial equine placenta.<sup>36,37</sup>

Degenerative changes (endometrosis) in the maternal endometrium can adversely affect the ability of the microcotyledonary placenta to facilitate optimal hemotrophic nutrition and exchange of waste products.\* If the pregnancy is maintained, dysfunctional placental attachment can lead to the birth of small, weak foals (intrauterine growth retardation) and may have detrimental consequences on the health and athletic performance of the mature horse.<sup>28,36,45-48</sup> Likewise, the presence of twin fetal sacs deprives variable areas of each allantochorion of the necessary endometrial contact to promote development of the diffuse microvilli. Failure of development of the microcotyledons results in the characteristic white, avillous portions on the maternal surface of aborted twin fetal membranes (see the section on early pregnancy loss and abortion).<sup>49,50</sup> Although the histotrophic form of nutrition is likely to remain important throughout gestation, adequate hemotrophic nutrition is essential to support the rapid fetal growth that occurs during the latter part of gestation.† The morphology of endometrial blood vessels in uterine biopsy can vary considerably, depending on the age and reproductive status of the mare. In a recent study inflammatory vascular alterations were observed in 20.5%

\*References 15, 28, 32, 33, 36, 38-45.

†References 2, 27, 28, 32, 35, 36, 38, 45

of the endometrial specimens examined.<sup>36,44</sup> Smaller and larger arterial and venous vessels demonstrated mild to severe degenerative lesions. Unaltered vessels were detected only in maiden mares.

The incidence and severity of angiogenesis increases with the number of previous pregnancies and with advancing age.<sup>36,40,44</sup> Changes in the endometrial vasculature of multiparous mares have been compared with the so-called pregnancy sclerosis of other species, with fraying and disruption of the membrana elastica interna, medial and adventitial elastosis and fibrosis, and calcification processes within the media.<sup>40,44</sup> Cycles of vascular growth during pregnancy and subsequent involution postpartum are thought to result in progressive degenerative vascular changes, as seen in multiparous mares. Aging processes, chronic inflammation, and short foaling intervals have been suggested as additional detrimental factors.<sup>36,40,44</sup> Severe angiogenesis is frequently combined with phlebotasia and lymphangiectasia, possibly indicating a reduced ability of the vessels to adapt to the varying demands of uterine circulation, with a decrease of uterine perfusion and lymph drainage. Angiogenesis in older, multiparous mares might therefore be intimately related to infertility, possibly because of detrimental effects on early embryo nourishment and subsequent placentation.<sup>32,40,44,51</sup>

Some interesting embryo transfer experiments have demonstrated the impact that uterine capacity—and placental area—can have on the size and birth weight of the foal.<sup>52-56</sup> In one study pony embryos were transferred into draft mare recipients, and then the genetic dams were permitted to carry a full sibling to term. The final experimental outcome was three pairs of sex-matched, full-sibling pony foals. The embryo transfer foals were all larger than their siblings at birth. Although the increased milk production of the draft mares may have explained the subsequent faster growth rates, it was noted that all three draft-gestated foals were still heavier at 4 years of age.<sup>52</sup> A similar embryo transfer experiment used a Thoroughbred-in-Pony (Tb-P) and Pony-in-Thoroughbred (P-Tb) comparison, with Thoroughbred-Thoroughbred and Pony-Pony transfers acting as controls.<sup>54,56</sup> The P-in-Tb foals were heavier than the Tb-in-P foals. Comparison of placental measurements (weight, volume, and surface area) confirmed the impact of nutrient supply on fetal growth and foal birth weight, and sudden mare weight loss in midgestation has also been shown to have detrimental effects on placental development.<sup>33,35,53-56</sup> These studies confirmed earlier work in which a Shetland pony mare was inseminated with Shire semen and a Shire mare was bred with Shetland pony semen. The foal out of the pony mare was 50% of the weight of the half sibling that was gestated in the Shire mare. The marked size discrepancy remained even after these half siblings reached maturity.<sup>57</sup>

Equids possess the unusual ability to interbreed freely among the phenotypically and karyotypically diverse member species of the genus to produce viable, but usually infertile, offspring.<sup>58</sup> The mule (female horse crossed with male donkey) is one example of this successful interbreeding. Even more amazing, mares and donkeys have been shown to be capable of carrying to term a range of true, xenogeneic extraspecies pregnancies created by embryo transfer. In these instances all of the allantochorion tissue is composed of foreign protein (see the following discussion of endometrial cups). Successful pregnancies include Przewalski's horse (*Equus przewalskii*; 2n = 66) carried-in-horse and Grant's zebra (*E. burchelli*; 2n = 44) carried-in-horse (*E. caballus*; 2n = 64).<sup>58</sup>

## ENDOCRINOLOGY

By day 35 a specialized, circumferential group of trophoblast cells (chorionic girdle) detach from the embryonic vesicle, and some successfully invade the endometrium.<sup>2,3,59-63</sup> Here they give rise to discrete aggregates of endocrinologically active tissue (endometrial cups).<sup>2,59,60,64</sup> These endometrial cups become visible by day 38 to 40 as a ring of small, pale plaques that surround the developing conceptus.<sup>3,4,32</sup> Because the maternal and fetal cells (sire contribution) have differing genotypes, the fetal antigens invoke a cell-mediated immune response.<sup>4,65,66</sup> The influx of lymphocytes creates a pronounced, localized immunologic reaction, and by day 120 of gestation the endometrial cups are sloughed.<sup>32,65-68</sup> The necrotic tissue and inspissated secretions form invaginations into the chorioallantois (allantoic pouches).<sup>69</sup> These structures can be seen on the allantoic surface of the fetal membranes after the mare has foaled.

The endometrial cups produce eCG—formerly known as *pregnant mare serum gonadotrophin* (PMSG). A large-molecular-weight glycoprotein, eCG has both FSH-like and LH-like activity.<sup>70</sup> Periodic surges (10 to 12 days apart) of pituitary FSH release drive a series of follicular waves on the equine ovary during early pregnancy.<sup>2,32,71,72</sup> The eCG promotes luteinization (and sometimes ovulation) of the dominant follicle in each wave.<sup>3,32,73-75</sup> These accessory (secondary) CLs augment the progesterone production from the original structure that developed at the time of conception. This process is critical to ensure pregnancy maintenance before the development of steroid production by the placenta.<sup>2,3,32,76-79</sup> The fully developed equine placenta produces significant quantities of progestins.<sup>2,3,32</sup> Pregnancy can be maintained in ovariectomized embryo transfer recipient mares provided that they receive an exogenous progestin supplement during the early period when CL progesterone is critical.<sup>80</sup> The need for progesterone therapy after day 100 of gestation is controversial and will be discussed later in this section.<sup>2,81-83</sup> High levels of eCG may be detected in the blood of pregnant mares from 40 to 120 days of gestation.<sup>2</sup> This forms the basis of the mare immunologic pregnancy (MIP) test. A positive MIP test can occur when a mare is no longer pregnant because pregnancy loss after days 35 to 40 will not eliminate the endometrial cups.<sup>3</sup> The endometrial cups can produce high levels of eCG in a mare that has suffered fetal loss during the second or third months of gestation.<sup>84</sup> This results in erratic estrous behavior, unreliable follicular development, luteinization of immature follicles, and unpredictable ovulation.<sup>32,85</sup>

Another unique feature of early gestation in the mare is an elevation in plasma conjugated estrogen levels associated with gonadotrophin stimulation of the luteal tissue.<sup>3,74,86,87</sup> A second, prolonged rise in estrogen levels begins by day 70, peaking around day 240, then gradually declining toward basal levels at term.<sup>79,88,89</sup> Peak estrogen levels range between 300 to 400 ng/ml.<sup>79</sup> These large quantities of estrogens are secreted by the fetoplacental unit after synthesis from precursors produced by the enlarged fetal gonads.<sup>2,78,89-94</sup> Bilateral fetal gonadectomy between days 197 and 253 of gestation causes a precipitous drop in plasma estrogen levels that then remains basal until small foals are spontaneously delivered in 70 to 97 days.<sup>79</sup> After day 220 the enlarged gonads gradually shrink into an insignificant size by birth.<sup>95</sup> Serum estrogens in the pregnant mare include estradiol, estrone, and the equine-specific steroid ring-B unsaturated estrogens—equilin and equilenin.<sup>94,96-98</sup>

Estrogen assays have been used by researchers to confirm pregnancy and fetal viability.<sup>99-101</sup>

Four separate components combine to produce the progesterone and biologically active 5 $\alpha$ -reduced pregnanes needed to maintain pregnancy in the mare.<sup>83,89,102</sup> The primary CL is prolonged beyond its cyclical life span by the downregulation of endometrial oxytocin receptors to prevent activation of the luteolytic pathway. Its waning progesterone production is supplemented from day 40 of gestation by the formation of a series of accessory CLs that develop in the maternal ovaries as a result of the gonadotrophic actions of pituitary FSH and eCG.<sup>102</sup> The equine fetoplacental unit produces significant quantities of progesterone and C-21 progestagens.<sup>2,76-79,89,103-105</sup> The placenta (chorioallantois and endometrium) initially uses maternally derived cholesterol to metabolize into pregnenolone and then progesterone. A significant amount of progesterone originates from this source—starting from approximately day 70 of gestation.<sup>76-79,89,105</sup> In normal pregnant mares the circulating progesterone concentration starts to decline by 4 months of gestation, reaching baseline levels by day 180.<sup>106</sup> Progesterone may be undetectable at levels of less than 1 ng/ml.<sup>83,89</sup> Thus plasma progesterone-specific assays are of limited clinical value after midgestation.<sup>83,89,107-109</sup> The circulating progesterone concentration is no longer indicative of what is happening at the uterine level, where the placenta secretes progesterone and progestagens directly to the endometrium and underlying myometrium.<sup>89,103-105,109</sup> In the second half of gestation, most of the placental-derived progesterone is further metabolized into 5 $\alpha$ -reduced pregnanes (5 $\alpha$ -dihydroprogesterone or 5 $\alpha$ -pregnane-3,20-dione; and 20 $\alpha$ -5P or 20 $\alpha$ -hydroxy-5 $\alpha$ -pregnane-3-one; together with other 5 $\alpha$ -reduced metabolites of progesterone and pregnenolone).<sup>83,89,105,109-113</sup> In the later part of gestation, it has been suggested that another steroid, perhaps 5 $\alpha$ -pregnane-3,20-dione (5  $\alpha$ DHP) and not progesterone, is the important steroid precursor for the other progestin metabolites found in circulating plasma.<sup>89,109,114</sup> A precise biologic explanation for this mechanism has not been elucidated to date.

In the last months of gestation, the enlarging fetal adrenal gland secretes appreciable quantities of pregnenolone, which is then utilized by the placenta to synthesize progestagens.\* Even at this late stage in equine gestation, there is insufficient adrenal 17 $\alpha$ -hydroxylase activity to convert the pregnenolone into fetal cortisol, and thus it passes out in the umbilical vessels and is converted to 5 $\alpha$ -reduced pregnanes in the placenta.† Thus, unlike the trend in ruminants, there is a significant increase in the mare's plasma progestagen concentrations during the last 4 to 6 weeks of gestation, followed by a precipitous drop in levels at the time of parturition.‡ A premature rise in progestins has been observed in mares with placentitis, and this phenomenon is thought to be associated with fetal stress and premature maturation of the pituitary adrenocortical axis.<sup>54,116,121</sup> When pony mares were subjected to intrafetal injections of adrenocorticotrophic hormone (ACTH) at day 300 of gestation, maternal plasma progestagen concentrations increased significantly.<sup>122</sup>

Physiology of parturition in the mare does not follow the well-documented ruminant model.<sup>123-125</sup> The precise

mechanism that couples the fetal hypothalamic-pituitary-adrenal axis in the foal that is carried to term is not known at this time, but it is invariably triggered when the fetus becomes fully mature.<sup>83,89,126,127</sup> In the mare the fetal cortisol level remains basal until the last 2 days of gestation, when a marked rise culminates in parturition.<sup>47,127,128</sup> Enhanced adrenocortical activity in the fetus is related to the onset of parturition in many species.<sup>122,127</sup> Final maturation of the fetus results in increased ACTH release from the pituitary and subsequent stimulation of the fetal adrenal cortex.<sup>110,115,116,129,130</sup> It is not until the maturing adrenal gland attains 17 $\alpha$ -hydroxylase capacity that the high levels of pregnenolone are metabolized into fetal cortisol.<sup>89,113,129</sup> Disruption of these fetal maturational processes, with suppression of fetal adrenocortical activity, appears to play an integral part in the pathophysiology of fescue toxicosis.<sup>118</sup> The normal fetal maturational change (pregnenolone conversion into fetal cortisol) causes the maternal progestagen levels to plummet, with the result that there is a rising estrogen-to-progestagen ratio, and in the final hours estrogen ultimately becomes dominant in the preparturient mare.<sup>79,120,131</sup> Estrogens promote the synthesis of PGs and increase the number of both oxytocin receptors and myometrial gap junctions.<sup>120,127</sup> Studies with intrafetal injections of ACTH have indicated that both precocious maturation of the equine fetus and a significant reduction in gestational length is likely to be mediated through adrenal regulation of fetal maturation and production of maternal progestagens.<sup>122</sup> Follow-up work by Ousey, Rosedale et al. demonstrated that administration of high doses of maternal ACTH appears to accelerate fetal maturation and delivery in pony mares. Further work is required to establish the optimal gestational age and dosage for maternal ACTH administration before clinical recommendations can be given for this therapy.<sup>132</sup> These same workers are currently investigating early (day 315) use of dexamethasone to promote precocious fetal maturation and early delivery.<sup>133</sup> It was thought that there is little transplacental transfer of cortisol from the mare to the fetus because of the presence of a placental enzyme (11 $\alpha$ -hydroxysteroid dehydrogenase), which converts cortisol to inactive cortisone.<sup>83,134</sup> However, the enzyme may not be 100% efficient, and some synthetic glucocorticoids may pass more readily.<sup>83</sup> This area warrants further study, and the timing of the glucocorticoid treatment with respect to gestational age may be important.<sup>83</sup> A rise in fetal cortisol is definitely essential for final maturation, and foals that are delivered without adequate cortisol stimulation will usually fail to thrive and eventually die as a result of multiorgan failure.<sup>83,126</sup>

Relaxin is produced by the placental trophoblast cells, but current knowledge about relaxin activity in the pregnant mare is limited.<sup>135,136</sup> Relaxin levels may serve to keep the uterus quiescent until parturition is imminent.<sup>135,137-139</sup> Relaxin is thought to be involved in softening the pelvic ligaments to facilitate fetal passage. Mares may be seen to develop a relaxed croup just before foaling. The myometrium becomes more responsive to oxytocin and PG, and eventually the high concentrations of oxytocin and PGs may overcome the inhibitory effects of relaxin.\* The sudden dominance of estrogen is thought to promote cervical production of PGE<sub>2</sub>. PGF<sub>2</sub>- $\alpha$  promotes myometrial contractility by acting on intracellular calcium, but PGE<sub>2</sub> promotes cervical relaxation.<sup>83,146</sup> The

contracting myometrium forces the chorioallantoic sac against the softening cervix, and stage I of parturition ensues. The expulsive efforts during vaginal passage of the foal are driven by rising oxytocin and PG levels.<sup>94,147-149</sup> Oxytocin and PG levels reach peak concentrations during the expulsive (stage II) phase of parturition.<sup>137,149,150</sup> Maternal straining (contraction of the abdominal muscles) is almost always associated with large sustained uterine contractions.

In the last week before foaling, the prolactin concentration increases, and it is this hormone that drives mammary development and the initiation of lactation.<sup>151,152</sup> Prolactin (PRL) release from lactotrophs in the anterior pituitary is regulated by hypothalamic secretion of PRL-releasing factor. The PRL-inhibiting factor is thought to be dopamine.<sup>153-156</sup> Oxytocin is synthesized in the supraoptic and paraventricular nuclei of the hypothalamus. Milk is produced in the alveoli and expelled into the lactiferous ducts and teat cisterns when oxytocin causes contraction of the myoepithelial cells. Although it is assumed that nursing by the foal stimulates the release of oxytocin from the neurohypophysis, recent research has revealed that the process is more complicated in the mare.<sup>149</sup> A significant effect of suckling on oxytocin release by the mare was detected in only two of nine mares, when oxytocin concentrations were evaluated 0 to 3 minutes after suckling. When foals were prevented from suckling for 1 hour, by being either muzzled ( $n = 2$ ) or separated from the mare ( $n = 2$ ), there was no significant association between resumption of suckling and oxytocin release by the mare.<sup>149</sup>

## MYOMETRIAL ACTIVITY

The myometrium of the uterus is composed of an inner circular and an outer longitudinal smooth muscle layer. This arrangement of muscle fibers permits regulation of luminal size (circular) and uterine length (longitudinal).<sup>3</sup> The uterus is palpably flaccid during and immediately after estrus and then increases in tone and becomes turgid if the mare is pregnant.<sup>157,158</sup> Myometrial activity is vitally important in the uterine clearance mechanism after breeding.<sup>159,160</sup> Uterine contractions also play an integral role during the embryo mobility phase.<sup>157,161-164</sup> Between at least day 9 and day 16 after ovulation, the spherical equine conceptus migrates continuously throughout the uterine lumen, propelled by peristaltic myometrial contractions.<sup>3,9</sup> This unusually long period of intrauterine movement ensures that the conceptus delivers its antiluteolytic signal to the entire endometrium. Conceptus mobility is high between day 10 and day 14 after ovulation but can be reduced immediately, and markedly, by an intravenous injection of flunixin meglumine. This suggests that PGs are the primary stimulus for the myometrial contractions that drive migration of the conceptus.<sup>9</sup> The embryo itself produces a myometrial stimulant, and the subsequent uterine contractions result in embryo mobility.<sup>6,161</sup> The conceptus produces estrogens by day 12, and these, along with embryonic production of PGE<sub>2</sub>, are thought to play a role in stimulating uterine contractions and increasing uterine tone during the mobility phase.<sup>165-170</sup> Progesterone is vital for embryonic development, and it plays a role in the mobility, fixation, orientation, and maintenance of the equine conceptus.<sup>171</sup>

Because there is little, if any, progesterone in the maternal circulation during late gestation, the quiescence of the uterus is thought to be maintained by progestagens—uteroplacental metabolites of pregnenolone and progesterone.<sup>83,109</sup> These

hormones are thought to play a significant role through a paracrine action within the fetus and uteroplacental tissues.<sup>83</sup> Administration of a progestagen (altrenogest) will prevent PG-induced abortion in the first trimester of pregnancy.<sup>172</sup> There is considerable controversy and confusion surrounding the use of progestagen supplementation in the later trimesters.<sup>83</sup> The cellular mechanisms involved in myometrial contractility have not been well characterized in the pregnant mare, and it may not be appropriate to extrapolate from studies in nonpregnant mares.<sup>11,12,173-176</sup> The classic theory in many species is that myometrial excitation and uterine contractility are suppressed by the so-called progesterone block.<sup>177</sup> Progesterone and progestagens were once assumed to be necessary for myometrial quiescence in the pregnant mare, and it was also thought that binding of 5 $\alpha$ -dihydroprogesterone to endometrial progesterone receptors controlled uterine PG production and inhibited myometrial activity.<sup>47,83,105,113,115,178</sup> It is now known that 5 $\alpha$ -dihydroprogesterone binds to uterine progesterone receptors more strongly than progesterone itself.<sup>179</sup> The oxytocin-neurophysin I gene is transcribed into mRNA in the endometrium of mares, and mRNA levels are negatively correlated with serum progesterone concentrations.<sup>180</sup> However, progestagens were ineffective at controlling myometrial contractility *in vitro* and did not inhibit the effects of oxytocin.<sup>181,182</sup> A pregnancy-induced inhibition of PGF<sub>2</sub>- $\alpha$  release is not associated with suppression of oxytocin release or oxytocin receptor density, and an embryo-derived factor is thought to be the most likely cause for the suppression of PGF<sub>2</sub>- $\alpha$  release and interruption of the oxytocin-PGF<sub>2</sub>- $\alpha$  interaction in mares during early pregnancy.<sup>11,12</sup> An oncofetal protein that is found in the placenta has been shown to reduce oxytocin-induced myometrial contractions *in vitro*, and this protein may play a role in controlling myometrial quiescence in mares as well.<sup>83,181</sup> A reduction in circulating progestagen levels by experimental blockade with the 3 $\beta$ -hydroxysteroid dehydrogenase inhibitor (epostane) did not increase myometrial activity (labor) in late-gestation pony mares.<sup>104,112</sup> However, despite a paucity of evidence that a deficiency of fetoplacental progestagen production is a cause of pregnancy loss in the mare, exogenous progestagen therapy is widely used as a form of preventive insurance in the belief that it will promote uterine quiescence and guard against the possibility of pregnancy failure.<sup>83,102,109</sup> The progestagens may enhance the activity of the endometrial enzyme 15-hydroxyprostaglandin dehydrogenase and thus promote rapid metabolism of PGs into inactive metabolites.<sup>83,105</sup>

Electromyographic activity in the uterus of pregnant mares increases during the last week before foaling—even though the circulating progestagen levels are still quite high.<sup>120,121,137,183</sup> There is a progressive, reversible rise in myoelectrical activity at night in the last 6 days preceding parturition.<sup>184</sup> The endocrine profile of the periparturient mare is characterized by increasing concentrations of progestagens and decreasing estrogens.<sup>89,131</sup> Despite this decline, estrogens are essential for normal parturition in the mare. Recent work suggests that nightly elevations in estradiol-17 $\beta$  levels may bring about changes in the uteroplacental tissues that facilitate the PG and oxytocin release that is necessary to promote the onset of myometrial contractions.<sup>83,131</sup> Pashen and Allen showed that if the fetal gonads were removed, the pregnancy would continue, but there were weak ineffective myometrial contractions and significantly reduced PG production during labor.<sup>79</sup> The high levels of relaxin in the periparturient

mare may act by inhibiting myometrial contractions until rising oxytocin and PG concentrations become overwhelming.<sup>120,137</sup> The number of oxytocin receptors and myometrial gap junctions may not increase until just before parturition in the mare.<sup>120,137,181</sup> At that time the myometrium becomes remarkably sensitive to even low doses of oxytocin.<sup>185</sup> A rapid membrane depolarization will result in the onset of strong, coordinated uterine contractions that characterize the first stage of labor. In the last 6 hours before rupture of the chorioallantois, a significant increase in PGF<sub>2</sub>- $\alpha$  concentrations occurs before there is a significant increase in oxytocin concentration.<sup>149</sup> Even if the PGF<sub>2</sub>- $\alpha$  concentrations are reduced by the cyclooxygenase inhibitor flunixin meglumine (1.1 mg/kg), oxytocin administration can still facilitate an expedient delivery.<sup>150</sup> Oxytocin levels in naturally foaling mares reach peak concentrations during the expulsive (stage II) phase of parturition.<sup>137,149,150</sup>

## TERATOGENESIS

Little is known about the embryotoxic, and possible teratogenic, effects of chemicals, drugs, and other agents that may be administered to pregnant mares. Goiter has been reported in two newborn Arabian foals after the mares had been supplemented with excess iodine during the final 24 weeks of pregnancy.<sup>186</sup> Phenothiazines, thiabendazole, and organophosphate anthelmintics have been reported to cause pregnancy loss.<sup>187</sup> Likewise, Sudan grass or sorghum pastures have been reported to be toxic to the fetus.<sup>187,188</sup> In recent years more definitive documentation has become available with respect to the toxic effects of some medications. When griseofulvin was used to treat dermatomycosis in a mare during the second month of pregnancy, the mare carried a male foal to 331 days' gestation.<sup>189</sup> The foal showed bilateral microphthalmia, severe brachygnathia superior, and palatocheilosis. The lesions were incompatible with life, and the animal was euthanized.<sup>189</sup> Griseofulvin administration during pregnancy has been associated with similar lesions in other species. Given that the development of the eyes and facial bones in the horse occurs in the second month of pregnancy, the lesions described in this case most likely can be attributed to griseofulvin administration.<sup>189</sup> Three weak, recumbent neonatal foals with skin lesions, including a thin, woolly coat, were born to mares being treated for equine protozoal myeloencephalitis. The foals were anemic, leukopenic, azotemic, hyponatremic, and hyperkalemic.<sup>190</sup> The pregnant mares had received sulfadiazine or sulfamethoxazole-trimethoprim, pyrimethamine, folic acid, and vitamin E orally. Serum folate concentrations in the three foals and two mares were lower than those reported in the literature for clinically normal brood mares.<sup>190</sup> At necropsy each foal had lobulated kidneys with thin cortices and a pale medulla. The spleen and thymus were small. Histologic examination revealed marked epidermal necrosis without inflammatory cells, thin renal cortices, renal tubular nephrosis, lymphoid aplasia, and bone marrow aplasia and hypoplasia.<sup>190</sup> These observations indicated that oral administration of 2,4-diaminopyrimidines (pyrimethamine with or without trimethoprim), sulfonamides, and folic acid to mares during pregnancy is related to congenital defects in newborn foals.<sup>190</sup> Further investigations are warranted to ascertain the toxic agent and to determine at what stage of gestation the fetus is most vulnerable.

## ☪ PREGNANCY DIAGNOSIS

Standard transrectal imaging technique will permit an experienced practitioner (using a 5-MHz ultrasound transducer under optimal lighting conditions) to detect up to 98% of embryos as early as day 11 after confirmation of ovulation.<sup>191</sup> The black (anechoic) spherical vesicle is characteristic of early equine pregnancy. Novices should realize that bright white (echoic) spots on the upper and lower surfaces of the black sphere are specular reflections generated by the ultrasound waves.<sup>192</sup> They also must appreciate that the equine embryo can be anywhere in the uterine lumen before fixation on day 16. Diagnostic errors can easily be made unless the entire length of both horns, and the uterine body down to the cervix, are meticulously searched during an ultrasonographic examination. Confirmation of mobility is useful in differentiating a vesicle from a cyst. At the time of fixation at the base of a uterine horn, the yolk sac has three germ layers (ectoderm, mesoderm, endoderm) near the embryonic pole, and only two layers (ectoderm and endoderm) at the opposite pole.<sup>3,4</sup> The difference in rigidity between the three-layered ventral wall, and the two-layered dorsal wall explains the characteristic guitar pick-shaped image on ultrasound by day 18.<sup>3,4</sup> The thickest portion of the yolk sac wall (embryonic pole) rotates to a ventral position. The change from the previous spherical shape is due to uterine turgidity and thickening of the dorsal uterine wall.<sup>174</sup> The increased uterine tone is responsible for the failure of the embryonic vesicle's diameter to enlarge between day 18 and 26, thus creating the classic growth profile that plateaus during this period.<sup>4,191</sup>

By day 21 the amniotic cavity has completely formed and the embryo itself can often be detected by ultrasound. The allantoic sac can be seen to be raising the embryo off the ventral floor by day 24. The embryo itself can be seen suspended on a thin echoic line that delineates the apposition of allantois and yolk sac.<sup>4,191,193</sup> This separating membrane tends to be horizontal and thus is a useful means for differentiating a singleton from twin embryonic vesicles. In the latter case the adjacent walls of the two vesicles tend to form a vertical separation. The primitive heartbeat can be detected between 22 and 25 days and is a useful indicator of embryonic viability. By day 40 the embryo (now fetus) has been elevated to the dorsal pole because the allantois has almost completely displaced the vestigial yolk sac. The membranes and blood vessels that separate the allantois and yolk sac give rise to the umbilical cord. The increasing size of the fetus causes the fetus and amniotic sac to gradually descend back to the floor of the chorioallantoic vesicle by day 48. The remnant of the yolk sac is incorporated into the umbilical cord. The site where the umbilical cord attaches to the chorioallantois identifies the horn and site where embryo fixation originally occurred. The dorsal attachment ensures that the developing fetus will not compress this vital area.<sup>4</sup>

Although ultrasonographic examinations have become standard practice for confirmation of pregnancy in mares, it is still essential that the veterinarian be competent at manual diagnosis. By 18 days after breeding, an experienced clinician may be able to perceive changes in uterine tone and consistency that, coupled with palpation of a narrow elongated cervix, are consistent with early pregnancy. However, it should be remembered that it is not uncommon for a persistent CL to provide a prolonged progesterone environment in a nonpregnant mare. It is important not to mistake the curvature at the base of the uterine horn for an embryonic vesicle.<sup>3,158,194</sup> An

ultrasound image of the embryonic vesicle is required to definitively confirm pregnancy at this early stage. However, the gradually enlarging embryonic vesicle will eventually create a discernible ventral bulge that has been described as being the size of a hen's egg (day 30), goose's egg (day 35), and orange (days 40 to 45).<sup>194,195</sup> Because there is minimal dorsal distention at this stage of pregnancy, it is essential that the ventral aspect of each uterine horn be examined. Errors can be made if the fingers are not passed far enough around the cranial aspect of the uterine horn so as to reach well under the uterine body and horns.<sup>194</sup> A ventral bulge that is consistent with a 35- to 45-day pregnancy can be identified by the distinct margins that are palpable when the fingers are moved along the ventral aspect of the uterus. The conceptus becomes more oval as it expands during the third month of pregnancy. At 90 days the chorionic vesicle is comparable in size and shape to a football.<sup>194,195</sup> The mare's age and the number of previous foals will affect the rate of descent of the gravid uterus over the pelvic brim.<sup>195,196</sup> Positive pregnancy diagnosis becomes progressively more difficult as the large, heavy uterus descends into the abdominal cavity. Normal pregnant mares should have a thin, pliable uterine wall, whereas pyometra cases have a thickened uterine wall and viscous purulent fluid in the uterus. The fetus itself is not always palpable before 120 days of gestation, but after that time gentle ballottement will usually reveal the fetus.<sup>194,195</sup> Palpation of some part of the fetus should be able to confirm pregnancy status between 5 months and term.

Blood tests for pregnancy are sometimes indicated, especially in miniature breeds.<sup>100</sup> Measurement of eCG levels verifies that the mare has endometrial cups but does not guarantee that a viable fetus is still present.<sup>3</sup> With this caveat in mind, eCG is suitable for determining pregnancy status in miniature mares between 40 and 100 days after mating.<sup>197</sup> However, mares that have been diagnosed as pregnant should undergo a blood estrone sulfate test 100 or more days after mating to eliminate the possibility of a false-positive diagnosis. Large quantities of estrogen are secreted by the fetoplacental unit.<sup>88,100</sup> Measuring blood estrone sulfate levels is recommended as the method of choice for determining pregnancy status in miniature mares 100 or more days after mating.<sup>198</sup> Fecal estrone sulfate measurements provide a noninvasive alternative to blood testing from 150 days after mating. However, the discrimination between pregnant and nonpregnant levels of estrone sulfate is not as great in feces as it is in blood.<sup>197</sup> An early pregnancy factor (EPF) test has recently been reported to be useful to confirm pregnancy in the mare.<sup>199</sup> EPF is an immunosuppressive protein detected by a rosette inhibition test in the early pregnancy serum. EPF appears in the maternal blood circulation 24 to 72 hours after mating. It can be detected until the second trimester, and after that it disappears from the maternal serum.<sup>199</sup> Unfortunately, the early conception factor (ECF) assay test that has been marketed for horses has not proved to be a reliable method for detecting the presence of an embryo.<sup>200,201</sup>

## MANAGEMENT OF TWINS

### MONITORING FOLLICULAR DEVELOPMENT AND OVULATION

Most twin pregnancies arise from double ovulations.<sup>202-205</sup> There is a higher incidence of twin ovulations in some breeds (e.g., Thoroughbreds, Warmbloods), and mares that

tend to double ovulate can be expected to do this frequently.<sup>3,203,205-209</sup> In one study of 1581 Thoroughbred mares, multiple ovulation occurred in 29.3% of cycles. Multiple ovulation incidence significantly ( $p < 0.05$ ) increased with age (20.7% in 2- to 4-year-olds; 35.6% in 17- to 19-year-olds).<sup>210</sup> Double ovulations may occur on the same day or 2 days apart.<sup>3,211</sup> If a fertile stallion was used to breed the mare on the first ovulation, it is possible that viable sperm will still be present in the reproductive tract when the second oocyte arrives. This possibility must be remembered when scanning mares for pregnancy at 13 to 16 days. At that time it is good practice to scan the ovaries for evidence of luteal tissue from a second ovulation. In a large Thoroughbred study, 25.2% of multiple ovulations were apparent as multiple pregnancies and 37.8% as single pregnancies at 13 to 14 days after ovulation.<sup>210</sup> In another study of English Thoroughbreds, the rate of twin vesicles being present at days 13 through 16 after ovulation was reported as between 10.3% and 13.1%.<sup>212</sup> This was similar to a Swedish study (n = 430) wherein the frequency of twin vesicles at days 14 through 15 was 10.5%.<sup>213</sup>

In the past veterinarians often elected to discourage breeding of a mare when two large (>30-mm) follicles were palpated or to recheck the second follicle 10 to 12 hours after the first detected ovulation.<sup>214</sup> Because an ovulated oocyte is less likely to result in a viable embryo after this time, a delayed breeding could be performed in anticipation of the second ovulation. Today the preferred strategy is to breed all eligible mares—irrespective of the number of preovulatory follicles. The widespread adoption of early ultrasonographic pregnancy examinations has permitted the focus to be placed on embryonic vesicle reduction after the presence of a twin pregnancy is confirmed.<sup>84,215</sup>

## MANUAL REDUCTION

The increasing size of the embryonic vesicle, coupled with the increasing tone of the early pregnant uterus, tends to fix the conceptus at the base of one uterine horn by day 16.<sup>3</sup> It is essential that the ultrasound scan of the uterus be thorough, with a complete examination of the length of both horns plus the uterine body as far back as the cervix. This is especially important before day 16 because the vesicle moves freely within the lumen of both horns and the uterine body.<sup>211</sup> If twin vesicles are detected, manually separating them before day 16 will be easier. Successful elimination of one vesicle is more likely at that time because the uterine walls are thin and minimal pressure is required to crush a vesicle.<sup>215</sup> A definite *pop* can often be felt when the vesicle ruptures, but success always should be confirmed by ultrasound. This sensation is attributable to the rupture of the embryonic capsule.<sup>5,216</sup>

The downside to this approach is that an early embryonic vesicle can easily be confused with an endometrial cyst. The embryo itself does not become readily identifiable until the fourth week of pregnancy. Thus it is good practice to note the size and location of any cysts at the time the mare is being examined for breeding. If there is no record of cyst size and location, then it is virtually impossible to tell early twin vesicles from a singleton and a cyst with a single examination. This is especially true insofar as asynchronous ovulations are likely to result in considerable size discrepancy between the two vesicles.<sup>3</sup> Under these circumstances it may be best to measure each suspect vesicle and note its location. A second scan in 1 or 2 days should note a size increase in any normally

growing vesicle (approximately 4 mm per day).<sup>191</sup> Unfortunately, this delay may make separation of unilaterally fixed vesicles more difficult because of their ongoing growth and the increased uterine tone.

Manual reduction of bilaterally fixed vesicles requires less manipulation than with unilateral twins. It is a relatively easy procedure, and success rates exceeding 90% are not uncommon if the vesicle is crushed before day 16.<sup>213,215,217,218</sup> After fixation a success rate of 75% is still possible if the bilateral twin is crushed before day 30.<sup>215</sup> If the vesicles are unilaterally fixed, then the clinician should attempt to move the more proximal vesicle toward the tip of the uterine horn. At this location the manual reduction procedure is less likely to disrupt the remaining vesicle. The vesicle can be crushed by pinching it between the thumb and fingers. Alternatively, the vesicle is squeezed against the mare's pelvis until it ruptures. If the twins can be separated before crushing, then the success rate may be similar to that for reduction of bilateral twins.<sup>219</sup> If the unilateral twins cannot be separated or are greater than 20 days' gestation, then the success rate is lower.<sup>84</sup> Because of the extra pressure used to eliminate a twin vesicle after fixation, many clinicians administer anti-inflammatory medications and progestin therapy. When crushing is performed within 19 days of conception, significant changes in 15-ketodihydro-PGF ( $\gamma$ - $\alpha$ ), cortisol, or progesterone plasma concentrations do not seem to occur.<sup>220</sup> The likelihood of success improves with experience.<sup>215,218</sup> If the unilateral vesicles are not detected until after day 20, manipulations can easily result in the disruption of both vesicles. The best option in these cases may be to wait and see whether natural reduction occurs.

### NATURAL REDUCTION

There is negligible natural reduction of twins before day 15, when the vesicles are close to the end of their mobility phase.<sup>215</sup> Thus manual reduction is the treatment of choice if twins are diagnosed before fixation. Almost three quarters (70%) of twin embryonic vesicles become fixed unilaterally, with only 30% of twin vesicles becoming fixed bilaterally.<sup>221,222</sup> When twin vesicles are dissimilar in size, there appears to be a much higher incidence of unilateral fixation. The larger vesicle is thought to serve as an impediment to the continued mobility of the smaller vesicle.<sup>4</sup> Fortunately, natural reduction to a singleton is far more likely with unilaterally fixed vesicles. More than 80% of unilaterally fixed twins are likely to naturally reduce to a singleton, with over half of these occurring between days 16 and 20.<sup>3,221,222</sup> On the other hand, the majority of bilaterally fixed vesicles will continue to develop. The proposed mechanism for reduction has to do with loss of apposition between the embryo's trophoblastic surface and the endometrium, especially if the embryo proper is adjacent to another vesicle.<sup>4,221,223</sup>

### PREGNANCY TERMINATION WITH PROSTAGLANDIN

The probability of natural reduction occurring decreases significantly by day 40.<sup>215,224</sup> If natural reduction does not occur, termination of the early pregnancy with a PG injection may be considered. This should lyse the CLs that resulted from the double ovulation, and the precipitous decline in progesterone will bring the mare back into estrus. However, treatment failures have been reported, and successful termination of the

pregnancy should be confirmed by ultrasound.<sup>225</sup> Certainly, this treatment must be given before day 35 because once the endometrial cups begin to form, repeated PG injections may be necessary to terminate the pregnancy.<sup>32,226</sup> Owners should be aware that the mare is unlikely to return to normal ovulatory cycles until the cups are sloughed. In the interim they secrete eCG, a hormone that causes the development of accessory CLs.<sup>3</sup> The result is erratic estrous behavior, unreliable follicular development, and unpredictable ovulation.<sup>32</sup>

If a mare carries twins into the latter half of gestation, it is quite likely that abortion will occur between 7 and 9 months. Induced abortion is not without risk, and owners should be aware of the potential for dystocia, cervical lacerations, and fetal membrane retention.<sup>215</sup> Although several researchers have investigated induction of parturition at term, few protocols for early termination of an advanced pregnancy have been published.<sup>215</sup> The natural PG analog cloprostenol has been used at various doses and frequencies, but results are inconsistent with respect to efficacy and duration to fetal expulsion.<sup>172,215</sup> Daels administered cloprostenol (250  $\mu$ g) daily until fetal expulsion, or for up to 5 days in mares that were 98 to 153 days pregnant. Fetal expulsion occurred after 2 to 3 cloprostenol administrations.<sup>172</sup> Wolfsdorf used a higher dose of cloprostenol (375  $\mu$ g IM) at 20-minute intervals for two doses, with repeated daily injections as necessary.<sup>215,227</sup> The addition of intracervical PGE on the second day may help dilate the cervix and hasten delivery.<sup>215,228</sup>

### TRANSVAGINAL ULTRASOUND-GUIDED TWIN REDUCTION

Even though the advent of transrectal ultrasonography has dramatically improved the ability of veterinarians to make an early diagnosis of twin pregnancies, diagnostic errors still occur.<sup>229,230</sup> This could be due to an early pregnancy diagnosis when the second vesicle was too small to detect; incomplete examination of the entire uterus; poor image quality; or an inability of the clinician to differentiate two embryonic vesicles that are closely apposed to each other.<sup>230</sup> If natural reduction does not occur or the diagnosis of twins is not confirmed until after 30 days, transvaginal aspiration of one vesicle is an option.<sup>84,215,231</sup> The results are best if the procedure is performed before day 35, preferably before day 25.<sup>84,215,231</sup> Although spontaneous reduction of twin pregnancies can occur even after day 40, the probability of this occurring is low.<sup>50,224,232</sup> Natural twin reduction is more likely to occur if an obvious size discrepancy between the two vesicles is present at this time.<sup>215,221,223</sup>

If a transvaginal reduction is to be attempted, the mare should be treated with flunixin meglumine. Many clinicians will also administer oral altrenogest. Because sedation causes significant uterine relaxation, most clinicians use a lidocaine enema to reduce straining.<sup>233</sup> The transvaginal aspiration technique employs a 5.0- or 7.5-MHz endovaginal curvilinear transducer. The transducer and casing should be cold-disinfected or sterilized before use. The assembled unit is then placed in a sterile transducer cover that has been filled with sterile lubricating gel. The transducer is advanced aseptically until it is seated lateral to the cervix. The clinician grasps the pregnancy rectally and advances a sterile, 60-cm, 18-gauge spinal needle with an echogenic tip along the needle guide in the transducer casing. A dotted line on the ultrasound screen can be used to select a path for the needle entry into the embryonic

vesicle. A sharp jab of the needle penetrates the vaginal wall, peritoneal lining, uterus, and ultimately the allantoic or yolk sac. A 60-ml syringe is attached to the needle, and the embryonic fluid is aspirated. Aspiration should be stopped when there is a danger of damaging the adjacent vesicle of unicornuate twins. If a bilateral twin is being eliminated, the needle can be moved within the vesicle until all detectable fluid has been aspirated.<sup>84,215</sup> The success rate is better for bicornuate twin reductions.<sup>233</sup> Death of the remaining twin is most likely to occur within 2 weeks of the procedure. Although reports are scarce, preliminary data suggest that experienced operators may achieve a live singleton birth in about one third of cases.<sup>215</sup>

## CRANIOCERVICAL DISLOCATION

Results of postfixation twin reduction techniques have been inconsistent with regard to producing a single healthy foal. A craniocervical dislocation method recently was proposed. The procedure entails dislocating the first cervical vertebra from the cranium, disrupting the ligamentous attachments, and severing the spinal cord.<sup>215</sup> A transrectal approach may be performed on a sedated mare between 60 and 90 days. Propantheline bromide (30 mg IV) is recommended to relax the smooth muscles of the uterus and rectum, and flunixin meglumine (1 mg/kg) is administered to inhibit PG release. Daily altrenogest (0.088 mg/kg) is suggested for 3 to 4 weeks. A surgical procedure has been used on twin pregnancies of between 2 to 4 months' duration, when attempts at the technically difficult transrectal reduction have been unsuccessful.<sup>215</sup> This new technique enables the twin to be reduced before complete placenta formation has occurred, allowing the remaining fetus to use the entire endometrial surface and to grow to its full potential.<sup>215</sup>

## TRANSCUTANEOUS (ABDOMINAL) ULTRASOUND-GUIDED FETAL PUNCTURE

In advanced twin pregnancies (up to approximately 5.5 months), it is possible to attempt reduction by a transabdominal approach.\* Fetal intracardiac injection of potassium chloride (KCl) is effective but requires accurate placement of the KCl into the fetal heart. Best results are obtained when the pregnancy is between 115 and 130 days.<sup>236</sup> At this stage experienced operators can achieve a 50% success rate.<sup>219</sup> Procaine penicillin G (PPG) can cause fetal death when injected into either the fetal thorax or abdomen, but the effect is not instantaneous. The advantage of the latter treatment is that it does not require precise placement of the injection into the fetal heart.<sup>219,226</sup> PPG also reduces the likelihood of bacterial infection, and the injection can be visualized on the ultrasound screen.<sup>226</sup> The author has managed a case that aborted the twins along with mucopurulent exudate, and it is likely that infection resulted from bacterial contamination at the time of the fetal injection. Mares should be started on oral altrenogest, systemic antibiotics, and flunixin meglumine on the day of the procedure. The antibiotic coverage and anti-inflammatory medication should be continued for 3 days.<sup>84,226</sup>

A 3.0-mHz transducer can be used to image the 90- to 130-day fetus in the caudal abdomen, just cranial to the udder, and

best results may be obtained after day 115.<sup>226,230</sup> Once the mare has been sedated, the uterus will relax and the location of the fetuses will shift cranially. A sedative-analgesic combination that works well for this procedure is acepromazine (10 mg), xylazine (100 mg), and butorphanol (10 mg).<sup>215,230</sup> The smallest or most easily accessible fetus is selected for reduction. The ventral abdomen should be surgically prepared, and local anesthetic infiltrated at the puncture site. An 18-gauge, 8-inch spinal needle with stylet can be used for most fetal injections, but the length of the needle is determined by the depth of the fetus from the abdominal wall.<sup>215,226,230</sup> Specialized needles with echogenic tips are available to provide better visualization via ultrasound.<sup>219</sup> Once the location of the selected twin's thorax is confirmed, the needle is introduced through the prepared skin, abdominal wall, and uterus. If PPG is to be injected, the needle may puncture either the fetal thorax or abdomen. Up to 20 ml is typically injected into the fetus.<sup>219,230</sup> Fetal death should be confirmed the next day.<sup>226</sup>

Although the benefits of supplemental progestin therapy are debatable, many clinicians suggest that the mare be medicated for at least 2 weeks if the initial twin reduction has been successful.<sup>226,230</sup> It is essential that fetal viability be checked regularly because supplemental progestin therapy may prevent elimination of the dead fetuses if both die.<sup>237</sup> Most abortions occur within 1 to 2 months after the reduction procedure.<sup>84</sup> If the operator is experienced in the technique, between 40% and 60% of cases can be expected to deliver a viable singleton foal.<sup>215,219,230</sup> The eliminated twin in these cases can be seen as a mummified remnant contained within an invaginated pouch that protrudes into the allantoic space of the viable foal's fetal membranes.<sup>215,226,235</sup> One theory for the loss of both twins after an intrafetal injection has to do with the presence of vascular anastomoses between the two fetoplacental units.<sup>238</sup> It has been suggested that circulation of either the injected solution or other tissue degradation products could result in the death of the adjoining twin fetus.<sup>230</sup> Small anastomosing vessels are present between twin vesicles as early as 40 to 60 days' gestation.<sup>239</sup>

## ☾ EARLY PREGNANCY LOSS AND ABORTION

### EMBRYONIC LOSS

Once conception has occurred, any pregnancy failure up to day 40 of gestation is defined as being early embryonic loss.<sup>3</sup> Between 10% and 15% of mares undergo embryonic loss or abortion at some time in gestation, and most of these losses occur during the first 40 days of gestation, when the primary CL is the sole source of progesterone.<sup>102,212</sup> However, all the available evidence suggests that untoward luteolysis is not common in this period, and the losses that do occur have other underlying causes.<sup>102</sup> In a study of 376 Thoroughbred pregnancies, 12.2% experienced embryonic loss within 45 days after ovulation,<sup>240</sup> whereas a much larger study (n = 3,373 mares) reported a loss of 7.2 to 8.0% by day 42.<sup>212</sup> Three quarters of the losses in the smaller study occurred between 16 and 25 days, and the loss was highest in previously barren mares, followed by aged mares (>15 years) and mares of more than 10 parities.<sup>241</sup> These results were similar to those reported in a Swedish study.<sup>213</sup> Increasing mare age was the single biggest limiting factor to an otherwise high rate of fertility in the larger study of

\*References 84, 215, 219, 226, 234, 235.

well-managed English Thoroughbreds.<sup>212</sup> A higher embryonic loss may be expected in mares that are bred during the first postpartum estrus and in those with cysts in the uterus.<sup>240</sup>

Fertilization failure rates and embryonic losses are higher in aged mares.<sup>242-246</sup> It is not easy to differentiate between fertilization failure and embryonic loss before day 10 because this is the earliest stage of development wherein ultrasonographic detection is possible under ideal research conditions. Fertilization rates in young, well-managed mares may exceed 90% and appear to be over 80% in aged mares.<sup>245,247</sup> Oocytes from aged mares may be more likely to result in nonviable embryos because of inherent morphologic defects.<sup>245,248</sup> Carnevale transferred oocytes from young and aged mares into young recipients so that fertilization and early embryonic development occurred in an optimal oviductal environment. The day 12 pregnancy rate in the recipients that received the oocytes from aged mares was significantly less than that achieved with the younger mares' oocytes.<sup>249</sup> Research has shown that embryo recovery rates are considerably lower in aged mares and that there are significant losses occurring before day 14 of pregnancy.<sup>243,250-252</sup> The uterine environment may not be the only reason for subfertility in some mares. Embryos collected from normal mares resulted in similar pregnancy rates in both fertile and subfertile recipients (significant uterine pathology) at day 28.<sup>253</sup> In a reversal of study design, embryos were collected from the oviducts of normal and subfertile mares 4 days after ovulation, then transferred into normal recipients. Pregnancy rates were lower in those normal mares that received embryos from the subfertile donors.<sup>250</sup> Thus, although the uterine environment may have a delayed effect on embryonic and fetal loss, it appears that oocyte quality and oviductal influences play a significant role in the problem of subfertility and early embryonic loss in mares.<sup>254</sup> In practice, embryonic losses that may be detected between days 14 and 40 can range between 8% to 15% in young, well-managed mares to 25% or 30% in aged mares.<sup>212,247,255</sup> The presence of endometrial inflammation and uterine fluid accumulation will have a detrimental effect on early embryo survival and can markedly increase the likelihood of early pregnancy loss.<sup>240,256,257</sup>

## EARLY FETAL LOSS

Formation of the endometrial cups is a defining moment with regard to early pregnancy loss in mares. If the embryo dies before day 35, the chorionic girdle cells do not invade the endometrium and the endometrial cups do not form. These mares should return to normal estrous cycle activity and may be successfully bred again during the same breeding season. However, if the fetus is lost after day 40, the endometrial cups are irreversibly established.<sup>3</sup> Thus, if an assay for eCG (a MIP test) is performed after the endometrial cups form, a false-positive test for pregnancy will be obtained until the endometrial cups are sloughed between days 120 and 140 after the original conception occurred.<sup>3</sup> Retention of the endometrial cups after fetal loss results in erratic estrous behavior, unreliable follicular development, and unpredictable ovulation.<sup>32</sup> Thus this unique physiologic mechanism typically prevents mares suffering fetal loss after endometrial cup formation from being bred back during the current breeding season.<sup>85</sup>

A large study of Thoroughbred mares revealed an overall pregnancy loss of only 4% to 6% between day 40 and day 150 of gestation and then only a further 2% to 3% until term.<sup>212</sup> The exact mechanism that causes most pregnancy

losses in the mare remains to be elucidated but may include chromosomal errors and endometriosis.<sup>44,51,212,258</sup> Beyond day 40 the secondary CLs receive powerful luteotrophic support from eCG, and from day 80 to day 100 until term the supply organ (placenta) and target tissues (endometrium and myometrium) are in direct contact with one another over their entire surfaces.<sup>32,102</sup> Little evidence suggests that a deficiency of progesterone production is a cause of pregnancy loss in the mare.<sup>102</sup> Certainly, fetal death may follow uteroplacental insufficiency, or an overwhelming sepsis.<sup>212,258</sup> In recent years there has been a broad consensus that the inflammatory mediator PGF<sub>2</sub>- $\alpha$  may play an integral role in many cases.<sup>107</sup> It is well known that PGs are luteolytic.<sup>3</sup> Thus, in the first 70 to 80 days, when the pregnancy depends on progesterone production by the CLs (primary and accessory), it is especially susceptible to the luteolytic effects of PGs. However, it is important to remember that repeated exogenous PG injections may be required to electively terminate a pregnancy once the endometrial cups have formed. This is because some of the immature accessory CLs may not be sufficiently developed to respond to the first PG injection.<sup>32</sup> Another probable abortogenic feature of PGs may be myometrial hypermotility. This may be associated with placental inflammation or high systemic levels of PG.<sup>259</sup>

An early pregnancy may be lost subsequent to PG-induced luteal deficiency associated with endotoxemia.<sup>260-262</sup> The detrimental effect of the endotoxin could be prevented only if a cyclooxygenase inhibitor (flunixin meglumine) was administered before clinical signs of endotoxemia were evident.<sup>82,261,263,264</sup> Thus, although gram negative septicemia and endotoxemia associated with many gastrointestinal crises are known to result in elevated levels of inflammatory mediators, any pregnancy-sparing effect of PG inhibitors is likely to be effective only if anti-inflammatory agents such as flunixin meglumine are administered in the acute phase of the disease.<sup>258</sup> Because a healthy fetoplacental unit can produce enough progesterone to sustain the pregnancy after 80 days of gestation, the concept of prophylactic altrenogest past 3 months of gestation is controversial.<sup>82,102,107,172,265</sup>

Although recent *in vitro* studies suggest that progesterone may not be the primary regulator of myometrial quiescence, in situations where elevated PG levels are likely there appears to be adequate clinical justification at present to provide exogenous progestagen support for high-risk pregnant mares.<sup>89,181</sup> Based on our current knowledge, the administration of a double-dose (0.088 mg/kg/day) of altrenogest is suggested during the acute phase of a medical or surgical condition when PG levels are likely to be elevated.<sup>182</sup> If oral medication is not possible, short-term use of progesterone in oil (300 mg/day IV) is warranted. An intramuscular injection of a compounded long-acting progesterone formulation (BioRelease P4 LA 150) every 7 days may also be an efficacious and suitable alternative to currently available progesterone formulations that require daily administration.<sup>266</sup> Administration of supplemental progesterone is based on further work by Daels et al. demonstrating that progestin treatment could prevent PG-induced abortion at 3 to 5 months of gestation if a higher dose (0.088 mg altrenogest per kg) of progestin was administered.<sup>82,172</sup> Abortion did not occur in five of eight progesterone-treated mares and eight of eight altrenogest-treated mares, and endogenous PGF<sub>2</sub>- $\alpha$  secretion was inhibited, compared with values in aborting mares.<sup>172</sup> It was concluded that circulating progestagen concentrations may play a role in the outcome of

pregnancy during PG-induced abortion, as may occur after exposure to endotoxin.

It seems logical that separation of the chorioallantois from the endometrium will disrupt local endocrine function.<sup>267</sup> The fetoplacental unit does attempt to compensate for this placental dysfunction by increasing progesterone production.<sup>89,268</sup> However, endotoxemia may harm placental circulation and disrupt vital steroid metabolism within the fetoplacental unit.<sup>269</sup> Thus administration of flunixin meglumine to pregnant mares is indicated early in the course of any condition in which endotoxemia is possible.<sup>263,270,272</sup> If a mare develops a surgical colic condition during late pregnancy, the fetus is at risk not only from the maternal endotoxemia that can be associated with gastrointestinal crises but also from any maternal hypoxic episodes that may occur during anesthesia.<sup>269,270,272,273</sup> Acute enteritis or colitis in a pregnant mare can also result in abortion caused by the effects of endotoxemia.<sup>272,273</sup> Because maternal hypoxia is a risk factor for abortion, intraoperative hypoxia must be avoided if a pregnant mare requires surgery.<sup>272</sup> Approximately 16% to 20% of mares can be expected to abort after colic surgery, but superior intraoperative ventilatory techniques may reduce this risk.<sup>272,273</sup> Stage of gestation and duration of anesthesia are less critical factors if maternal oxygenation is adequate.<sup>274</sup> Apparently, aberrations in the cardiovascular and metabolic status of the mare and fetus are more detrimental to pregnancy maintenance than the actual medical or surgical condition.<sup>271</sup>

## PLACENTITIS

Placentitis is a major cause of abortion in mares during the latter part of pregnancy.<sup>229,275,276</sup> Inflammation of the placenta can affect the interchange of gases, nutrients, and waste products along with disruption of both fetal metabolic and endocrinologic pathways.<sup>277</sup> The disease tends to be a sporadic, individual mare problem that seldom has any lasting effect on mare fertility.<sup>278</sup> Both bacterial (*S. zooepidemicus*, *Streptococcus equisimilis*, *E. coli*, *Enterobacter agglomerans*, *P. aeruginosa*, *K. pneumoniae*) and fungal (*Aspergillus* spp.) organisms may be incriminated.<sup>49,196,267,279-283</sup> Ascending infections are especially common, and these tend to result in a necrotizing, suppurative inflammation with detachment of the placenta in the area surrounding the cervical star.<sup>283,284</sup> The cervix is almost invariably softened, with purulent exudates draining into the vagina.<sup>267,279,280</sup> Thus this part of the fetal membranes should be closely examined whenever a mare aborts. The vestibular sphincter and vulvar lips are important barriers to ascending infections, and many aged mares require a Caslick procedure to reduce the likelihood of ascending infections. Hematogenous infection of the placenta is also possible.<sup>279,280</sup> *Leptospira* spp. induce a diffuse placentitis with large numbers of spirochetes in the placental tissues (see separate discussion).<sup>285,286</sup> A recent report incriminated *Rhodococcus equi* as the cause of placentitis that resulted in abortion.<sup>287</sup> *Mycoplasma* spp. have been associated with infertility, endometritis, vulvitis, and abortion in mares.<sup>288</sup>

A unique form of placentitis was reported as being a sporadic cause of abortion and weak foals in central Kentucky during the 1990s.<sup>229,275,282,287,289-291</sup> A review of nocardioform actinomycetes-related placentitis cases over a 9-year period (1990 to 1999) revealed that of the farms that had cases, 83% had two or fewer over the 9 years and 66% of the farms had only a single case during that time.<sup>291</sup> The number of nocardioform

placentitis cases in central Kentucky has since decreased significantly, with only 93 cases being reported over six foaling seasons (2001-2007).<sup>282</sup> The causative organisms have recently been identified as *Crossiella equi* and *Amycolatopsis* spp.<sup>289,292-294</sup> These bacteria are responsible for nocardioform placentitis and are among the few actinomycetes known to cause disease in animals. Although numerous gram positive branching bacilli can be seen on histologic sections, the bacteria are seldom present in fetal tissue.<sup>286,291,295</sup> In vitro testing has demonstrated that the nocardioform bacteria are susceptible to sulfonamides and trimethoprim.<sup>286</sup> This combination is an ideal choice for systemic medication of a pregnant mare when placentitis is suspected because these antimicrobial agents are known to gain acceptable levels in the fetal fluids.<sup>296-298</sup>

Nocardioform placentitis was first diagnosed at the University of Kentucky in 1986 and has since been confirmed elsewhere in the United States and in other countries.<sup>286,294,295,299,300</sup> Although it has been suggested that the organism may gain access to the uterus at breeding, this unusual form of equine placentitis does not become apparent until the latter part of gestation.<sup>278</sup> The initial lesion is localized on the most dependent aspect of the chorion, in the cranioventral aspect of the uterine body, and then extends cranially onto the base of the horns and circumferentially around the placenta.<sup>282,301</sup> Outcomes vary from abortion to birth of a normal foal. Some foals are premature, whereas others are delivered at term but are either stillborn or weak and compromised, with an emaciated appearance.<sup>282,286,301</sup> Most affected mares appear normal, although many display signs of placentitis (premature mammary development and lactation).<sup>278,286,291,301</sup> Vaginal discharge is not a feature of this condition because the area around the cervical star is not involved. Once the fetus has been expelled, these mares rapidly clear the infection and experience no adverse effects on subsequent fertility.<sup>286,291</sup> When the fetal membranes are examined, there is an obvious line of demarcation between diseased and normal tissue, with the affected area being covered by a characteristic thick, brownish mucoid, viscous material.<sup>286</sup> The underlying chorionic villi are reduced in size and, in the central portion of the lesion, the chorionic surface may be completely denuded.<sup>301</sup>

A recent report from the University of Kentucky Livestock Disease Diagnostic Center suggests that two newly emerging abortigenic pathogens should be considered when placentitis is suspected.<sup>282</sup> Six cases of mycobacterial abortion and placentitis were confirmed by microbiologic, polymerase chain reaction (PCR), and histochemical staining procedures. The atypical mycobacteria were within the nontuberculous group and are classified as saprophytic and opportunistic microorganisms acquired from the environment (soil, water, decaying vegetation).<sup>282</sup> Gross lesions observed within the submitted cases varied from none to those of a "nocardioform-like" placentitis. Affected fetuses exhibited varying degrees of malnourishment and chronic placentitis. Several fetuses had granulomatous to pyogranulomatous pneumonia, and one fetus without pneumonia contained disseminated granulomas in various organs.<sup>282</sup> The other emerging organism is *Cellulosimicrobium cellulans*, a gram positive branching bacillus that is an opportunistic microorganism found in the soil.<sup>282</sup> The nine equine cases of abortion and placentitis resulting from *C. cellulans* described had nocardioform-like placentitis lesions as well as granulomatous pneumonia. Because atypical *Mycobacteria* and *C. cellulans* organisms can cause similar gross and histologic lesions within the fetus and placenta, they should be

considered as differential diagnoses when encountering gross placental lesions suggestive of nocardioform placentitis.<sup>282</sup>

Placentitis continues to represent a significant problem and is a common cause of equine abortions.<sup>282,283</sup> Placental thickening and separation from the endometrium are consistent features in many abortions.<sup>229</sup> Placentitis is detrimental to the pregnancy not only because it disrupts nutrient exchange but also because of the inflammatory mediators (proinflammatory cytokines) that are released. The exact cause of fetal expulsion is not known, but ensuring myometrial quiescence is central to most therapeutic regimens.<sup>184,302</sup> Placentitis cases have substantially increased concentrations of PGF<sub>2</sub>- $\alpha$  and PGE<sub>2</sub> in the allantoic fluid.<sup>303,304</sup> Thus anti-inflammatory medication (flunixin meglumine at 1.1 mg/kg; phenylbutazone at 4 mg/kg, every 12 hours) is indicated.<sup>259,305</sup> Placentitis associated with early abortions tends to be acute, with the fetus succumbing to bacteremia.<sup>284</sup> Broad spectrum antibiotics that have been recommended include trimethoprim-sulfadiazine (15-30 mg/kg PO every 12 hours), procaine penicillin (30,000 IU/kg/day) and gentamicin (6 mg/kg/day), and ceftiofur (1 to 5 mg/kg, every 12 hours).<sup>259,297,298,305,306</sup> Gentamicin was undetectable in the plasma of newborn foals after mares were treated with the antibiotic (6.6 mg/kg) an hour before parturition, and it was initially believed that gentamicin does not cross the placenta of mares at term.<sup>307</sup> More recently, Murchie et al. monitored drug concentrations in the allantoic fluid of pregnant pony mares using *in vivo* microdialysis to determine whether this method could detect allantoic concentrations of drugs in normal mares and those with placentitis.<sup>308,309</sup> Pharmacokinetic comparisons indicated that potassium penicillin G (22,000 IU/kg, administered 4 times daily) persists much longer in allantoic fluid than blood, whereas gentamicin (6.6 mg/kg/day) exhibited similar profiles in the two compartments. Flunixin meglumine (1 mg/kg b.i.d.) was not detected in allantoic fluid.<sup>309</sup> In infected mares penicillin G achieved a similar peak concentration in allantoic fluid, whereas peak gentamicin concentration appeared to be reduced relative to drug concentrations in noninfected mares. Thus penicillin G and gentamicin appear to undergo effective placental transfer in pregnant mares, but transplacental drug transfer may be altered selectively if active placental infection is present.<sup>308,309</sup>

If the localized production of high concentrations of PGs stimulates the formation of gap junctions, then the subsequent myometrial hypermotility may impede placental blood flow as the uterus contracts.<sup>107,184,302,310</sup> This will reduce fetal oxygenation and increase fetal stress. Because it is known that progesterone inhibits gap junction formation, it is clinically valid to conclude that progestin supplementation may be beneficial when uteroplacental inflammation is suspected. This is the rationale behind the current recommendation to treat suspected placentitis cases with a double dose of altrenogest (0.088 mg/kg/day).<sup>107,259,268,305</sup> Delaying premature labor long enough to allow accelerated fetal maturation to occur may improve foal survival rates.<sup>283</sup> The progestagens may also enhance the activity of the endometrial enzyme 15-hydroxyprostaglandin dehydrogenase and thus promote rapid metabolism of PGs into inactive metabolites.<sup>83,89,105</sup> Although altrenogest is not metabolized to 5 $\alpha$ -pregnanes, both 5 $\alpha$ -DHP and 3 $\beta$ -5P levels may be increased as a result of supplementation.<sup>311</sup> However, Ousey has suggested that progesterone supplementation may be contraindicated because high levels could inhibit the placental enzyme 3 $\beta$ -hydroxysteroid dehydrogenase.<sup>83,89,114,312</sup> This enzyme produces progesterone from

pregnenolone, and thus inhibition could interfere with the normal fetoplacental steroidogenic pathway.<sup>83,89</sup> Thus at present this widely used therapy remains controversial, and even if it does no harm, the expense of long-term progestin supplementation may not be warranted in many cases.<sup>83,102</sup> Essentially, the use of hormone therapies is subjective and reflects, to a large extent, our lack of understanding about the endocrine relations among the mare, placenta, and fetus.<sup>83,89,303</sup> Recent studies suggest that measurement of relaxin levels may serve as a useful means of monitoring placental function and treatment efficacy in the mare.<sup>313-315</sup>

The rationale for other treatment regimens is based on extrapolations from the human-medicine literature and application of sound reasoning for the potential efficacy of a particular drug. Scientific investigation in this area is crucial. Many equine clinicians have been advocating the use of an oral  $\beta_2$ -sympathomimetic drug (clenbuterol) to suppress uterine motility.<sup>259,305,316</sup> In the United States the product is marketed as an oral formulation to treat chronic reactive airway obstruction. Research is needed to determine what oral dose of this bronchodilatory compound—if any—is actually effective on the gravid uterus. In countries where an intravenous formulation is available, a 300- $\mu$ g intravenous dose of clenbuterol will reduce uterine tone for approximately 2 hours.<sup>317-319</sup> However, daily intravenous administration of clenbuterol to mares showing maximal milk calcium levels was not effective in preventing the onset of myometrial contractions and delivery in normal foaling mares at term.<sup>320</sup> The administration of pentoxifylline (8.5 mg/kg PO b.i.d.) is recommended, on the basis of its use in treating tissue ischemia in humans and its ability to modulate the inflammatory process by downregulating proinflammatory cytokines.<sup>259,283,297,305,321</sup> Pentoxifylline increases erythrocyte flexibility. Inflammation-driven uterine hypermotility may impede circulation in the placental capillary bed, and it is thought that this drug may increase fetal oxygenation by facilitating blood flow.<sup>322,323</sup> Pentoxifylline appears to have good uterine penetration and has been detected in the allantoic fluid of mares.<sup>283,297,298,306</sup> Despite these conflicting studies, data from a large field trial suggest that a multipronged approach (i.e., antibiotics, anti-inflammatory agents, altrenogest) to long-term therapy for placentitis may improve fetal survival and foal viability.<sup>324</sup>

## LEPTOSPIROSIS

Leptospirosis has been incriminated as a sporadic cause of placentitis, abortion, and premature births in horses.<sup>229,275,290,325-337</sup> Leptospiral infections may cause abortions in the latter part of gestation, generally with no premonitory clinical signs, and occasionally an infected premature or full-term weak, icteric foal.<sup>325,327,330,331,333</sup> The placenta is edematous, with a necrotic chorion covered with a mucoïd exudate.<sup>286</sup> The gross placental lesions are associated with thrombosis, vasculitis, and inflammatory cell infiltrates. The spirochetes tend to be numerous and are readily demonstrated in the stroma and villi of the placenta.<sup>333,338</sup> A microscopic agglutination test (MAT) on fetal fluids (heart and body cavities) or maternal serum is likely to reveal a high titer (1:6400-1:819,200 or greater).<sup>286,327</sup> Leptospirae may be detected in the fetus by the fluorescent antibody test (FAT), silver staining, or darkfield microscopy.<sup>286,337</sup> Immunohistochemistry is more sensitive than silver staining and more specific than serology (MAT).<sup>337,339</sup> The fetal kidney should be submitted for a FAT because this tissue yields the

highest percentage of positive results and is also the best tissue for culture.<sup>286,327</sup> If urine is to be submitted from an infected mare (FAT or darkfield analysis), it is important to obtain collection instructions and an appropriate transport medium from the diagnostic laboratory.<sup>286</sup> The specimen must be obtained before any antimicrobial therapy has been administered.

In the genus *Leptospira*, the species *L. interrogans* contains several pathogenic serogroups (common antigens) and serovars (specific strain). Serogroups consist of closely related serovars. The predominant serovar affecting horses varies with country and region.<sup>337</sup> The *bratislava* serovar is most commonly isolated from aborted fetuses in Northern Ireland, but in central Kentucky most leptospiral abortions have been associated with the *pomona* serogroup, occasionally the *grippotyphosa* serogroup, and rarely the *hardjo* serogroup.<sup>325,327,329</sup> Equine leptospiral infections previously reported as being *L. pomona* are now thought to be more correctly identified as *L. interrogans* serogroup *pomona* serovar *kennewicki* and *L. kirschneri* serogroup *grippotyphosa* serovar *grippotyphosa*.<sup>286,336,337,340</sup> On the basis of recent serologic testing, those two serovars are thought to be responsible for 83% and 10% of leptospiral abortions, respectively.<sup>337</sup> In North America pregnant mares are considered to be incidental hosts that become infected after exposure from maintenance hosts (i.e., wildlife such as skunks and raccoons for *kennewicki* and *grippotyphosa* and cattle for *hardjo*).<sup>286,325,327</sup> Infected mares may shed leptospire in the urine for up to 14 weeks.<sup>286,337</sup> Thus therapy is aimed at prevention of urinary shedding and possibly prophylactic treatment of pregnant in-contact mares that have high titers.<sup>286,337</sup> A combination of penicillin (10,000 to 15,000 IU/kg, administered intramuscularly) and streptomycin (10 mg/kg administered intramuscularly) every 12 hours for a period of 1 week has been recommended, but streptomycin is no longer widely used in equine practice.<sup>286,332,341</sup> High doses of potassium penicillin G (20 million units, IV every 12 hours) may be effective in preventing infection of a fetus if the mare has a high titer, but this recommendation has not been validated in controlled studies.<sup>337,341</sup> The dosage and duration of treatment appear to be important. Oxytetracycline (5 to 10 mg/kg) has also been suggested, but it was less effective at preventing urinary shedding of leptospire in all cases tested (5 of 7 infected mares).<sup>286,332,341</sup> There is no approved vaccine available for the prevention of leptospirosis in horses in North America.<sup>337</sup> Attempts should be made to prevent direct contact between maintenance hosts and pregnant mares and also to prevent exposure to urine infected by these species (e.g., contaminated water and feed).<sup>337</sup> It may be prudent to vaccinate cattle with a multivalent vaccine if they are present on the same property as pregnant mares.<sup>286</sup>

## PROTOZOAL ABORTION

There is limited information available on the association between equine *Neospora* infections and abortions.<sup>342-345</sup> However, the apicomplexan protozoan parasite *Neospora caninum* has been recognized as a major cause of abortion in cattle.<sup>346</sup> A recent European study documented the prevalence of antibodies against *Neospora* spp. in mares that recently aborted.<sup>347</sup> Using an agglutination test, researchers found that the number of animals with elevated (>80) anti-*Neospora* sp. antibody titer was higher in a group of 54 aborted mares than in a randomly chosen group of 121 mares ( $p < 0.001$ ). *N. caninum* deoxyribonucleic acid (DNA) was found in 3 of 91 fetal brains,

2 of 77 fetal hearts, and 1 of 1 placenta and present in both brains and hearts of two fetuses.<sup>347</sup> The mere presence of the organism in an aborted fetus does not necessarily implicate it as being the cause of the abortion.<sup>346</sup> Antibodies to *Neospora* spp. were detected in the sera from 11.9% of 800 asymptomatic horses in Israel and from 37.5% of mares that aborted.<sup>348</sup> Antibodies to *Neospora* spp. have also been detected in mares in Brazil.<sup>343</sup> Further investigations will be needed to determine whether there is an association between equine reproductive failure and *Neospora* spp. infection.<sup>342,343</sup>

## MARE REPRODUCTIVE LOSS SYNDROME

In the spring of 2001, the equine breeding industry in central Kentucky was faced with a reproductive crisis that ultimately cost hundreds of millions of dollars, and the impact on the Thoroughbred industry is still being felt. Mares were foaling prematurely with premature separation of the chorioallantois (late-term “red bag” abortions). Many mares that were approximately 45 to 80 days pregnant suffered acute fetal loss, and most affected mares failed to resume normal cyclic activity until after the official breeding season had closed because endometrial cups had been formed before the occurrence of mare reproductive loss syndrome (MRLS). In addition, an unusual number of weak foals were born.<sup>349,350</sup> The Appalachian region to the north also reported a high number of similar cases. The author investigated more than 150 late-term abortions in southeast Ohio during the spring of 2001.<sup>351</sup> Reports of weather patterns and an unusually high emergence of Eastern tent caterpillars (ETCs; *Malacosoma americanum*) were identical in both the central Kentucky and southeast Ohio regions.<sup>351,352</sup> The epidemic that affected the horse industry in the Ohio Valley in late April and early May of 2001 and 2002 became known as MRLS.<sup>349</sup>

During the initial outbreak the state diagnostic laboratory was inundated with late-term aborted fetuses, and practitioners identified approximately 2000 early fetal losses.<sup>353</sup> Many of these were detected during what should have been a routine fetal gender determination. Fortunately, no contagious infectious cause was identified, and this newly recognized disease became self-limiting as the breeding season progressed. Veterinarians and scientists involved in the epidemic considered the possibility of mycotoxins, ergot alkaloids, phytoestrogens, and even cyanide from wild cherry tree foliage.<sup>354-356</sup> A temporal correlation was established between MRLS and the presence of ETCs was identified.<sup>349,350,354,357-369</sup> Mares inadvertently ingest ETCs when large numbers are present on pasture, hay, or in the water supply.<sup>368</sup> Abortions consistent with MRLS can be induced by oral administration of whole ETCs or their exoskeletons, which contain hairs (setae).<sup>354,366,367</sup> Setae embed into the submucosa of the gastrointestinal tract. Fetal loss occurs when bacteria from the alimentary tract (streptococci, actinobacilli) establish infection where the local immune system is compromised—the fetoplacental unit.<sup>367-369</sup> Management strategies for controlling ETC have been proposed to reduce the risk of MRLS.<sup>353,362</sup> A similar abortion syndrome in Australia is associated with ingestion of hairy processionary caterpillars (*Ochragaster lunifer*).<sup>370</sup>

## VIRAL ABORTIONS

Equine arteritis virus (EAV) and equine herpesvirus 1 (EHV1) are the most important causes of viral abortion in horses in the United States. Both viruses are associated with acute

respiratory tract infection and are discussed in detail in Chapter 9.

EAV is transmitted through inhalation or venereally in the semen of asymptomatic ("shedder") stallions.<sup>371-375</sup> Abortion may occur if pregnant mares become infected in the later stage of gestation (5-10 months).<sup>373,375-377</sup> Clinical signs are variable but may include fever, conjunctivitis, nasal discharge, and dependent edema that is associated with the vasculitis.<sup>374,377-379</sup> Clinical signs are mild or subclinical in many horses and may be clinically indistinguishable from other respiratory infections.<sup>380</sup> Viral myometritis with degeneration of myocytes and infiltration of mononuclear cells leads to transplacental infection of the fetus.<sup>381</sup> Affected placentae are edematous, and degenerated fibroblasts may be observed in the subvillos layers.<sup>381</sup> Lesions in the fetal tissue include an atrophy of the lymphoid follicles in the spleen and lymph nodes with degenerated lymphocytes.<sup>381</sup> Immunofluorescence can detect EAV antigen in the myometrium and the endometrial glands in the dams, in the subvillos layer of the placentae, and in the aborted fetuses.<sup>381</sup> The virus may be recovered from the uterus and fetus, but the placenta is likely to yield the greatest amounts of the virus.<sup>381</sup> The disease may be controlled by an effective vaccination program and screening tests.<sup>371</sup>

Most abortions associated with herpesvirus are caused by EHV1, but occasional abortions are associated with EHV2, EHV4, and EHV5.<sup>276,382</sup> The number of abortions resulting from EHV1 infection has declined over the past 20 years, and isolated abortions, rather than abortion storms, are now a more common feature of this disease.<sup>383</sup> This is due to the widespread adoption of stringent vaccination programs in combination with improved management practices on broodmare farms.<sup>384,385</sup> Pregnant mares should be vaccinated with an approved vaccine at 5, 7, and 9 months of gestation. Many farms also vaccinate at 3 months. New arrivals should be isolated for 3 weeks, and groups of pregnant mares should be isolated by stage of gestation. It is especially important to segregate pregnant mares from weanlings and other horses.<sup>386</sup>

EHV1 can infect the fetus if a mare is viremic during pregnancy. The virus causes abortion as a result of the rapid detachment of the placenta.<sup>387,388</sup> Endothelial cells in the endometrium and allantochorion are often infected by the virus, with accompanying vascular lesions. The fetus can be infected by way of the chorionic vasculature or by inhalation of infected amniotic fluid.<sup>389-391</sup> Abortion may occur soon after the mare is infected or several weeks have elapsed. Therefore maternal serology is of little diagnostic value.<sup>392</sup> The aborted fetus will be fresh, with copious amounts of pleural and peritoneal fluid. The trachea may contain a fibrin clot. Small necrotic foci may be discernible on the swollen liver. A hyperplastic, necrotizing bronchiolitis may be seen in lung sections, and large intranuclear eosinophilic inclusion bodies are a characteristic histologic lesion. Although vaccination is widely practiced, owners should be aware that the protection is not absolute. If a pregnant mare is exposed to infected animals that have recently been to a show or that are returning from a training facility, it is possible that any protective immunity possibly conferred by the vaccine will be overwhelmed. Abortions have been associated with reactivation of latent virus that was induced by transport stress.<sup>393</sup> Therefore a history of regular vaccination of an aborting mare does not eliminate the possibility of a herpesvirus-related abortion. Neutralization and indirect immunofluorescence tests, as well as PCR and virus isolation, are used for EHV1 diagnostics. Antigen

detection, in combination with virus isolation and PCR from fetal lungs, gives reliable results.<sup>394</sup> More detailed reviews have been published.<sup>196,395</sup>

A number of other acute viral infections have been associated with abortion in horses, especially if the horse suffers severe systemic illness at the time of initial infection. For example, mares may abort as a result of the systemic effects of acute infection with equine infectious anemia virus (EIAV), although it is not generally considered an abortogenic virus.<sup>396</sup> When widespread vaccination against West Nile virus was adopted in the United States, some suggested that the killed virus vaccine that was used might result in abortions, stillbirths, and deformities in foals. However, subsequent critical review clearly demonstrates that vaccination of pregnant mares during any period of gestation is not associated with an increased incidence of pregnancy loss.<sup>397</sup>

## NONINFECTIOUS CAUSES OF ABORTION

### TWINS

In North America the incidence of twin abortions has decreased significantly because of early intervention after ultrasonographic diagnosis of a multiple pregnancy.<sup>84,215,229</sup> Before the widespread adoption of this technology, twin abortions were a major cause of fetal loss.<sup>49,50</sup> A large European study (n = 12,648 pregnancies) of Thoroughbred mares revealed a twinning rate of 3.5%, with 443 twins and only two triplets.<sup>398</sup> The type of placentation in the mare (diffuse, microcotyledonary) makes it highly unlikely that a twin pregnancy will be carried to term. Obviously, there is a finite endometrial surface area available for allantochorion attachment. The more common unicornuate twin vesicles are a problem, because one conceptus is inevitably restricted to the proximal aspect of the gravid horn.<sup>21,255</sup> Thus the two conceptuses are literally in a deadly competition for adequate nourishment and subsequent placentation. If the twin pregnancy is maintained until the latter part of gestation, the nutrient demands of the rapidly growing fetuses outstrip the placental attachments. Fetal growth is such that nutrient demands may be met until the latter half of gestation, when the marked fetal development in the last trimester usually requires more exchange capability than the smaller placenta provides. The fetus becomes stressed as it becomes progressively emaciated and ultimately dies.<sup>215,232</sup> Death of one fetus or both fetuses is followed by abortion, with the characteristic avillous areas on the fetal membranes confirming the amount of placental disruption.<sup>50,208,226,229</sup> Affected mares develop premature mammary enlargement and may "run" milk before aborting.<sup>50,399</sup> Transabdominal ultrasonographic evaluation may be useful to confirm the diagnosis at this late stage.<sup>226</sup> Although the area of apposition of the two chorioallantoic membranes (twin membrane) may be seen, measurement of fetal thoracic diameters and heart rates can confirm the twin diagnosis.<sup>226,232</sup> Twin abortions in the last few months of gestation are likely to cause a dystocia. Bicornuate twins are more likely to survive because each membrane can attach to an entire horn and one side of the uterine body, but the resulting foals are likely to be stunted as a result of intrauterine growth retardation (IUGR).<sup>4,50,215</sup> The live birth of twin foals is extremely uncommon, and many of these neonates do not survive, with as few as 14% of surviving foals reaching the second week of neonatal life.<sup>50,217</sup> The mares are prone to fetal membrane retention and may be difficult to rebreed.

Thus it is not surprising that the equine breeding industry has always tried to prevent twin pregnancies. After such a diagnosis the owner is faced with three choices: attempt elimination of one fetus in utero, manage the pregnancy to term in the remote hope of two viable foals, or induce abortion.<sup>226</sup> Management of a twin pregnancy is discussed in more detail in a previous section.

### UMBILICAL CORD COMPROMISE

On rare occasions, a large ossified remnant of the yolk sac may compromise blood flow through the umbilical cord and result in abortion.<sup>400</sup> The pathologic condition referred to as *umbilical cord torsion* may be defined as excessive twisting of the cord such that there is complete or partial occlusion of the umbilical vessels or urachus.<sup>401</sup> The two umbilical veins that return oxygenated blood from the placenta fuse within the distal aspect of the amniotic portion of the cord, and a single vein enters the fetal abdomen.<sup>402</sup> Strangulation may occur if the cord becomes tightly wrapped around a portion of the fetus. Pressure sites on or around fetal parts may be due to the effects of constriction by prolonged tension on a strangulated umbilical cord.<sup>403</sup> Affected fetuses are not usually expelled immediately after death, and thus some degree of tissue autolysis should be expected.<sup>404</sup>

The length of the equine umbilical cord in normal gestation can be quite variable, and factors that affect cord length and the number of twists present are unknown. Lethal umbilical torsion appears to be a sporadic condition with no apparent increased risk for future problems in mares that abort as a result of fetal complications.<sup>405</sup> Whitwell has shown that some mares have have three or more foals with abnormally long cords.<sup>49</sup> A Canadian study involving 93 Standardbreds did not demonstrate an effect of sire on cord length, and much larger studies will be required to ascertain whether genetics are involved.<sup>29,406</sup> Although the possibility of a heritable component for cord length cannot be discounted, a more plausible explanation may be that abnormally long cords are associated with the amount of fetal movement.<sup>402</sup>

Ultrasonographic studies of fetal mobility have helped explain the characteristic twisting that is a feature of the normal equine umbilical cord.<sup>4,407-410</sup> As is not the case with ruminants, the equine amnion floats freely within the allantoic fluid. Fetal rotation within the amniotic cavity and amniotic sac rotation within the allantoic cavity result in the characteristic twisting of the equine umbilical cord.<sup>411,412</sup> The lumen of both uterine horns becomes constricted (presumably by localized circular muscle contractions) between 5 and 7 months, and the allantoic fluid along with the fetus is contained within the confines of the uterine body.<sup>4,407-409,412</sup> What Ginther has described as the noncord horn remains closed, whereas the cord horn gradually permits the entry of the hindlimbs between 7 and 9 months. The limbs can enter the horn only when the fetus is in dorsal recumbency because the angle between the horn and body is so acute by this stage of gestation. Thereafter, the hindlimbs remain enclosed within the cord horn and the hooves extend to the horn tip by the tenth month.<sup>4,407-409,412</sup> It is interesting that the peak incidence of abortions due to umbilical torsions occurs when the hindlimbs can become permanently enclosed in the uterine horn. It may be that in some instances this prevents the unraveling of those critical few rotations that can lead to circulatory compromise. There is no doubt that a longer umbilical cord predisposes the fetus to this condition.

Reports from the United Kingdom suggest that with the decline in twin abortions, excessive twisting of the umbilical cord has become the most frequently made diagnosis in some laboratories. These abortions were associated with excessively long cords, with many over 80 cm in length.<sup>276,413</sup> Because spiraling of the equine cord (4 to 5 times over its length) is a normal feature, it is important to ensure that the cause of fetal demise was in fact due to vascular compromise.<sup>402,411</sup> Evidence of pathologic twisting with tension and compressive forces on the affected portion of the cord may include aneurysms, tearing of the intima of vessels, hemorrhage, thrombosis of vessels, blanched constricted areas, local edema, and urachal dilations of varying sizes. Inadequate perfusion can cause intravascular thrombosis in the peripheral tissues of the chorioallantois and possible necrosis of the aspect of the placenta that is most distant from the attachment of the cord (the cervical pole of the body segment).<sup>402,404</sup> These findings are by no means definitive, and there may be variability in interpretation among laboratories. Other considerations should include general agonal changes and the potential effects of cord tension when a live fetus is expelled. Whitwell's morphologic studies have established normal metrics for equine fetal membranes. The average length of the umbilical cord in a Thoroughbred is 55 cm (95% confidence interval; 36 to 83 cm; n = 143).<sup>414</sup>

Williams reviewed 168 cases of umbilical cord torsion from the University of Kentucky Livestock Disease Diagnostic Center, representing 6% of equine fetus submissions over a 5-year period.<sup>415</sup> The gestational age ranged between 5 to 10 months, with a mean of 7.5 months.<sup>416</sup> Umbilical cord length varied between 62 to 125 cm, with an average length of 96 cm. The cords tended to be highly twisted, with areas of constriction, edema, hemorrhage, and fluid-filled sacculations. The fetuses were slightly to moderately autolyzed, in a manner consistent with fetal death before abortion. Urinary bladder dilation was observed in some cases. The most consistent histopathologic finding was evidence of necrotic changes with secondary deposition of calcified material in the blood vessels of the chorioallantois.<sup>405,417</sup> A less common cause of abortion resulting from cord obstruction is when an excessively long amniotic portion of the cord becomes tightly wrapped around a portion of the fetus.<sup>403,414,418</sup> Although it may be more common for a fetal extremity to be involved, the author managed a case in a pony mare in which the tightly wrapped cord left a deep groove around the lumbar region, with evidence of local edema.<sup>403</sup>

### ♀ GENDER DETERMINATION (FETAL SEXING)

The advent of fetal sexing has permitted early gender determination to influence the value of the pregnant mare. Factors that may vary depending on the predicted sex of the foal include choice of state for foaling, appraisals and insurance coverage, sales reserves, bookings for stallion service the next season, and retention or sale of the mare.<sup>419</sup> Accurate determination of the sex of the equine fetus can be made using either transrectal or transabdominal ultrasonography.<sup>410,419-421</sup> Fetal gender should be certified only when the identifying structures have been clearly delineated and the accuracy of the determination is guaranteed. Accurate determination of fetal sex may be difficult or impossible in some cases because of excessive mare or fetal movement or because the fetus is located too deeply to permit adequate imaging. Although tranquilization

(e.g., xylazine and butorphanol tartrate) is sometimes used, it may cause the uterus to relax and drop away from the examiner.<sup>419</sup> A 5.0-MHz linear array transducer is adequate for transrectal gender determination, but a 3.5-MHz transducer will ensure the depth of penetration that is required to obtain transabdominal images.<sup>191</sup>

Gender determination is based on ultrasonographic assessment of the relative location of the genital tubercle, an embryologic structure that is initially located between the rear limbs in both sexes. The genital tubercle differentiates into either a clitoris or a penis and has an ultrasonographically distinctive, hyperechoic, bilobulated appearance in both sexes. Curren reported that the optimal time for gender determination is between days 59 and 68, and Holder concurs that a window between days 60 and 70 is ideal.<sup>419,421</sup> A second ideal period for gender determination may be between days 110 and 120, because the genitalia are now well developed and the fetus tends to be more accessible again. After this time the increasing depth of the uterus means that a diagnosis may not be possible if the fetus is in an anterior (cranial) presentation at the time of the examination.<sup>419</sup> If the transabdominal approach is used, the optimal window of time in both sexes is between days 100 and 220 of gestation.<sup>410,420,421</sup> Thereafter, it may become increasingly difficult to identify the anatomic structures required to make an accurate gender determination. Detailed instructions for fetal sexing by ultrasonography have been described.<sup>410,419,420</sup> Transabdominal gender identifications based on the presence of the penis or prepuce (or both) in males and mammary glands and teats or fetal gonads in females can be quite accurate.<sup>421</sup>

## ☞ MONITORING FETAL WELL-BEING

Placentitis should be suspected in mares that develop premature mammary enlargement (with or without vulvar discharge). A reduction in plasma relaxin levels may indicate placental compromise because relaxin is produced by the equine placenta.<sup>135,140-142,145,313,422-424</sup> Low relaxin levels in late pregnancy have been associated with various causes of placental dysfunction, including fescue toxicosis, oligohydramnios, and placentitis.<sup>315</sup> Measurement of an equine fetal protein and estrone sulfate levels in maternal plasma has not proved useful for early detection of fetal stress associated with medical and surgical colics.<sup>99,100,425-428</sup> Estrogens are produced from C19 precursors that are secreted by the gonads of a viable fetus and thus are unlikely to reflect fetal stress per se.<sup>83</sup> However, Riddle has reported that measurement of total estrogens can be useful for differentiating between a normal and a compromised fetus.<sup>429</sup> Before day 310 of gestation, total estrogen levels of less than 1000 ng/ml may be indicative of fetal stress, and mares with levels of less than 500 ng/ml are likely to have a severely compromised or dead fetus.<sup>429</sup>

It is important to remember that the circulating concentrations of hormones in maternal plasma generally represent a small percentage of the levels that are being metabolized by the fetus and uteroplacental tissues.<sup>83,89,430</sup> The definitive studies on mare progestagens (progesterins) were performed using gas chromatography–mass spectrometry (GC-MS).<sup>83,110,430</sup> It is imperative that clinicians appreciate that assays (e.g., RIA, ELISA) using an antibody raised against progesterone will usually cross-react with several of the progestagens but to a variable extent. Thus the value that is typically reported by the laboratory as being progesterone should actually be

termed *total progestagens*. The level of cross-reactivity in a particular assay can cause substantial variation in the reported value.<sup>83,430</sup> Although placental pathology has been correlated with increased plasma progestin concentrations in some studies, others have not detected differences in plasma progestin concentrations in mares with impending abortion and mares with normal pregnancies when monthly blood sampling was performed.<sup>46,83,110,121,430-433</sup> Therefore it is recommended that serial samples (daily for 3 days, then weekly) be obtained from a mare in which the condition is suspected because doing so may help the clinician identify a clinically useful trend in progestagen concentrations.<sup>83,99,259,277,430-434</sup> Progestagen levels increase significantly in normal mares as gestation progresses, and concentrations in the maternal plasma may range between 5 to 50 ng/ml or even higher as mares approach term.<sup>83,430</sup> It is thought that chronic fetal stress may cause the elevated progesterone and pregnenolone levels (as well as those of several metabolites) that have been observed in mares with placentitis.<sup>430,435</sup>

Ousey has described three abnormal progestagen patterns that may be clinically useful: a rapid decline, precocious elevation, and failure to increase at term.<sup>83,430</sup> A rapid decline is consistent with fetal death or imminent fetal expulsion and may be seen after a uterine torsion or colic.<sup>430,436</sup> Pregnant mares that have experienced colic or uterine torsion and have progestagen levels below 2 ng/ml are at high risk for fetal loss.<sup>99</sup> Prolonged elevation of progestagens for several weeks before delivery (especially if earlier than 305 days' gestation) is consistent with metabolic activity in the fetus and uteroplacental tissues despite the presence of placental pathology.\* Although typically small with poor skeletal development, foals born after being exposed to chronic fetal stress (placentitis) tend to exhibit precocious maturation—even when delivered several weeks early.<sup>83,303,430,439</sup> Analysis of specific progestagen profiles by GC-MS may differentiate mares with placentitis from those with villous poverty or placental edema.<sup>83,430</sup> If the total progestagen levels in maternal plasma fail to rise at term, fescue toxicosis (ergopeptine alkaloid-producing endophyte) is the most likely cause (see separate discussion).<sup>83,118</sup>

Transrectal ultrasonography provides an excellent assessment of the current status of the caudal allantochorion, and as such it is an invaluable aid when examining a mare in late pregnancy that exhibits signs of placentitis.<sup>434,440,441</sup> An image of the ventral placental tissues in the area adjacent to the cervical star provides the ability to accurately diagnose the early stages of ascending placentitis.<sup>259,440,441</sup> Experienced clinicians are able to observe abnormal tissue thickness and even evidence of placental separation with an associated pocket of inflammatory exudate. Early therapeutic intervention may provide the best chance for a successful outcome. In a normal placenta the chorioallantoic membrane and endometrium are intimately connected, making them ultrasonographically indistinguishable from each other. Thus a combined tissue measurement is used, and normal values for the combined thickness of the uterus and placenta (CTUP) have been established.<sup>442</sup> The amniotic membrane should not be included, and this should be remembered if the fetal limbs are active at the time of the examination. The area 1 to 2 inches cranial and ventral to the cervix provides the most consistent CTUP measurement in normal mares, and this is the recommended

\*References 117,121,303,430,434,435,437,438.

site for any measurements. The ultrasound image should be frozen once the landmark vessel (a branch of the uterine artery) in the ventral uterine wall is located, and caliper measurements are taken from the inner surface of the ventral uterine vessel to the edge of the allantoic fluid.<sup>259,440</sup> Diagnostic accuracy can be improved by recording the average of at least three measurements. An increased CTUP at any point from midgestation until term indicates placental disruption and pending abortion.<sup>431</sup> Transrectal CTUP values indicative of placental pathology and impending abortion are greater than 8 mm (between days 271 and 300), greater than 10 mm (between days 301 and 330), and greater than 12 mm after day 330.<sup>259,434,440,443,444</sup>

It is important to employ strict hygienic procedures when performing a vaginal speculum examination on a mare with a high-risk pregnancy because the first two barriers to the pregnant uterus will be breached (i.e., vulvar lips, vestibular sphincter). Mares at risk for abortion often have a moist, hyperemic, relaxed cervix. Even if vaginal discharge has not been reported, many of these cases have a purulent cervical discharge if placentitis is present. However, whereas cervical softening and vaginal discharge may be present if the infection is localized around the cervical star, in the case of nocardioform placentitis the lesion does not involve the cervical star and vaginal discharge is conspicuously absent.<sup>286,291,301</sup> Thus, although transrectal ultrasound is an extremely useful aid in diagnosing ascending placentitis, the site of the nocardioform lesion makes it of limited diagnostic value in these cases.<sup>316</sup> Transabdominal examination of the ventral uterus may reveal separation of the chorioallantoic membrane from the uterine wall, often with evidence of inflammatory exudate accumulation between the two surfaces. Placentitis and associated placental edema will result in a thickened uteroplacental image. The uteroplacental thickness (CTUP) on a transabdominal ultrasound image should be between  $7.1 \pm 1.6$  mm and  $11.5 \pm 2.4$  mm.<sup>440,445,446</sup> If the uteroplacental thickness exceeds 2.0 cm in late gestation, placental pathology is likely to be present.<sup>446,447</sup>

Transabdominal ultrasonography of mares in late pregnancy has become a routine diagnostic aid for evaluating fetal well-being.<sup>399,433,440,446,447</sup> Although the 5.0-MHz linear array transducer is ideal for transrectal reproductive ultrasonography, its shallow depth of penetration (approximately 10 cm) limits its usefulness for transabdominal examinations in mares in late pregnancy. If the mare does not have a pronounced plaque of ventral edema, the 5.0-MHz transducer will often be sufficient to image the uteroplacental unit and some of the fetal fluids. Either a 3.5- or 2.5-MHz curved linear array or sector scanner transducer is best for transabdominal examinations because these can penetrate to a depth of 20 or 30 cm, respectively.<sup>192,440,448</sup> While the 70- to 90-day fetus may be imaged from the ventral abdomen, just cranial to the mammary gland, the late gestation gravid uterus extends along the ventral abdomen to the xiphoid.<sup>399,440,445-449</sup> By the ninth month of gestation, the fetus should be in anterior (cranial) presentation and dorsopubic or dorsolateral position.<sup>4,408,449</sup> Thus in late gestation the fetal head should be positioned near the mare's pelvis. An abnormal presentation or the presence of twins is possible if a fetal head is detected along the ventral abdomen during late gestation.<sup>448</sup> A more detailed examination is indicated in such cases. The posture of the extremities varies with fetal movement.<sup>449</sup>

A standardized methodology must be followed when scanning the uterus from the ventral abdomen, starting just cranial to the mare's mammary gland and moving cranially to locate the fetal thorax. The ribs cause multiple acoustic shadows that delineate the thoracic cavity. A complete examination of the fetus and uterus involves scanning cranially to the xiphoid in multiple parasagittal planes and then scanning from left to right sides of the abdomen in multiple transverse planes.<sup>448</sup> Transabdominal ultrasound examination is an important diagnostic tool when attempting to identify the presence of twin fetuses during late gestation. Identification of the non-gravid horn can be useful to help rule out the possibility of twins. Obvious size discrepancy often serves as confirmation that twins are in fact present. In other cases one thoracic cavity does not contain a beating heart, confirming that one of the twins has already died.

In a normal pregnancy the majority of the fetal fluids are within the allantoic cavity. The amnion is imaged as a thin membrane that surrounds the fetus and lies in close contact with the fetus over much of its body. The amniotic membrane divides the imaged fetal fluid into two distinct cavities. It is most easily seen around the fetal neck, shoulder, thorax, and foreleg. The largest pocket of amniotic fluid is usually imaged at the point where the forelimb and neck meet the thorax.<sup>448</sup> The maximum vertical depth of amniotic and allantoic fluid and the quality of amniotic and allantoic fluid are useful guides to fetal well-being.<sup>448</sup> Any measurements of fluid depth should be made as perpendicular to the uteroplacental surface as possible.<sup>447,448</sup> In the normal equine pregnancy the maximum ventral fetal fluid pocket depth for amniotic fluid is 8 cm; it is 13 cm for allantoic fluid.<sup>440,445,448</sup> Extremes in either direction are not normal. Obviously deficient amounts of fetal fluid indicate placental dysfunction, and excessive amounts suggest a hydrops condition.<sup>445,450</sup> Fetal fluid quantities should be considered excessive if the maximal vertical amniotic fluid depth exceeds 14.9 cm or the maximum vertical allantoic fluid depth exceeds 22.1 cm.<sup>448</sup> The quality of the fetal fluid is scored from 0 (clear) to 3 (echogenic fluid with numerous particles).<sup>447,448</sup> It is not unusual for echogenic particles to be noted in the fetal fluids, especially during periods of fetal activity. These represent sloughed cells and proteinaceous debris. The fetal skin releases vernix as the pregnancy advances, and these free-floating particles can increase the cloudiness of the amniotic fluid.<sup>440,446</sup> Thus an increase in the number of echogenic particles in late gestation may not be abnormal.<sup>447</sup> However, if a high-risk pregnancy is being regularly monitored and a sudden increase in fluid turbidity (grade 3) is observed, the prognosis is not good.<sup>446,447</sup> The clinician should consider the possibility of inflammatory exudates, meconium passage by a compromised fetus, or even hemorrhage. It should be remembered that hippomanes (allantoic calculi) are a normal feature of the equine pregnancy. These structures may be observed on the ventral aspect of the allantoic cavity.<sup>448</sup>

An equine biophysical profile has been proposed as a guide to assessing fetal well-being and predicting perinatal morbidity and mortality.<sup>440,446,447,451</sup> Although a low score is definitely indicative of a negative outcome, higher scores do not guarantee the birth of a viable neonate.<sup>448</sup> Fetal breathing, heart rate and rhythm, fetal tone, and general activity are useful guides when evaluating fetal health and well-being. Therefore chemical sedation of the mare is not recommended because commonly used drugs are likely to induce fetal bradycardia and suppress normal fetal activity.<sup>452,453</sup> Fetal breathing is characterized by

movement of the diaphragm between the thorax and abdomen, in conjunction with rib cage expansion—without any other movement by the fetus. Fetal breathing patterns should be monitored for at least 30 seconds.<sup>440,448,454</sup>

When fetal heart rate and rhythm is monitored, it is not appropriate to scan for only 10 or 15 seconds and then multiply by a correction factor to obtain the number of beats per minute. Beat-to-beat variations and observation of periodic accelerations are important. It is normal for the heart rate accelerations to occur in association with fetal activity. Multiple measurements of fetal heart rate and assessments of fetal heart rhythm should be made over a 30-minute period while evaluating the fetus, fetal fluids, and placenta.<sup>440,448</sup> Ideally, three measurements should be obtained with the fetus at rest and another three after periods of activity. It is difficult to accurately monitor the heart rate during periods of fetal activity, unless M-mode echocardiography equipment is available.<sup>440,448,449</sup> Fetal heart rates vary with the stage of gestation and the amount of fetal activity at the time of the examination.<sup>440,455-457</sup> The fetal heart beat is normally regular and will decrease from greater than 120 beats/min in midgestation to between 60 and 90 beats/min in late gestation.<sup>440,445-447,449,455-459</sup> Cardiac accelerations (20-40 beats/min above baseline) are normal if they are associated with fetal movement.<sup>440,445,446,448</sup> However, persistent tachycardia in the absence of fetal activity indicates fetal stress. A resting heart rate in excess of 104 beats/min indicates fetal stress in a late gestation fetus.<sup>447,448</sup> A heart rate of less than 57 beats/min in a fetus that is less than 330 days' gestation and a rate of less than 50 beats/min in a fetus older than 329 days' gestation should be considered abnormal.<sup>447,448</sup> A fetus suffering from hypoxia will have a slow heart rate, with minimal limb activity or fetal breathing, indicative of central nervous system depression.<sup>446-449</sup> However, if the condition is chronic and ischemic conditions are developing, the fetus will become tachycardic despite a lack of fetal activity. This is a prelude to fetal demise. In terminal cases extreme bradycardia ensues just before fetal death.<sup>447,454</sup> Whereas failure to observe fetal activity may be due to the stage of the normal rest-activity cycle, confirmation of a regularly beating heart at least confirms that the fetus is alive. This is a major advantage over transrectal fetal ballottement, wherein failure to detect movement can raise unnecessary concerns about fetal health.

If Doppler ultrasound equipment is available, the Doppler transducer is placed directly over the site where the best image was detected by the ultrasound scan. Tracings of fetal heart rate and rhythm can be recorded over time—usually intervals of 5 to 10 minutes.<sup>460</sup> This makes analysis easier and serves as a permanent record of the fetal status at the time of the recording. If there is some question about the presence of twins after a transabdominal ultrasound examination, fetal electrocardiogram (ECG) tracings may show two distinct fetal patterns.<sup>458,459</sup> Features of the ECG tracing that should be noted include fetal heart rate and rhythm, accelerations and decelerations, complex polarity changes, and beat-to-beat variation.<sup>440,454</sup> In the last weeks of pregnancy fetal foals usually have a baseline heart rate in the range of 60 to 75 beats per minute. Transient low heart rates of less than 60 beats/min are not uncommon. These troughs warrant concern only if they are not interspersed with accelerations. Likewise, transiently elevated rates in the order of 120 beats/min (occasionally >200 beats/min) are not abnormal provided that they return to baseline.<sup>440,454</sup> If the fetal heart rate is found to be less than

60 beats/min or greater than 120 beats/min during an observation period, then more frequent monitoring is justified to determine if the fetal is distressed. Beat-to-beat variations are normal, and a finding of no variability is an ominous sign. Maternal medications such as detomidine or butorphanol will reduce fetal heart rate variability transiently.<sup>440,454</sup>

The fetus is noted to have tone if it is observed to flex and extend the limbs, torso, or neck. Tone is poor or absent if the fetus appears flaccid.<sup>440,447,448</sup> Fetal movements include partial to full rotation around the long axis of the fetus as well as less marked activity such as extension and flexion of the extremities.<sup>440,447,448</sup> Fetal activity is rated on a scale from 0 to 3, with 3 being a very active fetus. A score of 0 indicates that no fetal movement was noted during the examination period.<sup>447,448</sup> Long periods without noticeable fetal activity are cause for concern and should be evaluated in conjunction with information about the fetal heart rate and rhythm. The fetus may be distressed, suffering from advanced hypoxia and central nervous system depression.<sup>446,447</sup>

Fetal aortic diameter is correlated with the weight of the pregnant mare, as well as the final neonatal foal weight.<sup>440,445-447</sup> Thus the pregnant mare's weight can be used to estimate what the fetal aortic diameter should be, using the regression equation ( $Y = 0.00912 \times \text{pregnant mare's weight in pounds} + 12.46$ ) where  $Y$  is the predicted fetal aortic diameter (mm).<sup>447,448</sup> The actual diameter of the fetal aorta should then be measured in the thoracic cavity, as close to the fetal heart as possible.<sup>440,445,447</sup> A smaller than predicted aortic diameter may indicate a dysmature or growth-retarded fetus (IUGR; intrauterine growth retardation) or twins. The maximal thoracic diameter is measured from the spine to the sternum over the caudal part of the thorax, and in a late gestation fetus it should be  $18.4 \pm 1.2$  cm.<sup>447,448</sup> It has been correlated with fetal aortic diameter and neonatal foal weight in high-risk pregnancies.<sup>447,448</sup> Foal girth measurements and hip height are also correlated with fetal aortic diameter measurements.<sup>446,448,461</sup> Fetal biparietal measurements and orbital diameters have also been used to estimate fetal size.<sup>440,448,461</sup> Eye length (sclera to sclera) is a useful predictor of days before parturition in small ponies.<sup>462</sup> Decreased blood flow to the placental unit inhibits fetal growth, and some form of chronic placental insufficiency should be suspected when small fetal size is detected.

It is important to monitor fetal viability if a high-risk pregnancy is being maintained on altrenogest supplementation. Although most nonviable fetuses will be aborted, there are reports of a mummified fetus being retained when the mare was receiving long-term progestagen supplementation.<sup>237</sup>

## ☞ COMPLICATIONS IN LATE GESTATION

Once confirmed to be at least 45 to 60 days pregnant, most mares can be expected to carry the fetus to term. The incidence of fetal loss after 100 to 120 days of gestation is low and accounts for only a small percentage of total pregnancy wastage. Fetal death and maceration is uncommon in the mare. However, the author has managed a case of macerated twins in a draft breed mare that suffered no ill effects systemically. The mare was evaluated only after the owner noticed a foul-smelling vaginal discharge.<sup>463</sup> Ventral body wall ruptures and uterine torsions are uncommon, and hydrops of the fetal membranes is an especially rare condition. Accurate diagnosis and appropriate management of these clinical cases can

prevent the development of a life-threatening condition. If a ventral body wall rupture or uterine torsion is present, the birth of a viable foal may still be possible provided that the case is managed correctly.<sup>464</sup>

## HYDROPS OF THE FETAL MEMBRANES

Hydrops is a condition of the last trimester, with the pregnancy developing normally until somewhere between 7.5 months and term. Hydrallantois and hydramnios are rare conditions that involve a pathologic accumulation of fluid within the allantoic and amniotic compartments, respectively. Normal volumes of allantoic fluid in mares vary from 8 to 18 L at term. In documented cases of hydrops, the allantoic fluid volume ranged from 110 to 230 L.<sup>419</sup> Just as with cows, hydrallantois accounts for most dropsical conditions in the mare.<sup>465-468</sup> The pathophysiology of hydrallantois in the cow has been related to an abnormality of placentation, whereas hydrops amnion has been associated with a fetal head anomaly that precludes swallowing.<sup>195</sup> Dysfunctional placentation may cause an increased production of transudate or disruption of transplacental fluid absorption. There does not appear to be any consistent abnormality of the fetus or fetal membranes that is characteristic of the condition in the mare.<sup>469</sup> In fact, a case at the University of Florida was confirmed to be hydrops amnion on the basis of analysis of fluid obtained through amniocentesis and allantocentesis, yet a viable foal was eventually delivered.<sup>470</sup> A mild diffuse placentitis or endometrial vasculitis has been incriminated in some cases.<sup>419</sup> In a report on 15 cases, all of the mares were pluriparous and ranged in age between 6 to 20 years.<sup>419</sup>

Generally, there is a sudden onset of abdominal distention, and walking becomes difficult.<sup>470</sup> The mare will exhibit variable degrees of colic. There is a progressive loss of appetite, and the mare may experience some difficulty in defecation. The increasing pressure on the diaphragm causes dyspnea, and the mucous membranes may appear cyanotic, especially when the mare is recumbent.<sup>419</sup> On physical examination the rectal temperature is normal, but the heart rate will be elevated. Rectal palpation reveals characteristic findings. Copious lubrication and extreme caution should be used because passage of the forearm will be impeded by pressure from the large fluid-filled uterus. The feces tend to be covered with mucus as a result of the prolonged passage through the lower gastrointestinal tract. The gross distention of the uterus means that the fetus is usually not palpable.<sup>470</sup> Failure to detect the fetus by external ballottement further supports the diagnosis. Transabdominal ultrasound may confirm the presence of excessive amounts of hyperechoic fluid.<sup>470</sup> A thorough examination from both sides of the abdomen should be performed to rule out the possibility of twins.<sup>464</sup>

Owners should be advised that this is a progressive condition and it is extremely unlikely that the mare will be able to sustain the pregnancy and deliver a live foal—although a recent report documented a case that was successfully managed until a viable foal was delivered at 321 days' gestation.<sup>464,470</sup> In that case the mare was provided with close monitoring of maternal and fetal health, in combination with supportive care that included a supportive belly-wrap, anti-inflammatory medication, and altrenogest. A partial drainage technique is sometimes used in an attempt to manage cases that were diagnosed within 2 to 4 weeks of term.<sup>419</sup> Affected mares receive abdominal support (belly band), intravenous fluids, broad spectrum

antibiotics, and anti-inflammatory medication. The technique of slow, repeated drainage requires a major time commitment and would not be cost effective in many cases. Fetal death may occur as a result of placental separation. There also appears to be a considerable risk for iatrogenic fetal infection after contamination of the fetal fluids, despite attempts to perform the drainage technique in an aseptic manner. Thus, despite heroic attempts in valuable mares, the fetus is likely to be lost in cases of hydrallantois.<sup>419</sup>

In most cases induction of parturition may be advisable before the mare's condition deteriorates further. Continued abdominal enlargement will predispose the mare to prepubic tendon rupture,<sup>470,471</sup> and uterine rupture has also been reported.<sup>472</sup> Induction is not without risk (shock, dystocia), but the prognosis for survival of the mare is good provided that appropriate supportive therapy is instituted.<sup>470</sup> The prognosis for the mare's reproductive future may also be favorable provided that there are no untoward sequelae (cervical lacerations, retained fetal membranes, metritis). Application of PGE to the cervix before induction may facilitate atraumatic fetal extraction.<sup>228,473</sup> In one report six of eight mares that had previously developed a hydrops pregnancy subsequently became pregnant and delivered normal healthy foals at term.<sup>419</sup>

Before a therapeutic induction of parturition, the tail should be wrapped, the perineal area cleansed, and an indwelling intravenous catheter inserted. Large-volume intravenous fluid therapy may become necessary if hypovolemic shock develops as the allantoic fluid is discharged.<sup>464</sup> In some cases controlled drainage may be beneficial before inducing delivery. An added complication in hydrops cases is that the thickened, edematous chorioallantoic membrane may be difficult to rupture.<sup>465</sup> If digital pressure alone is unsuccessful, an endometrial biopsy forceps can be used to bite a piece out of the chorioallantois. Some authors report that the lack of pressure from the atonic uterine wall will result in minimal release of fetal fluid from the punctured chorioallantoic sac, but in the few cases that the author has been involved with there was a massive release of fluid once the chorioallantoic membrane was ruptured.<sup>465,467</sup> If insufficient fluid release occurs, a sterile nasogastric tube can be introduced into the uterus to begin controlled siphoning of fluid. An alternative technique is to introduce a thoracic trocar catheter through the cervix and employ a sharp puncture of the chorioallantois.<sup>419</sup> This approach permits the excess fluid to be removed by controlled drainage. Administration of intravenous fluids with gradual removal of the excess allantoic fluid will permit the mare's cardiovascular system to adapt. Both oxytocin and PG injections have been employed in an attempt to abort these cases.<sup>465-467</sup> Although oxytocin is widely considered to be the most efficacious method for routine induction of parturition, in hydrops cases the distended uterine musculature may not be able to contract effectively.<sup>465,474</sup> This uterine inertia is common, and gentle manual dilation of the cervix, or perhaps prior application of PGE, may be warranted.<sup>473</sup> Bain and Wolfsdorf have reported a smooth induction after two doses of cloprostenol administered 30 minutes apart.<sup>419</sup>

The abdominal musculature may be weakened by stretching, and thus the typical stage 2 abdominal press may be compromised. Malpositioning and malpostures are not uncommon. The fetus may need to be extracted by assisted vaginal delivery, but care should be taken so as not to traumatize the cervix by overzealous traction.<sup>464</sup> The expelled fetus will generally be alive, and humane euthanasia is warranted.

In one report at least 50% of foals had some malformation.<sup>419</sup> Additional oxytocin (1.0 IU per minute) should be added to the intravenous fluids to promote uterine involution. Retention of the fetal membranes should be expected, and appropriate treatment for removal of these membranes and prevention of the metritis-laminitis complex is indicated. Uterine involution should be monitored by transrectal palpation and ultrasonography.

### VENTRAL BODY WALL HERNIAS AND PREPUBIC TENDON RUPTURE

Apart from those with pathologic pregnancies, mares with ventral body wall defects are generally close to term.<sup>474,475</sup> Damage to the abdominal sling of the pregnant mare may involve rupture of the transverse abdominis and oblique muscles, the rectus abdominus muscles, and the prepubic tendon.<sup>476</sup> In extreme cases the rupture may lead to hemorrhage, shock, and death.<sup>477</sup> The prepubic tendon attaches to the cranial border of the pubis, and lordosis occurs if the tendon is ruptured.<sup>464,474,475</sup> Although breed (draft-breed mares) and age (older mares) may predispose a mare to development of the condition, in most cases there is no apparent predisposing cause.<sup>471,475,476</sup> The extreme abdominal distention associated with the hydrops condition may cause rupture of the ventral musculotendinous support. Defects in the ventrolateral abdominal wall are more common than complete prepubic tendon rupture, and bilateral involvement of the abdominal wall seems to be most common.<sup>471,475,476,478,479</sup> In a retrospective study of 13 cases, only three were categorized as being caudal midline (prepubic tendon lesions), and all three had additional involvement of the body wall musculature.<sup>475</sup>

The most obvious clinical sign of an impending ventral body wall rupture is a thick plaque of ventral edema extending a variable distance cranial to the udder.<sup>464,476</sup> However, ventral edema may be a normal consequence of late pregnancy, and it can indicate external trauma. The author managed one case in which a large ventral swelling was associated with a massive hematoma that appeared to have originated from a kick. Mares in late pregnancy often develop a thick plaque of ventral edema that can extend from the udder to between the forelimbs. This is associated with the compressive weight of the gravid uterus on the venous and lymphatic drainage of the ventral abdomen. The presence of a hemorrhagic secretion in the mammary gland supports a diagnosis of tissue trauma rather than pregnancy edema.<sup>475</sup> Unilateral edema is more indicative of damage to the ventrolateral body wall, but it may be associated with partial rupture of the prepubic tendon.<sup>464,476</sup> The extreme pain that is associated with progressive enlargement of a ventral body wall rupture causes a marked tachycardia that may not be responsive to analgesics. Pregnant mares with a ruptured prepubic tendon or ventral abdominal wall show signs of colic and generally are reluctant to move. If the prepubic tendon is completely ruptured, the pelvis will be tilted such that the tailhead and tuber ischii are elevated, and a lordosis will be present.<sup>464,471,475,476</sup> The mammary gland is often displaced cranial and ventrad because of the loss of the caudal attachment to the pelvis. A rent in the abdominal musculature may be complicated by bowel incarceration.<sup>464,471,475,476</sup>

Confirmation of the tentative diagnosis is sometimes difficult. Because it is not always possible to be certain that a rupture has already occurred, mares with severe ventral edema should be confined to a stall, with exercise restricted to hand

walking. Rectal palpation of the defect is usually not possible owing to the advanced stage of the pregnancy. External palpation is generally unrewarding because of the thickness of the edema, although some crepitation of the ventral abdominal wall may be noted. The mare is generally extremely sensitive and resists palpation of the area.<sup>464,475,476</sup> Ultrasonographic examination of the posterior aspect of the ventral abdomen may be useful in some cases and can detect the presence of a bowel segment.<sup>448,464,475,477</sup> Rupture of the prepubic tendon can be identified as disruption of the tendon fibers immediately cranial to the pubis, whereas abdominal wall muscle tears are seen to be discrete tears within muscle fibers, often associated with hematomas.<sup>475</sup> An accurate assessment of the dimensions of the defect often cannot be made until the fetus and fetal fluids are expelled and the ventral edema has subsided.<sup>464,476</sup>

Depending on the degree of discomfort and stage of pregnancy, termination of the pregnancy may be the most humane treatment for the mare, given that further tissue damage is likely to occur to some degree until parturition. The possibility of a segment of intestine becoming incarcerated in the defect also should be considered.<sup>476</sup> In extreme cases the mare may eventually become recumbent, especially if there is a rapidly expanding body wall defect.<sup>464,475</sup> Owners should be aware that unless parturition is imminent, the prognosis for the foal is not good because fetal readiness for birth is difficult to predict.<sup>475</sup> Because the present fetus may well be the mare's last, owners often request that an attempt be made to maintain the pregnancy to term. In these cases the treatment is essentially supportive, and the prognosis for the foal is good.<sup>475,476</sup> Anti-inflammatory drugs will help alleviate the mare's discomfort. An abdominal sling (belly band) made of canvas or padded leather or a snug abdominal bandage help provide support for the ventral abdominal wall.<sup>475,476</sup> In the author's experience, abdominal bandages tend to be purely cosmetic because they soon stretch and thus provide minimal long-term support. If a sling is used, the area over the back must be well padded to prevent pressure necrosis because the purpose of this support is to transfer the weight of the gravid uterus to the vertebral column.<sup>464,476</sup> Reducing the bulk of the ration and feeding a mild laxative may help reduce the degree of abdominal exertion associated with defecation.<sup>477</sup>

Assistance with parturition should be available because the mare may experience difficulty in mounting sufficient abdominal pressure to expel the fetus.<sup>471,475</sup> However, one report suggests that some mares can position the foal and complete delivery unassisted.<sup>475,476</sup> Arrangements for an alternate source of colostrum should be made because ventral edema may prevent the foal from suckling. The owner should be informed that although in some cases surgical repair of the defect may be possible by mesh herniorrhaphy, rebreeding the mare may not always be advisable.<sup>471,475,476</sup> Some mares with small, unrepaired defects may subsequently foal without assistance, but the possibility that future pregnancies may exacerbate the condition should be considered.<sup>477</sup> Embryo transfer offers a viable alternative if this procedure is condoned by the relevant breed society.<sup>475</sup>

### UTERINE TORSION

Uterine torsion accounts for 5% to 10% of all complicated obstetric conditions in the mare.<sup>480,481</sup> Neither mare age nor parity appear to be significant risk factors.<sup>482</sup> The causes of

uterine torsion in the mare are not well defined. The condition is much more common in cattle, and in that species a large term fetus has been implicated as a major risk factor. Most uterine torsions in cows occur at term and are thought to be a direct result of fetal positional changes during late first-stage and early second-stage labor.<sup>483</sup> A striking difference between the mare and the cow is that more than 50% of uterine torsions in mares occur before the end of gestation.<sup>480</sup> In the author's clinical experience, the vast majority occur before term, and cases may be seen as early as 8 months of gestation.<sup>464</sup> In fact, one recent report documented a case as early as 126 days of gestation.<sup>484</sup> A multicenter retrospective study of 63 cases reported that 59% of the mares were at less than 320 days of gestation.<sup>482</sup> Although Ginther et al. have shown that the fetus is locked into a dorsopubic position during the final months of gestation, it is still possible for the entire pregnancy (uterus and fetus) to rotate approximately 90 degrees on the lower maternal abdominal wall.<sup>4</sup> This occurs because any rotational movement of the caudal half of the fetus (pelvis and hindlimbs) by necessity will involve the close-fitting uterus. It seems likely that in extreme cases this rotating action can lead to a clinical uterine torsion.<sup>230,419</sup> Owners who work closely with their mares may observe excessive fetal movements in the flank area 1 or 2 days before. In a recent study 80% of term fetuses were in dorsosacral position when the uterine torsion was corrected. This suggests that fetal righting reflexes may have played a role in creating the torsion.<sup>481</sup> The author believes that vigorous fetal movements during the latter stages of gestation are likely to be a significant factor in the etiology of this condition in the mare.<sup>419</sup>

The clinical signs that attract the owner's attention are the result of abdominal pain.<sup>464,485-488</sup> These include restlessness, sweating, anorexia, frequent urination, sawhorse stance, looking at flanks, and kicking at the abdomen. When the veterinarian is first summoned, the signs may have been present for a period ranging between 2 hours to 3 days or more, especially if signs are intermittent and moderate.<sup>464,486</sup> In mares that are close to term, the owner may assume that the signs indicate impending parturition. In more extreme cases the signs are more severe and may be associated with concurrent involvement of the small or large colon.<sup>482,484,487</sup> Veterinarians should always consider the possibility of uterine torsion when a mare that is in the last trimester of gestation exhibits a mild, persistent colic. Delay in making a definitive diagnosis increases the likelihood of fetal compromise.<sup>464</sup> In one study of 63 cases, the mean time to admission was more than 20 hours.<sup>482</sup> Occasionally, the condition may remain undiagnosed for several weeks.<sup>489</sup> In these instances an owner may have attempted treatment with analgesics that were prescribed for previous mild colic episodes.<sup>464,485</sup>

Rectal palpation is essential to determine whether a uterine torsion is present.<sup>464,485</sup> The author is of the opinion that all late pregnant mares that display signs of mild to moderate colic warrant a thorough rectal examination to rule out the possibility of uterine torsion. Although vaginal involvement in the torsion is very common in the cow, uterine torsions in the mare seldom cause detectable changes in the vagina.<sup>464,483,486,489,490</sup> Thus vaginal examination is generally not diagnostically useful. On rectal palpation the clinician should aim to carefully advance the forearm while palpating for a taut band on either side of the rectum. The ligament on the side of the torsion tends to be more caudal and is palpable as a tight vertical band. As the arm is advanced further,

the opposite ligament will be palpable as it is pulled horizontally across the top of the uterus before being displaced ventrally.<sup>464</sup> An accurate examination of the broad ligaments will confirm the diagnosis, determine the direction of the torsion, and give some idea of the severity of the torsion.<sup>419</sup> One study (n = 54 mares) reported that 79% of referred cases were rotated no more than 180 degrees, and 59% of cases involved clockwise torsion.<sup>482</sup> A transrectal ultrasound examination is useful to evaluate the condition of the fetal fluids and to note whether any placental detachment has occurred. The degree of uterine compromise can be gauged by noting the thickened uterine wall and distended vasculature. Compression of the veins and lymphatics occurs before occlusion of the arterial blood supply. Thus the initial changes will be associated with pooling of fluid within the uterine wall.<sup>464</sup> The compressive forces of the displaced broad ligaments may cause variable amounts of constriction of the small colon.<sup>486,491</sup>

Transabdominal ultrasonographic imaging may be used to assess fetal viability (heart rate and rhythm) and to evaluate the condition of the fetal fluid. Compression of the uterine blood supply can cause fetal hypoxia and a fetal stress response, especially in more advanced pregnancies. Abdominocentesis may provide prognostic information and guide the clinician in choosing a mode of correction.<sup>492</sup> Because it may be difficult to obtain peritoneal fluid from a mare in late gestation, transabdominal ultrasonography is sometimes useful in locating a pocket of fluid. Uterine rupture can be a complication of uterine torsion in the mare.<sup>486,493</sup> In the author's experience mild uterine torsions, or those of short duration, do not alter the color, cellularity, or total protein content of the peritoneal fluid.<sup>492</sup> Mares with severe or chronic uterine torsion may develop significant uterine compromise that results in changes in the composition of the peritoneal fluid. Any alterations in the composition of the peritoneal fluid may indicate the presence of a compromised or ruptured uterine wall or concurrent gastrointestinal involvement.<sup>493</sup> A flank laparoscopic examination can confirm the condition of the uterine wall.<sup>494</sup> This information will facilitate an informed choice of surgical approach or perhaps support a decision for euthanasia if economic considerations preclude surgical intervention.

The stage of gestation and the mare's heart rate are significant prognostic indicators for mare survival. A recent study reported that mares that died had significantly higher heart rates (mean 74 beats/min) at admission than survivors (mean 59 beats/min).<sup>482</sup> Increased fetal size and the weight of the gravid uterus make correction closer to term (>320 days) more difficult, and this may explain the poor mare survival rate (65%) when compared with cases in less advanced pregnancies (<320 days), wherein survival rates are excellent (97%).<sup>482</sup> Owners should be advised that fetal survival rates are not as good, but a similar effect of stage of gestation applies. The chances of the foal surviving exceed 70% if the mare is at less than 320 days' gestation, but only about 30% survive when mares are closer to term.<sup>482</sup>

If the mare is presented in stage I of labor and the cervix is sufficiently dilated to permit passage of a well-lubricated arm into the uterine body, then it may be possible to reach the fetus. It should be grasped ventrolaterally and then rocked back and forth until sufficient momentum is achieved to continue up in an arc. This manipulation should roll both fetus and uterus back into a normal position. Vandeplassche has reported that more than 80% of term torsions can be corrected in this manner.<sup>196</sup> Options for management of a preterm

uterine torsion are rolling the mare, flank laparotomy, or a ventral midline celiotomy. In the controlled referral hospital environment, the method of correction is not associated with mare survival, but both rolling and midline celiotomy require general anesthesia and thus entail those additional risks.<sup>482</sup> There is a significant effect on foal survival if the mare is at less than 320 days' gestation, and employing the standing laparotomy approach should provide a significantly better prognosis compared with the ventral midline approach.<sup>482</sup> However, the final decision must be based on several factors, including the severity of pain being exhibited by the mare, client financial constraints, and surgeon preference. Ventral midline celiotomy does permit assessment of uterine viability and evaluation of the gastrointestinal tract.<sup>464,482</sup>

The anesthetized mare may be rolled in an attempt to rotate the mare's body around the stationary gravid uterus.<sup>495</sup> It is essential that the mare be placed in lateral recumbency on the side of the torsion.<sup>419</sup> The aim of the procedure is to roll the mare such that the pelvis "catches up" with the displaced uterus. Correction by rolling the mare is controversial.<sup>464,477,486,496</sup> Citations in the literature report on a limited number of cases.<sup>480,487,496</sup> Concerns with this approach include the following: unsuccessful attempts to correct the torsion will prolong its adverse effects; misdiagnosis of the direction of the torsion means that rolling the mare may make the condition worse; the condition of the uterus cannot be evaluated; and displacement of the colon may result.<sup>464</sup> In addition, a higher risk of placental detachment and uterine rupture has been reported.<sup>477,479,487</sup> Another concern is that if general anesthesia is induced under less than ideal conditions, maternal hypoxia may cause fatal complications in the already compromised fetus.<sup>482,496</sup>

In the standing flank approach, a grid incision is made on the same side as the direction of the torsion.<sup>486</sup> The torsion is corrected by placing the forearm under the uterus. The uterus and contents are rocked back and forth to gain momentum. A combination of lifting and rotating movements generally results in easy correction of the torsion.<sup>419</sup> The presence of a live fetus greatly facilitates the detorsion manipulations. More difficulty may be experienced in mares that are close to term, and this may justify the more expensive ventral midline celiotomy approach.<sup>482</sup> If the standing procedure is attempted, an incision in the opposite flank will permit a second surgeon to assist by gently pulling across the top of the uterus as it is elevated from below.<sup>490</sup> If the fetus is dead, the mare should abort naturally once the uterine torsion has been corrected, thereby removing the need for hysterotomy and any associated complications.<sup>269,464,419</sup> However, the mare should be closely monitored, and obstetric assistance must be available to correct any malposition or malposture. Mares experiencing intractable pain should receive general anesthesia during the operation.<sup>480,486</sup> A ventral midline celiotomy is also indicated when significant uterine compromise is a concern or another problem co-existing in the abdomen is suspected.<sup>464,482</sup>

The prognosis for mares with uterine torsion depends on the degree of vascular compromise. The severity and duration of the condition affect placental circulation and subsequent fetal viability.<sup>464</sup> In chronic cases in which there is significant uterine compromise, it is feasible to perform an ovariohysterectomy to salvage the mare for nonbreeding purposes.<sup>485,489</sup> It has been this author's experience that if the fetus is alive and the uterine wall is not severely congested and edematous, then the prognosis for both the mare's survival and for the

birth of a live foal at term is good.<sup>464,484</sup> Progestin supplementation for 3 to 5 days after the manipulations involved in correcting a uterine torsion may be indicated to promote myometrial quiescence and thus maintenance of the placental attachment.<sup>107</sup> Although supplementation after a uterine torsion would be in the last 2 to 3 months of gestation, there are reports of mares retaining a nonviable fetus (one that died at 3 to 5 months' gestation) while receiving progestins.<sup>237</sup> Thus if progestin supplementation is administered to a mare after correction of a uterine torsion, it is prudent to monitor fetal viability at regular intervals.<sup>464</sup> There is probably little merit in continuing the supplementation once the mare has been discharged from the hospital. In one study 28 of 30 mares that were pregnant at the time of discharge subsequently delivered a live foal, and future fertility was good (24 of 29 were successfully rebred).<sup>482</sup>

## VAGINAL HEMORRHAGE

Visible blood on the tail hairs or hindlimbs of a pregnant mare warrants a careful examination. The integrity of placental attachment immediately cranial to the cervix should be evaluated using transrectal ultrasonography. A pocket of fluid may be evident if placental separation has occurred, and measurements of the CTUP should be made.<sup>431,442</sup> An increased CTUP measurement is a characteristic finding in cases of placentitis.<sup>419</sup> Because two of the three barriers protecting the fetus—vulvar lips, vestibular sphincter, and cervix—will be entered when performing a vaginal speculum examination, it is essential to ensure stringent hygiene.<sup>497</sup> Often, blood clots can be seen in the vestibule when the vulvar lips are parted. A sterile speculum should be covered with sterile lubricant and then gently inserted into the vagina. In some cases there may be evidence of a serosanguinous discharge from the cervical os. Mares that are aborting a twin pregnancy may also develop a bloody vaginal discharge. However, the practitioner should be aware that the most common source of vaginal hemorrhage in pregnant mares is from varicose veins in the hymenal remnants, not from an impending abortion. In many cases no blood is visible in the cranial vagina. If the cervix is closed, pale, and covered with tenacious mucus, it is unlikely that the blood is associated with fetoplacental unit. Although the blood could be associated with cystitis or urolithiasis, the source of the hemorrhage usually is varicose vessels in the remnants of the hymen at the level of the vestibular sphincter. It is not unusual to miss these as the speculum is inserted. Thus particular attention should be paid to this area as the speculum is withdrawn.<sup>497</sup>

Vaginal varicosities are most likely to occur in older, pluriparous mares during the latter months of gestation.<sup>497,498</sup> A large plexus of dilated veins can develop in the pedunculated mucosa at the level of the vestibulovaginal junction. The veins can become engorged from 1 to 2 cm during late gestation. If the vessels are ulcerated, there may be intermittent, mild episodes of bleeding from the ventral commissure of the vulva. An owner may report seeing large blood clots in the bedding when the mare is fed in the morning. Although this quantity may be alarming to an owner, it can be explained as merely representing the discharge of pooled blood while the mare was recumbent during the night.<sup>497</sup> Another explanation is that the pull of the rectal attachments when standing creates sufficient tension in the vaginal wall to control hemorrhage, whereas blood loss can occur when the mare is recumbent.<sup>498</sup> In more

severe cases there may be dried blood on the perineum, tail hairs, and hindlimbs.<sup>497</sup> The author managed one case in which the red cell count and packed cell volume were subnormal, and there are reports in which the overt vaginal hemorrhage was sufficient to cause anemia.<sup>498</sup>

The etiology of vaginal varicosities in mares is unknown. The condition is not an uncommon complication of pregnancy in pluriparous women, and it has been proposed that a similar obstruction of venous return is responsible for the development of vaginal varicosities in the mare. Poor vulvar conformation, with cranial displacement of the perineum, may be involved in some cases.<sup>497-499</sup> It is possible that repeated stretching of the vestibulovaginal tissues and changes in the vulvar conformation of pluriparous mares create a physical impairment of venous return from the vestibular and vaginal components of the internal pudendal vein.<sup>497-499</sup> The dilated veins are generally located on the cranial aspect of the vestibular fold and on the dorsal aspect of the caudal vaginal wall. Thus vaginal varicosities can be easily missed when a tubular speculum is introduced, and they may not be evident during withdrawal. In some cases a trivalve metal Caslick speculum may provide better exposure so that the tissues of the vestibular-vaginal fold can be everted and fully explored.<sup>497</sup> If the diagnosis is still inconclusive, the next logical step in the physical examination is endoscopic visualization of the bladder. The clinician should first advance the flexible scope toward the cervix and then angle the lens back to better evaluate the cranial aspect of the vestibular-vaginal fold. If vaginal varicosities are present, usually no treatment is necessary, because the vessels will regress spontaneously after foaling (benign neglect).<sup>497</sup> However, if there is persistent or excessive hemorrhage or the owner is distressed, the offending vessels can be cauterized (diathermy) or ligated.<sup>195,497,500</sup> Locating the source of the bleeding can be difficult. Traction on the adjacent vaginal mucosa may arrest the bleeding and help identify the site in such cases. Submucosal resection of a pedunculated plexus of varicose veins has been reported to be successful.<sup>497,498</sup> Treatment is generally successful, and no recurrence has been reported.

It is important to consider bleeding from the urinary tract when vaginal hemorrhage is the presenting complaint. If an owner reports having seen bloody urine on the stall floor, it should be remembered that normal equine urine contains pyrocatechine. This oxidizing agent can cause urine to turn red-brown after exposure to air.<sup>497</sup> Hematuria can result from several disorders of the urinary tract.<sup>501</sup> If it is present throughout urination, the lesion is likely to be in the kidneys, ureters, or bladder. If the endoscopic examination has not identified vaginal varicosities as the source of the hemorrhage, the endoscope should be advanced down the urethra to visualize the bladder lumen (cystoscopy).<sup>497</sup> Although cystic uroliths are more common in male horses than in mares, a urolith may cause mucosal irritation and hemorrhage, resulting in hematuria.<sup>502,503</sup> Rectal palpation may reveal a firm mass in the bladder that can be imaged by ultrasonography. The pelvic portion of the urethra should also be palpated.<sup>497</sup> Although neoplasia of the urinary bladder is rare, mares are reported to be twice as likely as male horses to develop primary bladder tumors.<sup>419,501,504</sup> Squamous cell carcinoma is the most commonly reported bladder tumor, but transitional cell carcinomas can also occur. The condition has been reported as a cause of hematuria—often with blood clots.<sup>505</sup> A more detailed discussion of hematuria may be found elsewhere in this text.

## ☪ FESCUE TOXICITY AND AGALACTIA

A wide range of reproductive problems (e.g., thickened placenta, abortion, prolonged gestation, dystocia, dead or weak foals, agalactia) have been attributed to the effects of the fungal endophyte (*Acremonium coenophialum*—now known as *Neothryphodium coenophialum*).<sup>506-508</sup> The endophyte produces a dopaminergic, vasoactive ergopeptine alkaloid (ergovaline).<sup>506</sup> This alkaloid disrupts the fetoplacental production of progestagens, but the precise mechanism has not been established.<sup>116,118,509,510</sup> Umbilical vein progestagen levels suggest that the disruption is not at the level of placental steroidogenesis—a remarkable observation when the fetal membranes are so edematous. Premature chorioallantoic separation and the failure of the membrane to rupture (“red bag”) are attributable to the edematous splanchnic mesoderm.<sup>506</sup> ACTH, T<sub>4</sub>, triiodothyronine (T<sub>3</sub>), progestagen, and cortisol concentrations are lower in foals born to endophyte-exposed mares, suggesting that the effects are actually at the level of the fetal hypothalamo-pituitary axis, thyroid, and adrenal cortex.<sup>118,511</sup> This is likely to be the basis for the prolonged gestation and fetal dysmaturity that are associated with fescue toxicosis.<sup>118,509</sup> The ergovaline also inhibits prolactin secretion in affected mares by acting as a dopamine agonist at the maternal pituitary level.<sup>154,155,510</sup> Prolactin secretion can be inhibited experimentally by administering dopamine agonists such as bromocryptine.<sup>156</sup> Not only does such prolactin-inhibiting treatment of pregnant mares result in agalactia, but it also mimics the other symptoms of fescue toxicosis (thickened placenta, prolonged gestation, and dystocia).<sup>156</sup> An effect of fescue toxicosis in pregnant mares is a lowering of the circulating relaxin levels.<sup>313</sup> Clinical observations suggest that a one-time injection with fluphenazine improved pregnancy outcome by reducing the adverse effects of fescue toxicosis concomitant with a stabilization of plasma relaxin concentrations. (Caution should be exercised with administration of fluphenazine to horses because this drug may cause severe extrapyramidal neurologic signs). These data support the hypothesis that systemic relaxin may be a useful biochemical means of monitoring placental function and treatment efficacy in the mare.<sup>313</sup>

Because mares in late pregnancy are so susceptible to the toxic effects of ergopeptine alkaloids, they should not be permitted to graze in endophyte-infected tall fescue pasture or ingest hay derived from such pasture. Short-term exposure by mares at 300 days of gestation results in a significant decline in both prolactin and total progestagen concentrations within 48 hours. Fortunately, removal of pregnant mares (300 days' gestation) from infected pasture results in a significant increase in prolactin and progestagen levels within 3 days. This will prevent the development of the typical symptoms associated with fescue toxicosis.<sup>118,509</sup> Even when alternate feed sources are limited, every attempt should be made to remove pregnant mares from endophyte-infected fescue by 30 to 60 days before the expected foaling date. When this is not possible, prophylactic administration of the dopamine receptor antagonist domperidone (Equidone) at 1.1 mg/kg, administered orally, can prevent the negative effects of fescue toxicosis.<sup>154-156,507,512-515</sup>

## ☪ INDUCTION OF PARTURITION

Induction of parturition may be indicated as a clinical management procedure for some high-risk pregnancies, including mares with hydrops, ruptured prepubic tendon, and ventral

herniation. These mares often require assistance with delivery because the stage II abdominal press may be compromised.<sup>464</sup> The author does not believe that induction should be practiced for convenience alone.<sup>516,517</sup> Owners should be advised that complications such as dystocia, premature placental separation, fetal hypoxia, and dysmaturity are not uncommon sequelae of the induction procedure.<sup>518-521</sup> The aim of a controlled foaling is not only to deliver a viable fetus but also to prevent any injury to the mare that may compromise future fertility.<sup>464</sup>

Induced foalings are sometimes indicated to ensure that optimal veterinary assistance is available when complications are expected and to optimize resuscitation attempts when a compromised fetus has been monitored in utero. When fetal stress is detected in a high-risk pregnancy, the clinician is faced with the dilemma of inducing delivery and attempting supportive care in a neonatal intensive unit or leaving the compromised fetus in utero. Owners should be informed that delivery is indicated only if the probability of extrauterine survival exceeds that for continued maternal support. Experience suggests that an abnormal uterine environment is often more conducive to maintaining a fetal foal's life than a neonatal intensive care unit.<sup>454</sup> A fetus that has been exposed to an adverse uterine environment for some time may be more tolerant of premature delivery.<sup>182</sup> Many clinicians administer a dose of corticosteroids to the mare if premature delivery appears inevitable. This may stimulate surfactant production and promote accelerated maturation of the fetal lung.

The normal physiologic processes in the parturient mare and fetus were discussed in a previous section. There is clear evidence that the fetal hypothalamic-pituitary-adrenal axis initiates the final stages of fetal maturation that initiates the hormonal cascade culminating in parturition.<sup>89</sup> Final maturation of the fetus results in increased ACTH release from the pituitary and subsequent stimulation of the fetal adrenal cortex.<sup>89,110,115,116</sup> It is not until the maturing adrenal gland attains 17 $\alpha$ -hydroxylase capacity that the high levels of pregnenolone are metabolized into fetal cortisol.<sup>89,113</sup> These vital changes lead to a fetal cortisol rise in the last 2 or 3 days before birth, and thus the equine fetus is at a substantially increased risk of dysmaturity or prematurity if the induction is not carefully planned.<sup>127,522</sup> This planning has traditionally involved confirmation of gestation length, monitoring mammary development and milk or colostrum production, and ultimately evaluating the amount of cervical softening.<sup>523</sup> The fetus will usually be in the dorsopubic position, with neck and limbs flexed before induction. The incidence of posterior and transverse presentations is rare, but detection of these abnormalities by rectal palpation before induction would be reason to re-evaluate the induction plans. Delivery by cesarean section may be a more prudent course of action, especially with transverse presentations.

Gestation length is notoriously unpredictable in mares, and the greatest predictor of gestation length may be the mare herself.<sup>524-526</sup> Although the frequently recommended minimum gestation length for successful induction is 330 days, it must be remembered that many mares will carry a foal past 340 days and occasionally to 360 days and beyond.<sup>3,523,525,527</sup> There also appears to be some breed variability in gestation length, with the mean for Friesians reported as 332 days, Lipizzaners reported at 334 days, Andalusians reported at 337 days, and Arabians reported at 340 days.<sup>526,528,529</sup> In a retrospective study of Standardbred mares, the mean duration of gestation

was 343.3 days, and it was significantly greater for colt fetuses (344.4 days) than for filly fetuses (342.2 days).<sup>530</sup> An average gestation length of 344.1 plus or minus 0.49 days was reported in a recent Thoroughbred study (n = 344 mares). Colt foal pregnancies were significantly longer (346.2  $\pm$  0.72) than fillies (342.4  $\pm$  0.65).<sup>531</sup> Colts were carried 1.5 days longer in a study of 495 Friesian mares.<sup>528</sup> The sire has been associated with duration of gestation; gestation after mating with certain sires was consistently less than 340 days in duration, whereas duration after mating with other sires was consistently more than 350 days.<sup>528,530</sup> Mares tend to carry foals longer if they are due to foal early in the season (shorter day length), whereas gestation length may be shorter if the foal is not due until longer days have arrived.<sup>525,526,528-530,532,533</sup> In Andalusians and Arabians, a delay of 1 month in breeding corresponded to a decrease of 3 days in the gestation length.<sup>526</sup> Placentitis and other placental pathology are often associated with precocious mammary gland development and premature changes in mammary secretion electrolyte concentrations. Milk electrolyte changes are unreliable for assessing fetal readiness for birth in abnormal pregnancies (e.g., placentitis, impending twin abortion). In these cases there may be elevated mammary secretion calcium concentrations (>10 mmol/L; >400 ppm; >40 mg/dl) before day 310 of gestation.<sup>121</sup>

Although mammary development is a useful sign of approaching parturition in normal mares, monitoring changes in mammary secretion electrolyte concentrations is the most reliable guide to imminent parturition.<sup>534-538</sup> An inversion in the sodium-to-potassium ratio, followed by a rapid rise in calcium (Ca) concentrations in the last 24 to 48 hours, has been correlated with fetal maturity in both mares and jennies.<sup>536,539</sup> Exact values may vary with the type of chemistry analyzer used by the diagnostic laboratory. In a normal term pregnancy, the combined mammary secretion levels of Ca (>40 mg/dl), potassium (>30 mEq/ml), and sodium (<30 mEq/ml) are indicative of fetal maturity.<sup>536</sup> Ca concentration of 10 mmol/L (40 mg/dl; 400 ppm) in mammary secretions is a reliable indicator of fetal "readiness for birth."<sup>524,534,536,538,540</sup> Several stallside tests are available that can measure the Ca ion (Ca<sup>++</sup>) concentration in mammary secretions based on a colorimetric change of pads on a test strip. Water hardness kits are also useful for determining the concentration of Ca in mammary secretions.<sup>522,540-544</sup> These involve titration of a diluted sample until an indicator dye changes color, and although they are more labor intensive than the test strips, they are reported to provide a more reliable guide for predicting the onset of parturition within the next 24 hours.<sup>544</sup> However, it is important to ensure that the water hardness kit is measuring only Ca levels if it is being used to determine the safest time to induce parturition.<sup>524</sup> Many kits merely test for divalent cations, which include magnesium as well as Ca.<sup>524</sup> Because magnesium levels peak earlier than Ca levels, misleading information about fetal maturity may be obtained.<sup>538,540</sup> If the intent is merely to predict the onset of spontaneous parturition, the type of test is not as critical.<sup>524</sup>

A recent publication has questioned the interpretation of calcium carbonate (CaCO<sub>3</sub>) test kit data that has formed the basis of recommendations that 200 or 250 ppm CaCO<sub>3</sub> be used as the benchmark for readiness for birth.<sup>524,544,545</sup> Paccamonti contends that because Ca in milk is not in the form of CaCO<sub>3</sub>, any test that measures CaCO<sub>3</sub> levels in solution must be adjusted to account for this fact.<sup>524</sup> Because the molecular weight of CaCO<sub>3</sub> is 100 and that of Ca is only 40, the conversion factor is 2.5 (i.e., divide the CaCO<sub>3</sub> ppm by 2.5 to obtain

Ca ppm). Furthermore, because mammary secretions usually must be diluted before a water hardness test can be used to measure Ca, Paccamonti recommends that 1 ml of secretion be diluted in 4 ml of distilled water. Thus the final reading should be corrected by a factor of 5.<sup>524</sup> The division by 2.5 to convert CaCO<sub>3</sub> to Ca and the multiplication by 5 to correct for the dilution mean that the test result need only be doubled to provide an accurate level of Ca ppm. Using this logic, Paccamonti contends that the reports using 200 to 250 ppm CaCO<sub>3</sub> as an indication of readiness for birth are actually using Ca values of only 80 to 100 ppm.<sup>524,544,545</sup> However, if these values are corrected for the reported test dilution (1:6) factor, the CaCO<sub>3</sub> level being reported would have been 1400 to 1750 ppm (560 to 700 ppm Ca; 14 to 17.5 mmol/L). These corrected values are thus in excess of the 400 ppm (10 mmol/L) Ca concentrations reported by other researchers.<sup>524,534-536,538,540</sup> It is obviously important to keep these calculations in mind because water hardness kits may vary and technicians may use different dilutions. Inappropriate application of the math could lead to an erroneous conclusion about fetal maturity and subsequent induction of a premature foal.<sup>524</sup>

In general, mammary secretion Ca concentrations are more reliable for predicting when a mare is unlikely to spontaneously foal rather than for determining when she is likely to foal.<sup>524,540</sup> Ley used a water hardness kit and reported that CaCO<sub>3</sub> levels greater than 200 ppm (see preceding discussion) indicated a 54% probability of spontaneous foaling within 24 hours, 84% probability of spontaneous foaling within 2 days, and 97% probability of spontaneous foaling within 3 days. A small percentage of mares foaled within 24 hours despite a CaCO<sub>3</sub> level below 200 ppm.<sup>544,545</sup> However, using Paccamonti's logic, this equates to a corrected value of less than 560 ppm Ca<sup>2+</sup>.<sup>524</sup> Because a value of 400 ppm Ca<sup>2+</sup> indicates readiness for birth, it is not surprising that some of these mares foaled. Although the fetus initiates parturition, the mare appears to be able to regulate the actual timing of delivery.<sup>517</sup> Thus any untoward changes in the mare's environment may cause her to postpone the delivery and thus create discrepancies with predictions based on mammary secretion electrolyte concentrations. Ca levels can change rapidly during a single day. Thus testing secretions in the morning and evening may be useful. If a single test is to be performed, it is preferable to check the Ca levels late in the day.<sup>524</sup> Generally, the more rapid the rise in milk Ca levels, the more imminent is parturition. Primiparous mares can be especially difficult to monitor because no change in mammary secretion electrolyte composition may be detected until immediately before foaling.<sup>522</sup>

The presence of cervical softening has traditionally been suggested as a prerequisite for optimal induction of parturition in the mare, and in a recent study mares with a relaxed cervix before induction had a more rapid delivery.<sup>474,523</sup> The same study found that foals delivered from mares with a preinduction, relaxed cervix stood and nursed sooner and had fewer signs of intrapartum asphyxia (hypercapnia, maladjustment) than foals delivered from mares with a nondilated cervix. Mares that developed parturient complications (premature placental separation, dystocia) all had a closed cervix before induction.<sup>474</sup> The status of the cervix is controversial because earlier reports suggest that inductions may proceed successfully even though the cervix is tightly closed and covered with mucus.<sup>518</sup> A recent innovation has been the administration of intracervical PGE<sub>2</sub> (2.5 mg) before induction, but no difference was apparent in the mean interval from initial oxytocin

treatment to rupture of the chorioallantois or to the delivery of the foal.<sup>473</sup> However, the impact on foal viability was positive in that foals delivered from PGE<sub>2</sub>-treated mares suckled sooner. The application of intracervical PGE<sub>2</sub> may have some merit when terminating a pathologic pregnancy (e.g., hydrops) wherein the induction is known to be premature and is aimed at salvaging the breeding prospects of the mare.<sup>228</sup> Although there is no correlation between myometrial strip (in vitro) response to oxytocin treatment and gestational age, in the author's experience premature induction with oxytocin can take much longer (1-2 hours) than an induction in mares at term.<sup>181,546</sup> This is consistent with the belief that a critical sequence of hormonal changes are required before fetal expulsion can occur.<sup>181</sup> Because the aborted fetus will generally be alive and gasping for air, it is advisable to have ready some euthanasia solution with which to humanely destroy the nonviable neonate.

Several experimental protocols have been reported for induction of parturition in the term mare, including glucocorticoids,<sup>133,518,520,547,548</sup> PGs<sup>518,520,536,549-554</sup>, and oxytocin.\* High (100 mg/day) and repeated doses (administered intramuscularly daily for 4 days) are required for glucocorticoid induction because, as is not the case with ruminants, this regimen has limited efficacy in the mare.<sup>518</sup> However, a more recent study suggests that multiple injections of dexamethasone given to healthy mares at days 315 through 317 of gestation can induce precocious fetal maturation and delivery of viable foals within 5 to 7 days. The mares remained healthy, with no evidence of laminitis.<sup>133</sup> Further studies are needed to determine whether dexamethasone treatment can be used safely in mares with compromised pregnancies.<sup>133</sup> PG induction is not very efficient in the mare. The synthetic products (fenprostalene, fluprostenol, and prostalene) are more effective than natural PG, but results can be quite variable.<sup>518,520,536,549-554</sup> Oxytocin is the preferred drug for induction of parturition in the mare. A wide range of protocols have been suggested over the years, including a bolus dose (20-75 units), low doses (2.5-20 units) repeated every 15 minutes to effect, and as a slow intravenous drip of 60 to 120 units total (1.0 unit/min).<sup>79,518,519,523,555-559</sup> Recent work suggests that the choice of oxytocin regimen is less important for foal viability than appropriate case selection and adherence to criteria for induction.<sup>474,522</sup> A low-dose protocol has been recommended because it appears to work only in those mares that have a mature fetus.<sup>185</sup> Mares were diagnosed as being ready for birth by mammary secretion Ca strip test measurements. A single injection of 2.5 IU oxytocin (administered intravenously) was given between 1700 and 1900 hr and resulted in the delivery of a normal foal within 120 minutes in 95% of mares. In response to the first oxytocin injection, 24 of 38 (63%) treated mares foaled. Another 9 of 38 (24%) foaled the next evening in response to the second injection, and 3 of 38 (8%) in response to the third treatment. It was concluded that the major advantage of injecting a daily low dose of oxytocin appears to be that such a low dose induces delivery in only those mares that are carrying a mature fetus and are ready to foal. It has been proposed that this low-dose, early-evening oxytocin protocol could be used as a reliable method to induce parturition or to predict that the mare would not foal that night, if parturition did not occur within 2 hours of treatment.<sup>185</sup> However, even this promising

\*References 185, 425, 473, 474, 518, 523, 555-558.

protocol has limitations because it is still possible to occasionally induce a mare to deliver a premature foal. Villani and Romano studied the effects of a daily oxytocin treatment (3.5 IU) on 174 full-term Standardbred mares that had mammary secretion Ca levels of greater than or equal to 200 ppm.<sup>559</sup> In this study 69% of the mares foaled within 2 hours of treatment (51.3% responded to the first oxytocin administration, 14.2% to the second, and 3.4% to the third). No significant difference between treated and control mares was observed in the gestational length ( $340 \pm 8$  days versus  $337 \pm 7$  days), duration of foaling ( $10 \pm 5.6$  minutes versus  $11 \pm 4.9$  minutes), incidence of dystocia (1.4% versus 1.7%), and failure of rupture of the allantochorion (0% versus 0.6%). No significant difference was observed in the incidence of placental retention between treated and control groups (8.1% versus 6.3%). Physical and behavioral characteristics were normal in foals of both groups. The authors concluded that daily injections of low doses of oxytocin in at-term mares showed only moderate efficacy for inducing parturition. However, the easy applicability and safety, for both mare and foal, of this method of foaling induction make it a useful tool to simplify the management of mares in commercial stud farms.<sup>559</sup>

Because most inductions will be performed because complications are expected, the clinician should be well prepared before administration of the induction agent (low-dose oxytocin).<sup>524</sup> Even if the induction is not being performed by an intravenous drip, it is recommended that an intravenous catheter be inserted. This will facilitate rapid induction of general anesthesia if obstetric difficulties ensue. A fully stocked obstetric kit and ample volumes of lubricant should be placed outside the stall. Neonatal resuscitation efforts should be anticipated, and appropriate supplies (e.g., oxygen delivery system) should be readily available. Premature separation of the placenta is not an uncommon complication of induced births. The clinician should immediately rupture the exposed chorioallantois and then assist with fetal delivery in conjunction with the mare's expulsive efforts. Overzealous traction at this time may cause a laceration of the cervix if it is not yet fully dilated. If necessary, an oxygen tube can be placed in the foal's nostril during the minute or two that may be required to complete the assisted delivery. Additional discussion of neonatal resuscitation and critical care is included in this text in Chapter 21.

## OBSTETRICS

### MANAGEMENT OF THE PREGNANT MARE

A series of publications that discuss the effects of nutrition on various aspects of equine reproduction have recently been published.<sup>560-563</sup> Copper is an overemphasized factor in the etiopathogenesis of osteochondrosis lesions. Supplementation of pregnant mares with copper had no significant effect on the concentration of copper in the liver of foals at birth or on the frequency or severity of lesions in articular cartilage at 160 days of age.<sup>564</sup> Regular exercise and routine hoof maintenance are important for broodmares. A regular anthelmintic program is essential to ensure the mare's well-being. It will also reduce the exposure of the foal to parasite eggs in the mare's feces and the transmammary transfer of *Strongyloides westeri* larvae. Pregnant mares should be current for all vaccinations that are recommended for their particular geographical locations.<sup>565,566</sup> In North America it is especially important

to advise owners about the importance of a regular vaccination program for equine herpesvirus. Owners and farm managers should be aware of the need to isolate pregnant mares from transient horses to reduce the risk of infectious disease, especially respiratory viral infections. A tetanus booster may be indicated 1 month before foaling. It is also recommended that the mare be transferred to the final foaling environment at least 1 month before the due date. Foals are born essentially agammaglobulinemic, and the neonate depends on passive transfer of colostral immunoglobulins to provide initial protection from environmental pathogens. If a vulvoplasty (Caslicks) has been performed, plans should be made to open this approximately 1 week earlier than the expected foaling date. If the mare has a history of a previous hemolytic foal (neonatal isoerythrolysis), plans should be made to prevent the neonate from suckling the mare until all the colostrum has been removed.

Those responsible for monitoring the foaling process should understand that mammary development, followed by distention and waxing of the teats and then relaxation of the perineal area, indicates approaching parturition in the mare. The use of mammary secretion electrolyte concentrations to predict foaling was discussed in a previous section. Although it is accepted that the fetus signals its readiness for birth, the mare can regulate the final timing of delivery.<sup>83</sup> Electronic monitoring systems that can be used to signal the start of parturition are also available. Inexperienced personnel should be counseled about normal foaling events and how to recognize when professional assistance is required. Inappropriate intervention by ill-informed individuals can jeopardize the foal's life and potentially cause life-threatening complications in the mare. Separation of the fetal membranes will deprive the fetus of oxygen, and this is the critical factor that must be considered when assessing an obstetric case that involves a live foal. Although most references suggest that fetal survival rates are very low if the foal is not delivered within 30 to 40 minutes of chorioallantoic rupture, one author reports having delivered live foals by cesarean section up to 90 minutes later.<sup>567</sup> These are cases that were promptly presented to the veterinary hospital and that had minimal—if any—vaginal intervention at the farm. It is likely that limited vaginal intervention is less disruptive to the placental attachment, and thus these foals are not deprived of their oxygen supply. Keeping the mare on her feet, and walking if necessary, may help to reduce straining while professional assistance is sought.

### NORMAL PARTURITION

#### TERMINOLOGY

The terms *presentation*, *position*, and *posture* are used to describe the disposition of the fetus as it enters the vaginal canal. Often a fetus is described as having been malpresented or malpositioned when the only anomaly present is postural—the most common cause of dystocia in the mare.<sup>568</sup> To prevent confusion, Vandeplassche introduced the all-encompassing term *fetal maldisposition* to describe the combination of presentational, positional, and postural abnormalities that can contribute to a dystocia.<sup>196</sup> *Presentation* describes the aspect of the fetus that enters the vaginal canal first and also the orientation of the fetal spinal axis to that of the mare (anterior or posterior longitudinal; ventrotransverse or dorsotransverse). More recently, use of the terms *cranial* and *caudal presentation* has become more common. *Position* describes the relationship

of the fetal dorsum (longitudinal) or head (transverse) to the quadrants of the mare's pelvis. The normal position for delivery is dorsosacral. A fetus that is still on its side would be right or left dorsoilial, and a fetus that is upside-down would be dorsopubic. The terms *right* and *left cephaloiliac* refer to the position of the fetal head relative to the mare's pelvic walls, and they imply that a transverse presentation was present. Posture is purely fetal and describes the relationship of the extremities (head, neck, limbs) to the foal's body.<sup>195,568</sup>

### FETAL KINETICS

Fetal mobility has been discussed with respect to umbilical cord torsion and abortion. Fetal rotation within the amniotic cavity and amniotic sac rotation within the allantoic cavity result in the characteristic twisting of the umbilical cord.<sup>411,412</sup> A highly efficient mechanism ultimately guides most equine fetuses into a cranial presentation.<sup>4</sup> Ultrasonographic studies have noted the percentage of anterior, posterior, and transverse presentations at 5 to 6 months to be 52%, 29%, and 19%, respectively, but the fetal presentation becomes predominantly anterior between 7 and 11 months.<sup>408-412</sup> Vandeplasse reported the incidence of anterior, posterior, and transverse presentations in the normal parturient mare population to be 98.9%, 1.0%, and 0.1%, respectively.<sup>196,569</sup> Ginther observed that muscular contractions close the lumen of both uterine horns between 5 and 7 months, and thus the allantoic fluid (with the fetus) is confined to the uterine body.<sup>407,409,412</sup> During this time the fetus positions itself so that its head end points toward the mare's cervix (cranial presentation).<sup>407,408,410</sup> It has been proposed that neurologic signals within the fetal inner ear may respond to the slope of the ventral uterine wall and guide the fetus to lie with its head elevated toward the cervix.<sup>409</sup> In most cases the noncord horn remains closed, whereas the cord horn gradually permits the entry of the hindlimbs between 7 and 9 months. The limbs can enter the horn only when the fetus is in dorsal recumbency because the angle between the horn and body is so acute by this stage of gestation. Thereafter, the hindlimbs remain enclosed within the cord horn and the hooves extend to the horn tip by the tenth month.<sup>407-409,412</sup> Thus the selective closing and opening of the uterine horns, with subsequent trapping of the hindlimbs, is believed to be a key feature of the mechanism that ultimately directs fetal orientation into cranial presentation.<sup>408,409</sup> Entrapment of the hindlimbs within the uterine horn generally means that the caudal portion of the anteriorly presented fetus will be lying in a dorsopubic, and occasionally dorsoilial, position.<sup>409</sup> Ginther's ultrasonographic investigations substantiate the classic radiographic study demonstrating that the full-term equine fetus is initially lying in a dorsopubic position with the head, neck, and forelimbs flexed.<sup>570</sup>

In early pregnancy the mesometrial attachments suspend the uterine horns so that they point cranially and dorsally, but by late gestation the horn containing the hindlimbs comes to rest on the dorsal surface of the uterine body, with the tip of the horn directed back toward the cervix.<sup>4,408</sup> The hooves and horn tip may be pushed so far caudally that they actually come to lie over the fetal head, meaning that when a rectal evaluation of a mare that is in late gestation is performed, the fetal hooves that are palpable may be attached to the hindlimbs. In some mares the vigorous, pistonlike thrusts of the hindlimbs in association with elevation of the fetal rump may push the hooves past the cervix into the rectogenital pouch.<sup>4,408,409</sup> This observation may explain the acute colic episodes that have

been previously attributed to uterine dorsoretroflexion.<sup>419</sup> Although the caudal aspect of the fetus is intimately associated with the uterine wall, the cranial portion has room to rotate within the uterine body itself. Ultrasonographic studies on mares close to term (>330 days' gestation) have shown that the cranial half of the fetus was in dorsopubic position approximately 60% of the time and in dorsoilial position in about 40% of the time. The forelimbs and head were usually flexed (about 80%), but in the remainder the head or limbs were extended.<sup>409</sup> Postural changes are common, and thus rectal palpation before the onset of first-stage labor is not a good predictor of impending dystocia.<sup>409,568</sup> However, detection of a posterior or transverse presentation at this late stage is cause for concern, and appropriate plans should be made to manage the impending delivery.

### STAGES OF PARTURITION

Behavioral changes that characterize the first stage of parturition include the mare looking at her flank, frequently lying down and getting up, stretching as if to urinate, and passing small amounts of feces. Patchy sweating may develop, and some mares will leak colostrum.<sup>195,568</sup> The restless behavior is similar to that of mild colic and is associated with the development of coordinated uterine contractions that increase uterine pressure and push the chorioallantoic sac (in the region of the cervical star) into the gradually dilating cervix. The increasing uterine tone during stage I of parturition may stimulate the fetus to extend its head and forelimbs up into the dilating pelvic canal.<sup>4</sup> Once the head and forelimbs are fully extended, they are unlikely to return to a flexed posture unless the foal reacts to manual intervention on the part of a foaling attendant. However, it is possible for the neck or a forelimb to develop a malposture if it is not correctly aligned when the mare begins an expulsive effort. Passage of the urineline allantoic fluid ("water breaking") concludes the first stage of labor. Rupture of the chorioallantois and passage of the allantoic fluid does not occur until the fetlocks, or sometimes the knees, are at the level of the external cervical opening. If the chorioallantois doesn't rupture, further separation from the endometrium can result in a "red bag" delivery, with the velvety red membrane appearing at the vulvar lips. In a normal delivery the chorioallantois is thought to remain attached to the endometrium until after the foal is delivered.<sup>568</sup>

Failure of the chorioallantois to rupture is a common complication of induced parturition.<sup>474</sup> If this happens, continued separation from the endometrium will compromise transplacental oxygen exchange, and fetal hypoxia is likely.<sup>568</sup> Thus premature separation of the placenta is an emergency situation, and foaling attendants should be instructed to break the membrane and provide gentle traction in unison with the mare's expulsive efforts. Although the foal should be delivered as quickly as possible, injudicious traction at this time may cause a laceration in an incompletely dilated cervix.<sup>568</sup> Applying traction only in conjunction with the mare's expulsive efforts will reduce the likelihood of creating cervical trauma.

As parturition progresses, passage of the fetus into the pelvic inlet initiates a reflex release of oxytocin from the posterior pituitary (Ferguson reflex), thereby enhancing uterine contractility.<sup>195</sup> Stage II is characterized by strong abdominal contractions that provide the expulsive force necessary to expel the fetus. Most mares will assume lateral recumbency once active straining commences. Many get up once or twice during stage II labor in what is believed to be a further attempt

to correctly position the fetus.<sup>568</sup> Appearance of the translucent fluid-filled amnion at the vulvar lips can be expected to occur within 5 minutes of rupture of the chorioallantois.<sup>571</sup> Any delay in the stage II expulsion process increases the likelihood of fetal asphyxia or neonatal problems associated with hypoxia caused by placental separation. At least one hoof should be visible within the amniotic sac, and the other should be located approximately 2 inches behind it. If everything is progressing normally, the soles of the hooves should face down toward the mare's hocks, and the foal's head should be resting between the carpi.<sup>568</sup>

By the time the nose has reached the vulva, the cranial half of the torso should have rotated from a dorsopubic to a dorsoilial position.<sup>4</sup> The mare probably assists the fetus to reposition itself by the characteristic side-to-side rolling each time she becomes recumbent.<sup>568</sup> It is likely that some dystocias involving fetal malposition and malposture are due to the failure of a compromised fetus to actively participate in the foaling process. Less vigorous or absent fetal righting reflexes early in the parturient process have been suggested by many authors as a cause of fetal maldisposition.<sup>195,481,570</sup> The observation that ventral deviation of the head and neck is more likely to be present if the fetus is in dorsoilial position than in dorsosacral position further substantiates the hypothesis that the fetal righting reflexes are compromised early in these cases.<sup>481</sup>

The second stage of labor in the mare is rapid, with the most forceful contractions occurring as the chest passes through the pelvic cavity. Most foals are delivered within 20 to 30 minutes after the chorioallantoic membrane ruptures. Primiparous dams generally require more time to expel the fetus than do multiparous dams.<sup>195,571</sup> The amniotic sac usually ruptures during these expulsive efforts.<sup>568</sup> However, the equine amniotic sac is not attached to the chorioallantois, as is the case with a ruminant placenta, and the foal sometimes may be delivered with a portion of the sac wrapped around its head.<sup>571</sup> Foaling attendants should be instructed to promptly free the foal's head from the amniotic sac to prevent suffocation. Active straining ceases once the foal's hips are delivered, and the mare will rest in lateral recumbency.<sup>568</sup> An active foal will extract the hindlimbs from the vagina as it struggles to stand. Stage III of parturition involves expulsion of the fetal membranes, which typically takes between 30 minutes and 3 hours.<sup>195</sup> Owners should be advised to seek veterinary assistance if passage of the membranes is delayed because life-threatening toxic metritis and laminitis are common sequelae of membrane retention.<sup>568</sup>

## ETIOLOGY OF DYSTOCIA

The incidence of dystocia in the general horse population varies among breeds (Thoroughbreds: 4%, Shetland Ponies: 8%, draft breeds: 10%).<sup>196</sup> Dystocia is one of the few true emergencies in equine practice; literally, a matter of minutes can determine a successful outcome (i.e., the birth of a live foal).<sup>568</sup> Perinatal asphyxia associated with dystocia is a major cause of equine reproductive loss.<sup>275,276</sup> The long fetal extremities (limbs, neck) predispose the mare to foaling problems.<sup>195,196,568</sup> Alert, informed foaling attendants are essential to ensure that abnormalities are recognized early. Attendants should suspect that the mare is experiencing obstetric problems if either the first or the second stage of parturition is prolonged, or not progressive.<sup>568</sup> Signs that a mare may be in dystocia include

the failure of any fetal parts, or of the amniotic membrane, to appear at the vulvar lips for a prolonged period after rupture of the chorioallantois; appearance of only one hoof at the vulva; hooves upside down at the vulva; hooves and nose in abnormal relationship; nose but not hooves at vulva.<sup>571</sup> The most common impediments to delivery are malpostures of the fetal extremities (head and neck, limbs).<sup>481</sup> An experienced foaling attendant may be able to correct minor problems and facilitate a successful delivery. However, inappropriate intervention can have potentially fatal consequences for the mare. Furthermore, obstetric manipulations can easily damage the uterus and cervix to the extent that the mare's reproductive future is jeopardized.<sup>568</sup>

## MANAGEMENT OF DYSTOCIA

When attending to a mare in dystocia, the veterinarian should make a rapid assessment of the mare's general physical condition, noting, in particular, mucous membrane color and refill time (hemorrhage, dehydration, shock).<sup>568</sup> A mare that is aborting in late gestation may experience a dystocia because the dead fetus cannot participate in the delivery process. A malodorous discharge strongly suggests the presence of an emphysematous fetus. The perineal area should be inspected to determine the presence and nature of any vulvar discharge and the presence of fetal membranes and to identify any fetal extremities. Excessive hemorrhage or vulvar swelling may indicate that nonprofessional intervention has caused trauma to the reproductive tract. Occasionally, a mare will exhibit a rectal prolapse, an everted bladder, or intestinal loops protruding from the vulvar lips.<sup>568</sup> The intestines may be of fetal origin if there is incomplete closure of the ventral abdomen, but a ruptured vagina is more likely. In the later scenario the foal's foot may have ruptured the floor of the cranial vagina, but injudicious manipulations by an inexperienced attendant should not be discounted. If a rectal prolapse or the urinary bladder is evident, then an epidural anesthetic should be administered to prevent further straining. Alternately, the mare may be anesthetized to facilitate hoisting the hindquarters.<sup>568</sup> The advantage of this approach is that the straining can be stopped immediately. This is especially important if the prolapse involves an intussuscepted colon (type IV).<sup>572,573</sup> In these cases a palpable trench may extend several feet into the rectum, and avulsion of the mesentery can be a fatal complication that is not readily amenable to surgical correction.

The author considers stocks to be contraindicated when examining a foaling mare and prefers to perform the initial examination on a standing mare with no more restraint than a twitch or lip chain if her demeanor will permit this to be performed safely. The behavior of a mare in stage II labor is unpredictable and may be violent. It is important to ensure that the examination area is clean, with good footing. There should be ample space for the mare handler, obstetrician, and assistants to move to safety if necessary. Although most veterinary tranquilizers readily cross the placenta and can compromise the fetus, adequate restraint is essential for the safety of all concerned.<sup>574</sup> Sedation with tranquilizers may be necessary for some uncooperative mares, and in extremely intractable cases it may be preferable to anesthetize the mare with a short-acting combination. In these cases a hoist should be available because manipulating the foal is sometimes difficult when the mare is in lateral recumbency. Although not essential, an initial rectal examination may help the practitioner

rule out the presence of a term uterine torsion and determine the condition of the uterine wall (tears, spasm). It also may provide useful information regarding the disposition of the fetus. Before any vaginal examination the mare's tail should be wrapped and the perineal area thoroughly cleansed. The clinician's arms and hands should be scrubbed with disinfectant soap.<sup>568</sup> In a hospital environment the author also wears sterile rubber obstetric sleeves. Cleanliness and lubrication are the cornerstones of obstetrics.

The mare's vagina and cervix are easily traumatized by the friction associated with vaginal manipulations. Once the mucous membrane has been abraded, it is likely that adhesions and fibrosis will follow. Thus copious amounts of lubricant are vital to ensure that the soft tissues of the genital tract are not traumatized and thus preserve the mare's future fertility.<sup>575</sup> Lubricants include methyl cellulose, polyethylene polymer, white petrolatum combined with 10% boric acid, and mineral oil. Water-soluble lubricants are generally not as desirable, because they rapidly lose their lubricating abilities in the presence of fluids.<sup>195</sup> If a large volume of lubricant is to be pumped around the fetus, investigating the possibility of a uterine laceration is essential. In a referral situation the author routinely performs an abdominocentesis. Serosanguinous to sanguinous fluid that contains elevated total protein levels and an increased white blood cell count is highly suggestive of a uterine rupture.<sup>492</sup> If a uterine tear is unlikely, the author prefers to mix a polyethylene polymer powder with warm water and then use a clean stomach tube and pump to gently instill large volumes of lubricant into the uterine lumen.<sup>575</sup> This is repeated as often as necessary during the procedure to keep the fetus and reproductive tract coated with lubricant.

The vagina, cervix, and accessible parts of the uterus should be carefully explored to ascertain the source of any hemorrhage. Lacerations should be noted and their presence discussed with owners or the attending personnel before any veterinary manipulations are attempted. Occasionally, the cause of the dystocia is a pelvic deformity (e.g., callus). It is important to determine the degree of cervical dilation.<sup>568</sup> If the mare has been in labor for some time, it is possible that the uterus is relatively dry and tightly contracted around the fetus. This will make intrauterine manipulations much more difficult, especially because it becomes difficult to repel the fetus back into the uterus safely. If the uterus is contracted, warm lubricant tends to induce some uterine relaxation, and the volume expansion creates additional space in which to perform manipulations.<sup>477,575</sup> Myometrial contractions (uterine spasm) can be controlled by tocolytic drugs (isoxsuprine, clenbuterol) if they are available for veterinary use.<sup>196</sup> Although fetopelvic disproportion is uncommon in the mare, it can be a factor in some equine dystocias.<sup>52,53,57,568</sup> The disposition of the fetus should be noted and fetal viability determined. Care should be exercised because active fetal response to manipulations can easily complicate an initially simple dystocia.<sup>568</sup> Placement of a rope snare behind the ears and into the foal's mouth ensures that the clinician always has control of the head. This will facilitate correction of a potentially life-threatening development such as lateral deviation of the head and neck if the fetus pulls away from the clinician's manipulations.<sup>568</sup> If the snare is placed around the mandible, it is essential that only gentle traction be applied to guide the fetal head through the vaginal canal. Excessive force may cause a fracture of the mandible. When obvious fetal movement is absent, digital withdrawal may be initiated in response to pinching of the coronary band.

Slight digital pressure over the eyelid onto the eyeball may arouse a response, as may stimulation of the tongue (swallowing). If the thorax can be reached, fetal heartbeat is definitive. In posteriorly presented cases the digital and anal reflexes are useful as indicators of fetal viability. Occasionally, it may be possible to reach the umbilical cord.<sup>195</sup>

The clinician should inform the owner of the various options, costs, and prognosis once the current status of the foal is known and the cause of the dystocia has been determined. Ensuring that the owner is aware of the potential complications that may arise is especially important because postpartum medical care can become quite expensive. If delivery of a live foal is anticipated, the clinician should consider the potential for fetal cardiovascular compromise before administering any tranquilizers to the mare.<sup>568</sup> Light sedation of the mare with acetylpromazine (2 to 3 mg/100 kg IV) has minimal effect on the foal and may be useful in some cases.<sup>576</sup> Xylazine is preferable to detomidine if the fetus is viable because its depressant effects are of much shorter duration.<sup>576</sup> However, neither xylazine nor detomidine should be used alone to sedate a dystocia case because some apparently sedated mares can become hypersensitive over the hindquarters.<sup>453,576</sup> The combination of xylazine and acepromazine provides good sedation in a quiet mare.<sup>585</sup> The author routinely uses a combination of xylazine (0.3 to 0.5 mg/kg IV) and butorphanol (0.01 to 0.02 mg/kg IV) for standing obstetric procedures if more sedation is required (e.g., fetotomy procedure). This provides good sedation and analgesia, and additional doses may be administered as necessary. Attendants are instructed to keep the lip chain loose and to tighten it only when instructed to do so. This will ensure that it retains its effectiveness when required to divert the mare's attention.<sup>568</sup> LeBlanc suggests a xylazine (1.1 mg/kg) and morphine (0.1 to 0.2 mg/kg) combination for sedation of fetotomy cases but cautions that gastrointestinal stasis is a frequent complication.<sup>574</sup> Although most dystocias can be resolved at the farm fairly quickly by brief manipulation and assisted vaginal delivery, the practitioner should consider the alternatives if resolution is likely to take more than 10 to 15 minutes. Prolonged, unproductive vaginal manipulations are contraindicated in equine obstetrics. Decisions on the next course of action should be based on the viability of the foal, the clinician's obstetric skills, the availability of equipment and facilities, and the financial constraints imposed by the owner.

An epidural does not prevent the mare's myometrial contractions or the abdominal press, and the time involved in administering an effective epidural anesthetic may make this form of restraint impractical when a live foal is present.<sup>568,576</sup> However, if the foal is dead, epidural anesthesia does reduce vaginal sensitivity and thus the mare's perception of vaginal manipulations (Ferguson reflex). Caudal epidural anesthesia should be used at the clinician's discretion, especially if general anesthesia or referral may become necessary. When an epidural is indicated, the author uses a combination of xylazine (0.17 mg/kg) and lidocaine (2 to 3 ml) diluted in saline, such that the final volume does not exceed 8 to 10 ml in order to reduce the likelihood of hindlimb weakness.<sup>576,577</sup> Excess volume can cause the mare to become ataxic. Short-term general anesthesia may be indicated when minor postural abnormalities are present and maternal expulsive efforts make correction difficult.<sup>505</sup> A xylazine (1.1 mg/kg IV) followed by ketamine (2.2 mg/kg IV) provides a general anesthetic with a smooth, short (10 to 15 minutes) duration. Addition of the central-acting muscle

relaxant guaifenesin (1 L of a solution of 5% guaifenesin in 5% dextrose) can provide an additional 10 to 20 minutes for fetal manipulation.<sup>576</sup> In specialist equine hospitals that are located close to well-managed broodmare farms, the fetus is often still alive when the mare arrives.<sup>567,578</sup> A well-coordinated dystocia team that uses a defined protocol can minimize time spent nonproductively. Intrapartum intratracheal intubation and positive pressure ventilation of the fetus (ex utero intrapartum treatment [EXIT]) during resolution of the dystocia has been shown to improve survival rates. It should be remembered that positive pressure ventilation must be continued once begun because it promotes the conversion from fetal circulatory patterns to neonatal patterns, essentially eliminating the role of the umbilicus.<sup>578</sup> In referral hospitals it is common practice to anesthetize the mare after a brief vaginal intervention and then maintain the mare on halothane-oxygen with controlled ventilation. Because halothane anesthesia has been shown to compromise umbilical circulation, the concentration should be kept to a minimum if the foal is still alive.<sup>496</sup> Total intravenous anesthesia (the so-called triple drip of ketamine, xylazine, and guaifenesin) may be preferable until the foal has been delivered.<sup>574</sup> The mare should be ventilated with oxygen, and intravenous fluids should be administered as required. If the hind-end elevation technique is used, almost three quarters of such cases can be resolved by controlled vaginal delivery. However, if the fetus is still alive and has not been delivered within 15 minutes, an immediate cesarean section is performed—with a 30% foal survival rate possible, provided that the time from rupture of the chorioallantois to presentation at the veterinary hospital is minimal.<sup>567,579</sup> Fertility after cesarean section is quite good, and adverse reports probably pertain more to the extent of vaginal manipulation after surgery.<sup>580,581</sup> If a hoist is available in the field, hobbles can be placed on the hind pasterns and the hindquarters briefly elevated 1 to 2 feet. The combination of a relaxed uterus and the effects of gravity can facilitate fetal repulsion and manipulation. If attempts at mutation are successful, the mare should be lowered into lateral recumbency to permit extraction of the foal.<sup>568</sup> Prolonged dorsal recumbency results in compression of the aorta and vena cava and reduction in venous return, cardiac output, and blood pressure.<sup>574</sup> Hindlimb paresis may develop after prolonged hindquarter suspension and can complicate the recovery process. The use of pads to support the hindquarters will help take some weight off the limbs while the mare is suspended.

*Mutation* is an obstetric term that is used to describe manipulation of the fetal extremities, with correction of any positional abnormalities, such that assisted vaginal delivery can proceed.<sup>195</sup> Although extra space is available for manipulations when the fetus has been repelled into the uterus, the clinician should remain cognizant at all times that overzealous obstetric manipulations are a major cause of uterine rupture.\* Repulsion of the fetus from the maternal pelvis is contraindicated if the uterus is contracted down around the fetus. In some cases pumping warm obstetric lubricant around the fetus induces some degree of uterine relaxation. In countries where they are legal, tocolytic agents are effective in relaxing a contracted uterus. If the fetus is dead, many cases may be amenable to correction by fetotomy provided that the clinician has the appropriate skills and equipment.<sup>586-589</sup> Although

poor technique and inappropriate fetotomy cuts often lead to infertility, experienced clinicians can rapidly resolve a dystocia while preserving the mare's future breeding potential.<sup>586,589,590</sup> The alternative is cesarean section.<sup>578,579,591</sup>

Traction must be applied with careful regard for both maternal and fetal well-being.<sup>575,592</sup> Traction applied entirely by hand often is all that is necessary. Obstetric straps or chains may provide a better grip. The author prefers to apply one loop above the fetlock, with a second loop encircling the pastern.<sup>575</sup> In assisted vaginal deliveries traction should be applied as an adjunct when the mare is exerting expulsive force and should be released when the dam stops straining, thereby permitting rest and recovery. This approach is critical to permit adequate dilation of the caudal reproductive tract.<sup>575</sup> Copious lubrication and slow traction with continuous monitoring of cervical dilation are especially important when a controlled vaginal delivery is performed on an anesthetized mare.<sup>579</sup> Excessive use of force may be associated with fetal fractures (ribs, vertebrae, and limbs) and maternal soft tissue trauma.<sup>592</sup> No more than two or three people (depending on size and strength) should apply traction to the fetus.<sup>575</sup>

### CRANIAL (ANTERIOR) PRESENTATION

An anteriorly presented fetus that is in dorsosacral position with head and forelimbs extended should require minimal traction to complete the delivery, assuming that the vaginal canal is well lubricated. By ensuring that slightly more traction is applied to one limb than the other, the practitioner reduces the width of the fetus across the shoulders and can successfully deliver most cases. If progress is not being made, then all traction should stop and the vaginal canal must be fully explored.<sup>575</sup> There are three likely possibilities: elbow lock (incomplete extension of the forelimb); dog-sitting or hurdling posture; and, occasionally, a fetus that is too large. Absolute or relative fetopelvic disproportion is uncommon in the mare, even when the foal has been carried several weeks past the expected due date. In fact, some cases of prolonged gestation may involve a smaller than normal, dysmature fetus.<sup>195,593</sup> In a referral hospital study, fewer than 2% of dystocias were attributed to this condition.<sup>481</sup> It is significant, however, that approximately 30% of referral hospital dystocia cases are in primiparous mares.<sup>481,569,571</sup> Primiparous mares were disproportionately represented in a report on dystocia and neonatal asphyxia from the central Kentucky area.<sup>229,594</sup> Thus, although fetopelvic disproportion is not common in the mare, obstetric assistance (traction) is required much more often in primiparous mares.<sup>196,594,595</sup> Dystocia in these mares is further complicated by a tight vaginostriatal sphincter, which may predispose primiparous mares to lacerations and rectovaginal tears.<sup>594</sup> If copious lubrication and gentle traction do not help, cesarean section or partial fetotomy are the only alternatives.

Incomplete elbow extension may be unilateral or bilateral and should be suspected if the fetal muzzle lies at the same level as the hooves.<sup>575</sup> In this posture the fetal elbows will be tucked back under the shoulder joint, causing increased depth and width of the fetus within the maternal pelvic inlet. Correction involves repelling the fetal trunk so that the forelimbs can be extended and thus raise the elbows up over the floor of the pelvic inlet.<sup>477</sup>

In a dog-sitting or hurdling posture, there is either bilateral (dog-sitting posture) or unilateral (hurdling posture) hip flexion. This causes the fetal hooves (or hoof) to push against the pelvic brim during attempts at fetal extraction.<sup>575</sup> The

\*References 195, 477, 491, 492, 419, 582-585.

unilateral posture is more common.<sup>481</sup> Severe trauma can be inflicted on the mare if this malposture is not recognized and inappropriate amounts of traction are applied. Thus it is important to stop all traction and repel the fetus enough to sweep the floor of the pelvic inlet. In extreme cases the hindlimb may actually extend under the fetus and up into the vagina.<sup>481</sup> Although the hindlimb may be successfully repelled if the fetus is alive, it is a difficult procedure and is associated with some risk of uterine laceration. Judicious use of a snare or fetotome may facilitate safe repulsion of the hindlimb by looping the pastern and using the instrument to repel the hoof away from the pelvic brim. Repulsion should not be attempted on a standing mare if the fetus is dead because the hindlimb may not return to its normal position.<sup>586,588</sup> In such cases the hoof of the flexed hindlimb can puncture the ventral uterine wall as the foal is being extracted. If a dog-sitting or hurdling foal is dead, it is recommended that general anesthesia and hoisting of the hindquarters be employed to reduce the risk of ventral uterine rupture.<sup>596</sup> In experienced hands partial fetotomy is a viable alternative to cesarean section.<sup>586-588,590</sup> A surgical alternative to a cesarean section involves manipulation of the hindlimb through a ventral midline celiotomy incision. An assistant may be able to extract the fetus through the vagina once the hindlimb has been grasped through the ventral incision. If successful, this technique will reduce the potential for contamination that may be associated with cesarean section. If a cesarean section is performed, some surgeons prefer to remove that portion of the foal that is protruding through the vulvar lips before withdrawing the hind end out through the surgical site.<sup>419</sup>

In a foot-nape posture one or both of the forelimbs is displaced over the foal's head and pushed against the roof of the vagina.<sup>575</sup> To correct this malposture the fetus must be repelled into the uterus by applying pressure to the head. Once the forelimbs have been replaced under the head, fetal extraction can proceed quite uneventfully.<sup>575</sup> If not corrected immediately, the mare's straining can cause the fetal hoof to lacerate the vaginal roof, and in extreme cases it can result in a rectovaginal fistula. A fistula is all that occurs if the foal withdraws its hoof from the rectum before delivery. A third-degree perineal laceration occurs if the strong expulsive efforts of the mare cause the limb that has penetrated the rectum to dissect through the caudal rectovaginal shelf and rupture through the anal sphincter, thereby creating a cloaca.<sup>597-598</sup>

Carpal flexion is a common cause of dystocia.<sup>589,590</sup> It may be unilateral or bilateral, and typically the affected carpus is located at the pelvic inlet.<sup>575</sup> To safely correct this malposture, the fetal body must first be repelled into the uterus. If the dystocia is prolonged, the amount of uterine contraction may preclude meaningful repulsion of the fetus back into the uterus. Because the fetus is likely to be dead in these cases, a relatively simple fetotomy cut can be made at the level of the distal row of carpal bones. This permits safe delivery of the foal without the need to traumatize the reproductive tract and generally facilitates extraction within minutes.<sup>586,588,590</sup> If the foal is alive, repulsion into the uterus will permit the flexed limb to be grasped at the level of the fetlock and pastern. By rotating the wrist, the obstetrician can rotate the carpus laterally while bringing the flexed fetlock medially and caudally into the birth canal. This maneuver allows maximal use of available space by obliquing the extremity through the pelvic inlet. The obstetrician should be aware that flexural deformities are considered to be the most common congenital anomaly of foals

and that the rigid deformity often means that a cesarean section or fetotomy must be performed.<sup>229,275,569,586-588</sup> Limb contractures are generally bilateral. Contracture is more common in the forelimbs than the hindlimbs but can involve all four limbs.<sup>569,575</sup> Severely affected limbs cannot be straightened, and needless trauma can be inflicted on the genital tract by unrewarding attempts to manually correct the malposture. It is important that the clinician cup the hand over the bottom of the fetal hoof at all times while attempting to straighten the limb. Failure to do so may result in injury to the reproductive tract. Application of an obstetric chain or rope to the distal limb can be a useful aid. This permits traction to be applied to the distal limb while the hand covers and guides the hoof.<sup>575</sup>

The single most common abnormality in referral hospital dystocia populations is a reflected head and neck.<sup>196,481,569,589</sup> Unfortunately, these malpostures are often iatrogenic in that a viable fetus has pulled back from the initial vaginal intervention that aimed to correct a minor postural problem. If the mare strains while the foal's head is pulled back, it is possible for the muzzle to engage the wall or floor of the pelvic inlet. The mare's forceful expulsive efforts may then drive the head and neck ventrally, or laterally along the thorax, while the forelimbs are pushed further into the vaginal canal. Ventral or lateral displacements of the head and neck can be very difficult to correct. The length of the foal's neck often makes it impossible to reach the head. Inexperienced clinicians should consider referral as soon as the condition is diagnosed because prolonged unrewarding manipulations can easily jeopardize the mare's future fertility.<sup>575,578</sup> A relatively simple fetotomy cut can resolve these cases quite atraumatically if the fetus is dead when the veterinarian arrives. The author believes that this approach is preferable to prolonged—and often unsuccessful—attempts at manual correction of this extremely difficult malposture.<sup>586,590</sup> If the fetus is alive, an attempt can be made to place eye hooks or to loop a snare around the mandible. Some obstetricians even suggest applying a clamp on an ear to pull the head back enough to place a snare. The author prefers to use a snare whenever possible. If traction can be applied to the head, the foal's body must be carefully repelled while attempts are made to bring the head and neck around into a normal posture for delivery. Factors influencing the successful outcome include uterine tonicity, clinician arm length and skill, and the presence or absence of torticollis and facial scoliosis.<sup>569,575</sup> As with contracted tendons, it is essential that the practitioner consider the possibility of a wry neck. This condition is not amenable to correction by mutation, and needless trauma can be inflicted on the genital tract by unrewarding attempts at correction. Ventral deviation of the head is relatively easy to correct if the fetal nose is just below the brim of the pelvis (poll posture). It is generally easier to rotate the head laterally before attempting to bring the muzzle up over the pelvic brim. In more severe cases the neck is tucked down between the forelimbs and the head is often beyond reach (nape posture).<sup>569,575</sup> If attempts to reposition the head and neck are unsuccessful, then cesarean section or fetotomy are indicated.<sup>579,586-588,590</sup>

Shoulder flexion posture may be unilateral ("swimming" posture) or bilateral ("diving" posture).<sup>569,575</sup> To gain access to the retained limb, it is usually necessary to repel the head and neck into the uterus. An immediate cesarean section may be preferable if the foal is alive because correction of this malposture can be difficult and time-consuming. If this is not an option, it is recommended that a soft rope snare be placed on the fetal head (behind ears and into mouth) so that the

head can be readily retrieved once the shoulder flexion has been corrected. If the limb can be reached, correction of this malposture is performed in two stages. Initially, the shoulder flexion is converted to a carpal flexion by grasping the limb in the area of the humerus and working down to the distal radius. The limb is then pulled caudally and medially as the fetal body is repelled. The carpus is then hooked over the brim of the pelvis to create a carpal flexion, which is then corrected as previously described. It must be remembered that it is not always possible to repel the head sufficiently to gain access to the retained forelimb. In these cases cesarean section is the only option for delivery of a live foal. If the fetus is dead, a fetotomy cut to remove the head and neck may provide sufficient room to correct the malposture.<sup>586-588</sup>

### CAUDAL (POSTERIOR) PRESENTATION

A foal in posterior presentation will have the soles of the hooves facing up. Although the author has seen dystocia in which an anteriorly presented foal was in dorsopubic position with both forelimbs extended, this is a very unusual complication. Foaling attendants should be instructed to wash the mare's perineum and then to use a clean arm to check for the hocks somewhere in the vaginal canal. Gentle traction on the hindlimbs in conjunction with the mare's expulsive efforts may facilitate delivery of a live foal. However, approximately half of the fetuses may be malpositioned as well, and they often require veterinary assistance to permit an atraumatic delivery. Foals in caudal (posterior) presentation are more likely to be in dorsoilial position than foals in a cranial (anterior) presentation.<sup>481</sup> Although a normally positioned fetus in caudal presentation may not be particularly difficult to deliver, it is more likely to suffer hypoxia because of compression of the umbilical cord under the fetal thorax or because of premature rupture of the umbilical cord.<sup>575</sup> Although only about 1% of foals are presented posteriorly, this malpresentation accounts for between 14% and 16% of referral hospital dystocia cases because any postural abnormalities create a major complication.<sup>196,481,569</sup> Typically, both hindlimbs are involved, and these types of dystocia cases (hock flexion, hip flexion) are extremely difficult to correct under field conditions. Hock flexion malposture accounts for about one quarter of referred posterior cases.<sup>196,481,569</sup> Correction of a hock flexion is dangerous because of the risk of perforation of the dorsal aspect of the uterus. The fetus must be repelled into the uterus while one hock is pushed dorsolaterally and the distal limb is directed medially. The procedure for obliquing the extremity into the birth canal is similar to that previously described for correction of a carpal flexion. An obstetric chain or strap can be used to apply traction to the limb while the hoof is cupped in the hand. Straightening a flexed hock entails considerable risk because the hock is invariably forced against the dorsal uterine wall. When the uterus is contracted, there is a real possibility of causing a laceration or perforation. Cesarean section may be preferable for delivery of a live fetus. The author strongly believes that fetotomy is a safer procedure than attempts at mutation if the fetus is dead.<sup>579,586-588</sup> Approximately half of referred posterior presentation cases are breech (bilateral hip flexion posture).<sup>196,481,569</sup> A cesarean section is indicated if the fetus is alive because the manipulations involved in correcting this malposture are time consuming and extremely difficult. The comments for managing a hock flexion apply because if mutation is attempted, the hip flexion must first be converted into a flexed hock posture.<sup>575</sup> A key point is to

remember to flex both hocks before attempting to straighten a limb. If one limb is extended into the vaginal canal while the other hip remains flexed, the fetal body will move back into the pelvic canal, and this will make it extremely difficult to access the retained limb.<sup>593</sup> If the fetus is dead, the author recommends attempting to convert the bilateral hip flexion into a hock flexion posture, followed by correction with two fetotomy cuts through the distal row of tarsal bones. This may be safer and less traumatic than attempting to straighten the limbs, provided that the clinician is experienced in the use of a fetotome.<sup>587</sup> Attempts to correct a bilateral hip flexion by fetotomy, without first creating a bilateral hock flexion, are often unrewarding because of the difficulty in correctly placing the fetotomy wire. Referral for cesarean section will often provide the best prognosis for future fertility in these cases.

### TRANSVERSE PRESENTATION

Only about 1 in 1000 foals is presented transversely. Successful resolution of these dystocia cases requires a significant amount of obstetric experience, which explains why these rare presentations account for between 10% and 20% of referral hospital dystocia cases.<sup>481,569,581</sup> Most transverse presentations are ventral transverse, with the abdomen and limbs of the fetus presented toward the birth canal.<sup>196,481,569</sup> Although the widespread adoption of ultrasonography has markedly reduced the likelihood of a twin birth, this possibility must always be explored when more than two limbs are present in the birth canal.<sup>229,275</sup> In some instances it may be possible to repel the head and forequarters of the fetus while extending the two hindlimbs into the pelvic canal. If the manipulations are successful, the transverse presentation is thus converted into a posterior presentation for vaginal delivery. The likelihood of successfully resolving one of these cases is improved if the mare has been anesthetized and the hindquarters elevated.<sup>575</sup> Transverse presentations may be associated with flexural limb deformities, angular limb deformity, and spinal deformity. If the fetus is alive, the delivery method of choice is cesarean section.<sup>579</sup> Dorsal transverse presentations, with the spinal column of the fetus presented toward the birth canal, are very rare. These cases warrant an immediate referral for cesarean section, even if the foal is dead.<sup>196,481,569</sup> Although an experienced obstetrician may be able to deliver a transversely presented fetus by fetotomy, the owner should be advised that this will be a difficult and time-consuming procedure, with a high risk of trauma that will likely impede the mare's future fertility.<sup>575,586-588</sup>

### FETAL ANOMALIES

Hydrocephalus is not uncommon in equine fetuses, especially in pony breeds.<sup>196,481,569,599</sup> The condition occurs when increased intracranial pressure causes the bones of the skull to enlarge, sometimes almost doubling the size of the head.<sup>569</sup> The skull is often very thin, and many affected foals can be delivered after incising the soft portion of the skull with a finger knife, allowing the skull to collapse.<sup>586</sup> The trunk of the hydrocephalic fetus is generally smaller than normal and seldom interferes with delivery.<sup>575</sup> If the enlarged cranium is bony, a fetotomy cut may be necessary to reduce the size of the head.<sup>586-588</sup>

## ☞ CARE OF THE POSTPARTUM MARE

The fetal membranes should be examined as a matter of routine to ensure that they have been passed intact and to check for any placental anomalies that may indicate impending

problems in the neonate. The chorioallantois often has tears that can be misleading, especially if the mare has trod on the membranes repeatedly. Examining the allantoic side of the membrane may be helpful in that the blood vessels can be pieced together and will give some idea as to whether a portion is actually missing.<sup>30</sup> Ideally, all foaling mares should receive a brief physical examination within 24 hours of parturition. If the mare's attitude is normal and she displays typical maternal behavior toward the foal, the udder should be checked and the perineal area inspected for evidence of trauma.<sup>196</sup> A detailed reproductive examination is usually unwarranted because it may unnecessarily disrupt the normal mare-foal bond that is developing at this time.<sup>600</sup> Routine postpartum use of oxytocin or PG (cloprostenol) therapy is not warranted because there is no apparent benefit for uterine involution in normally foaling mares.<sup>601</sup> All mares should receive a thorough reproductive examination at the foal heat.<sup>477</sup> Occasionally, an enlarged ovary is detected. This may be a GTCT that has enlarged during the course of the previous pregnancy. Prompt diagnosis and surgical intervention may permit the mare to resume normal cyclicity and conceive during the current breeding season.

Abdominal discomfort in the peripartum mare may be due to uterine contractions, especially if the mare has been treated with oxytocin to promote passage of the fetal membranes. However, other causes of abdominal pain should not be discounted.<sup>493,602-604</sup> When a postpartum mare displays abdominal discomfort, the author believes that abdominocentesis is indicated. The normal foaling process does not alter the composition of the peritoneal fluid from within the normal range. Even a dystocia does not necessarily cause significant changes in the peritoneal fluid. If an experienced obstetrician performs the vaginal manipulations or fetotomy, the fluid should remain normal.<sup>493</sup> If the peritoneal fluid is normal, the mare should be monitored closely for signs of clinical deterioration. Repeated abdominocentesis may be indicated when clinical signs suggest that a parturient-related abdominal lesion may be present because the peritoneal fluid constituents can change within hours.<sup>493</sup> A single elevated peritoneal fluid value (total protein, white cell count, or percent neutrophils) may be an incidental finding. Elevation of two or more values often signals the onset of clinical abnormalities. It has been the author's experience that if a postpartum peritoneal fluid sample has a total protein value above 3.0 g/dl, in conjunction with a white blood cell count greater than 15,000 cells/ $\mu$ l, and a white blood cell differential count greater than 80% neutrophils (especially if degenerative changes are present), then the presence of a potentially life-threatening lesion is likely.<sup>493</sup> The peritoneal fluid analysis should not be viewed in isolation and must be considered in conjunction with the history and clinical signs being exhibited by the mare. In the author's experience, detection of changes in the peritoneal fluid almost invariably indicates the presence of foaling-related trauma in either the reproductive or the gastrointestinal tract. An early diagnosis followed by appropriate medical or surgical intervention (or both) will often result in a favorable outcome. If treatment is not implemented until the affected mare has become depressed and febrile, with accompanying signs of shock and toxemia, the prognosis may be more guarded.

### PERIPARTURIENT HEMORRHAGE

The arterial supply to the uterus is supported by the mesometrium (broad ligament). The major blood supply to the uterus is from the uterine artery, a branch of the external iliac artery.

It forms a cranial branch that supplies the proximal uterine horn and a caudal branch that supplies the distal uterine horn and uterine body. The smaller ovarian artery gives off a uterine branch that anastomoses in the proximal horn with the cranial vessels from the uterine artery. The urogenital artery is a branch off the internal pudendal artery, and it gives rise to the caudal uterine artery along with vessels to the rectum, ureter, bladder, urethra, and vagina. The caudal uterine artery supplies the lateral side of the cranial vagina and continues past the cervix to ramify on the uterine body, where it anastomoses with the caudal branch of the uterine artery.<sup>3,605,606</sup> Hemorrhage from these vessels, especially the large-diameter uterine artery, is a significant cause of periparturient colic signs and death in older multiparous mares.<sup>195,419,583,604,605,607,608</sup> However, a retrospective study of 73 cases suggests that periparturient hemorrhage can occur in mares of any age or parity, and the condition may occasionally occur before foaling.<sup>609</sup> In a study of 98 postpartum deaths, almost 40% were due to uterine artery rupture.<sup>604</sup> The rupture may be anywhere along the vessel and is typically 2 or 3 cm in length and oriented parallel to the long axis of the vessel. There generally is no evidence of a predisposing aneurysm.<sup>604</sup> An association with low serum copper levels has been proposed as a reason for vessel fragility in aged mares.<sup>610</sup>

There appears to be a predilection for right-side uterine vessel rupture. It has been suggested that the extent of cecal displacement of the gravid uterus to the left may be sufficient to place increased tension on the vessels in the right broad ligament.<sup>604,608</sup> Although the added stress of dystocia may increase the chances of arterial rupture, many cases occur in mares that appeared to have an uneventful delivery.<sup>419,604</sup> Hemorrhage from the hypertrophied vessels that supply the gravid uterus may be rapidly fatal, especially if the artery ruptures directly into the peritoneal cavity. The mare may be found dead or moribund with pale mucous membranes, tachycardia (up to 140 beats/min), and tachypnea. Heroic attempts to administer blood transfusions, plasma expanders, and associated fluid therapy may save the life of some valuable mares, but costs are often prohibitive.<sup>321,419,477</sup> If the bleeding is contained within the broad ligament, the mare may be trembling and will exhibit signs of extreme pain (anxiety, sweating, colic), presumably as a result of the stretching of the broad ligament as the hematoma develops.<sup>477,583,604</sup> The color of the mucous membranes may not change initially because of vascular compensation, and often these initial colic signs are mistaken for the typical discomfort experienced by postpartum mares as the uterus contracts. However, if significant hemorrhage is present, the color of the mucous membranes will eventually become pale and capillary refill will be delayed.<sup>583</sup> These mares must be monitored closely because the hematoma can subsequently rupture out of the mesometrium and lead to rapid exsanguinations.<sup>608</sup>

If a ruptured artery is suspected, the mare should not be disturbed any more than is necessary to perform an examination.<sup>194</sup> In many cases, postponing, or even forgoing, rectal palpation may be prudent. Although an internal examination will reveal valuable diagnostic information, transabdominal ultrasound, abdominocentesis, and a hemogram may be all that is necessary to confirm that an acute hemorrhagic episode has occurred.<sup>196,477</sup> Transabdominal ultrasonographic evaluation will reveal free blood in the abdominal cavity if the hematoma has torn the broad ligament.<sup>321</sup> If the broad ligament tears after a uterine artery rupture, a bloody tap invariably

results, with an elevated red blood cell count in the peritoneal fluid.<sup>492</sup> The centrifuged sample will have a pink or hemolyzed appearance if hemoperitoneum is present. A smear that reveals phagocytosed erythrocytes indicates hemorrhage rather than contamination during sampling.<sup>321</sup> Even if a clot has contained most of the hemorrhage within the broad ligament, there is often considerable blood loss into the peritoneal cavity. The initial hemogram during an acute hemorrhagic episode can be confusing because the relative loss of erythrocytes and plasma may not alter the hematocrit immediately. Splenic contraction will also temporarily raise the hematocrit.<sup>321</sup> In the author's opinion, these mares should not be transported because movement could destabilize the clot and prove fatal. Any supportive therapy should be administered at the stall until the mare has stabilized. The foal should be kept safely nearby so that the mare does not become unduly distressed.

Most recommendations for the management of postpartum hemorrhage in mares are based on the collective wisdom of experienced clinicians and from methodologies that have been extrapolated from the human trauma literature. The approach taken will be governed by the facilities and expertise available and financial constraints. In some instances an extreme hypotensive state may actually offer the best chance for survival (conservative approach), whereas in other cases an attempt to restore intravascular pressures and circulatory volume could be indicated. The conservative approach is to confine the hypotensive mare to a dark, quiet stall with minimal disturbances. In some cases a platelet-fibrin plug allows the rent in the vessel to be sealed once the arterial pressure falls. Tranquilizers (especially acetylpromazine) should be used with caution because any induced drop in blood pressure may exacerbate the hypovolemic shock. Some clinicians employ hypotensive resuscitation by administering a vasodilating agent in conjunction with intravenous fluid therapy.<sup>321</sup> The idea in this instance is to provide lifesaving volume replacement while maintaining a low mean arterial pressure. In life-threatening situations anything that may stabilize the mare is worthwhile, but the clinician should consider the possibility of impeding resolution of the hematoma by rapid expansion of blood volume and elevation of blood pressure. The need to support cardiac output and ensure oxygen delivery must be balanced against the prospect of the increased arterial pressure promoting further hemorrhage.<sup>321</sup>

Although costly, an aggressive therapeutic approach can occasionally save the life of a valuable mare.<sup>321,604,611</sup> If a valuable mare presents in shock and appears to be deteriorating rapidly, a large intravenous catheter should be inserted and substantial fluid therapy begun. Whole blood transfusions must be given slowly and thus are of little benefit for resuscitative purposes when rapid volume expansion is required. One option is rapid administration of 2 to 3 L of hypertonic saline, followed with 10 to 20 L of lactated Ringer's solution over a period of 2 to 4 hours. An alternative to the hypertonic saline is the high oncotic pressure exerted by colloids (e.g., 3 L hydroxyethyl starch).<sup>321</sup> Synthetic oxygen-carrying fluids are commercially available but extremely expensive. Supplemental oxygen can be provided by nasal insufflation at a flow rate of 5 to 10 L/min. If the hematocrit continues to drop to under 15%, whole blood transfusions (6-8 L over several hours) may be warranted.<sup>321</sup> Benefits include provision of oxygen-carrying cells, clotting factors, and oncotic pressure (albumin).

A shock dose of corticosteroid is indicated. Because hemorrhagic shock can cause ischemic-reperfusion damage to the gut

and lungs (multiple organ failure), broad spectrum antibiotics, antioxidant drugs, and anti-inflammatory medication may be warranted if the mare survives the initial hemorrhagic crisis.<sup>321</sup> Flunixin meglumine (1.1 mg/kg) is administered to reduce the inflammatory cascades activated by ischemia, and may help to alleviate the mare's discomfort. Low-dose (10 to 20 IU) oxytocin therapy may be useful to promote uterine involution and thereby reduce the weight supported by the ligaments. Higher doses should be avoided because an induced colic episode may precipitate a fatal hemorrhage. Antifibrinolytic drugs (aminocaproic acid, tranexamic acid) may assist with clot stabilization. Pentoxifylline increases erythrocyte flexibility and may increase oxygen delivery to ischemic tissues.<sup>321</sup> It should be remembered that there is little refereed veterinary literature to validate the use of some of these medications in the horse. For instance, a conjugated estrogen product has been proposed on the basis of its ability to shorten prolonged bleeding times in humans. However, the benefit, if any, would not be realized until several days after the crisis has passed. Likewise, anecdotal reports suggest that naloxone (8 mg) may be efficacious, but the concept has been extrapolated from small animals, and controlled equine studies are lacking.<sup>321,419,477</sup> A controversial historical therapy to promote hemostasis in the horse is the use of intravenous buffered 10% formalin. Advocates suggest that dilute formalin solutions could enhance the activation of the clotting cascade. However, recent controlled studies were not able to demonstrate an effect on coagulation parameters or template bleeding times in normal horses.<sup>612</sup> Broad spectrum antibiotics should be administered to prevent infection of the hematoma.<sup>419</sup>

If hemorrhage is contained within the wall of the uterus, the intramural hematoma may be an incidental finding at the foal heat examination. However, some mares may exhibit variable signs of abdominal discomfort, even to the extent of warranting an exploratory celiotomy.<sup>419,597,613-615</sup> If an endometrial laceration severs an artery in the uterine wall, substantial hemorrhage may ensue, often with blood escaping from the vagina. The mare should be confined to a stall and low-dose oxytocin therapy instituted. Uterine irrigation is contraindicated because it will disrupt clot formation and prolong the hemorrhagic episode. The internal pudendal artery, one of the terminal branches of the internal iliac artery, gives rise to the umbilical artery and the urogenital artery before terminating in branches to the perineal area and the vestibular bulb. The small cranial vesicular artery supplies the apex of the bladder before the remainder of the umbilical artery terminates into the cordlike round ligament of the bladder. The urogenital artery gives rise to a caudal uterine branch that runs cranially on the side of the vagina and ramifies with the caudal branch of the uterine artery on the body of the uterus. The urogenital artery also supplies branches to the rectum, ureter, caudal bladder, and urethra and continues as the vaginal artery to the caudal portion of the reproductive tract.<sup>3,605,606</sup> A hematoma arising from these vessels may dissect along the fascial plane within the pelvic cavity and present as a large unilateral vulvar swelling.<sup>583</sup> Affected mares typically will be experiencing violent colic. Abscessation of a retroperitoneal hematoma can become a life-threatening complication after a dystocia, and thus prophylactic broad spectrum antibiotic coverage is warranted.<sup>604</sup> Mares with an infected retroperitoneal hematoma develop signs of toxemia. In these cases the peritoneal fluid has an increased total protein content (3.0 to 5.0 g/dl) with a massive increase in the white blood cell count (often exceeding 100,000 cells/ $\mu$ l).<sup>492</sup>

## UTERINE PROLAPSE (EVERSION)

Uterine prolapse, or eversion, is an uncommon complication of equine parturition that may occur up to several hours (and occasionally several days) after fetal delivery.<sup>419,616</sup> The condition may be complicated by bladder eversion (or prolapse), uterine rupture, or intestinal herniation and may be rapidly fatal if the uterine artery is ruptured.\* If the mare is standing and personnel are available, instructions should be given to place the uterus in a large plastic bag and elevate it to the level of the vulva. This may prevent further damage to the endometrium and, more important, will relieve the tension on the uterine vessels.<sup>616</sup> Fluid therapy may be indicated, and any calcium deficit must be corrected. Epidural anesthesia may reduce the amount of reflex straining provoked by vaginal manipulations, but it will not eliminate the mare's strong abdominal press.<sup>576</sup> General anesthesia may be necessary if the mare exhibits violent discomfort or if straining is excessive. Any uterine lacerations should be closed with absorbable sutures. The well-lubricated uterus is then pushed back through the vagina with a kneading motion. The fingertips can easily damage the edematous tissue, and manipulating the uterus through a plastic bag will reduce the likelihood of a finger rupturing the wall.<sup>477,617</sup> Ultrasonography is useful to evaluate any suspicious contents. A trapped bladder may be aspirated through a large-diameter needle, but a loop of bowel may require a ventral midline celiotomy.<sup>419</sup>

The replaced uterus should be distended with sterile saline to ensure that the tips of both horns are fully extended. Repeated low doses (10 to 20 IU every 2 hours) of oxytocin should be administered to promote uterine involution. Failure to ensure complete extension of the uterine horns into a normal position within the abdomen may result in discomfort, straining, and recurrence of the prolapse.<sup>477</sup> Vulvar retention sutures should not be necessary provided that the uterus has been completely returned to its normal position, that the calcium deficit has been corrected, and that low-dose oxytocin therapy has been administered. Broad spectrum antibiotics, nonsteroidal anti-inflammatory drugs, and tetanus prophylaxis are indicated. The mare should be closely monitored for evidence of internal hemorrhage. Affected mares may exsanguinate after the uterus has been replaced. Ischemic damage to trapped bowel is a potential complication. The clinician should be cognizant of the potential risks of endometritis-metritis, septicemia, endotoxemia, and laminitis. Between 2 and 3 days of intrauterine therapy may be warranted, depending on the condition of the exposed endometrium.

## PARTIAL INVERSION (INTUSSUSCEPTION) OF THE UTERINE HORN

Injudicious traction on a retained fetal membrane remnant may invert the tip of the uterine horn, and this may progress to complete uterine prolapse.<sup>477</sup> If only the horn is affected, compromised circulation and pressure on nerve endings may produce signs of abdominal discomfort. Thus the tips of both uterine horns should be rectally palpated when evaluating a postpartum colic case. The affected horn will be shorter than normal and extremely thickened.<sup>196,419,618</sup> Manual reduction by pressure from within the uterine lumen may be possible in

some cases, and infusion of several liters of saline solution will usually ensure extension of the affected horn.<sup>196</sup> Oxytocin (10–20 IU) should then be administered and the fluid drained from the uterus as it contracts. Resolution of the problem should be confirmed by rectal palpation.

## UTERINE RUPTURE

In any dystocia case there is a risk for iatrogenic tears, and the uterus should always be checked for any obvious lacerations immediately after extraction of the fetus. Early recognition is important because the prognosis is worse once peritonitis develops.<sup>492,582,583,604,619</sup> However, obstetric intervention is not always the cause of uterine tears. Occasionally, the foal's hoof may be forced through the dorsal uterine wall during the mare's expulsive efforts, and the mare may be found with a loop of bowel protruding through the vulvar lips.<sup>419,491</sup> The exposed bowel should be rinsed with sterile saline and replaced, but a ventral midline celiotomy may be warranted to fully evaluate intestinal damage and to repair the uterine laceration. A more common lesion in unassisted deliveries is a tear toward the tip of the gravid uterine horn.<sup>619,620</sup> Although the fetal hooves are covered with hard gel-like pads that presumably protect the placenta and uterine wall, the vigorous pistonlike thrusts of the hindlimbs may occasionally cause a rupture.<sup>4,408,621</sup> Affected mares generally experience bouts of colic and become depressed, febrile, and anorectic as peritonitis develops. The interval from occurrence of the tear to diagnosis and initiation of therapy has a marked impact on the prognosis for survival.\* It may not be possible to ascertain uterine integrity by vaginal palpation alone.<sup>583</sup> The tips of the horns may be especially difficult to palpate from within the postpartum uterus. The changes in the peritoneal cavity depend on the duration of the condition, but generally one can expect to see serosanguinous to sanguinous fluid containing elevated total protein, increased white blood cell counts, and often extracellular and intracellular bacteria.<sup>492,585,619,622</sup> Laparoscopic evaluation of the uterus may confirm the diagnosis and provide useful information when determining the need for surgery.<sup>623</sup> Complete perforation of the uterine wall is not necessary for peritonitis to develop if traumatic obstetric manipulations have damaged the uterine wall.<sup>624</sup> However, recent research shows that even a fetotomy procedure does not alter the composition of the postpartum peritoneal fluid if it is performed correctly.<sup>492</sup>

If a uterine laceration is suspected (partial or full), the mare should receive systemic broad spectrum antibiotic coverage. Nonsteroidal anti-inflammatory medication may prevent the development of endotoxemia. Oxytocin therapy (10 to 20 IU every 2 hours) will promote uterine involution. The dose can be increased if the mare does not become uncomfortable. Fluid therapy should be administered as necessary, ensuring that calcium levels are within the normal range. Intensive medical management may suffice for small dorsal uterine tears, but most warrant suturing if costs are not a limitation.<sup>619,620,622,623</sup> Opinions vary on the need for, and usefulness of, peritoneal lavage.<sup>619,623</sup> Large full-thickness tears warrant surgical intervention. In some instances a laceration in the uterine body can be sutured blindly in situ, but often a ventral midline celiotomy is the preferred approach.<sup>477,493,582,622</sup>

## RETAINED FETAL MEMBRANES AND TOXIC METRITIS

Once the umbilical cord ruptures, there is a sudden cessation in blood flow through the capillary network in the placenta.<sup>195</sup> This causes a reduction in the tissue volume of the microcotyledons, and the rhythmic tubocervical contraction waves cause the membrane tips to separate and invaginate into the horn. The ongoing tubocervical detachment process causes the membranes to be passed inside out, with the allantoid surface exposed. The membranes should be expelled within 3 hours after parturition, and the incidence of retention has been reported to range between 2% to 10% of foalings.<sup>419,480,625,626</sup> Membrane retention tends to be most commonly associated with the tip of the nongravid horn and appears to be associated with dysfunction of the initial separation process.<sup>31</sup> In circumstances wherein tissue inflammation is common (e.g., abortion, dystocia, cesarean section), it is more likely that membrane retention will occur. In these cases the endometrial edema may trap the microcotyledons within the endometrial crypts. Mares with membrane retention may have a significantly lower serum calcium level.<sup>627</sup> A recent study noted that the number of endometrial mast cells observed during the puerperal period is significantly lower in the endometrium of mares with retained fetal membranes.<sup>628</sup> It is likely that some dysfunction of the normal endocrine-related maturational processes within the microcotyledons is involved. One study suggests that there may be an association between inbreeding and the high incidence of fetal membrane retention in Friesian mares.<sup>528,629</sup>

Appropriate management of a mare with fetal membrane retention varies depending on the time since foaling.<sup>630</sup> Although some mares, especially those foaling in a natural environment, may not experience any complications, prophylactic medication is recommended under intensive husbandry conditions.<sup>626,631</sup> Bacterial contamination in this environment is highly likely. If a severe metritis develops, inflammation of the uterine wall permits bacteria and toxins to enter the systemic circulation, producing septicemia and endotoxemia.<sup>624,632</sup> Laminitis is a frequent sequela.<sup>477</sup> The approach to treating retained fetal membranes (RFMs) varies considerably, depending on the duration of membrane retention and the presence or absence of metritis with septicemia. In normal, unassisted foalings, one or two treatments with oxytocin may be all that is required to facilitate passage of the RFMs. The protruding placental remnants should be tied in a knot above the mare's hocks. An initial low dose (10 to 20 IU) of oxytocin is recommended because some postpartum mares are especially sensitive to this hormone and may experience a severe bout of colic within minutes of treatment. Higher doses are likely to be counterproductive because myometrial spasm will occur instead of the desired rhythmic tubocervical contractions. If colic does occur, the mare should be sedated so that she does not roll and possibly injure the neonate.<sup>477</sup> In these cases the next dosage of oxytocin should be reduced. Each mare's response to the initial treatment governs the subsequent dose recommendations of 10 to 20 IU incremental increases every 2 hours.

The author routinely distends the chorioallantoic sac with fluid after any obstetric procedure. This procedure, known as the *Burn's technique*, has promoted membrane expulsion (5 to 30 minutes) in most of the postdystocia mares that the author

has managed. A major advantage is that expulsion of the intact fetal membranes will remove any contaminants that may have been introduced by the obstetric procedures.<sup>633</sup> The technique works only if a sterile nasogastric tube can be passed beyond the torn distal fragments and is best performed while the membranes are still fresh. In more protracted cases the rapidly autolyzing chorioallantois becomes friable and generally tears once the fluid pressure increases. To perform the procedure the exposed fetal membranes are held tightly around the tube while 12 to 15 L of solution are infused. The opening is then tied off with umbilical tape. The exact mechanism is unknown, but expansion of the uterine lumen may dilate the endometrial crypts such that the weight of the membranes can atraumatically pull the microcotyledons free. Endogenous oxytocin release can be supplemented to enhance uterine contractions.

Because the uterine response to oxytocin wanes during the postpartum period, the dose may be increased in small increments every 2 hours in mares that retain their fetal membranes despite the initial therapy. If a hospitalized mare is receiving intravenous fluids, each oxytocin treatment can be added to the fluid line. Another option is to add oxytocin to the fluid bag at a dose that is calculated on the basis of the flow rate (1 IU/min).<sup>477</sup> However, a disadvantage of this approach is that these fluids must be discarded if the mare becomes uncomfortable yet still requires rehydration. The calcium ion plays a vital role in myometrial contractility, and it is important to ensure that calcium levels are within the normal range.<sup>538,634</sup> Supplemental calcium can markedly expedite the rate of passage, which suggests that uterine hypomotility is a component in some of these cases.<sup>626</sup> Controlled exercise is often beneficial in promoting uterine involution but is not always feasible if the mare is hospitalized or is being kept in a stall while a compromised neonate is being medicated.

It is widely accepted that excessive traction on the fetal membranes is contraindicated, but a recent study suggests that cautious manual removal of the membranes may not be as deleterious as previously thought.<sup>635</sup> When the membranes are extracted by force there is inevitably disruption of the epithelial barrier, making the traumatized uterine lining more susceptible to bacterial invasion and the development of metritis.<sup>632</sup> Endometrial trauma is also likely to contribute to the development of periglandular fibrosis. It is not uncommon for the membrane tip to tear off and remain firmly attached within the nongravid horn.<sup>31</sup> Injudicious traction on the membranes can also cause an inversion of the tip of the uterine horn, and this can progress to a complete uterine prolapse.<sup>477</sup> If the fetal membranes have not been expelled after 2 days of supportive therapy, the autolytic tissue becomes less firmly embedded and a gentle twisting technique—with minimal traction—applied within the attached horn will often result in successful removal of the entire chorioallantois. In the author's experience, this procedure works best while the uterus is being distended during a uterine lavage. Recent studies suggest that a safe and potentially effective treatment for RFMs in mares may be intraplacental injections of collagenase.<sup>636,637</sup>

If the membranes have been retained for 6 to 8 hours when the mare is first examined, then systemic antibiotic therapy is indicated.<sup>477</sup> Drugs that have been recommended for systemic administration include ampicillin, gentamicin, kanamycin, penicillin, ticarcillin, and trimethoprim-sulfamethoxazole.<sup>419</sup> If a remnant is missing when the membranes are examined,

then the approach to therapy should proceed as if the entire membrane were still present. Characteristic signs of toxic metritis are fever, depression, anorexia, tachycardia, and infected mucous membranes.<sup>632</sup> The foal will not be receiving adequate milk intake, and many of these mares will have bounding digital pulses and evidence of laminitis. Rectal palpation will reveal a large, thin-walled, atonic uterus that contains moderate to large amounts of fetid fluid.<sup>477</sup> A large volume of toxic, red-brown, watery fluid can accumulate within the pendulous postpartum uterus before any obvious vaginal discharge becomes evident. Often the history will reveal that the fetal membranes were discarded without being checked to ensure that they were passed intact.

Because the endometrium is likely to be necrotic, therapy should include broad spectrum antibiotics, anti-inflammatory drugs, and intravenous fluids if indicated. Tetanus prophylaxis is advisable. A combination of penicillin and gentamicin is widely used to provide broad spectrum systemic coverage, especially against the coliforms that frequently contribute to endotoxemia and laminitis.<sup>638</sup> Flunixin meglumine should be administered to ameliorate the effects of endotoxemia. It is commonly administered intravenously at a reduced dose (0.25 mg/kg) thrice daily.<sup>477</sup> Phenylbutazone (2 to 4 mg/kg) and provision of deep, soft bedding are useful to alleviate pain when laminitis appears to be imminent. Radiographs can be useful to monitor changes in the position of the pedal bone. Vasodilators such as acetylpromazine maleate may be administered by intramuscular injection (0.02-0.04 mg/kg every 4 to 6 hours).<sup>638</sup> Further discussion of the diagnosis and treatment of endotoxemia and laminitis are found in Chapter 15 and Chapter 11.

The uterus should be lavaged with sterile saline or very dilute ("weak tea") povidone-iodine solution. If povidone-iodine is used, the final concentration should not exceed 0.1%; this is equivalent to 10 ml of 10% povidone-iodine solution (e.g., Betadine) in 1 L of saline. If costs are a concern, 90 ml in a 9-L bucket of clean water may suffice. Extreme caution should be exercised to keep from puncturing the inflamed uterine wall with the tube. The lavage should be repeated until the returning fluid is relatively clear. The goal of therapy is to eliminate toxins and to prevent the rapid proliferation of bacteria—especially coliforms and possibly anaerobes. The administration of intrauterine antibiotics in the postpartum mare is controversial because little scientific validation has been performed. Intrauterine administration of antibiotics and antiseptics may depress the phagocytic activity of uterine neutrophils, and many chemicals are known to irritate the endometrium in mares being infused for endometritis.<sup>419</sup> The pharmacokinetic properties of each drug will influence its efficacy in the postpartum uterus. Most of the studies regarding intrauterine therapy in mares have addressed therapy for endometritis in nonparturient animals. The efficacy of antibiotic formulations in the presence of the mixed bacterial population and tissue debris associated with fetal membrane retention in the mare remains to be established. The antibiotic of choice should be added to a large infusion volume (2 to 3 L) to ensure uniform distribution across the inflamed endometrial surface once a lavage has removed the toxic fluid and necrotic debris. Unpublished microbiologic studies in the author's laboratory have demonstrated that many organisms cultured from metritis fluid are sensitive to amikacin.<sup>639</sup> Infusion of 2 g of this antibiotic after a uterine lavage is clinically effective. Polymixin B may have some merit because of its

endotoxin-binding ability. Powdered and propylene glycol-based oxytetracycline formulations are known to be irritating when infused into the involuted uterus and therefore should be avoided.<sup>187,640</sup> Other antibiotics that have been suggested for postpartum intrauterine therapy include ampicillin (3 g), ticarcillin/clavulanic acid (1 to 3 g), and gentamicin (2 to 3 g).<sup>419</sup> In the author's unpublished studies, less than 60% of isolates from metritis fluid were sensitive to ampicillin.<sup>639</sup>

## GASTROINTESTINAL COMPLICATIONS

Prolonged straining during dystocia can lead to variable amounts of rectal mucosa being forced out through the anal sphincter (type I rectal prolapse). The tissue then becomes subject to trauma, contamination, and vascular compromise. If not promptly corrected, pressure from the anal sphincter will cause venous congestion and swelling. This promotes more straining, and the condition can deteriorate rapidly. A type II prolapse involves all or part of the ampulla recti.<sup>419,598</sup> An epidural anesthetic may help decrease straining. Topical glycerin or dextrose may be applied to the prolapsed tissue to reduce edema.<sup>419,477</sup> A purse-string suture can cause additional straining and will impede defecation.<sup>419,641</sup> Fecal softeners should be administered and the diet modified (e.g., pellets, pasture) to help produce soft feces.<sup>419,642</sup> Chronic prolapses may warrant surgical resection of the devitalized mucosal mass.<sup>419,642</sup> In a type III prolapse, there is a full-thickness rectal prolapse and an intussusception of the peritoneal rectum or small colon.<sup>419</sup> In a type IV prolapse the intussuscepted bowel protrudes through the anus such that there is a palpable trench that may extend several meters into the rectum, depending on the length of the intussusception.<sup>419,572,573,641</sup> Midventral celiotomy is usually necessary to reduce the intussusception, although some smaller prolapses will reduce after an attendant has extracted the foal.<sup>419</sup> The short mesentery that supports this section of bowel is often torn from the colon. Thus these cases have a guarded prognosis, dependent on the vascular integrity of the affected small colon. The author has seen this condition develop when as little as 6 to 10 inches of bowel appears to be prolapsed. The avulsion most likely occurs when the mare's intermittent straining forces an extra 4 to 6 inches of bowel in and out of the rectum. Thus it is imperative to prevent straining as soon as possible. If the foal has not yet been extracted, it may be best to immediately anesthetize the mare, then elevate the hindquarters before attempting to correct the cause of the dystocia.

In rectal prolapse cases that have been managed conservatively, one of the first postpartum clinical signs may be discomfort attributable to impaction colic. If avulsion of the mesocolon has occurred, ischemic necrosis of the affected bowel will cause a delayed peritonitis. Because early intervention is essential, sequential abdominocentesis is indicated when a type III or IV rectal prolapse is being conservatively managed. Initially, there may be negligible changes in the composition of the peritoneal fluid. However, if an avulsion has occurred, the compromised segment of bowel will soon lose its integrity and a massively increased white blood cell count can occur within 24 to 48 hours as peritonitis ensues.<sup>492</sup> Laparoscopic evaluation of the abdomen can provide an immediate assessment of bowel integrity and permit an accurate prognosis to be given to the owner.<sup>494</sup> The affected colon is not readily accessible for resection and anastomosis, so the prognosis in most cases is guarded.<sup>642</sup>

Variable degrees of uncomplicated impaction are not uncommon in the postparturient mare, possibly as a result of localized perineal pain causing reluctance to defecate.<sup>477</sup> Astute managers will note an absence of fecal matter in the stall. Treatment with fecal softeners (e.g., mineral oil) and analgesics generally corrects the problem. Laxative feeds (e.g., bran mash) are effective in reducing the incidence of constipation in foaling mares.<sup>196</sup> Postpartum mares appear to be at an increased risk for development of a large colon torsion.<sup>273,604,643</sup> This condition presents as an especially violent colic with readily discernible abdominal distention. Extensive ischemic damage affects the prognosis, but early surgical intervention can increase the survival rate.<sup>583,644</sup> Bruising of the abdominal viscera can occur during foaling, with subsequent development of moderate to severe signs of impaction colic and peritonitis.<sup>419,583</sup> Occasionally, the mesentery may be torn from a segment of intestine, leading to ischemic necrosis and peritonitis. An early diagnosis and prompt surgical intervention may save the mare's life.<sup>492,494,602-604,645</sup> A rent in the mesentery or broad ligament at the time of foaling may permit a segment of bowel to become incarcerated even weeks later.<sup>270,597,603,604,646</sup> Owners should be advised that surgical correction is feasible only if the segment of devitalized bowel is accessible.<sup>270,603,645-647</sup>

Although mares tend to reduce their feed intake in the days leading up to foaling, ensuring a reduction in the amount of available roughage may help reduce the incidence of bowel rupture.<sup>196</sup> The tip of the cecum is the most likely site of a foaling-related rupture in the alimentary tract. On rectal palpation the inflamed serosal surfaces will feel roughened, with a discernible crepitus. Abdominocentesis will reveal dark green-brown gastrointestinal fluid that contains plant material and massively increased neutrophil numbers. Humane euthanasia is indicated because the leaking ingesta incites a severe peritonitis with accompanying septic shock, and the condition is likely to be rapidly fatal.<sup>419,604,648-652</sup> Diaphragmatic herniation has been reported as a rare parturient complication in heavily pregnant mares.<sup>491,653-655</sup> Colic symptoms are attributable to strangulating obstruction or tension on the mesentery. Some mares may exhibit respiratory distress. Transthoracic ultrasonography can help confirm the presence of bowel within the thorax.<sup>656</sup> Surgical repair of the defect may not be possible, and assisted ventilation will be required.<sup>654,655</sup>

## VAGINAL LACERATIONS AND BLADDER PROLAPSE

Primiparous mares are especially susceptible to vaginal trauma. Vaginal lacerations are most likely to occur during injudicious attempts to relieve dystocia. Although most lacerations are retroperitoneal, they still may contribute to severe vaginitis, fibrosis, and possibly abscessation. If ventral trauma is present, a urinary catheter should be passed to check for urethral integrity. In some instances ligation of a severed artery will be necessary. Emollient creams, tetanus prophylaxis, broad spectrum antibiotics, and anti-inflammatory drugs are indicated. A major concern is the possibility of herniation of intestine into the vagina if the tear is located just caudal to the cervix in the vicinity of the urogenital pouch.<sup>604,657</sup> If eventration has occurred, the bowel should be cleansed and examined for evidence of vascular compromise. If the involved intestine appears to be grossly normal, it should be rinsed with sterile saline and returned to the abdominal cavity. If vascular

compromise is detected at the time of the initial examination, then the prognosis is guarded and a ventral midline celiotomy to facilitate resection is warranted. A bladder prolapse occurs when the bladder is forced up through a vaginal laceration. The viscus rapidly becomes distended as a result of the continued accumulation of urine from the ureters and an inability to void urine because of kinking of the urethra. The edematous serosal surface of the bladder may protrude through the vulvar lips.<sup>477</sup> The exposed organ should be thoroughly cleansed, then gently returned the abdominal cavity. It may be necessary to administer an epidural and aspirate urine to facilitate replacement. If possible, the vaginal laceration should be sutured once any viscera have been returned to the abdominal cavity. In some cases the severity of the trauma precludes successful closure, and the wound must heal by second intention.<sup>657</sup> Placement of a Caslick suture reduces the possibility of bacterial aspiration. Mares may be cross-tied for several days to decrease the risk of eventration brought about by elevation of intraabdominal pressure as the mare lies down.<sup>477</sup> The mare should be treated for impending peritonitis (e.g., broad spectrum antibiotics, nonsteroidal anti-inflammatory drugs). Tetanus prophylaxis is indicated. If severe colic symptoms develop, bowel compromise should be suspected.<sup>492</sup>

## EVERSION OF THE URINARY BLADDER

The mare's urethra has a large diameter, and occasionally the bladder may be everted up into the vagina after severe straining.<sup>658</sup> If the everted bladder protrudes through the vulvar lips, the exposed mucosal surface will rapidly become edematous, and urine may be seen to drip from the ventral surface. Closer inspection will reveal that the urine is dribbling from the exposed papilliform openings of the ureters on the dorsal surface of the neck of the bladder.<sup>659</sup> A lip chain and epidural may provide adequate restraint to facilitate replacement. The mucosal surface should be thoroughly cleansed and any defects repaired. Sterile lubricant should be applied and the friable organ gently massaged back through the urethra. In some instances it may be necessary to incise the urethral sphincter if the bladder mucosa is especially thickened.<sup>659</sup> This incision should be closed once the bladder has been replaced. A Foley catheter can be inserted to lavage the bladder lumen and ensure complete repositioning. Broad spectrum antibiotic coverage, nonsteroidal anti-inflammatory drugs, and tetanus prophylaxis are indicated.

## RUPTURE OF THE URINARY BLADDER

Occasionally, the bladder may rupture as a consequence of increased intra-abdominal pressure in the foaling mare or because of direct trauma during parturition.<sup>660-662</sup> Clinical signs are delayed and are associated with electrolyte imbalances. Affected mares may be depressed and inappetent, with failure to void urine. Clinical examination will reveal tachycardia, tachypnea, and decreased gastrointestinal activity. Blood chemistry will reveal elevated serum levels of creatinine, blood urea nitrogen, and potassium, in addition to decreased sodium and chloride levels. Evaluation of a peritoneal fluid sample helps confirm the diagnosis. The fluid will contain elevated urea and creatinine levels and calcium carbonate crystals.<sup>660,661</sup> Cystoscopy is useful to evaluate the size and extent of the bladder injury. Once the mare's medical condition has been stabilized, surgical repair is indicated.<sup>597,660-662</sup>

A standing vaginal approach eliminates the need for general anesthesia and allows excellent observation and repair of bladder tears in adult mares.<sup>662</sup>

## RECTOVAGINAL FISTULAS AND PERINEAL LACERATIONS

A first degree perineal laceration involves the mucous membrane of the vestibule and the skin of the vulvar lips. In second-degree perineal lacerations, the deeper tissues of the perineal body are involved. Both of these conditions may be associated with unassisted delivery of a large foal or may be a sequela of dystocia. The laceration may be amenable to immediate repair and placement of a Caslick suture, or the clinician may elect to wait until the wound has granulated. The mare should be treated with broad spectrum antibiotics, anti-inflammatory medication, and tetanus prophylaxis. Provision of a bran mash diet and administration of mineral oil may facilitate defecation during the initial inflammatory period.

Third-degree perineal lacerations generally occur during unassisted foalings when the fetal hoof catches on the vaginal roof at the vestibulovaginal junction. Forceful straining by the mare can drive the hoof through the rectovaginal shelf such that the fetal hoof comes to lie within the rectum. If the fetus is viable, it may remove the affected limb and delivery will proceed unimpeded; a rectovaginal fistula results. If the limb remains within the rectum, continued passage of the fetus causes the trapped limb to tear out the perineal body and anal sphincter. The resulting defect is called a *third-degree perineal laceration*. These injuries do not respond well to immediate surgical intervention, and the general recommendation is to wait 4 to 6 weeks before attempting reconstructive surgery.<sup>597,658,663</sup> In the interim the mare should be treated with broad spectrum antibiotics, anti-inflammatory medication, tetanus prophylaxis, and fecal softeners.

Grade IV (full-thickness) rectal tears that communicate directly with the peritoneal cavity have a poor prognosis and can occur as a result of parturition.<sup>664,665</sup> Tears tend to occur just cranial to the caudal peritoneal reflection. Such cases warrant immediate intervention, and the rectum should be packed to prevent abdominal contamination during transport to a referral hospital. A standing technique that permits an easy and effective stapled primary closure repair has been described.<sup>664</sup>

## PERINEAL BRUISING AND VULVAR HEMATOMAS

Much of the swelling after prolonged obstetric manipulations is edematous. Fecal softeners such as oral mineral oil and bran mash are recommended to ease the passage of feces through the swollen and bruised perineal area.<sup>491,496</sup> Hematomas in the vaginal wall and vulvar lips are not uncommon, especially in primiparous mares and mares that have delivered an extremely large foal. It is important to differentiate a bulging vestibular hematoma from an everted or prolapsed bladder.<sup>196,605</sup> Needle aspiration of vulvar hematomas is not recommended because of the risk of abscessation. Broad spectrum antibiotics and tetanus prophylaxis are indicated. Most hematomas will resolve uneventfully, but some vulvar, vaginal, or pelvic hematomas may warrant drainage in 7 to 10 days.<sup>491</sup>

## POSTPARTUM ECLAMPSIA (LACTATION TETANY)

Postpartum eclampsia, or lactation tetany, is extremely rare in mares but may occur in animals that are lactating heavily. The highest incidence is reported in draft breeds, but the author has encountered a case in a pony mare. Equine eclampsia is generally associated with some type of stress (e.g., change in surroundings). Early signs include restlessness, tachypnea, staring eyes, twitching, trembling, and clonic spasms (especially diaphragmatic). The clonic spasms gradually become more tonic, and eventually the mare may be unable to stand. The differential diagnosis is tetanus, but the nictitating membrane is not prolapsed. The condition responds well to intravenous calcium gluconate administration.<sup>195</sup>

## ASSISTED REPRODUCTIVE TECHNIQUES

Elaine M. Carnevale, Marco A. Coutinho da Silva

## ☞ ASSISTED REPRODUCTIVE TECHNIQUES FOR THE MARE

The development of new assisted reproductive techniques for the mare has allowed production of offspring from mares that are infertile using standard breeding techniques or embryo transfer.

## OOCYTE TRANSFER

Although the first successful oocyte transfer was performed in 1988, the technique was not used for commercial transfers until the late 1990s.<sup>1-3</sup> Oocyte transfer involves the transfer of an oocyte from a donor into the oviduct of a recipient; the recipient is inseminated within the uterus. Fertilization, embryo development, and fetal development occur within the recipient, thereby preventing problems associated with ovulation or the tubular genitalia of donors. The incidence of ovulatory failure increases with age and during the autumn months.<sup>4,5</sup> Prolonged exposure to an abnormal follicular environment results in aging and death of the oocyte. Some types of ovulatory failure can be detected with ultrasound as an atypical morphology of the follicle or ovulatory site. Mares that repeatedly fail to ovulate can provide oocytes for transfer successfully if oocytes are collected before deleterious changes occur within the follicle.<sup>2</sup>

Historically, the uterus has been considered the primary cause of reduced fertility in the mare. Mares with pyometra or persistent endometritis are expensive to treat and frequently do not provide embryos. Mares with cervical lacerations, cervical or uterine adhesions, or urine pooling often fail as embryo donors. Oviduct dysfunction is a major impediment to fertility, especially in aged mares. When the oviducts of old mares (>20 years) and young mares (2 to 9 years) were flushed between 1 and 4 days after ovulation, collection rates of recently ovulated oocytes or oviductal embryos were significantly higher in the young mares than in the old ones (26 of 27 [96%] versus 17 of 29 [59%], respectively).<sup>6</sup> In subfertile mares pathologic changes of the oviducts were imaged using

scanning electron microscopy, and significantly fewer sperm were detected in the caudal isthmus in subfertile mares than in fertile mares. Few sperm found in the oviducts of subfertile mares were motile, whereas oviducts of the normal mares contained highly motile sperm.<sup>7</sup> Obstructions of the oviductal lumen are postulated to be the cause of subfertility in some mares. Globular masses composed of type I collagen were found more frequently in older than in younger mares.<sup>8</sup> Oviductal masses were found in the oviducts in 73% (16 of 22) of mares between 2 and 22 years of age; in a small number of mares (3 of 43), the masses occupied and distended the oviductal lumen and could have resulted in infertility. The equine embryo remains in the oviduct for 5 or 6 days before entering the uterus; therefore oviductal problems such as inflammation could affect embryo viability.<sup>9</sup>

### PROCEDURES FOR OOCYTE TRANSFER

Requirements for oocyte donors are minimal. Uterine infections in donor mares should be treated to prevent introduction of a pathogen into the abdominal cavity during transvaginal oocyte collections. Donors should have regular estrous cycles with growth of a preovulatory follicle. The age of the donor affects success rates. When oocytes were collected from the follicles of young donors (6 to 10 years) and old donors (20 to 26 years) and transferred into the oviducts of young recipients (3 to 7 years), significantly more oocytes from young than old donors developed into embryonic vesicles (11 of 12 [92%] versus 8 of 26 [31%], respectively).<sup>10</sup> A higher incidence of morphologic anomalies was observed in oocytes from older than from younger mares.<sup>11</sup> Although younger mares are better candidates for oocyte donors, older ( $\geq 20$  years) mares frequently are presented to commercial oocyte transfer programs, and pregnancies are obtainable through repeated transfers.<sup>2</sup>

### OOCYTE COLLECTION

Currently, most oocytes are collected from preovulatory follicles between 24 and 36 hours after the administration of hCG (hCG; 1500 to 2500 IU, IV) or deslorelin (1.5 mg, IM) to the donor, with the oocytes collected between 18 and 20 hours before anticipated ovulation. Therefore oocytes are probably at metaphase I or II. Criteria for hCG administration are as follows: (1) a follicle greater than 35 mm in diameter, (2) relaxed cervical and uterine tone, and (3) uterine edema or estrous behavior for a minimum of 2 days. Some mares, especially old mares, do not consistently respond to hCG. In these cases the authors use a combination of deslorelin acetate, (1.5 mg intramuscularly) and hCG (2000 IU, IV), with hCG administered between 4 and 5 hours after deslorelin. Oocytes have been collected from the follicles of mares by laparotomy,<sup>12</sup> colpotomy,<sup>13</sup> flank puncture,<sup>14,15</sup> and ultrasound-guided follicular aspiration.<sup>16,17</sup> Currently, most laboratories collect oocytes through the flank or with ultrasound-guided punctures.

For the collection of oocytes using flank puncture, trocar is placed through the flank ipsilateral to the preovulatory follicle at approximately the position of the ovary. The ovary is manipulated by way of the rectum to position the preovulatory follicle against the end of the cannula. While stabilizing the ovary by way of the rectum, the clinician places a needle (12 to 17 gauge) through the cannula and into the follicular antrum and removes the follicular fluid and oocyte by gentle suction and lavage of the follicle. Transvaginal, ultrasound-guided

follicular aspiration requires use of an ultrasound machine. Linear, curvilinear, and sector transducers have been used. The transducer is placed in a casing containing a needle guide. Rectal contractions may be minimized by administration of propantelene bromide (0.04 mg/kg, IV)<sup>2</sup> or N-butylscopolamine or intrarectal use of lidocaine. The clinician applies a nontoxic lubricant to the transducer and positions it within the anterior vagina lateral to the posterior cervix and ipsilateral to the follicle to be aspirated. The follicle must be carefully positioned through transrectal manipulations with the follicular apex juxtaposed to the needle guide and advances the needle through the needle guide to puncture the vaginal and follicular walls. In the authors' laboratory, a 12-gauge double-lumen needle is used. The follicular fluid is aspirated from the follicle using a pump set at approximately 150 mm Hg or with suction from a large syringe. After removing the follicular fluid, the clinician lavages the lumen with between 50 and 100 ml of flushing liquid; typically modified Dulbecco's phosphate buffered solution or a sterile commercial embryo flush solution heparin (10 IU/ml) is added to the flush solution to prevent coagulation of blood in the aspirate. Oocytes were collected successfully from between 70% and 80% of the follicles in client donors.<sup>2</sup>

### OOCYTE CULTURE AND TRANSFER

Oocytes are sensitive to temperature changes; therefore the clinician should warm media and equipment for handling the oocyte to 38.5° C. On collection the flushing solution is poured into large search dishes and examined under a dissecting microscope to locate the oocyte. One can transfer oocytes collected at least 30 hours after hCG administration to the donor immediately into a recipient's oviduct. Oocytes are usually collected 24 hours after administration to the donor and between 12 and 16 hours before transfer. Most oocytes are cultured in medium similar to that first described by Carnevale and Ginther.<sup>10</sup> The timing of oocyte collection (24 versus 36 hours after administration of hCG to donors) did not affect pregnancy rates.<sup>18</sup> A modification of these procedures was to collect oocytes 24 hours after hCG administration and immediately transfer them into the recipient's oviduct. Oocyte maturation was completed within the oviduct, and recipients were inseminated after oocyte maturation should have been completed, at 16 hours after transfer. Pregnancy rates were not statistically different for oocytes matured within the oviduct or within an incubator (43% versus 57%).<sup>19</sup>

Because the reproductive tract of the recipient provides the environment for sperm transport, fertilization, and embryo development, recipient mares should be young (optimally 4 to 10 years) and have normal reproductive tracts. Cyclic and noncyclic hormone-treated mares have been used as oocyte recipients. When cyclic mares are used, recipients are synchronized with the donor, and the recipient's own oocyte is removed by transvaginal or flank aspiration before transfer of the donor's oocytes.<sup>20</sup> Anestrus and early transitional mares are used as recipients during the nonovulatory season.<sup>2,21</sup> During the breeding season a high dose of a Gn-RH agonist (4.2 mg deslorelin acetate)<sup>22</sup> or injections of progesterone and estrogen (150 mg progesterone and 10 mg estradiol)<sup>3</sup> have been administered to reduce follicular development in potential recipients. The endocrine environment of the cyclic mare is imitated in the noncyclic recipient with administration of estradiol (1.5 to 5 mg daily for 3 to 7 days) before transfer.

Estradiol often is given to effect to obtain a recipient with a soft, open cervix and moderate endometrial edema. Progesterone (150 to 200 mg daily) or a progestin is administered after transfer. Pregnancies are maintained through the administration of exogenous progesterone or progestins.<sup>2</sup>

Because oocytes are transferred surgically, adequate exposure of the oviduct is essential, and mares with short, thick flanks or short, broad ligaments are not good candidates for recipients. Most oocyte transfers are performed through a standing flank laparotomy. Tranquilization, preparation, closure, and aftercare of recipients are similar to previously described methods for embryo transfer.<sup>23</sup> The authors generally use a fire-polished glass pipette to transfer oocytes. The oviductal os is located by following the outline of the oviduct along the external surface of the infundibulum. One identifies the end of the structure and inserts the pipette containing the oocyte into the os and carefully advances the pipette 2 to 3 cm. One deposits the oocyte and a minimal amount of medium (<0.1 ml) into the ampullar region of the oviduct, gently returns the ovary to the abdominal cavity, and closes the surgical site.

### INSEMINATION OF RECIPIENTS

In a commercial oocyte transfer program, use of stallions with good fertility is essential for success; however, cooled, transported semen frequently is provided from stallions of variable fertility.<sup>2,24</sup> The equine oocyte remains viable for approximately 12 hours after a natural ovulation.<sup>25</sup> Because of this limited life span, recipients must be inseminated before or directly after oocyte transfer or both. Pregnancies have occurred when recipients were inseminated only before<sup>26,27</sup> or after<sup>19</sup> the transfer of oocytes. However, for most experimental transfers, recipients were inseminated before transfer (approximately 12 hours) and after transfer (approximately 2 hours) with a total of  $2 \times 10^9$  motile sperm. In a commercial program using older donors and cooled semen from numerous stallions of variable fertility, pregnancy rates when recipients were inseminated before or before and after oocyte transfer were significantly higher than when recipients were inseminated only after transfer (18 of 45, 40%; 27 of 53, 51%; and 0 of 10, respectively).<sup>24</sup> The results suggest that insemination of a recipient only before transfer with at least  $1 \times 10^9$  progressively motile sperm from a fertile stallion is sufficient. However, if fertility of the stallion is not optimal, insemination of the recipient before and after transfer could be beneficial.

After insemination and transfer, the uterus of the recipient should be examined with ultrasound to detect intrauterine fluid collections. One treats recipients with intrauterine fluid collections as one treats ovulating mares, with oxytocin or PGs to stimulate uterine contractions or with uterine lavage and infusion.

### SUCCESS OF OOCYTE TRANSFER

Pregnancy rates for commercial transfers, using older donors and semen of variable quality, ranged between 27% to 40% per transfer.<sup>2,24</sup> In contrast, experimental transfers under similar conditions using oocytes from young mares and fertile stallions resulted in pregnancy rates between 54% and 83% per transfer.<sup>24</sup> However, one or more pregnancies were obtained for more than 80% of donors during the breeding season in a commercial oocyte transfer program.<sup>2</sup> All mares in the program had

histories of reproductive failure in breeding and embryo transfer programs, with a mean of 7 years (range of 3 to 15 years) from the last successful pregnancy or embryo collection.<sup>2</sup>

### IN VITRO MATURATION AND FERTILIZATION OF OOCYTES

In vitro fertilization is not repeatedly successful in the mare, with only two foals born after in vitro fertilization.<sup>28,29</sup> One problem in trying to study procedures such as in vitro fertilization in the horse is the paucity of equine oocytes. Oocytes often are collected from the preovulatory follicles of live mares. Collection of oocytes from small follicles during diestrus results in reduced collection rates compared with collection of oocytes from preovulatory follicles.<sup>30</sup> In one study,<sup>26</sup> oocytes were collected from small follicles and preovulatory follicles. Oocytes collected from small follicles were matured in vitro for 36 to 38 hours before transfer, whereas oocytes collected from preovulatory follicles were transferred immediately into a recipient's oviduct. Embryo development rates after transfers were 9% for in vitro maturation and 82% for in vivo. In contrast, some laboratories have been very successful in developing methods to collect and mature oocytes from small follicles. Colleoni and associates reported an oocyte recovery rate of 58%, or 11 oocytes per ovum pick-up session.<sup>31</sup>

Research involving oocytes from excised ovaries is aimed at developing a method to salvage gametes from the ovaries of valuable mares that have died or been euthanized. One can collect ovaries from mares immediately after death and ship them to a facility for oocyte recovery, maturation, and transfer. This technique was first attempted in 1999<sup>2</sup>; a pregnancy was established, which later underwent embryonic death. However, more recent attempts have resulted in pregnancies and healthy foals after shipment of ovaries from mares that were euthanized for various medical reasons.<sup>32,33</sup> In our laboratory we anticipate obtaining a late-term pregnancy or pregnancies from about one of four sets of ovaries that are shipped to the laboratory.

### CRYOPRESERVATION OF OOCYTES AND EMBRYOS

Cryopreservation of the equine oocyte results in the preservation of female genetics, whereas cryopreservation of the embryo results in the preservation of the female and male genome. The first foal was produced from a cryopreserved embryo in 1982.<sup>34</sup> Procedures for embryo cryopreservation have been reviewed.<sup>35</sup> Cryopreservation of small embryos (morulae or early blastocysts) has consistently resulted in acceptable pregnancy rates close to 50%.<sup>36,37</sup> Cryopreservation of larger embryos ( $\geq 300 \mu\text{m}$ ) is usually unsuccessful. Embryo collection is recommended on day 6 or 6½ after ovulation.<sup>35</sup> Embryo donors are examined twice daily for ovulation, or embryo collections are timed from administration of an ovulation-inducing agent.<sup>38</sup> In recent years vitrification procedures have been used to successfully cryopreserve small equine embryos.<sup>38-40</sup> Vitrification has the advantages over traditional slow-cooling methods of cryopreservation of being a rapid procedure (<15 min) that requires minimal equipment.

Although cryopreservation of the oocyte is difficult, successful fertilization of cryopreserved oocytes has been described.<sup>41-43</sup> In 2001 the first foals were born after cryopreservation of oocytes.<sup>27</sup> Clinical use of oocyte cryopreservation has not been reported.

## ☞ ASSISTED REPRODUCTIVE TECHNIQUES FOR THE STALLION

Maximum fertility was obtained when fertile mares were inseminated every other day during estrus with  $500 \times 10^6$  progressively motile sperm.<sup>44</sup> Insemination of low numbers of sperm would be beneficial for frozen semen that is of limited supply, semen from subfertile stallions with low sperm numbers, and insemination of sex-sorted sperm. The following discussion summarizes techniques for low-dose or assisted inseminations.

### DEEP INTRAUTERINE INSEMINATION

Uterine contractions move sperm into the tips of the uterine horns within 20 minutes of routine artificial insemination.<sup>45</sup> The aim of deep uterine insemination is to increase the number of sperm entering the oviduct ipsilateral to ovulation.<sup>46-48</sup> A flexible insemination pipette is passed through the cervix and into the uterine horn ipsilateral to the preovulatory follicle. One then uses rectal manipulation to position the catheter at the tip of the uterine horn where the sperm are deposited. Fresh, cooled, and sex-sorted sperm in volumes ranging from 0.2 to 1.0 ml of glucose milk extender have been used for deep intrauterine inseminations. Pregnancy rates after deep intrauterine inseminations with  $5 \times 10^6$  progressively motile sperm were between 30% and 50%,<sup>44,50</sup> and inseminations with  $25 \times 10^6$  progressively motile sperm ranged between 57% to 63%.<sup>49,51</sup> However, in the study by Woods, Rigby, Brinsko et al.,<sup>51</sup> control mares were inseminated with  $25 \times 10^6$  progressively motile sperm in the uterine body, and pregnancy rates were not significantly different between standard and deep uterine inseminations. Because control inseminations were not done in many studies, the true benefit of deep uterine insemination has not been determined.

### HYSTEROSCOPIC INSEMINATION

Hysteroscopic insemination entails deposition of sperm directly onto the papilla of the uterotubal junction. A minute volume of extended sperm (approximately 0.05 to 0.25 ml) is desired for hysteroscopic insemination. Sperm are centrifuged through a density gradient to select a sperm population with a high percentage of motility. Numbers of fresh sperm inseminated ranged between 1 to  $10 \times 10^6$  progressively motile sperm, with pregnancy rates between 40% to 75%.<sup>50,52-54</sup> Studies have been conducted using higher volumes<sup>55</sup> or lower sperm numbers<sup>52</sup>; however, fertility was reduced.

One aspirates semen into an equine gamete intrafallopian transfer (GIFT) catheter (Cook Veterinary Products) protected by an outer polypropylene cannula and loaded into the working channel of the videoendoscope. With a sterile gloved arm in the vagina of the mare, the operator guides the flexible endoscope (1.6 m in length) through the cervix and uterine lumen; directs the endoscope along the uterine horn ipsilateral to the preovulatory follicle; and on imaging the papilla of the uterotubal junction, extrudes the outer cannula and then the inner GIFT catheter containing the sperm suspension from the working channel of the endoscope. When the tip of the GIFT catheter touches the papilla, the operator bubbles the inseminate onto the surface of the papilla.<sup>52</sup>

Low-dose insemination with frozen-thawed sperm maximizes the use of a conventional dose of frozen sperm (800 to

$1000 \times 10^6$  progressively motile sperm) by reducing the number of sperm needed for insemination. Using 5 or  $10 \times 10^6$  frozen-thawed progressively motile sperm, different investigators obtained pregnancy rates between 33% and 47%.<sup>53,56,57</sup> Alvarenga, Trinque, Lima et al.<sup>58</sup> inseminated client mares with 100 to  $150 \times 10^6$  frozen-thawed sperm from 15 Warmblood stallions and obtained an overall pregnancy rate of 57%, demonstrating that hysteroscopic insemination can be applied immediately in the horse industry. Current rates for sorting sperm into X or Y chromosome-bearing populations are approximately 10 million sperm per hour, meaning that low-dose inseminations are necessary for sex-sorted sperm. Several studies have been conducted using hysteroscopic insemination of sex-sorted sperm, resulting in pregnancy rates between 25% and 44%.<sup>53,56</sup>

### GAMETE INTRAFALLOPIAN TRANSFER

GIFT involves transfer of oocytes and sperm into the recipient's oviduct. Compared with oocyte transfer, GIFT requires low numbers of sperm. The first successful GIFT in the horse was reported in 1998.<sup>21</sup> GIFT sperm are often selected through a density gradient to select a population with a high percentage of motile sperm, free of debris and seminal plasma, with 1 to  $5 \times 10^5$  progressively motile sperm transferred with an oocyte into the recipient's oviduct. Optimal procedures for GIFT have probably not been established, although pregnancy rates between 27% to 82% have been reported.<sup>19,59</sup> GIFT is a potentially valuable technique to produce pregnancies from subfertile stallions, frozen semen, and sex-sorted sperm. However, the type of sperm and even extenders may have an effect on the success of GIFT. Pregnancy rates with GIFT were lower when cooled or frozen semen was used for GIFT (pregnancy rates of 25% and 8%, respectively) compared with pregnancy rates with fresh semen (82%).<sup>60</sup>

### INTRACYTOPLASMIC SPERM INJECTION

Intracytoplasmic sperm injection (ICSI) has been successfully used for the assisted fertilization of equine oocytes. A single sperm is selected, aspirated into a fine-bore needle, and injected into a mature oocyte. The injected oocyte can be transferred into a recipient's oviduct or cultured to allow embryo development.<sup>61</sup> Cochrane et al reported the first successful ICSI of an equine oocyte that was matured in vitro. Foals have been produced by ICSI using oocytes matured in vivo or in vitro.<sup>62,63</sup> However, pregnancy rates per transferred oocyte were low (13% and 6%, respectively). Since that time, several investigators reported the in vitro production of blastocysts with higher efficiency,<sup>64,65-67</sup> and recently the clinical use of ICSI has been reported in the horse.<sup>31,68</sup>

The major clinical advantage of ICSI is that limited sperm numbers or poor-quality sperm can be used to produce offspring, and pregnancies have been obtained from epididymal or poor quality sperm.<sup>31,68</sup>

## ☞ CONCLUSION

New assisted reproductive techniques have been developed that allow for the production of offspring from mares and stallions that would be considered subfertile or infertile using more standard breeding procedures. Although cost, expertise, and availability of these procedures may be limiting factors in

their widespread use at this time, their clinical potential for the horse has been recognized.

## THE STALLION

Juan C. Samper

### ANATOMY AND PHYSIOLOGY OF THE STALLION

A breeding stallion is often the most significant financial asset of an equine breeding operation. A variety of factors may influence the future breeding potential of a colt as it is maturing. An understanding of the anatomy and physiology of the stallion assists the veterinarian in providing optimal monitoring, diagnostic, and therapeutic services to a farm.

### REPRODUCTIVE PHYSIOLOGY

#### TESTICULAR DESCENT

Normal testicular descent into the scrotum occurs between the last 30 days of gestation and the first 10 days after birth. In some colts the testes may descend into the inguinal region and remain there for some time before fully descending. Androgen production by the developing fetal testis probably plays an important role,<sup>1</sup> as may müllerian inhibiting factor.<sup>2</sup> Traction of the gubernaculum, which attaches the caudal pole of the testis to the inguinal region, is believed to draw the developing testicle and epididymis into the inguinal ring.<sup>3</sup>

Failure of the testis to descend into a normal scrotal position is termed *cryptorchidism*. The left testis is retained more commonly in stallions. Cryptorchidism is diagnosed by manual palpation of scrotal contents. Rectal palpation and careful inguinal palpation may assist in identification of an abnormally or inguinally retained testis. In some instances heavy sedation of the stallion is necessary to permit careful examination of the area. Ultrasonography has been recommended as a useful diagnostic tool for such examinations as well.<sup>4</sup> In horses with bilaterally retained testicles or apparent geldings with stallionlike behavior, hormonal profiles may be useful in diagnosis of a retained testis. Measurement of testosterone levels has been suggested as a method to diagnose retained testicular tissue in an apparent gelding. A stimulation test using hCG increases the chances of detecting testosterone. To do this, one injects 5000 to 10,000 IU of hCG intravenously. Testosterone concentrations are determined before injection and 60 to 120 minutes later. A fivefold or greater increase in hormone indicates a retained testicle. However, false-negative results are possible. A single measurement of blood estrone sulfate concentration is a reliable indicator of the presence of testicular tissue, especially in colts older than 3 years of age.<sup>5-7</sup>

#### PUBERTY

*Puberty* is defined as the age at which a colt is able to mount, copulate, and successfully impregnate a mare and occurs during the second spring after the year of birth. Puberty should not be confused with sexual maturity, which occurs after the age of 5.

Puberty is probably regulated by the reactivation of the hypothalamic pulse generator, a group of cells located in the arcuate nucleus of the hypothalamus.<sup>1</sup> The pulsatile secretion

of Gn-RH from the hypothalamus stimulates the secretion of LH and FSH from the anterior pituitary. Season, age, breed, nutritional status, and external hormones affect puberty, but in general puberty is complete by 18 to 24 months in the horse.<sup>8</sup>

### ENDOCRINOLOGY

The pineal gland plays a significant role in the seasonality of the horse. The retina captures photoperiod information and transports it by way of nerve fibers to the pineal gland, which in turn inhibits the production of melatonin during long days. Low levels of circulating melatonin are consistent with higher levels of Gn-RH and gonadotropins. Stallions, in contrast to mares, do not undergo a complete reproductive quiescence and continue to produce sperm during the short photoperiodic days. The cause for this partial refractoriness of the stallion to changes in photoperiod is not well understood.

The hypothalamus, pituitary, and testes (hypothalamic-pituitary-gonadal axis) must work in synchrony for a stallion to be able to start and sustain sperm production. The primary role of the hypothalamus, located on the base of the brain, is the production of the 10-amino-acid peptide Gn-RH, which is secreted in multiple daily pulses and then transported via the hypothalamic-pituitary portal system to the anterior pituitary. In addition to melatonin-mediated stimulus, the hypothalamus responds to tactile, olfactory, and visual stimuli.<sup>9</sup>

The pituitary, which is connected to the hypothalamus by neural fibers, has two lobes. The anterior lobe possesses Gn-RH receptors. Gn-RH binds to these receptors and induces secretion of FSH or LH. The anterior pituitary gland also produces prolactin, the role of which is unclear in the stallion. FSH and LH act on the Sertoli's and Leydig's cells, respectively, stimulating production of steroids and other protein hormones. The peptide hormones inhibit and activin regulate FSH at the pituitary level. Testicular steroid hormones, mainly estradiol and testosterone, in turn have positive or negative feedback actions at the level of the pituitary on FSH and LH, respectively.

The complexity of the interaction among hormones has kept clinicians and researchers in the field of stallion andrology from being able to develop a test or a series of hormonal tests to predict or diagnose infertility or subfertility. Until such diagnostic methods become available, hormonal supplementation is strictly empirical and sometimes worsens or elicits a reproductive dysfunction in otherwise normal stallions.<sup>9</sup>

### TESTICULAR CELLS

The endocrine role of the testes is to produce testosterone and estrone sulfate, whereas the exocrine role is to produce spermatozoa. The testicle is composed of 85% to 90% testicular parenchyma, of which seminiferous tubules comprise 70%. In turn, the seminiferous tubules are formed by Sertoli's and germinal cells. The interstitium, formed primarily by Leydig's cells and myoid cells, occupies close to 15% of the parenchyma.<sup>10</sup>

#### SERTOLI'S CELLS

Sertoli's cells, also known as *supportive cells*, contain the most testicular receptors for FSH. Some of the most important functions of the Sertoli's cell in the process of sperm maturation include the following:

1. Isolation of the advanced (haploid) stages of spermatogenesis by tight gap junctions forming the blood-testis barrier.
2. Production of androgen binding protein, activin, and inhibin. Androgen binding protein binds the bioactive form of testosterone, dihydrotestosterone, to maintain high levels of these products in the seminiferous tubules and epididymis. Activin and inhibin stimulate or suppress the release of FSH from the pituitary. The Sertoli's cells contribute to the regulation of Leydig's cell function and establish feedback mechanisms to the anterior pituitary primarily through the production of activin and inhibin. Sertoli's cells synthesize other proteins, such as SGP-2, ceruloplasmin, and transferrin, that are necessary to support spermatogenesis. Ceruloplasmin and transferrin act as carrier proteins for copper and iron, respectively, which are important regulators of spermatogenesis.
3. Germ cells begin the process of differentiation as large round cells on the basal compartment of the seminiferous tubule and approximately 55 days later finish as elongated cells in an adluminal position. This change in size, shape, and position occurs between two adjacent Sertoli's cells. The number of spermatogenic cells and ultimately the total sperm production of a given stallion are determined by the number of cells that can be accommodated between the tight gap junctions between two Sertoli's cells. Day length appears to be one of the most important factors in determining the number of Sertoli's cells per testis in adult stallions. Numbers of Sertoli's cells increase in young animals: 1 billion cells at 2 years of age, 2.8 billion at 3 years, and 3.6 billion after 4 to 5 years of age. The number of Sertoli's cells then decreases with advancing age.<sup>11</sup>

### LEYDIG'S CELLS

The interstitial, or Leydig's, cells contain most of the testicular receptors for LH and are the main site of testosterone production. Testosterone concentration in the testicular microcirculation is at least 10 times higher than that in the general circulation. Through steroid production, Leydig's cells provide the feedback mechanisms on the pituitary necessary to maintain spermatogenesis, secondary sex characteristics, and libido. Season and not age appear to affect the testosterone production in adult stallions, which is mediated through a change in total number of Leydig's cells rather than total volume of cells per testis. Unlike Sertoli's cells, Leydig's cell numbers do not increase dramatically with age (1.4 billion at 2 years and 4.7 billion as a mature stallion). However, a significant increase in cell volume occurs that is regulated primarily by season.<sup>12</sup>

### MYOID CELLS

The myoid cell has profound effects on germ cells and Leydig's cells primarily through the action of paracrine modulating factors. A paracrine modulating factor in the rat known as P-Mod-S is thought to stimulate or modulate some of the androgen binding protein functions. In addition, the myoid cells are responsible for the round architecture of the seminiferous tubule and probably for the intratesticular movement of sperm.

### GERMINAL CELLS

Sperm is the final product of a 57-day process that starts at the base of the seminiferous tubule. Testicular volume has a direct correlation with the number of sperm that a normal stallion should be able to produce.<sup>13</sup>

## SPERMATOGENESIS

Spermatogenesis is the series of chronologic changes that occur in the seminiferous tubule, transforming a large, round spermatogonium into a spermatozoon. This process in the stallion takes approximately 57 days and is not affected by frequency of ejaculation or season.<sup>14</sup>

The process starts when an A<sub>1</sub> stem cell spermatogonia undergoes mitosis, giving rise to (1) a second A<sub>1</sub> spermatogonia to maintain a constant population of stem cells and (2) an A<sub>2</sub> spermatogonia. In turn, the A<sub>2</sub> spermatogonia gives rise to A<sub>3</sub>, A<sub>3</sub> to B<sub>1</sub>, and B<sub>1</sub> to B<sub>2</sub>. The entire process of spermatogenesis has been divided into three phases of similar length known as *spermatocytogenesis*, *meiotic divisions*, and *spermiogenesis*.

Spermatocytogenesis is characterized by the mitotic divisions of A and B spermatogonia. Meiotic divisions result in the formation of primary spermatocytes from B<sub>2</sub> spermatogonia and the subsequent formation of secondary spermatids. Leptotene spermatocytes that form immediately after the first meiotic division are hidden from the immune system by the hematotesticular barrier. Spermiogenesis is characterized by the transformation of round spermatogonia to elongated spermatids and ultimately to spermatozoa. During spermiogenesis the formation of the acrosome arises from the Golgi complex and the compaction of DNA, partly because of the expression of protamine genes at the spermatid stage. The end of spermatogenesis is characterized by spermiation, the release of the elongated spermatids or spermatozoa into the lumen of the seminiferous tubule.<sup>15</sup>

## SEASONALITY

Although a reduction in testicular size, testicular volume, and daily sperm production during the nonbreeding season occur, the seasonal effect varies significantly between stallions and is not as significant as the effect on ovarian function in the mare. Stallions from which semen is collected throughout the year decrease their sperm output on the average by 1 to 2 billion during the nonbreeding season. In many of these stallions, libido is not affected adversely. Although the total number of sperm is affected, sperm morphology and motility remain unaltered, provided that stallions are maintained on a regular collection schedule. The effect of day length on sperm production can be explained by a decrease in serum LH during the nonbreeding season. This lack of stimulus to the Leydig's cell has a direct effect on intratesticular and extratesticular testosterone levels. Decreased testosterone concentration affects the number of Sertoli's cells and in turn the total number of germ cells that can be allocated between two Sertoli's cells.<sup>16</sup>

The effect of external lighting programs on spermatogenesis is uncertain. Burns and Douglas<sup>17</sup> reported increased sperm production and testicular size in stallions subjected to a lighting program but observed that this improvement was transitory, and in some cases detrimental, to stallion performance at the peak of the breeding season (April to May). Other investigators have found no detrimental effect on photostimulated stallions.<sup>16,18</sup> Several Thoroughbred breeding farms provide light to their stallions before the breeding season without significant reduction in conception rates.

## TESTICULAR CELL INTERACTIONS

Sertoli's, or nurse, cells have a direct interaction with germ cells, and Leydig's cells interact with Sertoli's and germinal cells through hormonal production. The myoid cell produces at least one paracrine factor that interacts directly with the Sertoli's cell. Paracrine and autocrine modulating factors, products of the peritubular cell, appear to have an effect on androgen binding protein function. In turn, the myoid cell is under regulatory influence of transforming growth factors  $\alpha$  (stimulatory) and  $\beta$  (inhibitory). Other factors involved in cell-to-cell communication of the testicular cells include collagen, plasminogen activator, vitamin A, pyruvate, and carbohydrates.<sup>19</sup> Most of these products and mechanisms have not been investigated extensively in the stallion.

## EPIDIDYMIS

The specific absorptive and secretory functions of each segment of the stallion epididymis remain the subject of considerable debate and investigation. The histologic structure of the epididymis changes as it continues through its different regions, with epithelial height being greatest proximally and smooth muscle components greatest distally.<sup>20</sup> As spermatozoa are transported from the excurrent ducts into the head, along the body, and into the tail, they undergo a number of morphologic and physiologic changes that ultimately render them motile and fertile. Specific maturational changes include (1) the capacity for progressive motility, (2) shedding of the cytoplasmic droplet, (3) plasma and acrosomal membrane alterations, (4) DNA stabilization, and (5) metabolic changes.<sup>21</sup> The tail of the epididymis generally serves to store the matured spermatozoa. All these changes occur primarily at the level of the mid to distal corpus.<sup>21,22</sup>

Throughout the epididymis fluid resorption occurs at a steady rate and results in a significant increase in sperm concentration.<sup>23</sup> Whether stallions with high-volume ejaculates and poor sperm morphology have epididymal dysfunction remains to be investigated.

## EXTERNAL GENITALIA

### PENIS AND PREPUCE

The penis of the stallion is composed of a root, a body, and a glans penis and is musculocavernous. The penile base arises at the ischial arch in the form of two crura that fuse distally to form the single dorsal corpus cavernosum penis enclosed by a thick tunica albuginea. The corpus cavernosum, corpus spongiosum, and corpus spongiosum glandis are the three spaces that make up the erectile tissue of the penis. Engorgement of these spaces with blood from branches of the internal and external pudendal arteries and obturator arteries is responsible for erection. The cavernous spaces within the penis are continuous with the veins responsible for drainage. The corpus spongiosum originates in the pelvic area and surrounds the penile urethra within a groove on the ventral side of the penis and forms the corpus spongiosum glandis at the distal end of the penis.<sup>24</sup> The corpus spongiosum glandis is responsible for the distinct bell shape of the stallion penis after ejaculation.

The urethral process is distinctly visible at the center of the glans penis and is surrounded by an invagination known as the *fossa glandis*. Accumulations of smegma secretions, known as "beans" are predisposed in one or all of the diverticulae of

the fossa glandis and urethral sinus. Careful examination and cleaning of this area are imperative during the reproductive evaluation of a stallion or before breeding.

The bulbospongiosus muscle located in the ventral aspect of the penis provides rhythmic contractions or pulsations to assist in moving the penile urethral contents (semen and urine) distally during ejaculation. Two retractor penis muscles also run ventrally along the length of the penis and are responsible for returning the penis to the sheath after detumescence.<sup>25</sup>

The prepuce is formed by a double fold of skin that is hairless and well supplied with sebaceous and sweat glands. The prepuce functions to contain and protect the nonerect penis. The external part of the prepuce, or sheath, begins at the scrotum and displays raphae that are continuous with the scrotal raphae. The internal layer of the prepuce extends caudally from the orifice to line the internal side of the sheath and then reflects cranially toward the orifice again before reflecting caudally to form the internal preputial fold and preputial ring. This additional internal fold allows the considerable lengthening (approximately 50%) of the penis during erection. During erection the preputial orifice is visible at the base of the penis just in front of the scrotum, and the preputial ring is visible at approximately the midshaft of the penis.<sup>25</sup>

One can best examine the penis and prepuce of a breeding stallion after teasing with an estrous mare, when one can observe the stallion drop the penis and attain a full erection.<sup>26</sup> The prepuce and penis should be free of vesicular, proliferative, or inflammatory lesions such as those found in horses with coital exanthema, squamous cell carcinoma, or cutaneous habronemiasis. Removal of smegma accumulations may be required for a complete examination of the skin surfaces.

### SCROTUM

The scrotum is slightly pendulous and forms two distinct pouches that contain, protect, and thermoregulate the testes and epididymides. The testes are located in the scrotum to maintain testicular temperature at 3° to 5° C below the normal body temperature, which is a requirement for normal spermatogenesis.<sup>19</sup>

The scrotal wall consists of four layers: the skin, tunica dartos, scrotal fascia, and parietal vaginal tunic.<sup>19,23</sup> The scrotal skin is thin, generally hairless, and slightly oily, containing numerous sebaceous and sweat glands that assist in thermoregulation. The tunica dartos adheres to the scrotal skin and consists of muscular and fibroelastic tissue. The tunica dartos lines both scrotal pouches and extends into the median septum, which appears externally as the median rapha of the scrotum. The scrotal fascia is between the tunica dartos and parietal vaginal tunic and allows the testis and associated parietal tunic layer to move freely within the scrotum. The parietal vaginal tunic is the innermost layer and is an evagination of the parietal peritoneum through the inguinal rings that forms during testicular descent. This layer forms a sac that lines the scrotum and is apposed closely to the visceral vaginal tunic, the outer layer of the testis itself. The vaginal cavity is the space between the parietal and visceral layers of the vaginal tunic and normally contains a small amount of viscous fluid to allow some free movement of the testis within. The vaginal cavity is a potential space within which considerable fluid may accumulate.

The scrotum of the normal stallion should appear slightly pendulous, globular, and generally symmetric. One may observe normal variations in the positioning of the testes if

one testis is anterior to or ventral to the other. The skin should have no evidence of trauma, scarring, or skin lesions. Palpation of the scrotum of a normal stallion reveals a thin and pliable covering that slides loosely and easily over the testicles and epididymides within.

### TESTICLES

The testes of a normal stallion are palpable as two oval structures of nearly equal size lying horizontally within the scrotal pouches. Normal orientation of the testis is ascertained by palpation of the body of the epididymis, which is always dorso-lateral to the testicle proper, and the tail of the epididymis and the ligament of the tail of the epididymis, which should be in a caudal position. The ligament is palpable as a fibrous nodule 5 to 19 mm in size that attaches the tail of the epididymis to the caudal pole of the testis. The ligament is particularly large in newborn colts and on palpation may be mistaken for a testis within the scrotum. Examination of a normal stallion may identify rotation of one or both testes, up to 180 degrees. Such rotations can be permanent, or the testis may rotate back and forth, usually with the stallion showing no outward signs of discomfort. A rotated testicle may have as much as a 40% reduction in blood flow.<sup>19</sup> Although this condition does not interfere with normal breeding by the stallion, it may be considered a criterion for failing a stallion during a BSE in some breed regulations. The presence of the condition must be clearly noted on the record, and the owner must be notified. Testis rotation should be differentiated from true testicular torsion in which stallions demonstrate signs of colic and for which palpation reveals a painful and swollen testicle.

Within the scrotum the testis is encapsulated by the tunica albuginea, a layer of tough collagenous tissue and smooth muscle that sends supportive trabeculae into the testicular parenchyma, dividing the testis into lobules. The muscular content of the tunica albuginea is thought to play a role in intratesticular sperm transport and determination of testicular tone.<sup>23</sup>

Testicular tone is described as the degree of turgidity of the testicle, which should be firm to turgid but resilient on palpation. Deviation from the normal toward a softer or firmer testis may be associated with degenerative, neoplastic, or traumatic conditions of the testis. Testicular degeneration is an acquired reversible or irreversible condition in which damage to the germinal epithelium results in eventual atrophy of the epithelium and an initial loss of testicular tone. As the disease progresses, the degenerating testicle becomes small and firm as fibrous tissue replaces testicular parenchyma.

Because testicular conditions may afflict only one testis, comparison of the size and consistency of the two testes of any individual stallion is imperative. Changes in testicular tone or consistency are best determined by sequential examinations of the stallion that allow the clinician to monitor the severity and rate of change as the disease progresses. Regular physical examinations of breeding stallions are an important part of routine stallion management and may allow early detection of problems that may affect fertility.

### TESTICULAR SIZE AND VOLUME

Testicular size in stallions increases from the pubertal period to reach maximal size at the age of 5 to 6 years and is affected by breed, season, and age. Each testis of an adult stallion weighs between 150 and 300 g and measures 50 to 80 mm in width, 60 to 70 mm in height, and 80 to 140 mm in length, with

breed being the biggest factor in determining size. Testicular volume correlates highly with daily sperm production and therefore is a useful predictor of the sperm-production potential of a stallion.<sup>27</sup>

To calculate the testicular volume, the clinician should obtain measurements of the length, width, and height of each testicle by calipers or ultrasound. Ultrasonographic measurements may be more accurate, although proper placement of the probe across the testis is critical to ensure that a cross-sectional image is obtained. Because a testis approximates the shape of an ellipsoid, the following formula converts length, width, and height measurements into testicular volume:

$$\text{Testis volume} = 0.5333 \times H(\text{cm}) \times L(\text{cm}) \times W(\text{cm})$$

Love et al.<sup>27</sup> also recommend using this volume to predict the expected daily sperm output (DSO) of the stallion, using the following formula:

$$\text{Predicted DSO} = (0.024 \times \text{combined testicular volume}) - 0.76$$

Predicted DSO can be compared with actual DSO as estimated by semen collection during the routine BSE. A stallion in which actual DSO falls below that predicted for his testicular size requires further evaluation for disease conditions of the testes, epididymides, and accessory glands.

Testicular measurements are a useful and important part of the physical examination of any breeding stallion and can be used to predict sperm output and determine the size of the book for a given stallion. A stallion with small testicles will have lower sperm production and may need modification of the management strategies that result in optimization of the fertility of such a stallion.

### EPIDIDYMIDES AND EXCURRENT DUCT SYSTEM

The epididymis is a single, highly convoluted duct approximately 70 m in length that has a grossly distinct head, body, and tail. The head of the epididymis is a flattened structure that lies dorsomedially along the cranial border of the testis and is attached closely to the testis. The body, or corpus, lies along the dorsolateral aspect of each testis and continues as the tail, or cauda, the large, prominent structure attached to the caudal pole of the testis. The deferent duct, the excretory duct for sperm, attaches to the tail of the corresponding epididymis, runs along the medial aspect of the testis, and ascends by way of the spermatic cord through the vaginal ring into the pelvis. Each deferent duct widens into its corresponding ampullary region and eventually terminates at the colliculus seminalis of the pelvic urethra. The colliculus seminalis is a rounded prominence situated on the dorsomedial wall of the urethra about 5 cm caudal to the urethral opening from the bladder. The colliculus is the common opening to the ampullae and the seminal vesicles. With care one can palpate all sections of the epididymis through the scrotal wall. However, the head of the epididymis may be difficult to ascertain because of its flattened nature and the close apposition of the cremaster muscle overlying it.<sup>28</sup>

### SPERMATIC CORD

Each spermatic cord is enveloped in the parietal layer of the vaginal tunic, which extends distally from the internal inguinal ring. Within each cord are the corresponding deferent duct, testicular artery, testicular veins, lymphatic vessels,

and nerves. The cremaster muscle is situated in the caudolateral borders of each spermatic cord. The testicular artery, a branch of the abdominal aorta, descends through the inguinal ring into the cranial border of the spermatic cord in a tortuous manner and divides near the testis into several branches to supply the testis and epididymis. These small branches, embedded in the tunica albuginea, enter the parenchyma by way of the trabeculae and septae of the testis. A corresponding network of veins leaves the testis and surrounds the testicular artery in a tortuous manner, forming the pampiniform plexus. This arrangement of artery and veins is responsible for much of the thermoregulation of the testis in the stallion when heat from the testicular arterial blood is transferred to the venous side, resulting in testicular arterial blood being several degrees cooler than systemic blood temperature. Abnormal distention of the veins of the pampiniform plexus is termed a *varicocele* and is an uncommon condition in stallions. Palpation of the spermatic cord of an affected stallion reveals the dilated and often tortuous vessels. Varicoceles are usually not painful but can result in fluid accumulation around the vaginal tunics, most often involve only one side of the spermatic cord, and usually are diagnosed by the observation of the dilation of the vessels from the pampiniform plexus with ultrasonography. The condition has been identified in stallions with normal semen parameters.<sup>28</sup>

#### ULTRASONOGRAPHIC EXAMINATION OF THE TESTICLES AND EPIDIDYMIS

Ultrasound examination of the testis and epididymis is a useful ancillary diagnostic tool that enables the clinician to assess palpable changes and to identify nonpalpable changes. Ultrasound is particularly useful in horses with generalized scrotal enlargement in which specific structures become difficult to palpate.

Examination is usually easier after semen collection, when the stallion is relaxed. A 5.0-, 7.5-, or 10.0-MHz linear array transducer is used.<sup>9</sup> The clinician usually begins the examination at the cranial end of the testis and slowly moves the probe caudally in a vertical position. Visualization of the scrotum reveals a thin, echogenic, uniform layer. Minimal, if any, fluid is visible between the scrotal skin and testicular parenchyma in the normal stallion. In the cranial third of the scrotum, the head of the epididymis, testicular parenchyma, blood vessels of the spermatic cord, and central vein are visible. As the probe is moved caudally, the central vein and spermatic cord vessels disappear and the head of the epididymis continues into the body of the epididymis. The head and body of the epididymis appear as heterogeneous areas just below the spermatic cord when the probe is positioned as described. As the probe continues further caudally, the body of the epididymis becomes indistinct.<sup>29</sup> With the exception of the central vein, the testicular parenchyma appears uniformly echogenic and homogenous. The central vein appears as a small anechoic area within the testicular parenchyma at the cranial third of the testis and should not be mistaken for a pathologic lesion. Dilation of the central vein may be visible in cases of varicocele or spermatic cord torsions and usually is accompanied by detectable dilations of the vessels of the spermatic cord. Well-defined and hypoechoic lesions within the parenchyma suggest testicular tumors.

After reaching the most caudal aspect of the testis, the clinician rotates the probe to face cranially in a vertical position and allow examination of the tail of the epididymis. This structure appears as a heterogeneous area, with a Swiss cheese-like appearance. Identification of the epididymal tail

may assist in diagnosis of testicular rotations. In horses with 360-degree torsions, the tail of the epididymis, although in its caudal position, is more dorsal because of the tension on the ligament of the tail of the epididymis by the deferent duct.

The spermatic cord is most easily visualized by placing the probe horizontally across the cord, just proximal to the body of the testis. The arrangement of the pampiniform plexus results in the mottled, heterogeneous appearance of the spermatic cord, and the testicular artery and veins are identifiable in cross-sectional images.<sup>29</sup>

### INTERNAL GENITALIA

#### ACCESSORY SEX GLANDS

The bulbourethral glands, prostate gland, and seminal vesicles collectively are referred to as the *accessory sex glands*. Their secretions produce the seminal plasma that makes up most of the ejaculate volume. The ampullae, which are dilations of the vas deferens before opening in the colliculus seminalis, are considered a storage place for sperm.

Although a short exposure to seminal plasma appears to be important for sperm function, long-term exposure to seminal plasma components may be detrimental to spermatozoa survival for some stallions. Artificial insemination programs deal with this potential detrimental effect by dilution of semen with extenders in fresh or fresh-chilled programs and by centrifugation to remove seminal plasma in frozen semen programs and some chilled-shipped programs. Seminal plasma appears to suppress the inflammatory response of the endometrium of the mare to sperm after insemination or natural mating. Although the functions of the specific components of the seminal plasma remain rather obscure, the fluid suspends the ejaculated sperm and also is thought to be a source of energy, protein, and other macromolecules required for sperm functions and metabolism.<sup>30-32</sup>

#### EXAMINATION AND ULTRASONOGRAPHY OF THE ACCESSORY SEX GLANDS

In some cases the reproductive examination of stallions should include rectal palpation and ultrasonography of the accessory sex glands.<sup>33,34</sup> Most stallions tolerate this procedure well with adequate restraint in stocks, and sedation is not usually necessary. Glands on sexually stimulated stallions are easier to palpate and visualize.

#### BULBOURETHRAL GLANDS

The bulbourethral glands, although not usually palpable rectally because of the urethralis and bulboglandularis muscles close to the ischiatic arch, are easy to evaluate by ultrasonography. Multiple ductules from the bulbourethral glands enter the medial aspect of the urethra distal to the prostatic ductules. Bulbourethral gland secretions compose most of the presperm or first fraction of the ejaculate and serve as a cleanser and pH stabilizer in the urethra before ejaculation. Using ultrasonography, one locates the bulbourethral glands 3 to 4 cm inside the anus off the midline, and in a stimulated stallion the glands appear as two distinct ovoid structures with multiple small hypoechoic spaces throughout the parenchyma.<sup>33</sup>

#### PROSTATE GLAND

In the stallion the prostate is formed by a central isthmus and two lateral lobes located on the caudolateral borders of each vesicular gland. Although not always palpable rectally,

the prostate is lobulated or nodular and firm, distinguishing it from the smooth, thin-walled vesicular glands lying next to it. Each prostatic lobe measures 5 to 9 cm long, 2 to 6 cm wide, and 1 to 2 cm thick. Multiple ductules from the prostate enter the lumen of the urethra lateral to the colliculus seminalis. The secretions of the prostate contribute to the sperm-rich fraction of the ejaculate. The lobes of the prostate are easily identifiable with ultrasonography, with the two symmetric and homogeneously echogenic lobes distinctly visible lateral to the area in which the penile urethra merges with the neck of the bladder. Hypoechoic dilations within the gland parenchyma of each lobe are evident in a teased stallion.<sup>33</sup>

### AMPULLAE

The ampullae are the enlarged distal portions of the deferent ducts measuring 1 to 2 cm in diameter and 10 to 25 cm in length. Palpable along the midline of the pelvic floor over the neck of the bladder, they converge caudally and pass beneath the prostate gland but lie dorsal to the pelvic urethra. At their distal ends they continue through the wall of the urethra, opening into the colliculus seminalis alongside the excretory ducts of the seminal vesicles. The ampullae, in addition to serving as a sperm storage area, have many branched tubular glands located within the thickened wall.<sup>34</sup>

Because of the longitudinal orientation of the ampullae, sometimes they are easier to find on rectal palpation. One can identify them by ultrasonography by their hypochoic central lumen surrounded by a uniformly echogenic wall and a hyper-echogenic outer muscular layer. Orienting the transducer in a transverse position inside the rectum can provide a good cross-sectional image of the ampullae. The ampullae can be a common site for blockage because of sperm stasis. In these cases dilation of the lumen may or may not be visible. Stallions with such blockage usually have a history of infertility or subfertility and often display severe oligospermia or, in severe cases, complete azoospermia. When sperm are present, they have a variety of morphologic abnormalities, with predominantly tail-less heads; in some instances the ampullae are palpably enlarged. This condition may render a stallion virtually infertile if undiagnosed. Recommendations for treatment include ampullary massage by way of the rectum and repeated daily semen collection after injection of low doses of oxytocin or PG.<sup>35</sup>

### SEMINAL VESICLES

The seminal vesicles or vesicular glands are paired, pyriform, and thin-walled structures lying lateral to the ampullae. On occasion they may extend far cranially to hang over the brim of the pelvis. Sexual stimulation results in dilation and elongation of the vesicular glands, up to 12 to 20 cm long and 5 cm in diameter. The distal ends of the glands converge, passing under the prostate as they lie parallel to the ampullae toward their termination at the urethra. The excurrent ducts of the vesicular glands open lateral to the excurrent ducts of the ampullae at the colliculus seminalis of the urethra. Secretions of the vesicular glands compose the gel fraction of the ejaculate. Higher gel volumes can be collected with pronounced sexual stimulation and season. The specific function of the gel fraction is unclear, and one should remove it when processing semen for evaluation or artificial insemination. Palpation of the vesicular glands may be easier after considerable teasing of the stallion with an estrous mare. The glands also are readily palpable in instances of pathologic enlargement.

With ultrasonography the vesicular glands appear in longitudinal section as flattened oval to triangular sacs, depending on the degree of sexual stimulation. A thin echogenic wall surrounds a generally uniformly anechoic lumen.<sup>33</sup> Increased echogenicity of vesicular gland fluid is associated with the highly viscous gel fraction produced by some stallions. The seminal vesicles are the glands that are most prone to bacterial infections. Diagnosis is based on the cytologic evaluation of the semen with presence of white blood cells.

### EVALUATION OF THE PELVIC AND PENILE URETHRA

Although the pelvic urethra can be evaluated by transrectal ultrasonography, in most cases such evaluation is unrewarding. Endoscopic examination provides better information regarding the anatomic integrity of the urethra and its accessory structures. The procedure is performed by gently passing a 1-m endoscope with an outer diameter of 8 to 9 mm into the urethra of a sedated horse so that the penis is relaxed. The clinician applies gentle and constant pressure so as to pass 70 to 80 cm of the endoscope into the urethra.<sup>36,37</sup> Care must be taken not to inflate the bladder with too much air because of a slight risk of rupturing the bladder.

The bulbourethral gland ductules are grouped about 2.5 to 3 cm distal to the prostatic openings and are visible as two rows of 6 to 10 small openings dorsal and close to the midline. The prostatic ductules are arranged in a similar way to the bulbourethral and visible as two groups of small openings lateral to the ejaculatory orifices about 5 cm deeper. Just ventral and cranial to the colliculus, the openings of the urethral glands are visible laterally on the widened pelvic portion of the urethra, at the level of the prostatic gland openings.<sup>36</sup>

One can identify the colliculus seminalis as a rounded prominent structure found on the medial aspect of the dorsal wall of the urethra approximately 5 cm caudal to the internal opening of the urethra from the bladder. On either side of the colliculus is an ejaculatory duct orifice, a small slitlike diverticulum within which the ampullary ducts and ducts of the seminal vesicle open. By passing the endoscope into this orifice, one can visualize and evaluate the seminal vesicles.<sup>36,37</sup> Samples can be taken for culture with endoscopic culturettes if seminal vesiculitis is suspected.<sup>38</sup>

Endoscopic examination of the urethra is indicated in horses with hemospermia or in horses in which one suspects a pathologic condition of the accessory sex glands. In cases of hemospermia the bleeding area may be visualized with the endoscope. These lesions are most readily identified in the region of the ischiatic arch and distal urethra. One should take care to assess the urethral mucosa as the endoscope is passed forward because some irritation and erythema of the mucosal lining often results from the endoscopic examination.<sup>38</sup> A false diagnosis of urethritis may result if one assesses the mucosa while withdrawing the endoscope.

## ☞ EVALUATION OF THE BREEDING STALLION

Equids in the wild are considered to be long-day seasonal breeders that live in a stable social group or harem. A free-running stallion interacts with a mare for hours or even days before copulation. In many management situations the domesticated stallion is restricted severely from its sociosexual activity. In general, breeding stallions are confined to a paddock or a box stall and do not have social interactions with other horses. In

addition, mating and ejaculation often are permitted under only two conditions: hand mating at the convenience of the farm manager, allowing only a few minutes for stallion and mare interaction, or mounting of a mare or a phantom for artificial insemination purposes.

Perhaps the most remarkable difference in the breeding pattern, particularly with performance horses such as Thoroughbreds and Standardbreds, is the fact that most breedings are done during February to June, well in advance of the natural breeding season (May to September).

## BEHAVIOR

### NORMAL BEHAVIOR

Stallions display several behavioral responses during teasing and breeding. However, the intensity of the response, also known as *libido*, and the type of response depend greatly on breeding experience; management; and, in some cases, season. Olfactory, visual, and auditory stimuli also influence libido. Typically, a normal stallion that has never mated with a mare takes a longer time to mount but displays good libido. However, a stallion that has had a negative previous experience might show no interest in the mare or in mounting. Some of the typical normal responses by stallions when exposed to an estrous mare include vocalization, flehmen response, striking, nipping or biting, and sniffing or licking. A normal stallion should show interest in the mare and drop the penis within 1 to 2 minutes of exposure to a quiet mare in standing heat and should try to mount within the first 3 minutes. Once stallions are allowed to mount, they give several (five to eight) intravaginal thrusts, followed by three to five short thrusts immediately before ejaculation. Signs of ejaculation are rhythmic and frequent urethral pulsation, flagging of the tail, and a head relaxation. A single stallion tends to be consistent in its breeding behavior, provided that the conditions under which he usually mates are the same.<sup>39</sup>

### ABNORMAL BEHAVIOR

Stallion behavioral dysfunction in many instances is difficult to define and is relative to the expectations of the breeding manager. A stallion that takes 30 minutes or more to mount and ejaculate or takes several mounts may be considered a problem in some intensive management situations. However, a stallion that takes several hours to achieve an erection, mount, and ejaculate may be considered normal if he breeds only two or three mares during the entire breeding season in pasture conditions.

A review of the incidence of problems in 250 stallions over a period of 5 years indicated that more than 50% of the cases had complaints related to poor libido or excessive aggressiveness. Of those, nearly half were described in stallions with no previous sexual experience. The rest were divided evenly between experienced stallions with low sexual interest and unruly and overly aggressive breeders. Mounting and erection dysfunction accounted for 11% of complaints, whereas ejaculatory problems accounted for 25% of the total cases. Other problems, such as self-mutilation and severe stereotypies that reportedly could be detrimental to fertility, accounted for 11% of the reported cases.<sup>40</sup>

### DIAGNOSIS OF ABNORMAL BEHAVIOR

A normal stallion exposed to a mare in standing estrus should vocalize, sniff or nuzzle the mare, display the flehmen response by curling his upper lip, drop his penis, and achieve

an erection within the first 3 minutes after initial exposure.<sup>41</sup> These precopulatory responses should be followed by mounting, intromission, and ejaculation. A normal, experienced stallion that is hand bred should require no more than 5 minutes from initial exposure to a mare until ejaculation. The frequency and intensity of the precopulatory responses are affected by management, breeding experience, and external stimuli. Stallions with no previous breeding experience are expected to be slower in mounting. However, interest in the mare and time to erection should be within normal limits. Once the novice stallion mounts, he soon gains confidence and ejaculation should occur following a normal thrusting pattern. After the first positive experience, time to mounting and to ejaculation should decrease. Novice stallions must be treated with patience, positive reinforcement, and perseverance. During this time unnecessary punishment and rough handling can aggravate a problem and may result in profound breeding disinterest. One should investigate any aberration in courtship or copulatory behavior carefully, always keeping in mind that sexual behavioral dysfunction is a problem with many possible causes involving management and the endocrine, cardiovascular, musculoskeletal, and nervous systems.<sup>42</sup>

### LACK OF LIBIDO

Libido, defined as sexual drive or interest in breeding, is high in most stallions. Sexual stimuli and environmental factors profoundly affect libido in stallions. Low libido is apparent in improperly stimulated stallions. The best stimulus is a mare in standing heat. If this is not possible, an estrogenized ovariectomized mare may be used. Some stallions might have a preference for or an aversion to a particular color or type of mare.<sup>42</sup> Experienced stallions frequently are aroused by exposure to a breeding phantom. A novice stallion or one that has never mounted a breeding phantom cannot be expected to be stimulated positively by a dummy.

Lack of libido may be observed in experienced stallions toward the end of the breeding season, particularly in heavily used or overused animals. This problem is easily corrected by decreasing the frequency of service or collection.

Stallions that have been kicked by mares or negatively reinforced for displaying sexual behavior in shows or while performing at the track may have reduced sexual desire. Unfortunately, circulating levels of steroids or gonadotrophins are often poor predictors of libido.

Treatment of a stallion with low sexual drive is directed best at correction of the underlying problem. However, assessment of the nature of the problem is often difficult. One may try several alternatives, such as the following:

1. Change of stimulus mare or environment
2. Breeding or collecting another stallion in the presence of the low-libido animal
3. Intravenous administration of Gn-RH, 50 µg, 2 hours and 1 hour before breeding or of LH (hCG), 5000 to 10,000 IU, 1 hour before breeding
4. Single injection of a short-acting testosterone
5. Intravenous administration of diazepam at a dose of 0.05 mg/kg (maximum 20 mg) 10 to 15 minutes before breeding to reverse mild shyness in some stallions<sup>9</sup>

The efficacy of most of these treatments is empirical and requires further investigation; however, chronic administration of steroids, particularly androgens, is well documented to affect spermatogenesis negatively.<sup>9</sup> Therefore injection of

stallions with exogenous steroids and particularly androgens to improve libido is not a recommended practice.

### ERECTION FAILURE

The inability of a stallion to develop and maintain a normal erection despite normal libido suggests an anatomic rather than a psychogenic problem. The most common problems are vascular damage associated with traumatic injuries or neurologic problems associated with other penile or lumbosacral compromise.<sup>43</sup> Therapy of either problem, extrapolated from the human medicine literature, may be medical with injection of vasoactive drugs directly into the corpus cavernosum or surgical with penile implants. To date, no reports indicate that either procedure has been used in horses. No reports of dose or efficacy exist to support the use of sildenafil (Viagra) in these stallions; anecdotal reports of its use suggest that results are inconsistent.

### EJACULATORY DYSFUNCTION

Some stallions show normal precopulatory behavior, mount, and copulate but fail to ejaculate. These stallions often attempt to ejaculate and may become exhausted or frustrated, becoming aggressive with the mare or handler. Before attempting to treat an ejaculatory dysfunction, the clinician must examine the horse for evidence of degenerative joint disease in the hocks, spine, vertebrae, and pelvis and for lesions or malformations in the hoof or foot abscesses. Recently, circulatory problems leading to iliac thrombosis have been reported to be associated with ejaculatory dysfunction.<sup>26</sup> Although difficult to diagnose, psychologic problems that can lead to ejaculatory dysfunction should always be considered when no organic causes account for the problem.<sup>43</sup> Often, typical behavior provides hints to the clinician about the psychogenic nature of the dysfunction. In most instances psychogenic ejaculatory dysfunction results from traumatic accidents associated with breeding. If the role of musculoskeletal pain in ejaculatory dysfunction is uncertain, the horse may be treated with 1 g of phenylbutazone every 12 hours for approximately 2 weeks. If the stallion refuses to ejaculate only under specific circumstances, such as into an artificial vagina (AV) or when breeding a mare, the systematic approach of a patient, knowledgeable, and creative person is important to determine the problem. A variety of behavioral and managerial aids have been used to help stallions ejaculate.<sup>44</sup> One should adapt these aids according to the physical condition of the stallion (i.e., stallions that cannot achieve a full erection; stallions that have difficulty mounting; stallions that refuse to ejaculate after normal erection, mounting, thrusting, and belling of the glans). Neither mounting nor full erection are necessary for ejaculation. Stallions that have difficulty mounting can be taught to ejaculate on the ground by stimulating the penis manually or with an AV. Stallions with erection problems can ejaculate, provided that proper stimulation is given to the penis. One can achieve proper stimulation to the penis by raising the temperature of the AV or by applying hot towels to the base of the penis during thrusting. It is also important to consider changes in footing and surroundings, stimulus mare, handler, and so forth before implementing pharmacologic therapy.<sup>45</sup>

Therapeutic regimens for ejaculatory dysfunction are empirical and include those already mentioned for the treatment of low-libido stallions. In addition, PGs, oxytocin, and xylazine have been used to aid stallions in the process of ejaculation. Oxytocin and PG also have been used to treat

azoospermia caused by ampullary blockage.<sup>46</sup> The tricyclic antidepressant imipramine has been used orally to lower the threshold for ejaculation in stallions.<sup>47</sup> The doses for these products are discussed later in this chapter.

### OTHER BEHAVIORAL PROBLEMS

In addition to the previously described problems, stallions may have other abnormal behavior and vices that could eventually limit their fertility. These problems include overaggressiveness and stereotypies such as weaving, cribbing, wall kicking, and stomping.

Overaggressiveness is managed best by a good stallion handler and patience; in most cases the problems can be corrected. Stable vices often can be solved or somewhat alleviated by putting a toy (rubber tire) or a companion animal (goat or sheep) in the stall with the stallion.

One of the most complex behavioral syndromes observed in stallions is self-mutilation. Self-mutilation in horses includes biting, stomping and kicking, rubbing, and lunging at objects. According to McDonnell, three distinct types of self-mutilation occur.<sup>48</sup> Type I represents a normal behavioral response to continuous or intermittent unrelieved physical discomfort. Type II, seen in stallions and geldings, can be recognized as self-directed intermale aggression. The behavior includes the elements and order of the natural interactive sequence typical of encounters between two stallions, except that the stallion himself is the target of his intermale behavior. Type III involves a more quiet, often rhythmically repetitive or methodical behavioral sequence of a stereotypy (e.g., nipping at various areas of the body in a relatively invariant pattern, stomping, kicking rhythmically against an object). Some researchers have speculated that self-mutilation has a genetic component. The prevalence of self-mutilation of one form or another has been observed in as many as 2% of domestic stallions.<sup>49</sup> Among and between stallions, self-mutilation varies in frequency and intensity and can reach levels that threaten the stallion's fertility and even his life.

Careful evaluation of the horse's behavior is often necessary to distinguish the specific type of self-mutilation that is occurring. Type I self-mutilation, in which physical discomfort is the root cause, can be eliminated by relieving the discomfort. For Type II and Type III, understanding of intermale interactive behavior of horses and the environmental factors that may trigger or exacerbate the self-mutilative form can be useful in guiding humane management or behavior modification. Pharmacologic interventions may be a useful adjunct to management and nutritional changes. The stallion compulsively nips or bites the chest, shoulder, or flank or aggressively kicks the walls. Although self-mutilation is limited to postpubertal horses, it is not limited to confined animals. In some animals the problem is exacerbated on presentation of a mare to a confined stallion or breeding in the presence of another stallion.<sup>50</sup> The compulsive behavior seems to be more dramatic during the breeding season.

Self-mutilation may be a problem exacerbated by olfactory stimuli. In most horses this behavior is triggered by smelling their own manure. The stallions often mistakenly recognize themselves as a threat, triggering the compulsive behavior. One must ensure that the horse does not develop the behavior out of frustration because of chronic pain, such as that caused by an inguinal testicle or chronic gastrointestinal ulcers.

Therapy of this complex syndrome depends on the type of self-mutilation and its underlying causes and may include

pain management, surgery, regular exercise, stall toys, and companion animals. Products to reduce the olfactory sense can be used, and the level of energy in the diet can be reduced. Treatment with L-tryptophan in the grain may help some horses. Physical restraint such as head cradles or muzzles most likely will lead to development of another self-mutilating technique.<sup>50</sup> In extreme, inhumane, and refractory cases, castration of the stallion has eliminated the problem for type III self-mutilation but not for the other types. Therefore an accurate diagnosis is a critical component of the treatment protocol.

## SEMEN COLLECTION

In addition to appropriate libido and behavior, a stallion must have good mating ability and be able to deliver an ejaculate. Mating ability and semen quality may be influenced by hereditary or environmental factors or learned patterns that are influenced greatly by management. An integral part of the diagnostic workup on a stallion with known or suspected infertility is the collection of semen. The collection process is critical because improper technique may result in poor fertility or inferior semen quality.

### SEMEN COLLECTION AREA

The area used for semen collection should be spacious; clean; and free of dust and distracting noises, animals, and persons. The size of the breeding shed should be designed with awareness for the space needed for animal and human safety in the event of an uncooperative mount mare or unruly stallion. Stallions with low libido or a reluctance to mount are frequently encouraged to mount a mare in estrus if the mare can be walked slowly forward or led in a large circle. There should be adequate space to permit safe handling of the stallion and mare. Additionally, the footing surface should afford the stallion good traction even when the flooring is wet.<sup>9</sup> Many stallions paw, strike, or kick out while teasing a mare or being washed or after dismounting. All loose dirt, stone dust, and shavings should be removed because some stallions paw debris and dust onto the washed, damp penis just before mounting. If the collection area is dusty, the area should be wetted regularly.

Collection of semen in an outside area is acceptable in most cases but sometimes compromises semen collection because of distractions by other animals, persons, and vehicles. Ambient temperature also may have a significant effect because it alters the rate at which the temperature of the AV declines during cold weather or adversely affects semen quality during hot weather. Semen collection in an outside, grassy area affords the stallion, mare, and handlers the best footing; is usually free of dust; and allows for plenty of space for safety. The distance from the semen collection area to the laboratory should be minimal.

### SEMEN COLLECTION TECHNIQUES

One can collect semen from stallions by allowing natural breeding with the addition of a condom; using pharmacologic stimulation to promote ejaculation; manually manipulating the penis; or using an AV on the ground or on a mount. Under certain circumstances, it may be necessary to use any one of these methods. However, for routine collection of semen for commercial use, an AV or manual stimulation of the penis of the stallion are the methods of choice.<sup>47,51</sup>

**Condom** The stallion is fitted with a latex condom and allowed to breed the mare naturally. Immediately after ejaculation and when the stallion has withdrawn the penis from the vagina, the condom is retrieved. Semen collected using the condom method is contaminated heavily by bacteria and debris. This method also requires that a mount mare be in estrus and increases the risk of mare contamination of the penis by vaginal entry, urination, and defecation during natural breeding. Many stallions do not tolerate breeding while wearing a condom. Condom and semen loss are also common. However, a stallion accustomed to natural service occasionally may be intolerant of semen collection with an artificial vagina until adequately trained for this method of breeding.

**Pharmacologically Induced Ejaculation** Numerous schemes have been published for the ex copula ejaculation of stallions using xylazine, imipramine, xylazine and imipramine, and PG.<sup>40,52-54</sup> Semen collected in this fashion is of low volume and high concentration. One can use the resulting ejaculate for cryopreservation or artificial insemination of mares in a cooled-semen shipment program. Fertility with the fresh, cooled semen is normal. However, the inability to obtain ejaculates on a predictable schedule limits the commercial usefulness of these methods. In experimental ponies semen was collected in 10 of 24 attempts using imipramine and xylazine.<sup>52</sup> In selected cases in which the stallion is physically unable to mount and copulate, it is possible to obtain semen specimens with the aid of pharmacologic agents. Under farm conditions semen is obtained in 25% to 30% of attempts. Keeping the stallion quiet and undisturbed is important. Intravenous treatment should be given quietly. The intravenous administration of 2.0 mg/kg imipramine sometimes yields a successful result. The use of intravenous imipramine must be closely monitored because it has induced episodes of serious hallucination in stallions, with stallions hurting themselves trying to escape their confinement. If the drug does not induce erection and ejaculation in 10 to 15 minutes, xylazine is administered intravenously at the rate of 0.2 to 0.3 mg/kg. With imipramine and xylazine ejaculation occurs in association with erection and masturbation. If one uses xylazine alone to induce ejaculation, masturbation and erection do not occur in association with ejaculation.

Ejaculation usually occurs as the stallion enters a period of sedation or when he is recovering from the sedation. This method of semen collection was used in a cooled shipped-semen program for a stallion with severe tenosynovitis of a rear leg.<sup>53</sup> Although successful about 25% of the time, the procedure was time consuming and unpredictable for mare owners. Success rate may increase if the dosages are altered for individual stallions.

**Manual Manipulation of the Penis** Ejaculates collected by manual manipulation of the penis are similar to ejaculates collected in an AV. This method of collection has not received widespread acceptance because of the training and dexterity required by the person collecting semen from the horse. Many stallions fail to ejaculate unless trained for this method of collection.<sup>44,51</sup> A major advantage of this method of collection is that only one or two individuals are necessary for semen collection. The stallion is usually not in direct contact with a teaser mare. Specialized equipment or facilities are not necessary for semen collection by the manual stimulation method.

With manual stimulation of the glans penis for semen collection, the stallion remains standing on the ground or is trained to mount a phantom. The stallion may be trained for

collection in his stall, an open barn aisle, or a corner of the breeding shed. An estrous mare is usually nearby, but mare stimulation for the stallion may need to be altered on the basis of stallion response. The horse is teased until erection occurs. The operator washes the penis of the stallion with warm water. Once full erection is achieved, the operator places a plastic sleeve or bag over the penis. The operator uses one hand to cup and stimulate the glans penis to achieve favorable thrusting and glans engorgement by the stallion. The operator uses the other to stimulate the base of the penis and urethra. The operator sometimes places a warm towel at the base of the penis to increase stimulation. Training a stallion for this method of collection may require considerable patience, although some stallions readily accept the procedure. Stallions trained for this method of semen collection become habituated to the routine of sights, sounds, and activities surrounding semen collection. These stallions may require little stimulation by a mare.

**Ground Collection** Ground collection may be particularly beneficial in stallions with tarsal arthritis, rear fetlock or tendon injury, laminitis, or hindlimb weakness associated with neurologic disease. The need for an estrous mare usually is eliminated, risk of injury to the horse by the mare is prevented, and one fewer handler is needed. This method of semen collection has been most useful on small farms that stand a stallion for artificial insemination and do not have adequate personnel and facilities for mare and stallion handling and collection.<sup>9</sup>

The semen can be collected in the breeding shed, barn aisle, or stall. The stallion is exposed to another horse that can stimulate the stallion to achieve an erection. The teaser animal may be free in a stall or 5 to 10 m away, being held on a lead shank. The penis of the stallion is washed with clear, warm water. With the stallion positioned against a smooth wall to prevent lateral movement or in front of a solid wall to prevent forward movement, the warm, lubricated AV is placed on the erect penis, and the stallion is encouraged to thrust into the AV. Once the stallion has engaged the AV, the collector uses the right hand to stimulate additional urethral pulsations while holding the AV against the abdomen of the stallion with the left hand. The stallion handler may help support the stallion by pushing against the shoulder of the stallion with the right hand. For safety reasons the person collecting the semen always should maintain shoulder contact with the stallion.

Stallions may stand on their rear legs or walk forward slowly while ejaculating or continue to stand with all four feet on the ground. The handler should not discourage the horse from walking forward or standing up. Once horses are trained in the procedure, they usually stand flat-footed with arched back and a head-down posture. At first application of the AV to the standing stallion, a few stallions may kick out or try to nip or bite at the handler. The veterinarian should inform the handler of the stallion and mare about likely responses before initiating this method of semen collection. After a successful collection, the procedure is repeated in 1 or 2 days, preferably in the same location with the same handler and collection person. A lightweight model of AV is recommended for this procedure.

The author has had good success by placing the chest of the stallion against a phantom when a stallion is not trained to mount. The thrusting into the AV usually causes the stallion to raise his front quarters, resulting in the collection on the mount.

**Artificial Vagina** Use of an AV is the most widely used method of semen collection. Many models of equine AVs are available. The device is fitted with a water jacket that allows for the passive control of the internal temperature of the liner, usually at 44° to 48° C. In most cases the internal diameter of the AV can be modified by the addition of water or air to the water jacket. The operator adds a lubricant manually to the innermost liner of the AV to alter the degree of friction during breeding. Lubricants containing bacteriostatic or spermicidal compounds are not recommended because they are detrimental to sperm motility and fertility.<sup>55</sup> In a recent study<sup>56</sup> Pre-Seed equine® was found to be the best type of lubricant, with the fewest effects on longevity of motility after 48 hours. The detrimental effects of other lubricants is most likely due to their high osmotic pressure or inadequate pH. Petroleum jelly may be used safely. Most commercially available AVs allow the incorporation of a filter into the semen collection system, if desired, so that one can remove dirt, debris, and gel from the semen sample. Otherwise, the entire ejaculate can be filtered after collection or the gel aspirated from the sample using a syringe. Most sperm losses during collection are accounted for by the filter and in the gel fraction of semen. Between 25% and 30% of the spermatozoa in an ejaculate can be lost in the gel and filter. Paper, polyester, or nylon filters can be used, with paper retaining the most sperm.<sup>57</sup>

Ideally, the AV should be constructed to maintain the desired temperature for a significant period of time, allow the direct ejaculation into the semen receptacle, and allow for ease of handling and manipulation by the operator. If the AV is large and heavy, the operator may have difficulty positioning it for tall stallions or holding it in place when the mount mare moves during collection. It is best for the collector to hold the AV in one hand at the appropriate position while using the other hand to deflect the base of the penis to the side of the phantom or mount mare. The arrangement is particularly helpful in stallions that thrust with significant force. Deflecting or stabilizing the base of the penis is stimulatory to most stallions and may help prevent penile accidents during collection.

Semen collection failures frequently are associated with inappropriate positioning of the AV for the particular stallion, an AV that has dropped in temperature below a critical point for the stallion, and the use of inadequate pressure in the AV (i.e., too loose or too tight). The operator should hold the device parallel to the ventral abdomen of the stallion and directly aligned with the base of the penis. By doing so, the operator prevents ventral or lateral bending of the penile shaft. In addition, the operator must ensure that the forceful thrusting of the stallion does not result in the forward movement of the AV because this will result in the stallion searching for the end of the AV and, in most cases, failing to ejaculate. In certain circumstances stallions having difficulty ejaculating into the AV necessitate elevating the internal temperature of the device to 50° C. However, the operator should make an effort to have the horse ejaculate directly into the semen receptacle or coned portion of the liner of the AV to prevent heat shock to the sperm. Sperm cells exposed to excess heat from the liner of the AV exhibit a circling type of motility, have reduced sperm longevity in raw and extended semen, and may be rendered infertile. Exposure of semen to elevated temperatures for as little as 10 to 20 seconds is sufficient to cause heat shock damage.

**Selection of an Artificial Vagina** All AVs used for semen collection from stallions are basically similar in that they have a water jacket that allows variation in the internal temperature and pressure of the AV liner. The specific characteristics of individual AV types vary in the overall length of the AV, its diameter, ease of filling the water jacket, ease of handling, weight of the AV, and location of ejaculation within the AV by the stallion. Commonly used AV models include the Missouri, Colorado, Hanover, Japanese HarVet, and Polish or-open ended models.<sup>9,41</sup>

**Missouri** Used commonly in the United States, the Missouri AV is inexpensive and easy to clean. It is not necessary to assemble this AV for each use because the water jacket is formed by two molded layers of latex rubber. A single rubber cone leads from the water jacket for attachment of a semen receptacle. The AV is held by a leather case with leather handle. Addition of water or air to the water jacket allows for adjustment in AV temperature and pressure. In most instances the glans penis of the stallion is beyond the warm water jacket at the time of ejaculation, which prevents heat shock damage to sperm. A clean plastic or glass bottle, a Whirl-Pak bag, or a disposable baby bottle liner can be attached to the AV for use as a semen receptacle. If desired, a filter can be incorporated into the semen receptacle.

**Colorado** The Colorado model of AV is substantially longer, larger in diameter, and heavier than other AVs when ready for use. The AV consists of a solid outer plastic casing and is assembled by adding two layers of rubber liners to the casing to form the water jacket. This AV maintains the working temperature for stallions for a significantly longer period. Because of the weight and size of this AV, some operators have difficulty holding it in the most appropriate position for some stallions and are unable to provide the necessary support for the stallion. A significant shortcoming of the Colorado model AV is that most stallions ejaculate midway along the length of the warm-water liner, exposing sperm cells to high temperatures. The operator must be extremely cautious when using this AV to prevent heat shock to sperm. Disposable filters and liners are available for the Colorado model AV to remove gel and reduce bacterial contamination from the rubber liners.

**Hanover** The Hanover model AV is used commonly in Europe, is shorter and smaller in diameter than the Colorado AV, and is made of a hard rubber casing and inner rubber liner. This AV should work well for most stallions. Ejaculation occurs at or near the end of the water jacket. Pressure of the Hanover model AV is critical. The AV has an eccentric opening. If the AV is too loose, the nonengorged glans can come through the ring and glans dilation occurs on the other side of the opening, which is very painful for the stallion.

**Japanese** Although the aluminium case Japanese AV is no longer commercially available in the United States, replacement latex liners are still available. The aluminum casing makes this a lightweight, easy-to-handle model, and most stallions ejaculate directly into the semen receptacle. The HarVet AV closely resembles the Japanese AV in its light weight and similar size with a plastic casing. This AV is designed to be used with disposable AV liners that form a semen receptacle at its distal end and therefore does not leak water, as the Japanese AV does.

**Polish or Open-Ended Artificial Vagina** The Polish model is substantially different from other models on the market. Using the open-ended AV, one can visualize the process of ejaculation and can collect individual jets of presperm,

sperm-rich, or gel fraction of semen. This AV has been valuable in the diagnosis of hemospermia, urospermia, internal genital tract infections, and ejaculatory failure.<sup>58</sup> Additionally, this AV has been useful in obtaining semen for commercial use from stallions with hemospermia and urospermia, because most of these affected stallions ejaculate the blood or urine after the initial jets of sperm-rich semen. The open-ended AV also has been useful in cryopreservation programs to obtain sperm-rich and bacteria-free ejaculates from stallions. This method of collection is also used to obtain "clean" ejaculates from stallions that are untrained and intolerant of penile washing. The Polish AV also allows the use of high internal AV temperatures without the risk of sperm cell damage because the ejaculate usually is emitted directly into a funnel with an attached receptacle held by a second person.

Open-ended AVs are not currently available in the United States but can be made by hand from plastic or polyvinyl chloride tubing or by removing the coned portion of the Missouri model AV and using only the innermost rubber liner to form a water jacket.

To reduce the risk of chemical residue exposure of the semen from the AV liner cleaning process or to allow the use of the same AV by multiple stallions, sterile, plastic disposable liners have become commercially available for most types of AVs. However, many stallions object to these liners, and the number of mounts per ejaculation increases. Breakage of the plastic liner may occur during thrusting, and complete eversion of the liner may occur during dismount. If stallions ejaculate on first entry into an AV fitted with a disposable liner, the bacterial contamination of semen is reduced sharply. However, as the number of entries into the AV or the number of thrusts in the AV increases, the bacterial contamination of semen also increases.

The AV should be cleaned immediately after each use, rinsed thoroughly with hot water, and wiped clear of dirt, debris, and smegma. If disposable liners are not used, the rubber liners should be immersed in 70% alcohol for 1 hour or more, rinsed thoroughly with hot water, and hung in a dust-free, dry environment. Soaps and disinfectants should not be used on the rubber equipment to prevent the accumulation of chemical residue. If disposable AV liners are not used or the AV and its liners are not thoroughly cleaned, the AV may become contaminated by *Pseudomonas* spp., *Klebsiella* spp., *E. coli*, *T. equigenitalia*, or other harmful bacteria and therefore contaminate subsequent semen samples and inoculate the penile surface of the stallion. For these reasons many farms maintain an individual AV for each stallion at the breeding farm.

## SELECTION OF A BREEDING MOUNT

Semen can be collected from the stallion while the stallion is mounted on a behaviorally estrous mare, phantom mare, or breeding mount or while the stallion is standing on the ground.

**Live Mare** Selection of a suitable mount mare frequently depends on the experience and breeding mannerisms of the stallion. For example, the inexperienced stallion may need to be taught to mount the mare from the rear quarters. This training requires a disciplined, cooperative mount that will tolerate being mounted from the side. Some stallions vocalize loudly in the breeding shed and may frighten maiden or timid mares. The mount mare needs to tolerate a certain amount of nipping and biting of the neck, shoulders, flank region, and hocks to be suitable for some stallions. Mares with foals at their

sides are frequently protective of their foals and less cooperative than barren mares. The mount mare also should be an appropriate size match for the stallion. For routine breeding farm activities, the reliance on an estrous mare as a mount has significant shortcomings. Additionally, in a cooled, shipped semen program, the breeding farm may not have access to nonpregnant mares, particularly at the end of the breeding season. Therefore some breeding farms maintain one or more ovariectomized mares as mount mares. One should select from these ovariectomized mount mare candidates on the basis of their size, tolerant attitude toward handling, and their strong estrous behavioral signs as intact mares. A mare with gonadal dysgenesis (XO) may be a good mount mare candidate without requiring an ovariectomy. Most ovariectomized mares perform well as mount mares while being restrained with a twitch or lip chain placed on the upper gum. In some cases it may be necessary to administer a low dose of estradiol cypionate (0.5 to 2 mg) at intervals of 3 days to 3 weeks to maintain receptivity by the mare.

During the semen collection process, the mount mare usually is restrained using a twitch. Hobbles also may be applied to rear pasterns or hocks, but the novice stallion may become entangled in the hobbles if the collection procedure does not go as planned. The long tail hairs at the base of the mount mare should be wrapped to prevent the tail from interfering with deflection and entry of the penis into the AV.

**Phantom Mare or Dummy** Because of the lack of readily available mount animals, increased expertise required of an additional horse handler, and increased safety risks associated with use of a mount mare, many farms prefer to train the breeding stallions to mount a phantom or dummy mare for semen collection. Most stallions, including novice stallions, readily accept the phantom as a mount during semen collection. The working area around the phantom should be dust free and allow good footing by the stallion. Adequate space should surround the phantom for the safety of the handlers and to allow a teaser mare to be positioned alongside or in front of the phantom. Many stallions are trained to mount the phantom even when the teaser mare is not close to the phantom.

When the phantom is used to collect semen from a stallion, the stallion should approach the mount in a controlled fashion, mount the rear of the phantom, and use his forelimbs to stabilize himself by grasping the padded barrel of the mount. The operator should quickly deflect the penis to the side of the phantom. While on the left side of the stallion, the operator deflects and stabilizes the base of the penis with the right hand. This practice minimizes potential injury to the penis and prepuce during thrusting by the stallion. Some phantom mounts are fitted with a Colorado-type AV on the posterior end, which works well for some stallions and requires only one person for the collection procedure. However, some stallions need manual stimulation that is easier to provide when the operator has control of the AV. Stallions regularly used for live cover breedings can be difficult to train to accept the phantom as a suitable mount. For this reason, certain circumstances may require access to an estrous mare.

The breeding phantom usually is made of a hollow cylinder with closed ends. The barrel is covered with 1 to 2 inches of firm padding. The padded cylinder then is covered by a tough, nonabrasive cover that is free of wrinkles. Stallions that repeatedly mount and dismount a phantom abrade the medial aspects of the forearms and knees. The stallion should

be taught to dismount the phantom in a controlled manner by backing off of the mount rather than making a side dismount. The diameter of the phantom's body should be 20 to 24 inches total. The legs of the phantom should be kept away from its mounting end to prevent injury to the hindlegs of the stallion during breeding and dismounting. The mount should be adjustable for height, and the angle of the phantom should be adjustable to accommodate older stallions, stallions with hock problems, and stallions of varying stature.<sup>9,59</sup>

**Semen Collection Procedure** Preparation and planning are the keys to the efficient collection of semen from stallions and to ensure proper handling of the semen immediately after collection. The laboratory should be prepared so that the equipment and any extenders used in semen handling after collection are clean and at the desired temperature (35° to 37° C). The AV should then be assembled and filled with warm water (usually at 48° to 52° C) because the AV equipment quickly drops in temperature during equilibration. The final temperature of the AV is adjusted, if necessary, to between 45° and 48° C for most stallions; the inner liner is lightly lubricated with a nonsporicidal lubricating gel; and the AV pressure is adjusted at this time.

A suitable area for semen collection should be selected. If an estrous mare is to be used as a mount mare, the tail should be wrapped and the perineal area washed to prevent undue contamination of the stallion's penis during mounting. With the mare adequately restrained, the stallion is brought into the collection area. Once the stallion has achieved full erection, the operator cleans the penis with clear, warm water; wipes the urethral diverticulae clean to reduce further bacterial contamination of the semen; and wipes the penis dry, if necessary, using a clean, soft towel.

The operator presents the stallion to the side of the mare and encourages him to mount after he has achieved a full erection and the mare has demonstrated her receptivity. For safety reasons the mare and stallion handlers should be on the same side of the mount mare as the individual collecting semen from the stallion. After the stallion has mounted, the operator directs the erect penis into the AV using the hand placed on the ventral surface of the penis. This hand continues to stabilize and deflect the base of the penis during thrusting and ejaculation. The operator should hold the AV to accommodate the stallion, which usually involves holding the AV parallel to the ventral abdominal wall of the stallion. Just before the stallion ejaculates, the operator can feel strong urethral pulsations with the right hand. Once ejaculation begins, the operator should tilt the AV downward to allow rapid entry of semen into the collection vessel to prevent heat shock to the sperm.

Semen collection from the stallion mounted on a phantom is done in the same manner. As soon as the stallion dismounts, the semen is taken to the laboratory for processing and evaluation. It is critical that the person who is collecting provide enough support to the stallion so that the operator is not pushed forward to the front end of the mare or phantom when the stallion is thrusting.

## SEMEN EVALUATION

Depending on the reason for semen collection and its ultimate purpose, the ejaculate must be handled, processed, and preserved in different ways. Evaluation of raw semen for a routine BSE or a prepurchase examination might require more detailed analysis than that done for semen collected regularly for an

artificial insemination program at the farm. However, semen that will be processed for an artificial insemination program away from the site of collection requires different processing.

### EVALUATION OF RAW SEMEN

The goal of most semen evaluations is to predict the fertilizing ability of a given ejaculate or the potential fertility of the animal undergoing the evaluation. However, the low predictive value and frequent lack of objectivity of traditional tests such as motility and morphology have led to the refinement of old techniques and the development of new methodologies for semen evaluation.<sup>60</sup> The standard evaluation of a given ejaculate involves the following:

1. Volume and color. One should record the color and volume (in ml) of the ejaculate. In general, the color of the ejaculate ranges from watery to creamy and depends on the sperm concentration per ml. Abnormal colors or volumes can indicate contamination of the ejaculate with blood, urine, or pus. Normal volumes of ejaculates range from 20 to 250 ml, with an average of 50 to 60 ml.<sup>61</sup> Factors that influence the volume are degree of sexual stimulation before collection, breeding conditions, and foreign material in the ejaculate. A large semen volume, however, in no way reflects the quality of the ejaculate. Low volumes of ejaculate with low sperm concentration in an otherwise normal stallion suggest an incomplete ejaculation, and another sample should be collected.
2. Sperm concentration. The number of sperm per ml must be accurately estimated in order to calculate total sperm numbers in the ejaculate as well as sperm available for insemination. Sperm concentration, or density, is reported in millions per ml. Average counts are between 100 and 300 million; however, it can range from less than 50 to over 500 million per ml, depending on the stallion and the frequency of collection. Although subject to as high as 10% variation, the Neubauer chamber or hemacytometer is regarded as the gold standard for evaluation of sperm concentration.<sup>62</sup> Even though the hemacytometer is regarded as the most accurate method to measure sperm concentration, it is time consuming and therefore not regularly used for routine counting of raw semen. Other systems, such as the SpermaCue, Equine Densimeter, or the Accucell, are used. With all these systems it is critical to have a very clean sample free of foreign particles, debris, or extender. All these systems are very accurate and repeatable at the 100 to 300 million sperm range; however, their accuracy diminishes out of this range.<sup>62</sup> Other methods for sperm counting are the computer-assisted sperm analysis (CASA) systems. In addition to providing sperm numbers, these systems report sperm motility and the number of fast-moving and progressively motile sperm. A fluorescence dye (propidium iodide) has been recently used to label and count sperm. The NucleoCounter SP-100 counts sperm cell nuclei stained with the DNA-specific fluorescent dye propidium iodide.<sup>63</sup>
3. Osmolarity and pH. Osmolarity of stallion semen ranges between 290 to 310 mOsm. Values greater than 350 mOsm may indicate urospermia, and one should measure the level of creatinine. Values less than 250 mOsm suggest water contamination, and values over 500 mOsm reflect possible lubricant contamination. Seminal pH ranges between 6.9 to 7.5, and values higher than those should warn the clinician that there may be extraneous material in the ejaculate or an infectious process in the reproductive tract of the stallion.
4. Spermatozoal motility. Sperm motility is a rough estimate of the percentage of viable sperm in the ejaculate. Several methods have been used to evaluate motility. First, visual motility is the most widely used assay for evaluating semen because of its simplicity and low cost. However, many factors greatly influence the evaluation: individual judgment, thickness of the sample, concentration of sperm in the ejaculate, degree of contamination, degree of agglutination, and temperature. For this reason, one should estimate motility by evaluating a number of fields in a 10- $\mu$ l drop of well-mixed semen in a microscope with a heated stage.<sup>41</sup> Conversely, motility can be estimated by diluting a portion of the ejaculate with extender to a concentration of 25 to 50  $\times 10^6$  sperm per milliliter.<sup>64</sup> Even under the most tightly controlled conditions, repeatability of visual motility is poor between technicians and laboratories. Visual motility estimates of freshly ejaculated stallion sperm have been reported to account for only 50% to 70% of the variation of fertility in that sample. The correlation is even worse ( $r = 0.3$ ) when trying to predict fertility of a frozen-thawed sample of semen based on post-thaw motility.<sup>65</sup> CASA provides data on characteristics of sperm such as linear velocity, linearity, path velocity, and lateral head displacement that otherwise would be difficult to obtain. In addition, CASA provides information on sperm concentration and percentage of motile cells. Although analysis of sperm motion with a computer is more objective and provides a highly consistent way of evaluating spermatozoa, the fertility of stallion sperm is not well correlated with any of the sperm characteristics measured with these analyzers.<sup>66</sup>
5. Longevity of sperm motility. Duration of motility can be determined using raw, undiluted semen or extended semen. Dilution factor of semen to extender affects the longevity of sperm, so ratios of 1:3 to 1:4 are recommended. To evaluate longevity of motility, one should evaluate semen samples immediately after extension and at regular intervals thereafter for up to 96 hours.<sup>64</sup>
6. Sperm morphology. Several attempts have been made to try to correlate the percentage of morphologically normal sperm present in a given ejaculate with fertility.<sup>67,68</sup> However, because of the lack of consistency among clinicians in reporting sperm morphology, results have been inconclusive. Among the problems that clinicians encounter are the definition of normal and abnormal in light of the tremendous range of normality and the fact that little knowledge exists regarding specific sperm defects that interfere with fertility. This problem is even more vexing when a clinician is trying to interpret the results from a referring veterinarian or a veterinary technician. Some of these inconsistencies can be avoided by recording specific morphologic defects rather than grouping defects into primary and secondary because this last method erroneously assumes origin of sperm defects (i.e., testis and post-testicular, respectively). For any sperm morphology evaluation, a minimum of 200 cells should be counted. Normal sperm cells, as well as those with acrosomal, head, midpiece, droplets, and tail defects, should be recorded, with the specific type of defect noted for each part. Although only 200 cells are counted routinely, sperm cells with more than one defect should be

recorded as such to help the clinician evaluate the incidence of defects in a particular semen sample. One can evaluate cells as wet mounts under phase-contrast microscopy or differential interference contrast microscopy after fixation in buffered formal saline or 4% glutaraldehyde. If samples are to be preserved for longer periods of time, an antibiotic should be added to the fixative. Alternatively, cells can be evaluated after staining. One drop of semen is well mixed with the stain and then smeared on a glass slide. Common stains currently used include India ink, eosin-nigrosin, eosin-aniline blue, Giemsa, Wright's, and several others. The clinician should be aware that severe changes in the osmolarity of the stain as well as mechanical damage to the sperm could alter the normal morphology of the cells.

Additional morphologic information can be gained by performing scanning or transmission electron microscopy. Although these procedures are not recommended as a routine, they can prove valuable in cases of stallions with unexplained infertility.

### ALTERNATIVE ASSAYS FOR SPERM EVALUATION

Other assays for evaluating sperm in stallion semen include the following:

1. Hypo-osmotic stress test. As with many other cells, when sperm with intact membranes are exposed to hypotonic solutions, the influx of water across the intact membrane causes swelling of the cell and is evident by a characteristic coiling of the tail.<sup>69</sup>
2. Flow cytometry. Flow cytometry now is used widely to evaluate stallion spermatozoa. This technique, based on labeling of sperm acrosomes or DNA with fluorescent dyes, has the advantage of analyzing a large population of cells, which in turn provides information on the distribution of acrosomal or chromatin integrity.<sup>70-72</sup>
3. Biochemical evaluation. Activity of enzymes such as aspartate aminotransferase, glutamine-oxaloacetic transaminase, lactate dehydrogenase, adenosine triphosphate, hyaluronidase, and acid and alkaline phosphatase are correlated positively with the number of sperm in the ejaculate. Because these enzymes are located mostly in the acrosome or midpiece, their activities—particularly those of glutamine-oxaloacetic transaminase, lactate dehydrogenase, and hyaluronidase—increase proportionally with the level of damage inflicted on the sperm. Therefore enzyme activities in the seminal plasma can be used as indicators of the degree of acrosomal or membrane damage.<sup>73-75</sup> Further research is needed in this area to establish normal enzyme activities in stallion seminal plasma. Levels of alkaline phosphatase can be used to determine excurrent duct blockage in azospermic stallions. Levels of over 10,000 Iu/L are indicative of epididymal fluid contribution to the ejaculate.<sup>76</sup>

**Preservation of Semen** The specific processing of the ejaculate is determined by the length of time that the semen needs to be stored before insemination. Semen can be used fresh, cooled, or frozen.

**Fresh Semen** Semen that is collected and used immediately or up to 12 hours later need not be refrigerated and in most cases can be diluted with appropriate prewarmed extender at ratios of 1:1 to 1:4, depending on raw semen concentration and ejaculate volume. Immediately after extension, semen should be removed from the incubator and cooled to

room temperature (15° to 20° C) without loss of its fertilizing potential. Raw semen may be used for artificial insemination within 30 minutes to 1 hour after collection, provided that it is kept at 37° C. Extension of all collected semen before insemination is highly recommended.<sup>77</sup>

**Chilled Semen** To retain its fertilization potential, semen that is going to be used 12 and up to 72 hours after collection should be cooled to 5° to 8° C. Besides storage temperature, the most important factors affecting the longevity of extended semen are semen quality, sperm concentration immediately after ejaculation, type of extender and antibiotic used, dilution rate, and cooling rate. Several systems of passive cooling for stallion semen are available; however, the Hamilton Thorne Equitainer system has proved to provide excellent cooling rates and is considered the most reliable method for shipping cooled semen. In addition to cooling the semen at an appropriate rate, the Equitainer maintains the semen at the desired temperature for up to 72 hours. Furthermore, the Equitainer II has been shown to be the most appropriate container to use if the container is likely to be subjected to freezing conditions for an extended time.<sup>77</sup>

Semen should be diluted at a ratio of 1:3 to 1:10, depending on the initial volume and concentration of the ejaculate. In general, the longevity of fresh cooled sperm is directly proportional to the dilution ratio, ensuring that the total dose has 1 billion sperm cells and concentrations between 25 million and 50 million sperm per ml.<sup>77</sup>

Idiosyncratic differences in individual stallion semen in tolerating the cooling process or to particular extenders or antibiotics are not uncommon. Although the factors that determine why the semen of some stallions does not preserve well are unknown, particular components in the seminal plasma, such as oxygen free radicals, are suspected of being involved. In fact, in some instances the longevity and fertility of some stallions can be significantly increased by removing the seminal plasma and resuspending the semen in the appropriate extender.<sup>78</sup>

When processing or evaluating shipped semen, one must remember the following:

1. Extenders should have an antibiotic. The combination of amikacin and potassium penicillin is popular and does not appear to interfere with fertility.
2. The modification of the traditional nonfat, dried milk solids-glucose extender may improve the semen quality of selected stallions, especially if all seminal plasma is removed.
3. The semen-to-extender dilution ratio may need to be altered for each individual ejaculate, with dilutions of 1:5 or greater not uncommon.
4. A commercial storage container should be selected in light of the transport time, method of shipment, and ambient temperatures to which the container will be exposed.
5. The use of nontraditional laboratory probes, such as the sperm chromatin structure assay, can provide meaningful information regarding the effects of semen storage on spermatozoal function.

A common practice for some breeding farms is to ship semen for two inseminations 12 hours apart. In recent years it has become evident that mammalian sperm, including stallion sperm, reaches the oviduct within a few hours after insemination and subsequently attaches to the oviductal epithelium and remains motile for at least 72 to 96 hours. This has led researchers to suggest that the oviduct of the mare is

a better storage place than any of the transport systems available. Therefore using all available semen for insemination of the mare as soon as it arrives is highly recommended. However, one must take into account sperm quality and reproductive history of the mare to decide whether the mare's uterus can tolerate two inseminations.

**Freezing Semen** When the semen is intended to be inseminated more than 72 hours after collection, it must be frozen to retain some of its fertilizing potential. The only way to preserve sperm for long periods of time (i.e., for months or years) is cryopreservation or freezing. Different stallion semens tolerate the freezing and thawing process differently, and unfortunately, the number of motile sperm after thawing is a notoriously poor indicator of fertility of frozen-thawed semen.<sup>78</sup>

In general, the freezing process involves the collection of semen from the stallion, evaluation of the semen, dilution and centrifugation of the semen, and resuspension of the sperm in freezing extender. Unfortunately, frozen-thawed sperm appears to have a shorter life span in the reproductive tract of the mare than raw semen or fresh sperm. The reduced life span appears to be related partially to differences in calcium metabolism between fresh and frozen sperm.<sup>79</sup> Because of the apparent short life span of frozen semen, timing of insemination appears to be critical when using frozen semen.

**Semen Processing for Freezing** The equine frozen semen industry has made significant improvements in the last decade. Although it is standard to freeze semen in 0.5-ml straws, the lack of a laboratory test that relates to fertility, and the inability of some stallions to tolerate the freezing and thawing process have been major obstacles in the refinement of freezing techniques.

Extenders for freezing stallion sperm must have energy and protein sources similar to those needed by fresh or cooled semen. However, in addition, freezing extenders must contain a cryoprotectant such as glycerol.<sup>80,81</sup>

Recently, a combination of a low level of glycerol (1%) combined with 4% dimethyl formamide has been used as a cryoprotectant for freezing stallion semen. Preliminary evidence indicates that stallions whose semen does not freeze well have better fertility and a reduced number of cycles per pregnancy when semen is frozen in this combination rather than on glycerol alone.<sup>76</sup> Semen that is intended for freezing should be processed as soon as possible. Although some semen holds up well after transportation, processing the semen more than 1 hour after collection is not advisable.

The raw semen from a stallion that is classified as a "good freezer" generally has a lower volume, higher motility, and higher number of total motile sperm than semen classified as a "poor freezer."<sup>82</sup> However, classification of stallion semen as a good or poor freezer based solely on the percentage of motile cells after thawing is risky. One should perform longevity of motility, detailed morphology, and in some cases acrosomal and flow cytometric evaluations to determine the quality of the semen before its commercial use.<sup>83</sup>

Processing an ejaculate for cryopreservation involves the following steps:

1. Collection and evaluation of the raw semen
2. Dilution of raw semen in a sugar- and protein-based extender
3. Centrifugation of extended semen and removal of the supernatant
4. Reconstitution of the pellet with freezing extender

5. Packaging of the sperm in an appropriate packaging system after adjusting suspension to the desired number of sperm per dose

6. Placement of straws in liquid nitrogen vapors or in a programmable freezer

Each frozen unit should be identified with at least the name and breed of the stallion, registration number for that breed, date of the freeze, and identification of the laboratory processing the semen.

**Thawing and Evaluation** The handling of frozen semen greatly depends on the recommendations given by the laboratory processing the semen and the type of package in which the semen is presented. In general, single 0.5-ml straws are thawed at 75° C for 7 seconds or at 38° C for at least 30 seconds. When an insemination dose consists of multiple 0.5-ml straws, the most common thawing protocol is 37° C for at least 30 seconds, making sure that the straws do not stick together during the thawing period. Frozen semen packed in 2.5-, 4-, or 5-ml straws should be thawed at 50° C for 40 to 45 seconds. Regardless of the thawing protocol or packaging system, the well-accepted fact is that once semen has been thawed, it should be inseminated almost immediately.<sup>41</sup>

Although the freezing procedure is simple, the evaluation after thawing and the prediction of the potential fertility of a given ejaculate after thawing are not so simple. Sperm quality has a profound effect on the pregnancy rates achieved with frozen-thawed semen. Motility after thawing, concentration per dose, morphology, and acrosome integrity are parameters one should evaluate to determine the quality of frozen semen. Unfortunately, a battery of tests, let alone a single test, cannot predict the fertility of frozen-thawed sperm so as to determine what is good and what is poor semen. In general, semen with higher motility is considered to be of better quality; unfortunately, this is not always the case. The motility of most stallion semen after thawing, regardless of the motility before freezing, is 30% to 45% less than for fresh sperm. But some stallion semen with motilities of less than 30% after thawing have acceptable pregnancy rates per cycle, whereas others with motilities greater than 40% have low pregnancy rates.<sup>83,84</sup>

## ☞ MANAGEMENT OF THE BREEDING STALLION

One should consider many factors to optimize management of the breeding stallion, including feeding, exercise, and vaccination programs. Many management decisions are made on the basis of the number of mares that a stallion will breed in a season, breed, type of housing, and the method of breeding.

### GENERAL MANAGEMENT

#### FEEDING PROGRAM

Successful breeding programs require a balanced feeding program. Overfeeding and oversupplementing of stallions are probably the most common forms of malnutrition in stallions. Obesity may adversely affect libido and mating ability. In general, the nutritional needs of a stallion during the breeding season do not appear to differ from those of maintenance. A maintenance ration consists of sufficient balanced nutrients to support normal, basic bodily functions. Adequate pasture or good-quality hay usually can meet these requirements. Free access to trace mineralized salt and fresh water ad libitum are also necessary. Grain as an energy supplement in cold weather

or under certain stressful conditions also may be warranted. The size, condition, activity, and temperament of the stallion play a role in his nutritional needs.

The healthy stallion consumes 2% to 3% of his body weight daily. At least 50% of this should be in the form of roughage.<sup>85</sup> Stallions generally require 10% protein in their feed, with younger stallions requiring 12% to 14%.<sup>86</sup> Although micronutrients such as vitamins A and E, selenium, copper, and zinc play an important part in the successful completion of spermatogenesis, to date no evidence exists that any of these nutrients fed in excess increase sperm numbers or quality. However, recent evidence would suggest that feeding docosahexaenoic acid (DHA)-enriched nutraceuticals may have a significant effect on the quality of fresh, cooled, and frozen stallion semen.<sup>87</sup>

### EXERCISE

Horses naturally are roaming and grazing animals. Exercise for stallions is an integral part of their management and affects their mental and reproductive well-being. The goal is to keep a stallion fit for the breeding shed, not the racetrack, so that he has a good attitude toward his daily duty (i.e., covering mares). The amount of exercise time must be tailored to the temperament and needs of the stallion. The owner should provide regular exercise to maximize the stallion's fertility and longevity, as well as physical and mental fitness. In addition, lack of exercise may lead to vices such as weaving, stall walking, or cribbing.<sup>9</sup>

### ESTIMATION OF STALLION BOOK AND FREQUENCY OF SERVICE

A stallion usually is chosen as a breeding animal on the basis of pedigree, performance, and conformation. Little or no emphasis is placed on reproductive potential, and a significant number of stallions enter the breeding pool with poor or marginal fertility. A complete BSE on maiden stallions or a complete review of past reproductive performance for new stallions is an integral part of the management process. Information regarding the number of mares bred, number of covers made, pregnancy rate per cycle, and covers per pregnancy is helpful in evaluating reproductive efficiency. If a stallion has stood at stud in previous breeding seasons, collection of one or two ejaculates is sufficient to determine that his semen quality has not declined during his off time because of illness, trauma, or age.

Libido certainly can play a large role in determining the number of mares that a stallion can service during a breeding season. Libido, which is thought to be a genetically acquired trait, can be modified by handling and environmental conditions such as housing. Therefore testosterone levels and libido can be altered by exercise and interaction between stallions and mares. Many times, poor libido is a limiting factor in the number of mares that a stallion can cover. The number of covers that a stallion can make in a day varies with the individual stallion. Factors such as age, physical abnormalities, and testosterone levels play an important role. Some stallions can breed twice or thrice daily, 7 days a week, whereas some can cover only one mare a day.

The length of the breeding season also plays a role in the number of mares with which the stallion can mate. The Thoroughbred season is generally from February 15 to July 15. Therefore the number of mares that can be presented during

this time is limited in a natural breeding program. In Warmblood stallions more than 500 mares can be bred with every-other-day collection of average-quality semen.

The age and physical condition of the stallion also must be considered. Stallions typically retire to stud at 3 to 5 years of age. Age influences reproductive capacity. Stallions reach puberty at 12 to 24 months of age but continue to mature and increase reproductive performance until at least 5 years of age or older. During the breeding season seasonal fluctuation of sperm production occurs.<sup>88</sup> In addition, physical problems, especially of the hind legs, may limit the number of mares that the stallion can mount and service. Furthermore, the quality of the book of mares that the stallion has for a particular year can have a significant effect on the number of mares that he can cover. For example, a stallion that has a book in which most of his mares are maiden or young foaling mares will be able to cover significantly more than one who is booked to a majority of old barren mares.

The effect that the reproductive potential of a stallion has on the overall breeding program is significantly more important than that of a single mare. However, for veterinarians and managers to understand the complex interactions among management, endocrinology, and the quality of the mares that a stallion breeds is imperative so that they can diagnose or treat infertility problems in the stallion.<sup>9</sup> One can estimate potential sperm production by using the combined testicular volume, as described in a previous section of this chapter.

### STALLION AS A SOURCE OF DISEASE TRANSMISSION

With increasing breeding management—that is, more mares bred to a stallion in a given year—the significance of venereally transmitted diseases in horses has gained importance. Thoroughbred stallions commonly may breed more than 100 mares by natural cover, and Standardbred or Warmblood stallions may breed twice that number or more in a single 5- to 6-month breeding season through artificial insemination. With the implementation of frozen semen technology, semen from virtually any country can spread disease in a country or continent far removed from the stallion's direct area of influence.

Veterinarians must be aware of the risk factors for disease transmission, diagnostic methods, and some management measures that can reduce the incidence of disease with its potentially devastating effects on fertility.<sup>9</sup>

### RISK FACTORS

Several risk factors may increase the chances of disease transmission through semen:

1. Natural mating: Direct sexual contact may pose the greatest risk for venereally transmitted disease. All mares, particularly those with poor fertility histories, should be cultured before breeding. Stallions breeding by natural cover should be monitored regularly.
2. "Backyard stallions": Stallions that are not standing at a breeding farm tend to have lower numbers of mares per season and poorer reproductive management. Hygienic procedures in these cases often are neglected, and these stallions or mares can be carriers of infectious disease. These horses often are poorly housed, which can contribute to colonization of the penis by pathogenic bacteria.
3. Inconsistent breeding method: In breeds for which artificial insemination is allowed, a stallion commonly may

breed several mares by natural cover at the farm, under no veterinary supervision. The owner also may request that semen from the stallion be collected to be shipped to other mares. These inconsistent practices can increase the risk of a stallion becoming contaminated or of spreading microorganisms to several mares.

4. Artificial insemination: Artificial insemination has been advocated as a technique that greatly reduces the risk of disease transmission. Stallions breeding artificially could breed more than 200 mares during the year. These horses usually are scrutinized carefully for venereal diseases and are housed with other animals of similar health status. Other factors—such as the hygiene of the artificial vaginal, lubricants, collection bottles, dummy mount, teaser mare, and semen packing material—could serve as sources of contamination for venereal disease transmission. If cleanliness and hygiene factors are overlooked, the process of artificial insemination may serve as a multiplier of disease.<sup>89</sup>

## TYPES OF DISEASE

The types of diseases that can be transmitted through semen include bacterial, viral, protozoal, and genetic.<sup>9</sup>

**Bacterial Diseases** The source of bacterial infections can be from the external or the internal genitalia.

**External Bacterial Infections** Virtually every stallion and all ejaculates have contaminants that could be potential pathogens in the mare because a variety of commensal bacteria inhabit the surface of the penis and prepuce. These bacteria constitute the normal flora of the penis and rarely produce genital infections in reproductively sound mares. One commonly can culture an unwashed stallion penis or fossa glandis and harvest myriad bacteria, including *E. coli*, *S. zooepidemicus*, *S. equisimilis*, *S. aureus*, *Bacillus* spp., *K. pneumoniae*, and *P. aeruginosa*.<sup>90</sup> However, when the normal bacterial flora is disrupted, potentially pathogenic bacteria, particularly *P. aeruginosa* and *K. pneumoniae*, can colonize the penis and prepuce. These organisms rarely produce clinical disease in stallions but can be transmitted to the genital tract of the mare at the time of breeding, resulting in infectious endometritis and associated subfertility. The factors that contribute to the colonization of the penis by these bacteria have not been determined clearly. Normal bacterial microflora of the external genitalia of the stallion may combat proliferation of pathogens, and frequent washing of the penis, especially with soaps, may remove these nonpathogenic resident bacteria, increasing the susceptibility of the penis and prepuce to colonization by pathogenic organisms.<sup>91</sup> Others dispute this concept, asserting that repeated washing of the external genitalia alone does not contribute to overgrowth of pathogenic microorganisms. The environment in which a stallion is housed may influence the type of organisms harbored on the external genitalia. The stallion also can acquire these organisms at the time of coitus with a mare that has a genital infection.<sup>92</sup>

One diagnoses pathogenic colonization of the stallion's penis first by careful evaluation of breeding records and early pregnancy diagnosis. A sudden and unexplained drop in pregnancy rates should warn the stallion manager about a possible problem. Definitive diagnosis is by isolation of the microorganism in culture. In addition, isolation of the same microorganism with a similar sensitivity pattern from the nonpregnant mares helps confirm the diagnosis.

Treatment of penile colonization depends on the type of bacteria and method of breeding. For stallions breeding by artificial insemination, a thorough penile wash before semen collection is recommended. One then dilutes the filtered semen with extender containing antibiotic to which the bacteria is sensitive. Incubation should be for at least 30 minutes before insemination. Operators thoroughly should wash and scrub each stallion breeding by natural cover and dry the penis after washing. After the stallion covers the mare, the operator lavages the uterus, infusing the mare with appropriate antibiotics between 4 and 6 hours after breeding.

Stallions with penile colonization by *Klebsiella* or *Pseudomonas* spp. can be washed with a weak solution of HCl or sodium hypochlorite. Systemic treatment is not recommended because it has proved unrewarding in most cases.<sup>93</sup>

**Contagious Equine Metritis** Contagious equine metritis, caused by the coccobacillus *T. equigenitalis*, is perhaps the only true venereal sexually transmissible disease in horses. CEM is an endemic disease in Europe and recently was diagnosed in the United States in several stallions with normal fertility and no clinical signs in them or in the mares that they have bred. The strain of the CEM, as well as its virulence, is still being investigated.<sup>94</sup> Stallions infected with CEM are asymptomatic carriers and harbor the organism in the urethral fossa, the urethra, or the sheath. Mares bred to infected stallions develop a severe purulent vaginitis, cervicitis, and endometritis. Infection in these mares appears to resolve, but they remain infected and the organism can be cultured from the clitoral fossa. Diagnosis of CEM is by culture of the organism. Amies medium supplemented with charcoal is recommended for transport of culture specimens. Swabs are plated on Columbia blood-chocolate agar at 37° C and 7% carbon dioxide. Because of the slow growth of *T. equigenitalis*, the possibility of false-negative results is high.<sup>95</sup>

**Internal Bacterial Infections** Although infections of the accessory sex glands are uncommon, unilateral or bilateral seminal vesiculitis can occur. Bacterial infection of the seminal vesicles is not accompanied by clinical signs except for white blood cells in the ejaculate.<sup>7</sup> In some stallions with seminal vesiculitis, the glands may be enlarged, firm, and painful on palpation if the condition is acute. One cannot consider gland size alone and the character of seminal vesicle fluid on ultrasound examination as accurate indicators of infection, because the glands vary in size and appearance within individual stallions and across breeds. Diagnosis of seminal vesiculitis is best made by rectal palpation, observation of large numbers of neutrophils in the semen, bacterial culture of semen, and endoscopy of the urethra and seminal vesicles. Direct culture of the seminal vesicles during endoscopy increases the clinician's confidence in the significance of organisms cultured. Treatment is difficult, and the prognosis is guarded. Reported treatments include systemic treatment with antibiotics or addition of extenders containing appropriate antibiotics to the semen of the affected stallion. Recently, endoscope-aided direct lavage followed by antibiotic instillation into the vesicular gland lumen has been advocated.

Bacterial infections of the accessory genital glands, epididymides, or testes are uncommon in stallions but are clinically important because of their persistent nature, tendency for venereal transmission, and detrimental effect on fertility of stallions. These infected stallions are usually identified by the presence of numerous neutrophils in their ejaculates, whereas other diagnostic procedures, such as ultrasound and

endoscopy, are used to localize the site of infection. Treatment generally consists of combining local and systemic therapy.<sup>41</sup>

**Viral Diseases** Although many viruses can affect the reproductive performance of a stallion, only two are considered to be venereally transmissible. Equine herpesvirus 3, the causative agent for equine coital exanthema, and EAV, which is responsible for equine viral arteritis (EVA).

**Equine Coital Exanthema** Equine coital exanthema can be transmitted by the stallion to the mare or from the mare to the stallion. The disease is characterized by the formation of small (0.5- to 1-cm) blisterlike lesions on the penis and prepuce or on the perineal area of the mare. These lesions eventually break to form skin ulcers that usually resolve completely in 3 to 4 weeks, leaving some round white scars in the affected area. Sometimes mild fever and slight depression are apparent. The effect on fertility is not known, but stallions and mares during the acute phase of the disease should be rested sexually to prevent further spread of the disease.<sup>89</sup>

**Equine Viral Arteritis** EAV is a small RNA virus that can infect horses and donkeys and is thought to be present in most countries except Iceland and Japan. Presently, EAV is responsible for major restrictions in the international movement of horses and semen. Although most EAV infections are asymptomatic, acutely infected animals may develop a wide range of clinical signs, including fever, limb and ventral edema, depression, rhinitis, and conjunctivitis. The virus may cause abortion and has caused death in neonates. After natural EAV infection most horses develop a solid, long-term immunity to disease. Mares and geldings eliminate the virus within 60 days, but 30% to 60% of acutely infected stallions become persistently infected and maintain EAV within the reproductive tract, permanently shedding the virus in the semen and efficiently transmitting the virus through the semen.<sup>96</sup> Mares infected venereally may not have clinical signs, but they shed large amounts of virus in nasopharyngeal secretions and in urine, which may result in the lateral spread of infection by an aerosol route.

The consequences of venereally acquired infection are minimal, with no known effects on conception rate, but mares infected at later stages of gestation may abort. Identification of carrier stallions is crucial to control the dissemination of EAV. These animals are identified by serologic screening using a virus neutralization test. If the test is positive at a titer of 1:4 or higher, the stallion should be tested for persistent infection by virus isolation from the sperm-rich fraction of the ejaculate or by test mating. Shedding stallions should not be used for breeding or should be bred only to mares seropositive through natural infection or vaccination that are isolated subsequently from seronegative horses for 3 weeks after natural or artificial insemination.

One of the greatest risks of EAV infection is abortion, which may occur even if the mare had no clinical signs. In cases of natural exposure, the abortion rate has varied from less than 10% to more than 60% and can occur between 3 and 10 months of gestation. The abortions appear to result from the direct impairment of maternal fetal support and not from fetal infection.<sup>96</sup>

Although mares and geldings are able to eliminate virus from all body tissues by 60 days after infection, 30% to 60% of stallions become infected persistently. In these animals virus is maintained in the accessory organs of the reproductive tract, principally the ampullae of the vas deferens, and is shed constantly in the semen.<sup>97</sup> Three carrier states exist in the

stallion: (1) a short-term state during convalescence (duration of several weeks), (2) a medium-term carrier state (lasting for 3 to 9 months), and (3) a long-term chronic condition that may persist for years after the initial infection. The development and maintenance of virus persistence depend in large part on the presence of testosterone. Persistently infected stallions that were castrated but given testosterone continued to shed virus, whereas those administered a placebo ceased virus shedding. In addition, virus could not be detected in geldings after 60 days after infection.<sup>16</sup> The ability of a large percentage of stallions to eliminate the virus effectively in time suggests that differences in the immune response of the host may be involved or that virus strains may have biologic differences influencing their ability to persist in the reproductive tract. Establishment of persistence may involve a multifactorial process, with dependence on host and viral factors.<sup>96</sup>

After clinical recovery from initial infection, no significant decrease in the fertility of shedding stallions occurs. Mares infected after service by a carrier stallion do not appear to have any related fertility problems during the same or subsequent years, and no reports indicate that mares becoming EAV carriers or chronic shedders or virus passage by the venereal route from a seropositive mare cause clinical disease or seroconversion in a stallion.<sup>96</sup>

The two major routes by which EAV is spread are aerosol transmission, generated by secretions (respiratory or urine) from acutely infected animals or by secretions from recent abortions, and venereal transmission, from the semen of a shedding stallion. Close contact between animals generally is required for efficient virus spread in aerosol transmission. Personnel and fomites may play a minor role in virus dissemination. Virus is viable in fresh, chilled, and frozen semen, and venereal transmission is efficient, with 85% to 100% of seronegative mares seroconverting after being bred to stallions shedding virus. In several cases outbreaks of clinical disease have been traced to a persistently infected stallion.<sup>97</sup>

Clinically, EVA resembles several other viral infections of horses, and a definitive diagnosis requires laboratory confirmation. Acute infections are diagnosed by virus isolation or by serologically identifying a fourfold or greater rise in neutralizing titer between acute and convalescent serum samples. In the case of abortion, one can attempt virus isolation from fetal and placental tissues or can demonstrate seroconversion in the mare. Persistent infection in stallions is diagnosed by first screening serum for antibody in a serum neutralization test. If the serum is seropositive at a titer of 1:4, one should perform virus isolation on the untreated, sperm-rich fraction of the ejaculate or should test-mate the stallion to seronegative mares and monitor them for seroconversion.

The method of choice for antibody detection is the serum neutralization test. Antibody titers develop 2 to 4 weeks after infection, are maximal at 2 to 4 months, and remain stable for several years. A titer of 1:4 or greater in duplicate sera is considered EAV seropositive. Semen from a seropositive stallion must be tested to determine the EVA status of the stallion as a carrier.<sup>98</sup> The current test for identifying virus in tissues and semen is virus isolation in cell culture. In EAV-related abortion the fetus and placenta contain large amounts of virus. Samples of placenta, spleen, lung, and kidney, along with fetal and placental fluids, must be collected in a sterile manner as soon as possible after the abortion occurred, chilled on ice, and submitted for virus isolation. One should obtain blood from the

mare at the time of the abortion and 3 weeks later for testing by serum neutralization.<sup>96</sup>

After having determined that a stallion is seropositive at a titer of 1:4 in a serum neutralization test, one should collect a semen sample using an AV or a condom and a phantom or a teaser mare. If this is not possible, a dismount sample can be collected at the time of breeding; however, this is less satisfactory. The sample should be from the sperm-rich fraction of the full ejaculate and should be chilled immediately and shipped at 4° C to arrive at the diagnostic facility within 24 hours. If this is not possible, the sample should be frozen at below -20° C and shipped to the diagnostic facility under these conditions. Submission of two samples, collected the same day or on consecutive days, is recommended. The penis should not be washed with antiseptics or disinfectants before collection of the samples. Samples of commercial frozen semen also may be tested, but the sample must have at least 2 billion sperm cells to be representative. False-negative results have been reported because of the lack of seminal plasma in cryopreserved semen.<sup>97</sup>

**Prevention and Control of Equine Viral Arteritis** A modified live (ARVAC, Fort Dodge, Iowa) and a formalin-inactivated (ARTERVAC, Fort Dodge, Iowa) vaccine are available. Both vaccines induce virus-neutralizing antibodies, the presence of which correlates with protection from disease, abortion, and the development of persistent infection. EAV has a worldwide distribution, and its prevalence is increasing. As a consequence, an increasing number of EVA outbreaks are being reported. The trend is likely to continue unless action is taken to slow or halt the transmission of this agent through semen. The modified live virus vaccine (ARVAC) does not produce any adverse effects in stallions apart from a possible short-term abnormality of sperm morphology and a mild fever with no overt clinical signs. However, live virus can be isolated sporadically from the nasopharynx and blood after modified live virus vaccination. Serum neutralization antibody titers are induced within 5 to 8 days and persist for at least 2 years. The modified live virus protects against clinical disease and reduces the amount of virus shed from the respiratory tract in experimental infection. Horses in contact with and mares served by vaccinated stallions are not infected by EAV, and vaccinated mares experimentally challenged by artificial insemination are protected from clinical disease but not infection. In the field the modified live virus vaccine has been used to control EAV outbreaks in some states since 1984, but the vaccine is not licensed worldwide.<sup>95</sup>

EVA is entirely preventable if horse owners, breeders, and barn managers follow simple serosurveillance and hygiene procedures. Controlling the dissemination of EAV requires a concerted effort on the part of all those involved in the equine industry. The presence of neutralizing antibody that correlates well with protection from disease, abortion, and the development of persistent infection in stallions is evidence that a control program, once instituted, can be successful.

**Protozoal Diseases** *Trypanosoma equiperdum* is the causative agent for dourine, or mal du coit. The organism is not present in the United States or Europe but is still endemic in Africa and some areas in Asia and South America. *T. equiperdum* is perhaps the only protozoal organism that can be transmitted venereally. Tentative diagnosis is by the clinical manifestation of the disease, which includes intermittent fever, depression, progressive loss of body condition, and severe purulent discharge from the urethra. Definitive diagnosis is by complement fixation and culture.<sup>95</sup>

Other microorganisms with the potential to be transmitted venereally include *Chlamydia* spp. and *Mycoplasma* spp. Although both of these organisms have been isolated from the urethra of stallions, their effect on equine fertility is not well known. It is possible that these agents cause infertility in mares and stallions. *Candida* spp and *Aspergillus* spp., although not commonly present in semen or the genital tract of the stallion, can be potential pathogens, particularly in artificial insemination programs in which the hygiene of the collection and processing equipment is not well monitored.

**Genetic Diseases** One of the main reasons for stallions standing at stud is to produce offspring with their genetic attributes. However, sometimes stallions can be carriers of a hereditary condition that may be expressed in their foals when they are mated to certain mares. Perhaps the clearest example of the potential effect of the genetic effect is the Impressive syndrome of American Quarter Horses, in which thousands of mares were bred by one stallion, named Impressive, that transmitted the gene for hyperkalemic periodic paralysis (HYPP).

Conditions such as genetic mosaics (63 XO/64 XY or 65 XYY), certain sperm defects such as detached heads, and mid-piece defects and testicular characteristics such as small testicular size or premature testicular degeneration are or could be transmitted genetically. Progress is being made in this area with the advances in the mapping of the Y chromosome.<sup>99</sup>

Other conditions that have been proved to have or are suspected of having a hereditary basis include combined immune deficiency in Arabians, umbilical and scrotal herniae, parrot mouth, cryptorchidism, and testicular rotation. The expression of any of these genetic traits can have profound and devastating effects on a breeding program. When such a condition is suspected, cytogenetic or molecular diagnostic procedures must be used to identify undesirable traits that will be expressed in the adult animal. In addition to HYPP, and with the availability of the equine genome, animals carrying the genes for other diseases, such as severe combined immunodeficiency disease (SCID) in Arabians, lethal white syndrome of frame overo Paint horses, and hereditary equine regional dermal asthenia (HERDA) in Quarter Horses, will be readily identified.<sup>9</sup>

The pivotal point in prevention and control of infectious disease is the identification of infected stallions and mares and the institution of management procedures to prevent the further spread of any disease to susceptible populations through the breeding of mares by natural service or artificial insemination. If a stallion proves to be a carrier, he should not be used for breeding through natural service or his semen should be treated with proper antibiotics in cases of bacterial disease. In the case of EVA a stallion might still be used, provided that the mare owners are informed that the stallion is a shedder so that they can take preventive measures, such as vaccinating the mares.

The option to use a particular stallion in a breeding facility may depend on the value of the stallion as a breeding animal and individual regional regulations. Whatever the case may be, all stallions should have a diagnosed status before each breeding season. Breeding managers and stallion owners must be aware that poor genital hygiene of a breeding stallion and the mares at the time of breeding greatly increases the chances of spreading disease from a stallion to a group of mares or from a mare to a stallion. Poor management, poor breeding records, and poor hygiene at the time of breeding are perhaps the most common reasons for venereal diseases, which can cause severe and irreversible problems in a breeding operation.

## ☞ PATHOLOGIC CONDITIONS OF THE REPRODUCTIVE TRACT

Clinicians must be able to accurately identify pathologic conditions to make sound decisions regarding the therapy and management of stallions. Acquired conditions may be reversible by surgical or other therapeutic means, but diagnosis of irreversible or terminal conditions must be well substantiated because the conditions could have a significant effect on the budget of the breeding operation. Ethical considerations are also pertinent because some genetic diseases can have a significant effect on the breed as a whole.

### CONGENITAL DEFECTS

For an individual to develop into a normal male the Y chromosome must be expressed. Horses with genetic abnormalities can vary in their genotype, anatomic features, and behavior.<sup>100</sup> The most common causes of congenital defects are hermaphroditism, XY sex reversal, and testicular feminization or androgen insensitivity.

Hermaphrodites are classified on the basis of the type of gonadal tissue present. True hermaphrodites have testicular and ovarian tissue,<sup>100</sup> whereas pseudohermaphrodites have testes (male pseudohermaphrodites) or ovaries (female pseudohermaphrodites), with various combinations of male and female internal reproductive organs.<sup>101-104</sup> Perhaps the most common of the intersexes is the male pseudohermaphrodite. For the veterinarian to examine a "mare" with a small vulva and an extremely large clitoris or what appears to be a glans penis is not uncommon. Behavior in these animals most likely depends on the gonadal tissue present.

Horses with XY sex reversal syndrome are characterized by female external genitalia but a normal 64XY karyotype.

Androgen insensitivity or testicular feminization syndrome is a well-characterized genetic disease in human beings and in some domestic species. Animals have a normal XY karyotype and male behavior but female genotype. The syndrome has two possible causes: a mutation at the level of the gene that codes for the androgen receptor or a deficiency in 5 $\alpha$ -reductase, the enzyme responsible for conversion of testosterone to the active androgen dihydrotestosterone.<sup>103</sup> In either situation the reproductive tract is underdeveloped and only female genitalia are present.

Genetic defects can be tentatively diagnosed by visual inspection of the external genitalia, rectal palpation, and ultrasonography. However, a definitive diagnosis requires cytogenetic evaluation. Blood samples must be submitted in tubes with EDTA anticoagulant to the appropriate laboratory.

Segmental aplasia of the vas deferens or the epididymal duct has also been reported recently.<sup>105,106</sup> Obviously, these conditions render the stallion sterile as a result of permanent azoospermia. A stallion recently was diagnosed with failure to mature sperm past the late spermatogonial stage because of a gene microdeletion in the Y chromosome.<sup>107</sup>

### DISEASES OF THE SCROTUM

The scrotum in the horse is a pliable and thin-skinned pouch with a fine layer of short hair, numerous sweat glands, and the thick muscle layer (dartos). The scrotum is usually darkly pigmented. Functional integrity of the scrotum is vital because it is perhaps the most important structure regulating testicular

temperature.<sup>108</sup> Abnormal conformation, absence, or increase in thickness can have a dramatic effect on spermatogenesis. The scrotum is easily accessible for examination by visual inspection and palpation. An absent or extremely small scrotum usually indicates a genetic abnormality such as bilateral cryptorchidism and intersex conditions. Any increases in the thickness of the scrotal wall, surface irregularities, or changes in skin should be recorded. Lesions of the scrotum can be physical or infectious in origin.

### PHYSICAL PROBLEMS

Traumatic insults to the scrotum or the scrotal area and other inflammatory processes in the genital area often result in scrotal edema. The clinician must identify the cause or possible causes of the swelling to initiate adequate therapy. Chronic edema of the scrotum can result in abrasions or secondary lacerations and can be complicated further by cutaneous bacterial contamination. Differential diagnoses for scrotal swelling include systemic infectious processes, scrotal herniae, spermatic cord torsion, or hemorrhagic processes associated with the testicles or spermatic cords. One must be sure not to confuse primary edema of the scrotum with peritoneal fluid accumulation between the vaginal and parietal tunics of the testicle.<sup>109</sup> Ultrasonographic examination or fine-needle aspiration can be used for the differential diagnosis.

Therapy of scrotal edema should be directed toward removing the primary cause and controlling the inflammation with supportive therapy. Anti-inflammatory drugs, diuretics, and frequent cold-water therapy are measures aimed at re-establishing the circulation in the area. If the skin is broken, broad spectrum antibiotic therapy should be instituted. Gentle and continuous lubrication of the scrotum with emollients and a tetanus toxoid booster are recommended. Depending on the degree of involvement, unilateral or bilateral orchiectomy also may be indicated.<sup>109</sup>

### INFECTIOUS CAUSES

**Viral Causes** Equine infectious anemia or diseases causing severe hypoproteinemia can cause scrotal edema. Hypoproteinemia is confirmed by analyzing levels of total protein in serum. The presence of the equine infectious anemia virus is demonstrated by agar gel immunodiffusion or Coggins test.

During the acute phase of EVA, male horses often display different degrees of lower abdominal edema that may involve the scrotum.

Neoplastic conditions of the scrotum that have been reported include melanomas and sarcoids. Melanomas have the characteristics of benign tumors of the dermis and epidermis but may become metastatic in some horses. Sarcoids are common nonmetastatic skin tumors. Both conditions are diagnosed by their general appearance; definitive diagnosis is made by histologic sections.<sup>109</sup>

**Parasitic Causes** Although *T. equiperdum*, the causative agent of dourine, is not present in North America, scrotal edema is a typical sign of the initial phases of this venereally transmitted disease.

*Onchocerca cervicalis*, a microfilaria, and summer sores caused by *Habronema* spp. are seldom a cause of scrotal dermatitis. These infections are transmitted by several species of flies and mosquitoes. Ivermectin therapy at regular intervals is recommended for treatment of these conditions.<sup>110</sup>

**Bacterial Causes** Scrotal infections most often result from secondary breaks in the skin caused by castrations, traumatic

lacerations, or puncture wounds. Less often, infections of the scrotum can result from septic processes in the testis or peritoneum.<sup>109</sup> In addition to appropriate antibiotic therapy, continuous washing of the infected area, anti-inflammatory drugs, and supportive therapy should be implemented.

## DISEASES OF THE TESTES

The four major cell types of the testis are Sertoli's, Leydig's, myoid, and germ cells. During the last month of gestation or first month of life in the normal horse, the gonads migrate through the inguinal canal into the scrotum. Because of this migration the testis is surrounded by the tunica vaginalis or peritoneum and the tunica albuginea or the capsule proper.

Abnormalities in sexual development often are expressed as testicular problems. Among the congenital testicular defects that have been reported in stallions are monorchidism, anorchidism, and polyorchidism, which are the absence of one or both testicles or the presence of more than two testes, respectively.<sup>111</sup>

### ECTOPIC TESTIS

A gonad that fails to reach the scrotum and deviates from the normal path of descent is termed an *ectopic testis*. These testes may be subcutaneous in the inner thigh or abdominal or perineal region. Some authors report splenic-testicular fusion on the left side.

### CRYPTORCHIDISM

In a cryptorchid animal one or both testicles are in an ectopic location for an adult animal, although the gonads remain in the normal path of testicular descent. Cryptorchid testes may be abdominal or inguinal. Because of the complexity of the process of testicular descent, the exact mechanism for the failure of normal gonadal migration is not well understood. Although cryptorchidism has been speculated to be a hereditary condition, none of 56 colts sired by a cryptorchid Quarter Horse had abnormalities in their testicular descent. If the condition is heritable, perhaps a gene with low penetrance controls the process or is associated with several autosomal genes, as has been shown in men. The incidence of the condition according to Stickle and Fessler<sup>112</sup> and Hayes<sup>113</sup> is believed to be between 15% and 20%. Prevalence is higher in Percherons, followed by Palominos and Quarter Horses. Prevalence in Thoroughbreds is lower than in other breeds.

The unilateral cryptorchid horse is easily diagnosed by palpation of the scrotal contents and the inguinal region. When the testis is closer to the internal inguinal ring, in an abdominal or ectopic location, diagnosis can be difficult. Although frequently unrewarding, rectal palpation and ultrasonography are used as diagnostic aids. The experienced clinician can locate the testis and epididymis in or around the internal inguinal ring just cranial to the pelvic brim slightly off the midline. When palpation and ultrasonography have failed to identify testicular tissue, hormonal assays should be performed. Circulating testosterone and estrone sulfate levels are of great diagnostic value. Because of the variation in baseline testosterone levels, the hormone should be measured after stimulation with 5000 to 10,000 IU of hCG.

Collection of serum samples immediately before stimulation and 30 and 60 minutes or 60 minutes and 4 hours after the injection is recommended. A twofold to threefold increase in the level of testosterone is diagnostic for testicular tissue.

Although false-positive results are rare, false-negative results do occur in 5% to 10% of horses. A single measurement of estrone sulfate has been reported to be highly accurate for diagnosis of the condition in adult cryptorchids. In very young equids low hormonal levels should be interpreted carefully because false-negative results may be more common than in adult horses. The treatment for the condition is invariably castration.

### GONADAL HYPOPLASIA

Small testes may result from a number of underlying complex processes such as spermatogenic arrest and germ cell deficiencies. Testicular hypoplasia is the failure of the gonads to reach their full adult size and must be differentiated from gonadal atrophy or testicular degeneration, which is the reduction in testicular size after the gonad has reached full adult size. The cause of the hypoplastic gonad is complex and is thought to be congenital or acquired. Although not clear for horses, a genetic component has been identified in other species.<sup>114</sup> In general, testicular hyperthermia, malnutrition, and endocrine imbalances, particularly in steroid-treated young stallions, can affect testicular size negatively. It is important to remember that the testicles do not start developing before 15 to 18 months and continue to increase in size until the age of 4 to 5 years. Testicular hypoplasia should not be confirmed before the stallion is 2 to 3 years old. The breeding of mares to stallions with hypoplastic gonads is discouraged; however, often because of the value or the performance record, animals with small testicular size are used at stud. In these cases implementation of managerial practices to maximize the reproductive performance of the animal is important and should include reducing the number of mares in the book and breeding mares only once when they are close to ovulation.

### GONADAL ATROPHY

Also known as *testicular degeneration*, gonadal atrophy is found most commonly in the mature stallion and is a consequence of the disruption of the process of spermatogenesis. Atrophy and hypoplasia must be differentiated. A thorough reproductive examination and an accurate history are fundamental in differentiating the two conditions. One should note inconsistencies between sperm output and testicular size and patterns of agglutination of the sperm cells. Small testicular size in relation to the epididymis indicates atrophy. However, developmental abnormalities such as a small penis and enlarged inguinal rings associated with small testicular size often indicate hypoplasia. The veterinarian should know that atrophy or degeneration is an acquired condition that in some cases is reversible.

Testicular atrophy most commonly is caused by administration of anabolic steroids or other products, such as altrenogest, to colts or stallions during their racing or show careers. Although the negative effects of steroids on testicular function are considered to be reversible, a relationship is suspected between the length of exposure and the age at which the product is first administered. Therefore colts injected with anabolic steroids during their first year of life are at greater risk of having permanent damage of the testicular parenchyma. The detrimental effects on spermatogenesis are caused by an increase in the circulating levels of androgens, which in turn have a negative feedback on LH secretion by the pituitary with a consequent decline in endogenous testosterone. The reduction of endogenous testosterone reduces testicular function with a significant reduction in sperm production.

Hyperthermia or severe hypothermia caused by prolonged recumbency; trauma; torsions; infections with disruption of the blood-testis barrier and the consequent production of anti-sperm antibodies; inappropriate or prolonged steroid therapy, especially with testosterone or anabolic steroids; accumulations of fluids such as in hydroceles; and advanced age have been implicated as possible causes of testicular degeneration. Scrotal lesions that impair the normal testicular thermoregulation may be a significant factor causing gonadal atrophy. Other causes of testicular degeneration include radiation exposure; nutritional disorders, particularly those of vitamin A and zinc; and toxicity with heavy metals or nitrogen, phosphorus, and halogenated compounds.

In the initial phases of testicular degeneration, the testis feels softer. As the process becomes more chronic, the testicular tissue is replaced by connective tissue, making the testis feel firmer on palpation.

Leydig's and Sertoli's cells and spermatogonia and spermatozoa are more resistant to degeneration than cells of the intermediate stages of spermatogenesis; therefore semen analysis varies depending on the extent of damage.<sup>115</sup> In most cases gonadal atrophy does not affect libido.

Although not easy to do, the condition can be diagnosed by evaluating circulating levels of LH, FSH, testosterone, and total estrogens and inhibin. Elevated serum concentrations of FSH often indicate seminiferous epithelial damage,<sup>9</sup> whereas low levels of LH could indicate a pituitary problem. Evaluation of sperm production efficiency also can aid in the diagnosis of gonadal degeneration.

A degenerative process in the testicle often is reversible, provided that the causal factor is removed. The condition of hypogonadotropic hypogonadism in men is treated routinely with Gn-RH administered in a pulsatile manner. Anecdotal evidence suggests that similar conditions in stallions respond to Gn-RH therapy administered as subcutaneous osmotic minipumps. To date, no study indicates the benefit of Gn-RH therapy in stallions with poor-quality semen.<sup>9</sup>

### TESTICULAR HYPERTROPHY AND HYPERPLASIA

*Hypertrophy* refers to a condition in which the individual cells of the testes increase in size. The most common cause of testicular hypertrophy is removal of one testis or the abdominal retention of one that triggers a compensatory growth of the contralateral gonad.

*Hyperplasia* refers to an increase in the number of cells and can be focal or generalized. Testicular hyperplasia is rare in stallions.

### TESTICULAR NEOPLASIA

Among domestic species the stallion has a low incidence (4%) of testicular neoplasia.<sup>116,117</sup> Of 30 equine testicular neoplasias, McEntee reported that teratomas were the most common (37%), followed by interstitial cell tumors (30%), seminomas (23%), lipomata (7%), and mast cell tumors (3%).<sup>116</sup>

The cause of testicular tumors is not clear. Environmental and genetic factors may be important. Because of the alteration in temperature and hormone supply, cryptorchid stallions appear to have a higher incidence of germ cell tumors, particularly Leydig's cell tumors or seminomas, of the retained testis.<sup>118</sup> In general, equine testicular tumors have a low degree of metastatic activity; however, because of the potential of spreading to somatic organs, they are considered malignant. The incidence of regional lymph node

involvement appears to be low compared with that of other domestic species.<sup>119</sup>

Diagnosis of testicular neoplasia if both testicles are in the scrotum is based on a careful examination of the suspect and the contralateral testis. One should palpate the scrotal contents and note soft spots, nodules, or asymmetry. Ultrasonographic examination is crucial for the identification of fluid-filled or solid nonpalpable lesions embedded deep in the testicular stroma. Spermogram can be useful if the semen collected has a high incidence of abnormal spermatozoa combined with round spermatids and other testicular cells. Low sperm numbers but otherwise normal seminal parameters are common in horses with testicular neoplasia.<sup>120</sup>

A testicular tumor in an abdominal testicle is diagnosed by rectal palpation and ultrasonography, combined with endocrinologic tests. Depending on the size and location of the testicle, an inguinal, flank, or ventral midline incision is recommended. Abdominal tumors often are only an incidental finding during routine postmortem examinations.

The gross appearance of some tumors can help the clinician make a presumptive diagnosis. Leydig's (interstitial) cell tumors are usually soft, orange, and nodular, with no clear demarcation with the adjacent testicular tissue. Seminomas can vary in color from white to dark gray with a glistening appearance; the neoplastic area frequently bulges above the adjacent testicular tissue. Fluid-filled cysts often are present. Sertoli's cell tumors are usually firm and nodular and pale gray. Teratomas are easily identifiable by the presence of tissue of different origins (e.g., bone, hair). Ultimately, diagnosis is confirmed by histopathologic examination. Samples for histopathologic examination are obtained by fine-needle aspiration or testicular biopsy. Unilateral or bilateral orchiectomy is the treatment of choice regardless of the type of tumor. Ligation and removal of as much of the cord as possible is strongly recommended. If metastasis is suspected, excision of the adjacent lymph nodes is recommended.

### ORCHITIS

An inflammatory process of the testicles is referred to as *orchitis*. The cause of orchitis in stallions may be bacterial, viral, parasitic, or aseptic after trauma. Orchitis can be primary or secondary as a postoperative complication of abdominal surgery. It is important to differentiate the condition from the more common periorchitis or scrotal edema, although the conditions may be present simultaneously. Bacterial orchitis in horses may be caused by *Brucella abortus*, *Actinobacillus equuli*, *Pseudomonas pseudomallei*, *S. zooepidemicus*, *S. equismilis*, *Salmonella* spp., *E. coli*, and *Staphylococcus* spp.<sup>116</sup>

Parasitic orchitis is usually a sequela of migratory larvae of the parasite *Strongylus* spp.<sup>121</sup> The condition can affect descended or undescended testicles and the tunics and spermatic cords. A possible secondary lesion associated with the larvae is the condition known as focal lymphocytic orchitis, which occurs around the seminiferous tubules.<sup>122</sup> Focal lymphocytic orchitis is different from the condition of autoimmune orchitis reported for the mouse in which foci of lymphocytes are localized exclusively at the rete testis and efferent ductules. Initial diagnosis of the granulomatous-type lesions in the testicle caused by strongylosis sometimes can be done by ultrasonography; however, histopathologic identification is necessary for a definitive diagnosis. Regular deworming programs with ivermectin can help control this condition.

EVA and equine infectious anemia are the primary viral diseases that may affect the testis. The viral agents of equine infectious anemia and EVA are shed in the semen of affected stallions. Focal lymphocytic infiltrations may be observed in affected stallions.

As soon as spermatogonia enter the leptotene stage during the meiotic phase, they become isolated from the general immune system by tight junctions between adjacent Sertoli's cells. These gap junctions are known as the *blood-testis barrier*. A fine balance is maintained so that maturing spermatids can migrate toward the adluminal compartment without eliciting an immunologic response. In addition to the blood-testis barrier, local immunosuppressors are present in the testicular interstitium. Factors that disrupt the blood-testis barrier with the consequent formation of antisperm antibodies include tumors, trauma, biopsies, and testicular torsions of more than 360 degrees. The association between antisperm antibodies and infertility, although reported for the stallion, warrants further investigation.<sup>123</sup>

### DISEASES OF THE EPIDIDYMISS

Problems that affect the epididymis can be grouped into congenital abnormalities and into infectious or physical causes. In the stallion a condition known as *blind-ending ductules* has been observed. If sufficient numbers of tubules are blocked, the condition may lead to spermiostasis with development of cystic dilations, formation of epididymal sperm granulomas, and reduction of fertility. These cystic dilations may be diagnosed by palpation and ultrasonography.

Because the epididymis in the stallion is not fused completely with the testicle as in other species, a diagnosis of epididymal aplasia or agenesis is not uncommon. In some cases an abdominal testicle may have a caput attached with the corpus and cauda epididymis present in the scrotum. The inexperienced clinician sometimes mistakenly removes an epididymis and leaves the testicle in the inguinal canal or in the abdomen when performing a castration. Epididymal aplasia is rare in the stallion and if present is related to other anomalies of the wolffian duct system. One commonly detects spermatoceles and cystic dilations by palpation or ultrasonography. Other, less common conditions include adenomyosis and tumors.<sup>124</sup>

Bacteria or trauma to the scrotal area may cause inflammation of the epididymis, or epididymitis. Infectious epididymitis as a primary disease is rare in stallions and is considered a sequela to orchitis or to deep lacerations of the scrotal area. However, some authors report the presence of *S. zooepidemicus* in association with epididymal infection. Migration of *Strongylus edentatus* larvae also may cause epididymitis, with the consequent formation of granulomas.<sup>125</sup>

One confirms a diagnosis of epididymitis by palpation, ultrasonography, the presence of inflammatory cells in the ejaculate, or bacterial growth on culture.<sup>126</sup>

Other causes of epididymal dysfunction can be attributed to abnormal accumulation of sperm in the cauda epididymides or generalized dysfunction of the epididymal epithelium associated with deficiencies in electrolyte, protein, or steroid secretion or resorption. Such dysfunction would cause changes in pH and osmolarity that might adversely affect the ability of sperm cells to fertilize. This condition is diagnosed by frequent semen collections (twice daily for 7-10 days) and evaluation of sperm morphology and motility.

### DISEASES OF THE SPERMATIC CORD

Problems associated with the spermatic cord are limited to infections or vascular problems. Infectious processes of the cord result from larvae migration or secondary contamination with *Streptococcus* spp. after castration. Failure of the castration site to heal and continuous draining of purulent material with intermittent febrile periods often indicates an infection of the spermatic cord known also as *scirrhous cord* or *champignon*. Therapy includes opening the area and aggressive therapy with penicillin.

Vascular problems associated with the cord include torsion, varicoceles, and thrombosis.<sup>127,128</sup> Torsion of the cord is significant when the cord has rotated more than 180 degrees. Torsions of less than 180 degrees are an incidental finding and can be permanent or transient and are of little clinical significance. Torsions greater than 270 degrees are associated with scrotal swelling, severe pain, abnormal gaits, and colic symptoms and are considered an emergency. Diagnosis is by palpation and history, and torsion must be differentiated from scrotal herniae. If the tail of the epididymis is palpable, in torsions of 360 degrees the tail will be located in a dorsal position with respect to the normal stallion. The treatment of choice is hemiorchiectomy because the affected testicle will be non-functional. In addition, it is possible that immune-mediated infertility may result because of antisperm antibody production.<sup>122</sup>

Varicoceles and thrombosis of the spermatic cord are rare in stallions; however, they might interfere with testicular thermoregulation.<sup>127</sup> The presence of varicoceles is of questionable significance in the stallion and is diagnosed easily by ultrasonography. One must ensure that no adhesions of the spermatic cord occur because adhesions may result in fluid accumulation between the testicular tunics.<sup>129</sup> Thrombosis of the cord is a more serious condition. The clinical signs resemble those of higher-degree torsions, and unilateral castration is recommended.

### SEMEN

Problems associated with semen may be divided into two distinct groups: (1) abnormalities of seminal fluids, such as volume, color, pH, and osmolarity, and (2) abnormalities of spermatozoa.

Abnormal volumes may be too small or too large. Extremely low volumes are associated with incomplete ejaculation or nonejaculation. Large volumes may be associated with extraneous fluids such as water, urine (uro spermia), blood (hemospermia), or pus (pyospermia).<sup>129</sup>

### UROSPERMIA

Urine-contaminated semen is often readily detectable because of the typical change in color, odor, and increase in volume. However, when urine is not obvious but suspected to be a contaminant, the presence of urea nitrogen and creatinine in the semen are diagnostic of urospermia. The effect of urine on the sperm cells is not well documented. However, the reduction in motility and perhaps infertility is significant because of the effects of hyperosmotic medium and water removal from the sperm cells. Neurologic or behavioral dysfunctions have been associated with urospermia.<sup>130</sup> The author has observed several cases of urospermia associated with self-mutilating stallions. Pharmacologic therapy of the problem is purely empirical and

limited to drugs that act to close the neck of the bladder such as  $\beta$ -blockers. A more common approach is to use managerial procedures such as collection of the semen directly into extender and immediate centrifugation. The ideal procedure is to fractionate the ejaculate during collection with an open-ended AV. In breeds for which artificial insemination is not allowed, extender may be infused into the uterus and flushed out 4 to 6 hours later.

### HEMOSPERMIA

Lacerations of the penis and urethra can result in the presence of blood cells in the semen. Diagnosis is often obvious because of the pinkish or red color of the ejaculate. The presence of blood is believed to interfere with fertility, but there is no scientific evidence to confirm this clinical impression. However, stallions infected with *P. aeruginosa* may be at a higher risk for hemospermia.<sup>131</sup> Diagnosis is based on identification of the site of bleeding. If the bleeding site cannot be found externally, a common bleeding site is where the urethra folds over the ischium. Urethral bleeding can be diagnosed with a pediatric endoscope. The urethroscopy can be used to visualize the penile and pelvic urethra. If the source of bleeding can be identified in the urethra, a common approach to therapy is to rest the stallion so that cauterization takes place. Alternatively, a urethrostomy of the area is indicated sometimes until the urethra heals by second intention. Some of the management procedures described for urospermia also may be considered.

### BACTERIOSPERMIA AND PYOSPERMIA

Every ejaculate contains a small amount of mixed bacteria, with no signs of inflammation. These bacteria are of little significance and should be interpreted in light of the fertility of the stallion. The presence of large numbers of white blood cells in the ejaculate usually indicates accessory sex gland infection. One should culture quantitative pre-ejaculatory and postejaculatory swabs and semen samples in an attempt to isolate the causative bacteria. If the clinician suspects that the stallion is the cause of bacteria-related fertility problems in a group of mares, it is important to culture the mares in an effort to identify the same bacteria in stallion and mares. Giemsa, Wright's, or Diff-Quik stains of the semen aid in identifying the type of white blood cell present.

### SPERMATOZOAL PROBLEMS

Spermatozoal defects may be in number, motility, and morphology. Reduction in number, also known as *oligospermia*, can have several levels of severity, culminating in azoospermia, or the lack of sperm in the ejaculate. Poor motility is referred to as *asthenospermia*, whereas poor morphology is known as *teratospermia*. If the defects are in number, motility, and morphology simultaneously, the condition is described as *oligoteratoasthenospermia*. Testicular problems such as degeneration or hypoplasia; sperm stasis in the efferent ducts, epididymis, vas deferens, or ampullae; inadequate collection procedures or ejaculation failure; and increased frequency of ejaculation have a dramatic effect on the total number of sperm present in the ejaculate. Accurate assessment of the sperm production of the stallion and a good history are essential for diagnosis and prognosis of the condition.

Abnormal spermatozoal motility and morphology can result during the process of sperm formation and during post-testicular sperm transport, epididymal storage, and collection

and handling. Improper handling procedures also may adversely affect the quality of a semen sample.

Stallion spermatozoa do not always display the same type of forward progressive motility as observed in human or ruminant sperm with a less linearity index. Sperm from some stallions may tend to swim in a wide circular pattern.<sup>131</sup> Backward motility, tight circular movement, or static motion (not bound to the glass slide) is considered abnormal. Midpiece and tail abnormalities—whether induced by cold shock or other mechanical means or as a direct result of spermatogenesis, spermiogenesis, and epididymal transport—are the most common causes of motility abnormalities.<sup>129</sup>

Every ejaculate contains some degree of sperm abnormalities, but in general normal stallions are expected to have at least 60% morphologically normal sperm. Spermatozoal morphology is evaluated by diluting raw semen in buffered formal saline under phase-contrast microscopy or under light microscopy using eosin-nigrosin or eosin-aniline blue stains (see the previous section).

## DISEASES OF THE PREPUCE AND PENIS

### PREPUCE

Preputial inflammation, or posthitis, may be traumatic or infectious. Regardless of the origin, inflammation of the prepuce invariably results in phimosis or paraphimosis, which is the ability to exteriorize or retract the penis, respectively. Inflammation caused by trauma, infection, or parasitic diseases should be differentiated from edema following priapism or penile paralysis. Traumatic injuries to the prepuce most commonly are associated with breeding accidents that can be prevented with proper breeding management practices.

Infectious, parasitic, and neoplastic preputial problems are similar to those affecting the scrotum and were described previously. Infections caused by equine herpesvirus 3 or coital exanthema are a common occurrence, as is colonization of the penis by gram negative bacteria. Congenital problems affecting the prepuce, penis, and scrotum often are linked to developmental abnormalities and are diagnosed easily.

### PENIS

**Penile Tumors** The most common neoplasia affecting the penis is squamous cell carcinoma. Smegma accumulation on the penis may be a predisposing factor for this type of neoplasia.<sup>132</sup> The tumors start as small keratinized plaques that slowly progress into necrotic foci with foul-smelling material caused by secondary bacterial contamination. The papilloma virus was suggested recently as a predisposing factor, a hypothesis that warrants further investigation.<sup>133</sup> Conclusive diagnosis is based on histopathologic examination. The condition is treated with cryosurgery, reeving, or phallectomy.

Penile warts or squamous papillomas, sarcoids, melanomas, fibromas, and lipomas may occur on the penis. Cryotherapy or autogenous vaccines have been used with varying degrees of success to treat these conditions.

**Penile Paralysis and Priapism** Malnourished or exhausted horses, horses with neurologic disease, and those treated with phenothiazinic derivatives such as fluphenazine or acepromazine can sometimes lose tone of the retractor penis muscle that culminates in chronic relaxation of the penis, extensive penile edema, and secondary trauma.<sup>134,135</sup> Because venous return is impaired, the condition progresses to the development of ulcers, secondary bacterial contamination, and necrosis.

Treatment of the condition aims to restore the venous blood flow. Hydrotherapy; mechanical support of the penis; and application of topical emollients, anti-inflammatory drugs, and diuretics are recommended. In some instances flushing of the corpus cavernosum penis with heparinized saline or intracavernous injection of phenylephrine may aid in blood drainage and penile retraction. Traumatic accidents involving the penis are not uncommon. Cuts with mare tail hair, poorly constructed breeding phantoms with fixed AVs, and severe bending of the erect penis may result in laceration or abrasion varying from simple skin cuts to severe hematomas. These wounds are treated with supportive therapy or surgical intervention. Prevention of secondary contamination and adhesion formation is important.

Other mechanical problems observed in the penis and prepuce of stallions include fibrosis, strictures, or lacerations caused by the misuse of penile rings or brushes to dissuade the stallion from masturbation. The use of such instruments is inhumane and should be discouraged.

# DISORDERS OF THE URINARY SYSTEM

## CHAPTER 19

*Bryan Waldrige*

### ANATOMY AND DEVELOPMENT

*Harold C. Schott II*

#### ANATOMY

The urinary system of the horse, like that of most mammals, consists of paired kidneys and ureters, the bladder, and the urethra. With the exception of the abdominal portion of the urinary bladder, the entire urinary tract is located in the retroperitoneal space. In a newborn foal, each kidney weighs about 175 g. In an adult horse the left kidney weighs between 600 to 700 g, and the right kidney is usually 25 to 50 g heavier, although this is not a consistent finding, and one may observe the reverse relation.<sup>1,2</sup> Thus the kidneys account for approximately 0.65% to 0.75% and 0.27% to 0.37% of the total body mass of the foal and adult horse, respectively.<sup>1,3</sup> The right kidney is located immediately below the dorsal extent of the last two or three ribs and the first lumbar transverse process, is shaped like a horseshoe, and measures about 15 cm long, 15 cm wide, and 5 to 6 cm high (dorsal to ventral). Craniolaterally, the right kidney is embedded into the liver, and its more cranial position compared with the left kidney prevents it from being accessible on rectal palpation. Although not the classically bean-shaped organ found in human beings and small animals, the left kidney in the adult horse is more elongated than the right kidney, with the cranial pole at the level of the hilus of the right kidney; in equids, the left kidney is about 18 cm long, 10 to 12 cm wide, and 5 to 6 cm high. Because of its more caudal location, one routinely can palpate the caudoventral aspect of the left kidney during rectal examination. The blood supply to the kidneys comes from one or more renal arteries branching from the aorta. Accessory renal arteries (which generally enter caudally) may arise from the caudal mesenteric, testicular or ovarian, or deep circumflex iliac arteries.<sup>1,2</sup>

The ureters are 6 to 8 mm in diameter and travel about 70 cm to their insertions in the dorsal bladder neck or trigone, close to the urethra. The distal 5 to 7 cm of each ureter courses within the bladder wall. This intramural segment of the ureter functions as a one-way valve to prevent vesicoureteral reflux (VUR) with progressive bladder distention. The urinary bladder lies on the pelvic floor when empty but can increase in size and drop forward over the pelvic brim when filled with urine.

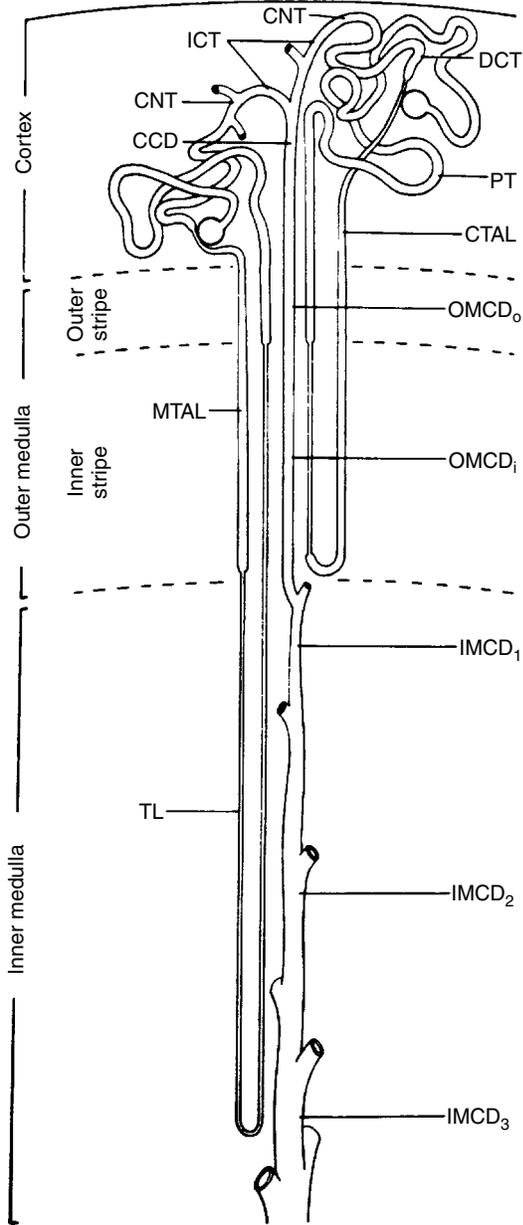

The bladder can accommodate up to 3 to 4 L of urine before stimulation of micturition. In the foal the bladder is attached to the ventral abdominal wall by the urachus and remnants of the umbilical arteries. Consequently, when empty, the bladder is commonly a band-shaped structure in a neonatal foal. During the first few months of life, this ventral attachment loosens as the urachal remnant becomes the middle ligament and the umbilical arterial remnants become the round ligaments of the free border of the paired lateral ligaments of the bladder.<sup>1</sup>

The urethra is about 2 to 3 cm long in a mare and 75 to 90 cm long in a male. In the intact male the pelvic urethra, which is 10 to 12 cm long, widens in an elliptic pattern to a diameter of 5 cm across and 2 to 3 cm from dorsal to ventral. A rounded dorsal prominence, the colliculus seminalis, is located immediately caudal to the urethral orifice and is the site of the common openings of the ductus deferens and ducts of the seminal vesicles. The openings of the prostatic ducts are on two groups of small papillae lateral to the colliculus seminalis. Between 2 and 3 cm farther caudad, the ducts of the bulbourethral glands open in paired dorsal lines. The smaller openings of the ducts of the lateral urethral glands open at the same level on the lateral aspect of the urethra.<sup>1</sup>

A fibrous capsule that peels easily from the normal kidney covers the surface of each kidney. The equine kidney consists of an outer cortex slightly wider than the inner medulla. The cortex is dotted with dark spots—renal corpuscles or glomeruli within Bowman's capsules. In horses, the corticomedullary junction is less distinct than in other species and is typically a deep red that contrasts well against the paler medulla and red-brown cortex. This region undulates along renal pyramids (cortex) and renal columns (medulla). The pyramids are subdivisions of the renal parenchyma, which are separated by arcuate arteries at the level of the corticomedullary junction. The equine kidney contains a total of 40 to 60 pyramids arranged in four parallel rows. The renal pelvis is the dilated proximal portion of the ureter. Microscopic examination reveals numerous small openings of the collecting ducts (ducts of Bellini). Additionally, the renal pelvis and proximal ureter are lined with compound tubular mucous glands and goblet cells that secrete thick, viscid mucus usually found in the renal pelvis and urine of normal horses.<sup>1,4</sup>

The functional unit of the kidney is the nephron. Each nephron is composed of a renal corpuscle (glomerulus within

Bowman's capsule), a proximal tubule (convoluted and straight components), an intermediate tubule (loop of Henle), a distal convoluted tubule, a connecting tubule, and cortical, outer medullary, and inner medullary collecting ducts (Figure 19-1). The two populations of nephrons are (1) the superficial (or cortical) nephrons possessing short loops of Henle and

**FIGURE 19-1** Diagram of a superficial and juxtamedullary nephron. *TL*, Thin limb of the loop of Henle; *MTAL*, medullary thick ascending limb (mTAL) of the loop of Henle; *CCD*, cortical collecting duct; *CNT*, connecting segment; *ICT*, initial collecting tubule; *DCT*, distal convoluted tubule; *PT*, proximal tubule; *CTAL*, cortical thick ascending limb of the loop of Henle; *OMCD<sub>0</sub>*, collecting duct in outer stripe of outer medulla; *OMCD<sub>1</sub>*, collecting duct in inner stripe of outer medulla; *IMCD<sub>1</sub>*, outer third of inner medullary collecting duct; *IMCD<sub>2</sub>*, middle third of inner medullary collecting duct; *IMCD<sub>3</sub>*, inner third of inner medullary collecting duct. (From Brenner BM, Rector FC, editors: *The kidney*, ed 8, Philadelphia, 2008, WB Saunders.)

(2) the juxtamedullary nephrons with long loops of Henle. Gradations exist between these two general categories of nephrons, as well as species variation in the ratio of short-looped nephrons to long ones. For example, human beings have seven times more short- than long-looped nephrons, whereas essentially 100% of nephrons in dogs and cats have long loops.<sup>5</sup> An early anatomic study found approximately 4 million glomeruli (nephrons) in the adult bovine kidney<sup>6</sup>; however, a recent study of kidney organogenesis using unbiased stereologic techniques to examine 45 equine left kidneys indicated that the left kidney of the horse may contain closer to 10 million glomeruli (for a total of 20 million in both kidneys).<sup>7</sup> The latter study also confirmed that the total number of glomeruli does not increase after birth despite continued growth of the kidney until about 1 year of age. At present, little information is available on the ratio of short- to long-looped nephrons in horses. Histologically, equine nephrons are similar to those of other mammalian species; however, the diameter and epithelial height of the tubule and collecting duct segments are comparatively larger. In addition, the equine macula densa (segment of the ascending loop of Henle that lies in close association with the juxtaglomerular apparatus of the afferent arteriole) appears more prominent than that of other mammals.<sup>8</sup> Whether or not these subtle histologic differences are accompanied by functional differences has not been investigated.

Relative to its size, the mammalian kidney has a richer innervation than almost any other organ.<sup>9</sup> Although the neuroanatomy of the equine kidney has not been well studied, autonomic nerves course from the aorticorenal and renal ganglia along the major renal vessels into the kidneys.<sup>1</sup> These nerves are predominantly sympathetic, because the kidneys appear to be poorly supplied by cholinergic nerves. Although the best-recognized effect of renal nerves is control of renal vascular resistance (for regulation of renal blood flow [RBF] over a wide range of perfusion pressures), the nerves also act directly on renal tubules and juxtaglomerular cells. For example, low-frequency stimulation of renal nerves (below the threshold for vasoconstriction) increases proximal tubular sodium reabsorption and renin release by activation of  $\alpha_1$ -adrenoceptors.<sup>10</sup> In addition to  $\alpha$ - and  $\beta$ -adrenoceptors, renal vasculature is rich in dopaminergic adrenoceptors, and activation of the latter, specifically dopamine type 1 receptors, leads to increased perfusion of the outer renal medulla. Presence of these receptors is the basis for use of dopamine, and more recently the DA-1 receptor agonist fenoldopam, in an attempt to improve RBF in acute renal failure (ARF) or to decrease the risk of radiocontrast nephropathy.<sup>11-13</sup> The administration of drugs also can activate renal adrenoceptors unintentionally. A common clinical example is the diuresis induced by administration of the  $\alpha_2$ -agonists xylazine and detomidine. Although the diuresis has been attributed to a transient hyperglycemia and glucosuria, the latter is often absent.<sup>14,15</sup> An alternative explanation may be drug binding to  $\alpha_2$ -adrenoceptors located on collecting duct epithelium. Activation of these receptors can lead to antagonism of the effects of antidiuretic hormone on cortical collecting ducts, which results in diuresis.<sup>16</sup> More recently, renal afferent nerves have been identified, and these nerves appear to play a role in the pathogenesis of hypertension in species affected by this disorder.<sup>9</sup>

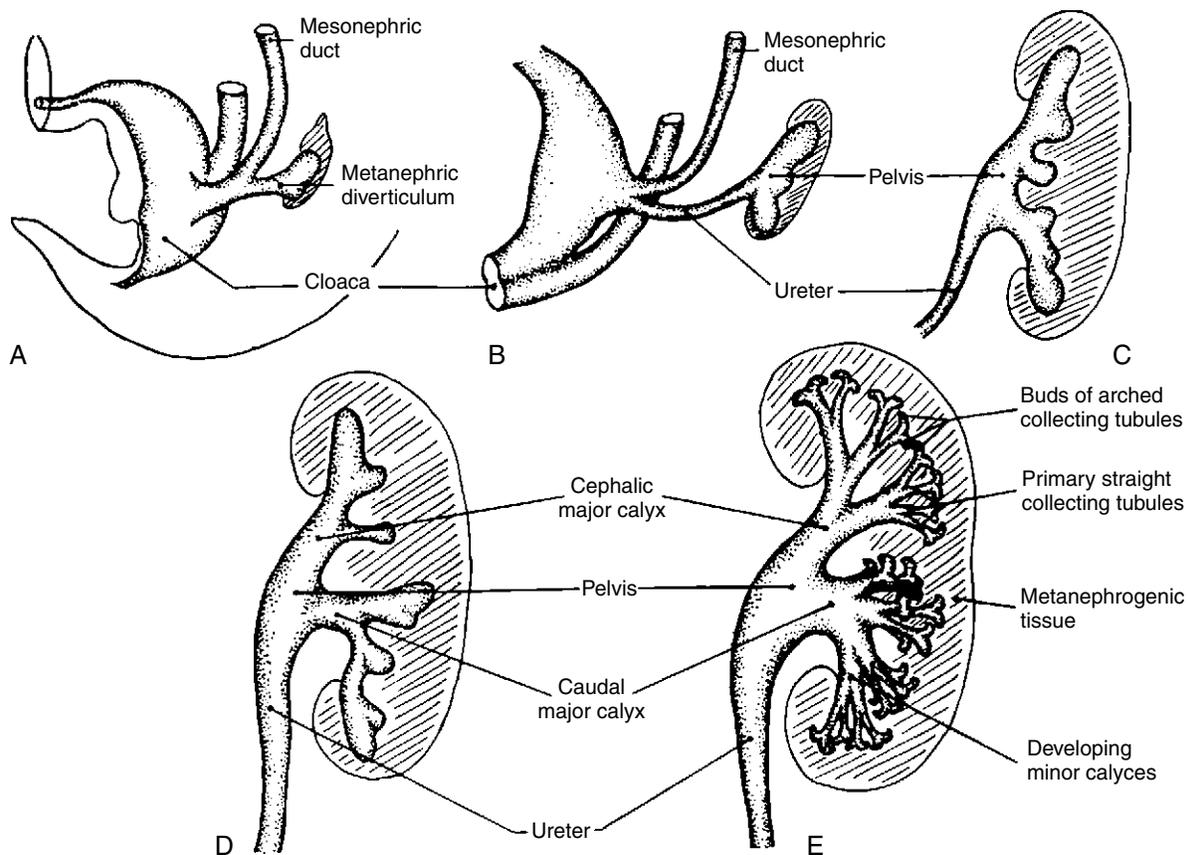

Autonomic innervation of the ureters, bladder, and urethra is important to ureteral peristalsis and micturition. The equine ureteral smooth muscle contains  $\alpha_1$ - and  $\beta_2$ -adrenoceptors,

which induce contraction and relaxation, respectively, when activated by norepinephrine.<sup>17</sup> Recent studies of the innervation of the equine ureter demonstrated greater densities of adrenergic neurons in the proximal (renal pelvis) and intravesicular (bladder wall) portions of the ureter.<sup>18</sup> Increased densities in these regions are consistent with the suspected pacemaker activity of the renal pelvis, which initiates ureteral peristalsis and the sphincterlike function of the distal segment of the ureter. The sympathetic nerve supply to the urinary bladder is provided via the hypogastric nerve, with preganglionic fibers arriving from spinal segments L1 to L4 to synapse in the caudal mesenteric ganglion. Postganglionic fibers supply the bladder ( $\beta_2$ -adrenergic receptors) and proximal urethra (primarily  $\alpha_1$ - and some  $\alpha_2$ -adrenergic receptors).<sup>19,20</sup> In addition to adrenergic innervation, cholinergic and peptidergic nerve fibers also innervate the equine bladder.<sup>21</sup> Parasympathetic innervation originates in the sacral segments of the spinal cord, with neurons joining to form the pelvic nerve.<sup>19,20</sup> Many complex interneuronal connections exist between sympathetic and parasympathetic nerves in the wall of the bladder, along with small adrenergic cells that facilitate interaction between sympathetic and parasympathetic pathways.<sup>22</sup> As a result, complete denervation of the bladder is virtually impossible. Somatic innervation of the lower urinary

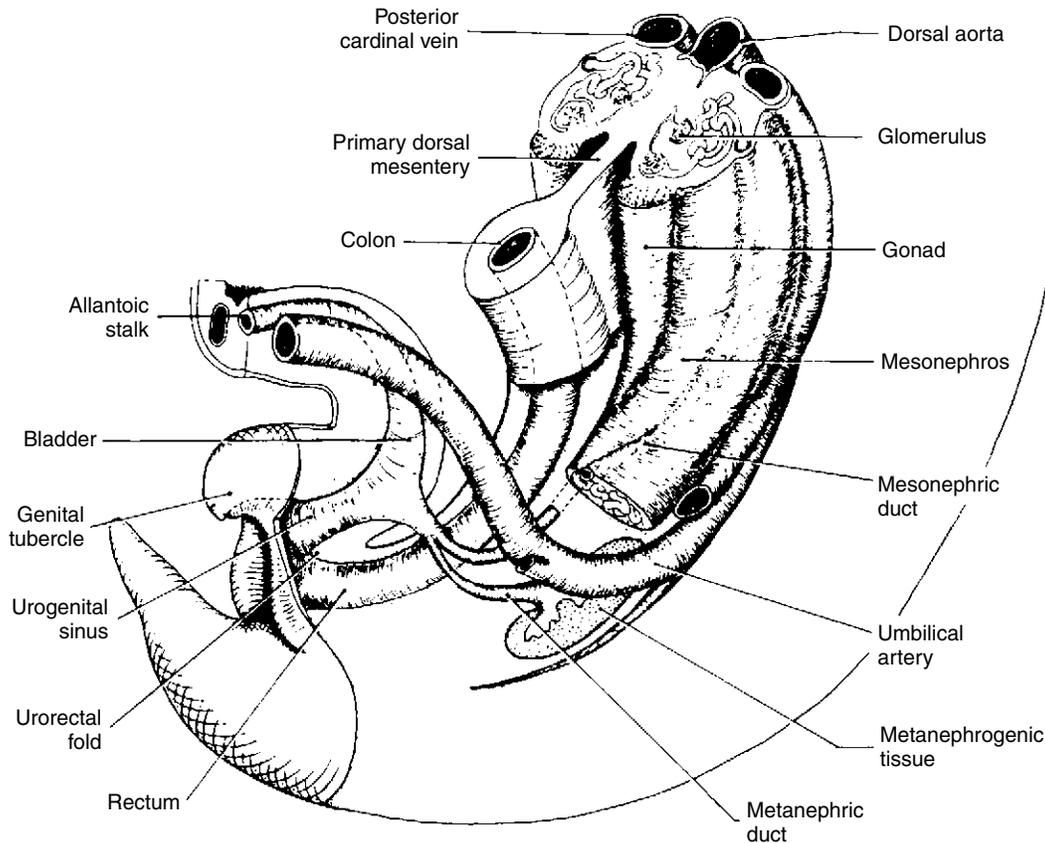

tract is primarily to the striated muscle of the external urethral sphincter via a branch of the pudendal nerve, which originates from the sacral cord segments (S1 to S2).<sup>1</sup>

## DEVELOPMENT

The embryonic upper urinary tract arises from bilateral primordial mesonephric ducts and intermediate mesoderm. The metanephric diverticulum originates from the caudal end of each mesonephric duct and develops cranial to become the ureter and renal pelvis. The advancing metanephric diverticuli collect about their ends intermediate mesoderm (metanephrogenic tissue), which becomes the collecting system and parenchyma of the mature kidney (Figure 19-2). The vascular supply is derived from a branch of the aorta (renal artery) that invades the metanephrogenic tissue. The urinary bladder develops as a dilated proximal portion of the allantois. The bladder is separated from the hindgut by the craniocaudal growth of the urogenital fold, which divides the rectum from the urogenital sinus. The latter structure gives rise to the urethra (Figure 19-3). The mesonephric and metanephric ducts initially open into the urogenital sinus, but as development continues, the distal segments of the mesonephric ducts are absorbed into the bladder wall and the openings of the

**FIGURE 19-2** Progression of the differentiation and development of the metanephric diverticulum into the collecting system of the mature kidney. **A**, Metanephric diverticulum originates from the caudal end of the mesonephric duct. **B**, Metanephric diverticulum develops cranial, and intermediate mesoderm (metanephrogenic tissue, hatched lines) collects about its cranial end. **C** to **E**, The metanephric diverticulum becomes the ureter and renal pelvis, and the metanephrogenic tissue becomes the collecting system and parenchyma of the mature kidney. (From Carlson BM: Patten's foundations of embryology, ed 6, New York, 2003, McGraw-Hill.)

**FIGURE 19-3** Developing urogenital tract of the young mammalian embryo. (From Carlson BM: Patten's foundations of embryology, ed 6, New York, 2003, McGraw-Hill.)

metanephric ducts are pulled craniad to their final site in the dorsal bladder neck.<sup>23</sup>

The fate of the mesonephric tubules (mesonephros) and mesonephric ducts varies with gender. Paired paramesonephric ducts (müllerian ducts) arise parallel to the mesonephric ducts in both sexes. In the female, the ducts fuse distally to become the vagina and uterine body, whereas proximally they remain separate to give rise to uterine horns and oviducts. The mesonephric ducts regress into vestigial remnants termed the *epoöphoron* proximally (near the ovaries) and *Gartner's canals* distally (near the vagina and uterus; Figure 19-4). In the male, sexual differentiation of the gonads and production of androgenic steroid hormones lead to regression of the müllerian ducts. The duct system of the male reproductive tract is appropriated from the mesonephros and mesonephric ducts (also termed *wolffian ducts*). Androgenic steroid hormones also stimulate these structures to develop into the seminiferous tubules, epididymis, and ductus deferens. The distal portion of the mesonephric duct becomes the ejaculatory duct, the terminal portion of the ductus deferens.<sup>23</sup>

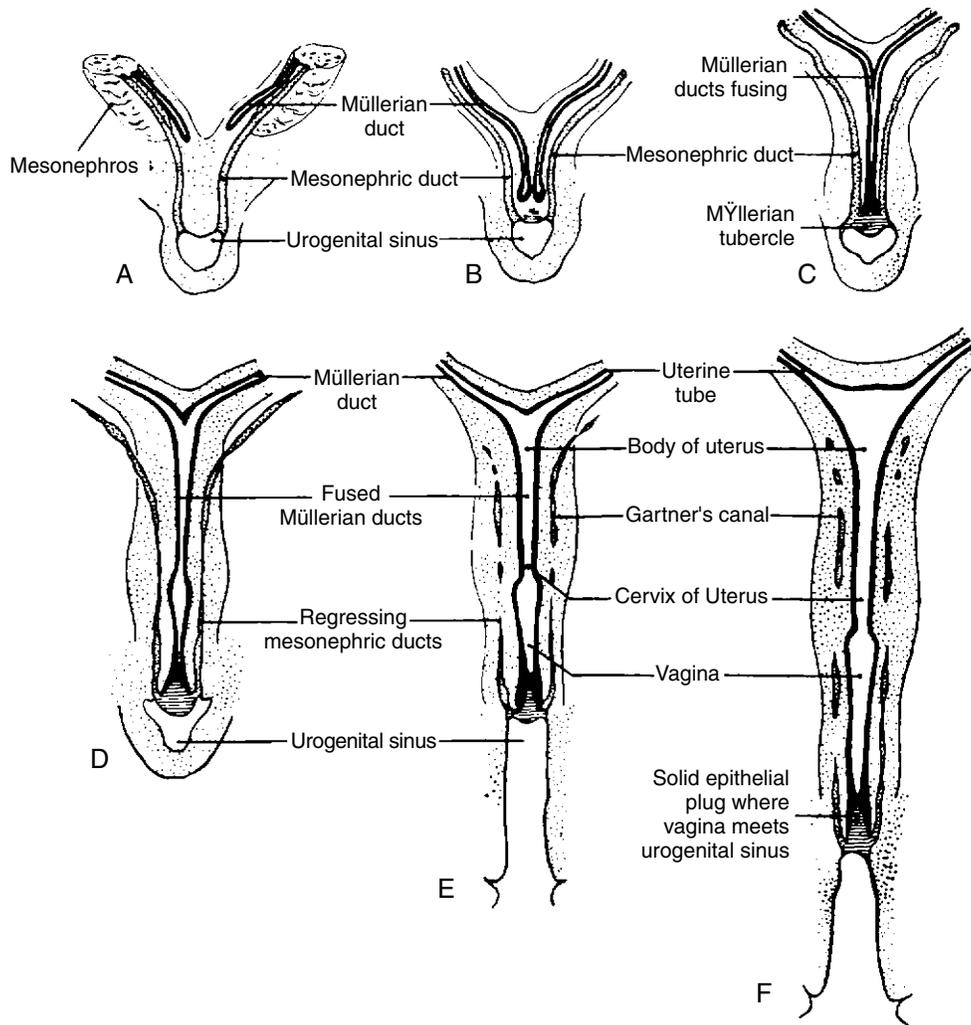

## ☞ DEVELOPMENTAL MALFORMATIONS OF THE URINARY TRACT

Anomalies of the urinary tract are uncommon in horses. A survey by Höflinger<sup>24</sup> revealed a similar frequency of unilateral renal agenesis (0.07%) in horses and human beings (0.10%).<sup>5</sup> In contrast, horseshoe kidneys (attached at the cranial or

caudal poles) are the most common anomaly in human beings (0.25%) but rarely have been described in horses.<sup>5,25</sup>

## RENAL AGENESIS, HYPOPLASIA, AND DYSPLASIA

Renal agenesis, which may be unilateral or bilateral, results from failure of the metanephric duct to fuse with the metanephrogenic mesodermal tissue. Although unilateral anomalies have been described more frequently, this simply may reflect the incompatibility of bilateral agenesis with postnatal life.<sup>24,26-28</sup> Brown et al.<sup>28</sup> described a foal with bilateral renal agenesis in which severe azotemia was detected shortly after birth. Bilateral ureteral dysgenesis and cryptorchidism, agenesis of the right adrenal gland, and atresia ani accompanied the renal agenesis in this foal. Unilateral defects may be incidental findings in otherwise healthy horses<sup>29</sup> or may be detectable during examination of the reproductive tract, because many horses have associated anomalies of that system. Occasionally, unilateral agenesis may result in clinical renal disease if a problem arises in the contralateral kidney. Johnson et al.<sup>27</sup> described a 4-year-old Quarter Horse with unilateral renal agenesis and a ureterolith causing contralateral hydronephrosis. The gelding was presented for weight loss, pollakiuria, and stranguria. In addition to the renal anomaly, unilateral agenesis of the ipsilateral testicle also was found on necropsy. Renal agenesis may be a familial disorder in several species.<sup>25,30</sup> Although no information is

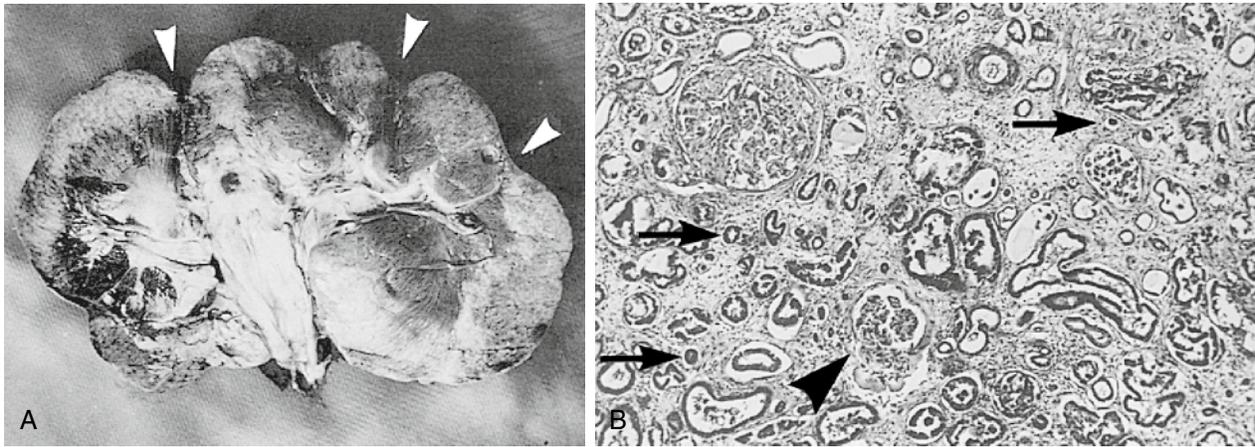

**FIGURE 19-4** Development of the mesonephric tubules (mesonephros) and mesonephric ducts into the female reproductive tract. **A and B**, Paired paramesonephric ducts (müllerian ducts) arise parallel to the mesonephric ducts in both sexes. **C to E**, In females, the paramesonephric ducts fuse distally to become the vagina and uterine body but remain separate proximally to give rise to uterine horns. **D and E**, The mesonephric ducts regress into vestigial remnants termed *Gartner's canals*. (From Carlson BM: *Patten's foundations of embryology*, ed 6, New York, 2003, McGraw-Hill.)

available to suggest a hereditary basis in horses, one probably should discourage repeat matings after detecting such an anomaly.

One diagnoses renal hypoplasia when one kidney is at least 50% smaller than normal or when the total renal mass is decreased by more than one third.<sup>25</sup> Renal hypoplasia is a quantitative defect caused by a reduced mass of metanephrogenic tissue or by incomplete induction of nephron formation by the metanephric duct. The condition may be confused with renal dysplasia. Unilateral renal hypoplasia usually is associated with contralateral hypertrophy and normal renal function, whereas bilateral hypoplasia generally leads to chronic renal failure (CRF).<sup>25,30</sup> Andrews et al.<sup>31</sup> described bilateral renal hypoplasia in a foal presented after death and in three young horses with CRF that had poor growth from birth. Anomalies in these four horses were limited to the upper urinary tract.

Renal dysplasia is disorganized development of renal tissue caused by anomalous differentiation, intrauterine ureteral

obstruction, fetal viral infection, or teratogens.<sup>25,32</sup> Bilateral dysplasia usually leads to renal failure. In general, dysplastic kidneys are normal in size unless concurrent hypoplasia exists or the animal lives for months to years before developing renal failure. Roberts and Kelly<sup>33</sup> reported a case of bilateral renal dysplasia in a 19-month-old pony gelding. The pony was presented for weight loss over a 3-month period, and clinicopathologic assessment revealed CRF. A small, firm, and nodular left kidney was palpable per rectum. At necropsy, the kidneys weighed 280 g each (33% smaller than normal for body weight) and were nodular. Renal dysplasia was suspected because glomeruli in the collapsed areas of the kidneys were small, tubules were immature, and inflammatory cells were scant. Six similar cases of bilateral renal dysplasia resulted in CRF in horses from 2 months to 7 years of age.<sup>34-38</sup> Small kidneys with increased echogenicity and an indistinct corticomedullary junction were typical ultrasonographic findings,<sup>36-38</sup> and these findings were corroborated by computed tomography in one Miniature Horse foal.<sup>38</sup> At necropsy, kidneys were typically small and

**FIGURE 19-5** **A**, Longitudinal section of the right kidney from a 7-year-old Arabian gelding with renal dysplasia shows focal, irregular thinning of the cortex (*arrowheads*) resulting in a nodular surface and poor delineation of the corticomedullary junction. **B**, Histologic section of same kidney (Masson trichrome stain; original magnification  $\times 35$ ) reveals an immature glomerulus (*large arrowhead*) and primitive tubules (*arrows*) surrounded by persistent mesenchyme. (From Ronen N, van Amstel SR, Nesbit JW et al: Renal dysplasia in two adult horses: clinical and pathological aspects, *Vet Rec* 132:269, 1993.)

irregular, the cortex and medulla were not well-delineated, and immature glomeruli and primitive tubules were found on histologic examination (Figure 19-5). Renal dysplasia also may cause renal failure in neonates. For example, Zicker et al.<sup>39</sup> reported a case of renal dysplasia in a 2-day-old Quarter Horse foal presented for diarrhea and depression. Clinicopathologic assessment revealed azotemia, hyponatremia, hypochloremia, and urinary sodium wastage. At necropsy, the kidneys were normal in size (380 g), but histologic examination revealed immature glomeruli, hypoplastic tubules and vasa recta, and extensive myxomatous connective tissue occupying 90% of the total medullary volume. Finally, renal dysplasia also may be a unilateral problem that does not result in renal failure. Jones et al.<sup>40</sup> found ureteropelvic polyps to be the cause of unilateral hydronephrosis and renal dysplasia in a Trakehner colt. Poor growth and hematuria for several weeks were the presenting complaints. Renal function remained normal for 8 months after nephrectomy until the colt developed a severe bout of colic, prompting euthanasia. Ureteral obstruction by the polyps was the suggested cause of renal dysplasia, because urinary tract obstruction has been found in a large percentage of cases of human renal dysplasia.<sup>32</sup>

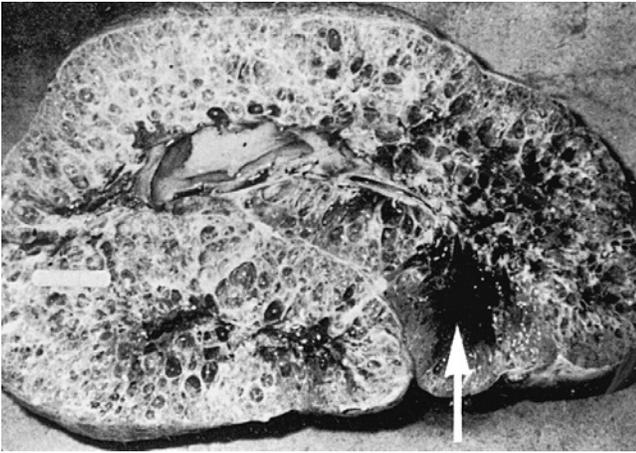

## RENAL CYSTS

One or more renal cysts occasionally are discovered as incidental findings on necropsy examination. The cysts may arise from any portion of the nephron but more often occur in the cortex than in the medulla. The pathogenesis is not known, but a defect in the basement membrane that allows tubular dilation is suspected. Renal cysts vary in size from microscopic to as large as the organ itself and routinely have a clear to slightly opaque wall and contain a thin, clear fluid. Congenital cysts are differentiated easily from acquired cysts (after obstruction) by the extensive scarring that accompanies the latter. Renal cysts also may develop as a consequence of drug therapy (i.e., long-acting corticosteroids) or exposure to certain chemicals.<sup>25,30</sup>

## POLYCYSTIC KIDNEY DISEASE, GLOMERULOCYSTIC DISEASE, AND OTHER HEREDITARY NEPHROPATHIES

Polycystic kidney disease (PKD) is a disorder in which numerous, variably sized cysts are found throughout the cortex and medulla. With glomerulocystic disease, cysts are microscopic and limited to Bowman's spaces. Cysts of the bile duct and pancreas also may occur with PKD, and both conditions have been described in stillbirths in many species, including foals.<sup>25</sup> The two major types of human PKD are (1) a rare congenital or infantile form inherited as an autosomal recessive trait (which may be found in stillbirths) and (2) a more common adult form inherited as an autosomal dominant trait that leads to renal insufficiency in later life in association with dramatically enlarged, cystic kidneys.<sup>41,42</sup> The latter form of PKD develops because of mutations in genes encoding for polycystins, integral membrane proteins responsible for cell-to-cell interaction.<sup>43</sup> Autosomal dominant PKD also has been documented in Persian cats and related breeds and in bull terriers.<sup>44-46</sup> The genetic defect in Persian cats is thought to be similar to the most common defect in human beings (PKD1 gene) and leads to end-stage renal disease by 3 to 10 years of age.<sup>45</sup> As in human beings, the disorder is detectable by renal ultrasonographic screening of juvenile cats and preventable by avoiding subsequent mating of affected animals. Nevertheless, because of heavy inbreeding the prevalence of PKD in Persian cats and related breeds is between 40% and 50%.<sup>44,45</sup>

Ramsey et al.<sup>47</sup> described polycystic kidneys in a 9-year-old Thoroughbred mare that exhibited anorexia and weight loss. Clinicopathologic assessment revealed CRF, and euthanasia was performed. At necropsy, the kidneys were grossly enlarged and each weighed 12 kg (Figure 19-6). A similar case of bilateral PKD was described in a 15-year-old pony with a 4-week history of hematuria and moderate weight loss. Evaluation revealed azotemia and presence of large masses in the

**FIGURE 19-6** Longitudinal section of the left kidney (35 cm long, 25 cm wide, 20 cm deep, and weighing 12 kg) from a 9-year-old Thoroughbred mare with polycystic kidneys. A calculus is located in the renal pelvis, and the arrow demonstrates the only grossly normal-looking renal parenchyma. (From Ramsey G, Rothwell TLW, Gibson KT et al: Polycystic kidneys in an adult horse, *Equine Vet J* 19:243, 1987.)

area of both kidneys on rectal examination, and dramatically enlarged polycystic kidneys weighing 11.4 and 9.1 kg, respectively, were found at necropsy.<sup>48</sup> Bertone et al.<sup>49</sup> reported a third case of adult PKD in a 10-year-old Paint gelding with weight loss. The horse was mildly azotemic, and several 2- to 15-cm diameter cysts were imaged in both kidneys during ultrasonographic examination. In human beings, polycystic kidneys are believed to result in renal failure as cysts expand (sometimes under pressure) and compress adjacent normal renal tissue. Altered compliance of tubular basement membranes and proliferation of renal tubular epithelium result in outflow obstruction and proximal ballooning, leading to renal cyst formation.<sup>42</sup> In some human cases, pressure within cysts may be 5 to 10 times higher than surrounding interstitial tissue pressures. Bertone et al.<sup>49</sup> found no increase in pressure in several cysts catheterized percutaneously in a gelding with PKD, but differences in sodium concentrations suggested that the sampled cysts had arisen from different segments of the renal tubule. Euthanasia was performed after a prolonged hospital course (235 days), and the kidneys were not grossly enlarged except where distorted by large cysts. Although not well documented, PKD has been described anecdotally in two additional Paint horses, suggesting that an inherited form of PKD may occur in that breed. A recent report also documented PKD in an 11-year-old Andalusian gelding.<sup>50</sup>

In addition to PKD, a variety of other hereditary nephropathies have been described in human beings.<sup>48</sup> Similar disorders are starting to be recognized in domestic animals, including hereditary nephritis in bull terriers, Samoyeds, and English cocker spaniels. Analogous to Alport's syndrome in human beings, a defective molecular structure of type IV collagen, an important component of the glomerular basement membrane (GBM), appears to be the cause of hereditary nephritis in these dog breeds.<sup>46</sup> Similarly, a syndrome of renal tubular dysplasia with autosomal recessive pattern of inheritance recently has been described in a population of highly inbred Japanese black cattle,<sup>51-53</sup> as has a syndrome of suspected hereditary renal

oxalosis in Beefmaster calves.<sup>54</sup> Similar hereditary nephropathies are likely to occur in horses; however, to date the only one documented is a syndrome of nephrogenic diabetes insipidus in Thoroughbreds.<sup>55</sup>

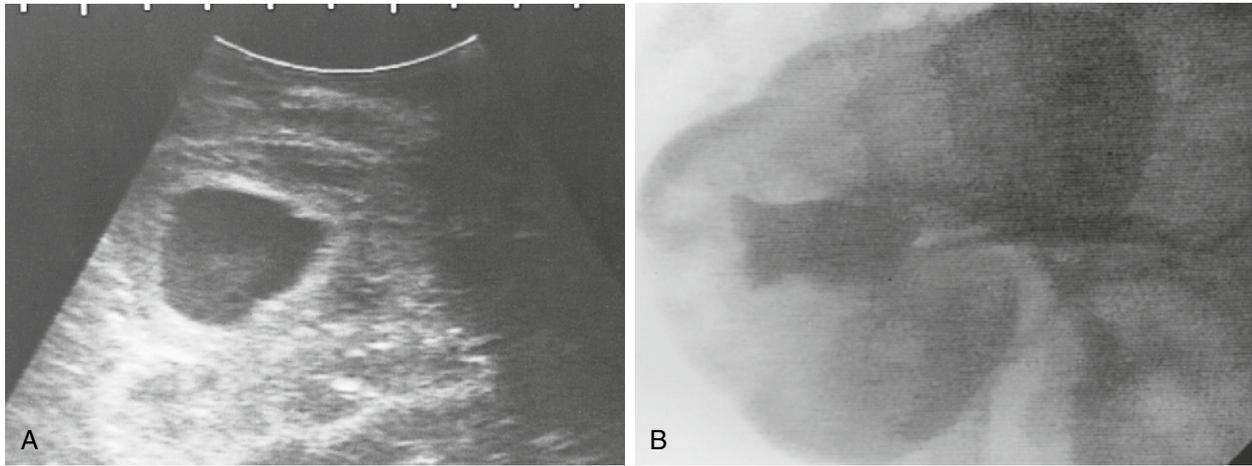

## VASCULAR ANOMALIES

Anomalies of the vascular supply to the equine urinary tract are rare but may result in hematuria, hemoglobinuria, partial ureteral obstruction, or hydronephrosis.<sup>30,56</sup> Latimer, Magnus, and Duncan<sup>57</sup> described a distal aortic aneurysm and associated extrarenal arterioureteral fistula in a 5-month-old colt presented for intermittent hematuria, colic, and lameness. Partial ureteral obstruction and hydronephrosis were observed on the affected side. Intrarenal vascular anomalies, termed *renal arteriovenous malformations*, are similarly rare (reported frequency of 0.04% in human beings).<sup>58</sup> Interestingly, these vascular malformations may be silent until later in life, when varying degrees of hematuria and flank pain may ensue. The anomalous vessels are often tortuous and may be enlarged focally and devoid of elastic tissue. Hematuria and hemoglobinuria are thought to arise from areas where the anomalous vessels lie close to the collecting system.<sup>58,59</sup> With vascular anomalies, one should attempt to determine the extent of the defect (unilateral or bilateral) via ultrasonographic examination, contrast radiographic studies, or cystoscopy (visualization that hematuria is coming from only one ureteral orifice). When a unilateral defect is documented in the absence of azotemia, unilateral nephrectomy or selective renal embolization has been recommended to prevent possible fatal exsanguination through the urinary tract<sup>56,57</sup>; however, one may consider conservative treatment if the urinary tract bleeding is minor and has not resulted in anemia.

A large vascular anomaly resulting in transient hemoglobinuria has been reported in a Quarter Horse colt.<sup>60</sup> Over several weeks the large anomalous vascular structure (Figure 19-7) spontaneously filled with a thrombus so that specific treatment (a nephrectomy) was not pursued. Severe adult-onset, idiopathic renal hemorrhage also has been described in horses.<sup>61</sup> Whether this latter syndrome may have been a consequence of congenital renal vascular malformations has not been determined (see Hematuria section later in this chapter). Occasionally gross hematuria with passage of blood clots can accompany omphalitis or bladder rupture.<sup>62</sup> One usually can detect these problems during ultrasonographic examination of the umbilical structures and sometimes can image tissue echogenicity within the bladder that is attributable to a blood clot.

## PENDULANT KIDNEY

A pendant kidney is a rare anomaly in the horse.<sup>63</sup> Rectal examination reveals an extremely mobile kidney attached to the dorsal body wall by a thin band of tissue. Although a pendulous kidney could result from extreme weight loss, hydronephrosis, or perirenal trauma, the condition usually is thought to be congenital. The abnormality is an incidental finding unless displacement or rotation leads to partial or complete ureteral obstruction. As an example, the author has palpated the entire right kidney of one mare immediately cranial of the pelvic canal, and ultrasonographic imaging revealed normal size and structure of the anomalously located kidney.

**FIGURE 19-7** Ultrasonographic image of the right kidney of a 9-day-old Quarter Horse colt shows a 2×3-cm hypoechoic cavity on a dorsal oblique view. **A**, A swirling pattern, similar in appearance to blood in the ventricles of the heart, was consistent with an arteriovenous malformation. **B**, In a selective nephrogram of the right kidney of the same colt at 20 days of age, immediately after injection of contrast, a dilated vascular space was demonstrated (contrast appears dark because of reverse gray scale) and the renal cortical tissue abaxial to this structure appeared to have reduced capillary phase contrast. (From Schott HC, Barbee DD, Hines MT et al: Renal arteriovenous malformation in a Quarter horse foal, *J Vet Intern Med* 10:204, 1996.)

## ECTOPIC URETER

Although ureteral ectopia occurs rarely in the horse,<sup>64</sup> the condition is the most commonly reported developmental anomaly of the equine urinary tract.<sup>64-82</sup> Ectopic ureters may develop when (1) the ureteric bud (metanephric duct) fails to be incorporated into the urogenital sinus or fails to migrate cranially to the bladder neck or (2) the mesonephric duct fails to regress. In the former case, the ectopic ureter opens near the urethral papilla in females or into the pelvic urethra near the colliculus seminalis in males, whereas in the latter, the ureter may open anywhere along the vagina, cervix, or uterus (but only in females because this portion of the mesonephric duct becomes the wolffian duct system in males). In 118 reported cases of ectopic ureter in horses, 105 (89%) were females<sup>65-68,72-77,79-82</sup>; however, this sex distribution may reflect easier recognition in females of the presenting complaint of urinary incontinence rather than a true sex predilection. Incontinence is recognized more often in females because urine entering the pelvic urethra in males may pass retrograde into the bladder. Although a genetic predisposition for ectopic ureter exists for several dog breeds,<sup>83</sup> no breed predilection has been established in horses. However, Quarter Horses may be at greater risk because the condition has been reported in five Quarter Horses, three Standardbreds, two Thoroughbreds, two Appaloosas, an Arabian, a Clydesdale, a Shire, a Fresian, a Foxtrotter, and a Warmblood. The author also has seen the condition in two Quarter Horse fillies (one unilateral and one bilateral), yielding a total of 20 cases.

In horses with ureteral ectopia, urinary incontinence is generally apparent from birth, and affected animals are presented for extensive scalding of the hindlimbs. With unilateral ectopia, horses also void normally, because the other ureter enters the bladder in the appropriate location. Renal function is usually normal, but the affected ureter may be greatly dilated. Urine pooling in the vagina and uterus was a complicating

factor in one case.<sup>73</sup> To determine the site of the ectopic ureteral orifice (or orifices), one initially visually examines the vestibule and vagina (using a blade speculum) to look for intermittent urine flow from the area of the urethral papilla. Ectopic ureteral openings usually are not apparent unless urine flow is visible. Endoscopy may be helpful in females (while inflating the vestibule and vagina with air and using a hand to form a seal at the vulva) and is required in males to visualize the ectopic ureteral opening. Intravesical placement of methylene blue dye was performed in one filly to provide evidence for ureteral ectopia. Continued dribbling of clear urine (from the ectopic ureter) followed by passage of blue, discolored urine indicated that only one ureter emptied into the bladder but provided no information on the location of the opening of the ectopic ureter.<sup>66</sup> Intravenous administration of dyes—including sodium fluorescein (10 mg/kg IV; yellow-green), indigotindisulfonate (indigo carmine, 0.25 mg/kg IV; blue-purple), azosulfamide (2.0 mg/kg IV; red), or phenolsulfonphthalein (1.0 mg/kg IV; red)—to discolor the urine may help locate ectopic ureteral openings.<sup>84</sup> Contrast radiography (excretory urography or retrograde contrast studies via catheterization of the bladder and ureters) has been used to detail renal architecture and the course of the ureters in some affected animals; however, results of intravenous urograms are frequently inconclusive in foals weighing more than 50 kg (contrast agent is poorly imaged). In a recent report, ultrasound-guided pyelography, in which contrast agent was injected directly into the renal pelvis using a spinal needle, proved to be a more effective technique than imaging after intravenous administration of contrast agent to detail the course of an ectopic ureter, and one should consider this technique in future cases.<sup>82</sup>

Treatment has included ureterocystostomy (surgical reimplantation of the ectopic ureter or ureters into the bladder) or unilateral nephrectomy. Before surgery, one must determine whether the condition is unilateral or bilateral, which side is affected if unilateral, and whether urinary tract infection

(UTI) is present. Further, one should attempt to rule out other anomalies, especially of the reproductive tract. If the problem is bilateral (8 of 20 cases), then one should establish the presence of a normal micturition response by measuring the intravesicular pressure response to progressive distention until the fluid infused is voided spontaneously. This procedure provides an estimate of bladder volume and ensures competency of the urethral sphincter before reimplantation. Among 14 cases in which surgical correction was pursued, ureterocystostomy was successful in establishing a functional urinary system in nine published cases\* and one foal seen by the author, but four died of postoperative complications.<sup>68,75,82</sup> In contrast, all four cases treated by unilateral nephrectomy had a favorable outcome.<sup>72,73,79</sup> Because affected ureters often are dilated and tortuous, surgical reimplantation can be difficult and may not result in a functional ureteral orifice. Consequently, when the problem is unilateral, nephrectomy of the affected side may be the preferred treatment option.<sup>85,86</sup>

### URETERAL DEFECTS OR TEARS (URETERORRHESIS)

Retroperitoneal accumulation of urine and uroperitoneum has been described in seven foals with unilateral or bilateral ureteral defects<sup>87,93</sup> and has been observed in three additional foals by the author. These included seven male and three female foals of several breeds (five Standardbreds, two Thoroughbreds, one Belgian, one Oldenburg, and one Appaloosa). Clinical signs (decreased nursing, depression, abdominal distention, diarrhea, and muscle twitching or other signs of neuromuscular irritability) and clinicopathologic abnormalities (hyponatremia, hyperkalemia, hypochloremia, and azotemia) are similar to those in horses with bladder rupture but may have a slightly later onset (4 to 16 days of age). Mild protrusion of the vagina may occur in fillies in which the peritoneum has remained intact.<sup>94</sup> In affected foals, ultrasonographic examination may reveal dilation of the renal pelvis and affected ureter, as well as fluid accumulation around the kidneys or farther caudad within the retroperitoneal space. As with ectopic ureters, excretory urography generally has been an unrewarding diagnostic procedure, but contrast pyelography was used successfully to image leakage of contrast agent from a proximal ureteral defect in a recent report.<sup>93</sup> Contrast radiography has not been pursued routinely because exploratory celiotomy generally was performed shortly after a diagnosis of uroperitoneum. Catheterization of the ureters via a cystotomy and retrograde injection of methylene blue allowed localization of the defect (or defects), and surgical correction was performed successfully in four cases by suturing the defect around an indwelling catheter.<sup>89,90,93</sup> Although ascending UTI should be an expected complication with a stent, repair of a defect in one foal without use of an indwelling catheter resulted in further urine leakage from the ureter, prompting a nephrectomy 4 days after the initial surgery.<sup>91</sup> Of the remaining five foals, one died after three unsuccessful attempts at surgical repair,<sup>88</sup> and euthanasia was performed in four cases without attempting repair.<sup>87,92</sup>

At surgery or necropsy a single defect was found in six foals, whereas bilateral defects were found in four foals and multiple defects were apparent in one ureter. In most cases

the defects have been located in the proximal third of the ureter near the kidney. Interestingly, distended, tortuous ureters, occasionally accompanied by hydronephrosis, also were described in three affected foals,<sup>88,91,93</sup> and distal obstruction of the ureters at the bladder was suspected in two of these cases, prompting ureteroneocystostomy. Although several reports suggest that these ureteral defects may be anomalies of development, the actual cause of these ureteral defects is not known. Traumatic disruption was suggested in the initial report in which histologic examination of the margins of the defect revealed hemorrhage and proliferation of immature connective tissue.<sup>87</sup> A traumatic cause was further supported by a subsequent report in which histologic examination of the defects revealed absence of transitional epithelium and inflammation in a foal that had been attacked by dogs.<sup>92</sup> Inflammation and granulation tissue also were visible in the apparently obstructed distal ureter in one of the foals with ureteral distention, again suggesting an acquired lesion. Blunt abdominal trauma, often sustained during automobile accidents, can cause retroperitoneal accumulation of urine and uroperitoneum in human beings.<sup>95</sup> Disruption of the ureter is usually near the kidney, and this complication of trauma may not be recognized for several days after injury. In one foal evaluated by the author, multiple rib fractures found at necropsy suggested that these ureteral tears actually could be a complication of foaling trauma.

### RECTOURETHRAL AND RECTOVAGINAL FISTULAE

If the urorectal fold fails to separate completely the primitive hindgut from the urogenital sinus, then a rectourethral fistula may be found in a colt or a rectovaginal fistula or a persistent cloaca may be found in a filly.<sup>96</sup> These anomalies are rare in horses and when present usually are associated with atresia ani and other anomalies, including agenesis of the coccygeal vertebrae and tail, scoliosis, adherence of the tail to the anal sphincter area, angular limb deformities, and microphthalmia.<sup>70,71,97-102</sup> Affected foals usually are presented for atresia ani, although one also may observe signs of colic and straining. Evidence for a fistula is passage of fecal material from the vulva or urethra. In fillies one may detect rectovaginal fistulae by digital palpation of the dorsal vestibule and vagina, but in colts a definitive diagnosis usually requires contrast radiographic procedures such as a barium enema or a retrograde urethrogram (Figure 19-8). Surgical correction of atresia ani and fistulae has been performed successfully in several foals, but multiple surgical procedures may be required. Because ascending UTI may be a complication, one should submit a sample of urine collected via bladder catheterization (preferably during surgery) for bacterial culture.<sup>96</sup> In human beings the evidence suggests that these anomalies are hereditary, and in one report several foals born with atresia ani were sired by the same stallion.<sup>97</sup> Consequently, affected horses should not be used for breeding after surgical correction of the anomalies.

A urethrorectal fistula resulting in passage of urine from the anus also has been described in a 3-year-old Thoroughbred gelding.<sup>103</sup> The fistula in this gelding was thought to be acquired after trauma or straining because no other developmental problems were detected and the edges of the defect were irregular and inflamed when examined with a speculum inserted into the rectum.

\*References 67, 68, 75, 76, 81, 82.

**FIGURE 19-8** A positive contrast urethrogram in a 3-day-old burro that had atresia ani and intermittent passage of fecal material from the urethra. A catheter passed via the urethra and contrast agent injected into the catheter resulted in accumulation of a large amount of contrast agent in the rectum and a lesser amount in the intrapelvic portion of the urethra. A small amount of contrast agent is visible in the urethrorectal fistula (*arrow*).

## BLADDER DEFECTS

Uroperitoneum may result from bladder rupture during parturition in foals (most commonly males)<sup>104</sup> or as a consequence of urachal leakage after infection of the umbilical structures.<sup>105,106</sup> In addition, Wellington described uroperitoneum in two foals that were full brothers.<sup>107</sup> Urine entered the abdomen from a dorsal defect in both colts, and smooth margins to the defects combined with a lack of appreciable inflammation provided evidence in favor of anomalous development rather than trauma. Other authors have suggested that some cases of uroperitoneum likely are associated with anomalous bladder defects because of the size, location, or lack of apparent inflammation of the margins of the defects.<sup>70,108-111</sup> For example, Bain<sup>108</sup> described uroperitoneum in a foal in which the ventral portion of the bladder was absent between the lateral ligaments (umbilical artery remnants) from the umbilicus to the urethra.

Anomalous fusion of the bladder to the inner umbilical ring (absence of the urachus) has been described in one foal.<sup>112</sup> The malformation precluded normal contraction and evacuation of the bladder, and a megavesica—a greatly enlarged bladder—developed. The clinical appearance was similar to that of uroperitoneum, and surgical separation of the bladder from the umbilical ring restored normal anatomic and functional integrity of the bladder. A similar case with a greatly distended bladder was reported in a foal evaluated for abdominal distention<sup>70</sup> that was attributed to an adhesion of the bladder to the urachus or umbilical remnant. An enlarged, flaccid bladder also was described in a foal undergoing exploratory celiotomy for suspected urinary tract disruption.<sup>105</sup> Adhesions to the abdominal wall were not reported, and the foal survived after the surgery during which 50% of the distended bladder was resected. In addition to bladder distention, persistent attachment of the bladder to the area of the umbilicus via a urachal remnant was reported to cause pollakiuria and dysuria in a

15-month-old Thoroughbred filly.<sup>113</sup> The author also has seen postpartum bladder rupture in a mare in which a persistent urachal attachment was suspected to be a contributing factor.

Excessive bladder distention or megavesica has been described further in four stillborn foals<sup>114</sup> and one neonatal foal.<sup>115</sup> In the latter foal and in another report,<sup>116</sup> chronic bladder distention appeared to lead to loss of smooth muscle in the dorsal bladder wall and replacement with collagen. The result was bladder rupture during parturition. Although these reports are similar to an early report by Rooney<sup>104</sup> describing the dorsal bladder wall as the anatomic weak link and likely area for rupture, they differ in that chronic distention of the bladder in utero with smooth muscle loss is not recognized in more typical bladder ruptures in neonatal foals. Why bladder distention should occur in utero without obstruction of the lower tract (not found in these cases) is not clear. Although an excessively long umbilical cord (longer than 85 cm) may lead to urachal obstruction,<sup>114,117</sup> urine produced in utero alternatively could drain into the amniotic cavity via the urethra. Thus this form of megavesica remains poorly characterized and poorly understood.

Bladder distention also is recognized in some foals with hypoxic-ischemic encephalopathy. Affected foals may posture to urinate frequently, and ultrasonographic examination may reveal an enlarged bladder or incomplete bladder emptying. In recumbent foals, one may note abdominal distention, and temporary use of an indwelling bladder catheter to keep the bladder empty is helpful; however, ascending UTI may be a complication. Cystometrography would be useful to assess detrusor function in affected foals, but no reports describe use of this diagnostic test in equine neonates. Although administration of cholinergic drugs (e.g., bethanechol) to improve detrusor function or  $\alpha$ -adrenergic blockers (e.g., phenoxybenzamine, acepromazine) to decrease urethral sphincter tone has been described anecdotally to be of benefit, no reports describe the efficacy of these medications in foals with this problem.

Some neonatal foals examined for abdominal pain are apparently unable to urinate normally. Ultrasound examination will reveal a normal gastrointestinal tract and a greatly enlarged but intact urinary bladder. These foals can be treated with indwelling urinary catheters for 2 to 3 days along with phenazopyridine (4 mg/kg PO every 8 to 12 hours) for 5 to 7 days.<sup>118</sup> Phenazopyridine acts a local analgesic on the lower urinary tract and may relieve spasm or allow better relaxation of the bladder sphincters and promote normal micturition.

## PATENT URACHUS

The urachus is the conduit through which fetal urine passes from the bladder into the allantoic cavity. Normally, the urachus closes at the time of parturition, but incomplete closure is the most common malformation of the equine urinary tract. Patent urachus occurs more commonly in foals than in other domestic species.<sup>30</sup> Greater than average length or partial torsion of the umbilical cord has been suggested to cause tension on the attachment of the umbilical cord to the body wall. The result is dilation of the urachus and subsequent failure to close at birth.<sup>70,71,114,117,119</sup> Patent urachus results in a persistently moist umbilicus after birth, from which urine may leak as drips or as a stream during micturition. One must distinguish this malformation from septic omphalitis, which also can result in urine leakage from the umbilicus within a few hours to days after birth. Ultrasound examination of the umbilical

remnants is indicated to rule out or monitor for concurrent omphalophlebitis. Patent urachus has been referred to as a *congenital problem* and the latter as an *acquired problem*, but both may result in urine leakage from the urachus from birth. Neither is life threatening, but local sepsis often is accompanied by more severe illness, including septicemia or localized infection, particularly in joints.

The congenital patent urachus traditionally has been treated with frequent (two to four times daily) chemical cauterization of the urachus with swabs dipped in a concentrated phenol or 7% iodine solution or with silver nitrate applicators.<sup>69</sup> Because the urachus may close spontaneously in a number of cases, and because these agents desiccate and irritate tissue (and may predispose to infection), the rationale for this approach has been questioned.<sup>119</sup> In a study comparing the effects of disinfectant solutions on the bacterial flora of the umbilicus of normal foals, use of a 7% iodine solution was observed to cause rapid desiccation of the umbilical tissue and subsequent development of a patent urachus when the stump fell off a few days later.<sup>120</sup> Chlorhexidine diacetate (0.5%) appears to be more effective than 1% to 2% iodine solutions in reducing umbilical bacterial counts. Chlorhexidine is less irritating to tissue, binds to the stratum corneum, and has prolonged antiseptic effects.<sup>120</sup> The use of caustic or irritating solutions for routine umbilical dipping or treatment of patent urachus should probably be avoided because it may lead to localized necrosis and infection that may actually result in umbilical infections.

Consequently, in the absence of apparent infection, no local treatment may be indicated specifically, but affected foals frequently are given antibiotics prophylactically. For acquired patency (which may be associated with local infection, cachexia, or septicemia), broad spectrum antibiotic therapy is indicated, and resolution of the systemic disease may be accompanied by elimination of the umbilical infection and closure of the urachus. Most cases of patent urachus without septic omphalophlebitis will resolve with supportive care, routine umbilical disinfection, and antibiotic therapy. Empiric antibiotic therapy with antibiotics that are eliminated (and concentrated) in urine, such as potentiated sulfonamides, cephalosporins, aminoglycosides, or penicillins usually provides adequate antimicrobial protection with uncomplicated patent urachus in otherwise healthy foals. Chemical cauterization is contraindicated with local sepsis because it may increase the risk of urachal rupture and development of uroperitoneum.<sup>121</sup> If one observes no decrease in urine leakage after 5 to 7 days of medical therapy, or if ultrasonography reveals abnormalities of multiple structures in the umbilicus,<sup>122,123</sup> then surgical exploration and resection of the urachus and umbilical vessels may be indicated. In a retrospective study of 16 foals treated for sepsis of umbilical cord remnants, six of nine (67%) survived after surgical resection and antibiotic treatment, whereas only three of seven (43%) survived after antibiotic treatment alone.<sup>124</sup> Although this series of 16 foals often is cited in support of surgical intervention, one should note that the series studied a small number of foals and that the cases were evaluated over 10 years (1975-1985), during which time many aspects of neonatal care improved. In a more recent retrospective report of 33 foals with umbilical remnant infections, no difference in survival was observed between foals treated with antibiotics combined with surgical resection or with antibiotic therapy alone.<sup>123</sup> Further, emphasis was placed on the insensitivity of palpation of the umbilicus in detection of umbilical remnant

infection (compared with ultrasonographic examination) and the poor outcome of cases in which the umbilical vein was involved. In addition to the possibility of omphalitis leading to urachal rupture and development of uroperitoneum, urachal leakage also may occur into the abdominal musculature and subcutaneous tissues and lead to swelling and cellulitis of the ventral abdominal wall.<sup>125</sup> Both instances require surgical intervention. Finally, trauma or tearing of the urachus also can lead to umbilical evagination of the urinary bladder,<sup>126</sup> which can result in partial or complete obstruction of urine flow, and surgical correction is indicated.

## RENAL PHYSIOLOGY

*Harold C. Schott II*

The kidneys perform two essential functions in the maintenance of homeostasis: (1) elimination of nitrogenous and organic waste products and (2) control of body water content and ion composition. In addition, the kidneys are important endocrine organs that produce renin, erythropoietin, and the active form of vitamin D; they also play an important role in the degradation and excretion of a number of other hormones, including gastrin and parathormone. To gain an understanding of the pathophysiologic alterations associated with renal disorders in horses, one must first review some aspects of normal renal physiology in this species.

## ☞ PRODUCTION AND ELIMINATION OF NITROGENOUS AND ORGANIC WASTES

The two most commonly recognized waste products excreted in urine are urea and creatinine (Cr), but many other nitrogenous or organic wastes are produced each day and subsequently are eliminated by the kidneys (Box 19-1).<sup>1</sup>

### UREA METABOLISM

A molecule of urea is produced in the liver from two ammonium ions that are liberated during catabolism of amino acids. For each urea molecule the carbon atom is derived from bicarbonate. One ammonium ion is cleaved from an amino acid via an  $\alpha$ -ketoglutarate-dependent transamination coupled to oxidative deamination of glutamate. The second ammonium ion is derived from aspartate in the urea cycle.<sup>2</sup> Urea synthesized in the liver is released into the blood, and clearance by the kidneys represents the major pathway (75% to 100%) of excretion. Extrarenal urea excretion includes losses in sweat and through the gastrointestinal tract. With normal intestinal function, enteric excretion is minimal because of enterohepatic recirculation (reabsorption of ammonia from the degradation of urea by bacterial ureases and subsequent reformation of urea in the liver).<sup>3</sup>

In human beings, inborn errors of metabolism leading to deficiency of a specific transaminase or of one of the five enzymes of the urea cycle can result in accumulation of ammonia and other intermediates of amino acid catabolism. These disorders typically are inherited as autosomal recessive traits, and the consequence is moderate to severe mental dysfunction because the accumulated intermediates can be toxic

## BOX 19-1

## COMPOUNDS EXCRETED BY THE KIDNEYS

Urea  
 Phenols

 Hippurate esters  
 Aliphatic amines  
 Aromatic amines  
 Middle molecules

to the central nervous system (CNS; i.e., ammonia) or can act as false neurotransmitters (i.e., aromatic amines).<sup>1</sup> Because urea production is limited in these disorders, blood urea nitrogen (BUN) concentration is often low.<sup>2</sup> Although such defects in metabolism appear to be rare in domestic animals,<sup>4</sup> development of encephalopathy in association with hyperammonemia has been recognized in horses.<sup>5,6</sup> Furthermore, in one report of two related Morgan weanling fillies, persistent hyperammonemia was suspected to be caused by a defect in a mitochondrial ornithine transporter similar to an autosomal recessive syndrome of hyperornithinemia, hyperammonemia, and homocitrullinuria (HHH) in human beings.<sup>7</sup>

BUN concentration depends on age, diet, rate of urea production, and renal function. For example, a low BUN typically is found in neonatal foals after an anabolic demand for amino acids.<sup>8</sup> Investigations of nitrogen use in ponies have demonstrated that urea production is proportional to dietary protein content. Similarly, urinary urea excretion increases in proportion with urea production.<sup>9,10</sup> As a result, with increased levels of dietary protein or when urea is supplemented in the diet, BUN may increase twofold or greater.<sup>11-13</sup>

In human beings and small animals, BUN is routinely higher in samples collected postprandially because diets are typically high in protein.<sup>3</sup> Postprandial elevation of BUN has not been described in horses or other herbivores. However, fasting leads to enhanced protein catabolism to meet energy demands and increased BUN in horses.<sup>14,15</sup> In ponies, however, BUN decreases with fasting.<sup>16</sup> This opposite response suggests differences in the metabolic responses of horses and ponies to anorexia, consistent with a greater capacity of ponies to mobilize and use fat during starvation. Other causes of protein catabolism, including fever, infection, trauma, myositis, burns, and corticosteroid therapy, also can produce an increase in BUN.<sup>3</sup> Finally, a decrease in RBF or renal function produces

an increase in BUN. The former may occur with dehydration or during periods of anesthesia or exercise; the latter is a reflection of renal disease.<sup>3</sup> With short bouts of moderate to intensive exercise, BUN often does not change<sup>13,17</sup>; however, during prolonged exercise BUN can increase by 50% or more because of the combined effects of decreased RBF and protein catabolism.<sup>18,19</sup>

Most renal nitrogen excretion occurs in the form of urea in urine. One must recognize that urea excretion is completely passive and that the high concentrations achieved in urine are merely a consequence of medullary tonicity produced by the countercurrent-multiplier function of the loop of Henle. Thus although variations in dietary protein intake lead to parallel changes in urea excretion, the idea that low-protein diets decrease the workload on the kidney is a fallacy.<sup>3</sup> Urinary urea nitrogen concentrations can vary from as low as 50 mg/dl in neonatal foals or horses with primary polydipsia to greater than 2500 mg/dl in normal horses on high-protein diets. Total daily urea excretion usually ranges between 100 and 300 g per day in horses with normal renal function.

### CREATININE METABOLISM

Cr is produced by the nonenzymatic, irreversible cyclization and dehydration of creatine. Three amino acids in the kidney, liver, and pancreas are indirectly responsible for its production; subsequently Cr is transported to other organs such as muscle and brain, where it is phosphorylated to store energy in the form of phosphocreatine.<sup>3,20</sup> In human beings, 1.5% to 2% of the creatine pool is converted to Cr daily and results in fairly constant excretion of Cr within a given individual.<sup>3</sup> With normal renal function, a direct relationship exists between daily Cr production, serum Cr concentration, and Cr excretion, all three being proportional to total muscle mass. The fact that Cr is 30% higher in male humans than in female humans and that urinary Cr excretion is correlated to body size across a wide range of animal species supports this relationship.<sup>3,21</sup> Cr is excreted principally in urine, but sweat and the gastrointestinal tract are secondary routes of excretion.<sup>3</sup> In contrast to urea, enterohepatic recycling of Cr does not occur, and the gastrointestinal tract may represent a major route of excretion when renal function is compromised. For example, in a group of azotemic human patients, between 15% and 65% of radiolabeled Cr was found to be excreted through the intestine.<sup>22</sup> Cr excreted by this route is degraded rapidly by bacteria so that little is found in feces.

Like BUN, Cr can vary with age, activity level, and renal function. In contrast, dietary protein intake has little influence on Cr in horses.<sup>11</sup> Newborn foals routinely have Cr values 30% to 50% higher than those measured in the mare, and values as high as 20 to 30 mg/dl have been measured in some premature or asphyxiated foals.<sup>8</sup> These high values may result from limited diffusion of Cr across the placenta. For example, the Cr in equine amniotic fluid collected at term is proportionately much greater than urea nitrogen concentration (Cr, 10.1 mg/dl; urea nitrogen, 38.8 mg/dl).<sup>23</sup> If the foal appears healthy and all other laboratory values are within reference ranges, then a Cr value in the range of 5 to 15 mg/dl should not cause alarm. In most healthy foals with normal renal function, Cr decreases to values below 3.0 mg/dl within the first 3 to 5 days of life.<sup>22</sup> After the first few days of life, Cr is usually lower in foals than in adults<sup>12</sup> because of the combined effect of rapid growth and the fact that skeletal muscle comprises a smaller percentage

of body weight in foals than in adult horses. Other nonrenal factors that may influence Cr include fasting, rhabdomyolysis or muscle wasting caused by disease, and exercise. Although fasting can increase the measured value for Cr, a substantial portion of this increase actually is due to other compounds (possibly ketones) that increase during fasting and are measured as non-Cr chromagens in the commonly used Jaffe's colorimetric assay for Cr determination (see Examination of the Urinary System).<sup>12,14,24</sup> In contrast, the increase in Cr (up to 80% in some reports) associated with various types of exercise is likely the combined result of increased release of creatine from muscle and decreased urinary Cr excretion during the exercise bout.<sup>12,14,17-19</sup>

Cr is filtered freely at the glomerulus and is concentrated to values of 100 to 300 mg/dl in equine urine, which results in a total daily urine excretion of 15 to 25 g of Cr.<sup>25,26</sup> In comparison to urea, Cr excretion is responsible for only one tenth as much urinary nitrogen excretion. Minor species and sex differences have been reported for renal tubular handling of Cr, with a weak proximal tubular secretory mechanism in human beings and male dogs (accounting for 7% to 10% of total urinary Cr excretion).<sup>3,20</sup> To determine whether tubular secretion of Cr occurs in equine kidneys, Finco and Groves<sup>27</sup> fitted anesthetized ponies with ureteral catheters and performed simultaneous inulin and exogenous Cr clearance studies. Because inulin is filtered freely at the glomerulus and is neither secreted nor reabsorbed by renal tubules, inulin clearance ( $Cl_{in}$ ) provides a standard of comparison for Cr clearance ( $Cl_{Cr}$ ). Tubular secretion of Cr should result in a greater value for  $Cl_{Cr}$  than for  $Cl_{in}$ , whereas the opposite should occur with tubular reabsorption of Cr. To magnify any minor tubular secretion of Cr, stop-flow studies were performed by temporarily occluding the ureteral catheters. During obstruction, tubular lumen pressure increased and tubular flow decreased. As a consequence, fluid remained in contact with tubular epithelium for a prolonged period, enhancing local tubular secretory or resorptive processes. Analysis of a series of urine samples collected after release of ureteral occlusion revealed no differences in tubular handling of inulin or Cr, leading to the conclusion that Cr neither was reabsorbed nor secreted by equine kidneys. In contrast, simultaneous measurement of endogenous  $Cl_{Cr}$  and  $Cl_{in}$  in several horses with CRF (author's unpublished observations) has revealed higher values for  $Cl_{Cr}$ , indicating that tubular secretion of Cr may develop in horses as renal function declines (see the Chronic Renal Failure). Whether significant excretion of Cr occurs in sweat or through the gastrointestinal tract has not been investigated in horses.

### **METABOLISM OF OTHER NITROGENOUS AND ORGANIC COMPOUNDS**

Although the kidneys excrete a number of nitrogenous and organic wastes in addition to urea and Cr (see Box 19-1), these compounds are quantitatively unimportant in terms of nitrogen balance.<sup>1</sup> Two of the more commonly recognized molecules are ammonia and uric acid. In proximal tubular epithelial cells, ammonium ions and  $\alpha$ -ketoglutarate are produced from glutamine. Subsequent metabolism of  $\alpha$ -ketoglutarate results in generation of two bicarbonate molecules that are returned to the systemic circulation. Ammonium ions are secreted in exchange for sodium into the tubule lumen, where they remain trapped, because tubules are relatively impermeable to ammonium ions. Furthermore, because the  $pK_a$  for ammonia

is greater than 9.0, most of the tubular ammonia remains in the form of ammonium ions, even in alkaline equine urine. Although ammonium ion excretion is of little significance in overall nitrogen excretion, it plays an important role in acid (hydrogen ion) excretion. In fact, glutamine metabolism and ammonium ion excretion can increase severalfold in response to metabolic acidosis.<sup>28</sup> Although urinary ammonium concentration is not measured routinely, one can estimate it because it is directly related to the urinary anion gap ( $[Na^+ + K^+] - Cl^-$ ) in human patients with normal anion gap metabolic acidosis.<sup>29</sup> More important, impairment of this proximal tubular acid secretion pathway contributes to development of metabolic acidosis in patients with renal insufficiency.

Uric acid is a product of purine nucleotide degradation and is the major nitrogenous waste product formed in amphibians and reptiles. In mammals, however, uric acid excretion (mostly in the ionic form of urate) is unimportant in terms of overall nitrogen excretion.<sup>1</sup> Uric acid metabolism has received little attention in veterinary species with the exception of Dalmatian dogs. This breed exhibits high urate excretion rates and is predisposed to uric acid stone formation; however, this problem results from decreased hepatic uricase activity rather than any abnormality in renal urate handling.<sup>30</sup> Finally, hyperuricemia (leading to gout in human beings) also can be attributed to a lack of uricase activity in human tissues and greater renal reabsorption of urate compared with other mammalian species. Thus crystallization of urate in tissues appears to be limited to human beings.<sup>1</sup> Urate metabolism has been studied little in horses, although Keenan<sup>17</sup> observed that plasma concentrations increased dramatically in response to exercise (from  $<1 \mu\text{mol/L}$  at rest to 150 to 200  $\mu\text{mol/L}$  1 hour after racing) and that these increases were accompanied by a transient increase in urinary urate excretion (from  $<40 \mu\text{mol/L}$  at rest to 250 to 1270  $\mu\text{mol/L}$  after racing).

The proximal tubule is also the major site of excretion (by tubular secretion) of a number of endogenous organic anions and cations.<sup>1</sup> The anions share the common pathway measured by p-aminohippurate clearance, the substance traditionally used to measure effective renal plasma flow (because more than 90% is excreted via this pathway). A number of exogenous compounds also are excreted via these pathways—acetazolamide, furosemide, probenecid, penicillin G, sulfadiazine, salicylate, atropine, cimetidine, and neostigmine. Thus administration of these compounds can interfere with tubular secretion of endogenous organic wastes or other exogenous products by healthy kidneys.<sup>31</sup> More importantly, the pharmacokinetic effects of these products vary widely in patients with renal insufficiency. Combined with the fact that anion binding to plasma proteins is decreased with azotemia, dosing protocols of many medications may need to be readjusted for patients with renal failure.

## **☞ BODY WATER AND ELECTROLYTE BALANCE**

### **BODY FLUIDS: VOLUME AND COMPOSITION**

Water accounts for at least 60% of total body mass, equivalent to 300 L in a 500-kg horse.<sup>1,29-34</sup> About 200 L of total body water is intracellular fluid, and the remaining 100 L is extracellular fluid. Extracellular fluid is divided between plasma (4% to 6% of body mass, approximately 25 L), interstitial fluid and

lymph (10% to 12% of body mass, approximately 45 L), and transcellular fluid (6% to 10% of body mass, approximately 30 L, most of which is in the lumen of the gastrointestinal tract). Despite significant differences in ion composition (Table 19-1), the extracellular fluid and intracellular fluid compartments exchange water freely to maintain osmotic equilibrium.<sup>28</sup>

From the values in Table 19-1 one can estimate the total amount of exchangeable sodium, potassium, and chloride in the body fluids of a 500-kg horse: approximately 16,000 mEq, approximately 28,800 mEq, and approximately 10,800 mEq, respectively (including gastrointestinal fluid ion contents). These values are accurate except for that of sodium, which may be twice as great; however, 40% to 50% is sequestered in bone and is not readily available to buffer sodium alterations in body fluids.<sup>32-34</sup> Thus the 16,000-mEq estimate is accurate for the exchangeable sodium content in body fluids. Similarly, one can estimate body fluid contents of calcium, magnesium, and phosphorus at approximately 1000 mEq (20 g), approximately 6875 mEq (84 g), and approximately 8150 mEq (140 g), respectively (excluding gastrointestinal fluid ion contents, because these vary with the amount and solubility of the dietary source). As for sodium, the values underestimate the total body content of calcium, magnesium, and phosphorus, because more than 99%, 70%, and 85% of these elements, respectively, are contained in the skeleton.<sup>3</sup>

## WATER BALANCE

Appropriate water balance maintains plasma osmolality in a narrow range (270 to 300 mOsm/kg) and is achieved by matching daily water intake with water loss.<sup>35-37</sup> Water is provided from three sources: (1) free water intake (drinking), (2) water in feed, and (3) metabolic water (Table 19-2). Horses consume

most of the water by drinking (about 85%), but feed and metabolic water provide about 5% and 10% of daily water, respectively. Water can be lost by three routes: (1) in urine, (2) in feces, and (3) as insensible losses (evaporation) across the skin and respiratory tract (Table 19-3). Investigations of water balance have revealed a maintenance water requirement of 60 to 65 ml/kg/day or 27 to 30 L/day for a 500-kg horse.<sup>35,38</sup> These values are consistent with traditional recommendations that 5 to 10 gallons/day of fresh water be provided to a stabled horse under mild environmental conditions.<sup>39</sup> Urinary and

‡Groenendyk S, English PB, Abetz I: External balance of water and electrolytes in the horse, *Equine Vet J* 20:189, 1988.

§Water intake includes imbibed water (23.6 L), water in feed (1.1 L), and metabolic water (2.9 L).

fecal water losses range between 20% to 55% and 30% to 55%, respectively, of the total daily water loss.<sup>35,38,40,41</sup> The remaining (insensible) loss accounted for up to 15% to 40% of daily water loss, despite mild ambient conditions and the lack of observed sweating in most studies of water balance.

Water drinking and urine production are the mechanisms by which water balance is finely tuned; however, they can vary widely between individual horses and also are affected by age, environmental conditions, level of exercise, and diet. Often, for example, neonatal foals consume milk in excess of 20% of their body mass daily,<sup>42</sup> which equates to fluid intake approaching 250 ml/kg/day. Water intake by horses increased 15% to 20% when ambient temperature increased from 13° to 25° C.<sup>43</sup> Under conditions of high ambient temperature and humidity, urine concentration also may increase to conserve water, whereas fecal water content tends to remain fairly stable, at about 75% of fecal weight. Exercising horses, especially endurance horses and racing horses treated with furosemide, can increase water consumption by 100% to 200% to replace body water lost in sweat (and urine). Horses and ponies on all-roughage diets also drink more and have greater daily fecal water loss (because of greater daily fecal volume) than animals fed a large amount of concentrate or complete pelleted diets.<sup>40,41</sup> Diets high in nitrogen (protein) and calcium, such as legume hays, typically increase urine volume by 50% or more and are associated with a similar increase in urinary nitrogen excretion. These diets are also more digestible so that fecal water excretion generally decreases because of a decrease in total fecal material.<sup>9,14,40,41</sup> Although high dietary levels of salt have been suggested to increase drinking and promote diuresis, no increase in water consumption or urine volume was observed in ponies fed 5 to 10 times the daily salt requirement (equivalent to about 350 g of sodium chloride [NaCl] for a 500-kg horse).<sup>44</sup> The effects of water access, continuous versus intermittent, have received less attention, although a recent study showed no difference in water balance in horses provided water three times daily compared with horses that had continuous access to water.<sup>45</sup> Furthermore, horses drink the most water within the hour after feeding,<sup>46</sup> and feral horses and ponies often drink only once or twice daily.<sup>47</sup> Thus horses are unlikely to require continuous access to water. An obvious exception is a patient with renal insufficiency that should have access to fresh water at all times.

Two main stimuli for thirst are (1) increased plasma osmolality and (2) hypovolemia or hypotension.<sup>48</sup> The former is mediated through osmoreceptors in the hypothalamus that have a high threshold for activation (about 295 mOsm/kg) in human beings. Hemodynamic stimuli are mediated by low- and high-pressure baroreceptors. Osmotic and hemodynamic stimuli can produce their dipsogenic effect in part by activating a local renin-angiotensin-aldosterone system in the CNS.<sup>49,50</sup>

Renal water reabsorption is controlled principally by the action of arginine vasopressin (antidiuretic hormone) on the collecting ducts.<sup>51</sup> Vasopressin is produced in the neurosecretory neurons of the supraoptic nuclei, packaged in granules, and transported down axons for storage in the neurohypophysis (pars nervosa or posterior pituitary). As for thirst, increases in plasma osmolality and hypovolemia or hypotension are the stimuli for vasopressin release. Osmoreceptors for vasopressin release also are located in the hypothalamus, adjacent to the osmoreceptors mediating thirst. Activation of these receptors is the signal for vasopressin release from the neurohypophysis.

Furthermore, these osmoreceptors are not equally sensitive to all plasma solutes. For example, increases in plasma sodium concentration and infusion of mannitol are potent stimuli, whereas increases in plasma glucose and urea concentrations are weak stimuli. These differences have led to the suggestion that osmoreceptor activation is caused by an osmotic water shift that produces cell shrinkage (which would be greater for sodium and mannitol than for glucose or urea). Activation of osmoreceptors signaling vasopressin release also appears to have a threshold value; however, this threshold appears to vary highly between individuals. In addition, the threshold for vasopressin release in human beings is significantly lower (270 to 285 mOsm/kg) than that for thirst. Thus vasopressin release can be thought of as the initial line of defense against a mild increase in plasma osmolality, whereas thirst and drinking are secondary responses to even greater increases.

Studies in horses, ponies, and donkeys have demonstrated that increased plasma osmolality (induced by water deprivation or infusion of hypertonic saline) and hypovolemia (induced by furosemide administration) are stimuli for thirst.<sup>45,51-55</sup> Furthermore, after a period of water deprivation, dehydrated ponies, horses, and donkeys appear to be able to replace water deficits within 15 to 30 minutes of gaining access to water. The increases in plasma osmolality and vasopressin concentration associated with water deprivation also are corrected in this same period of time, indicating that imbibed water is absorbed rapidly from the gastrointestinal tract.<sup>52</sup> Although increases in plasma vasopressin concentration have been measured in horses and ponies during water deprivation,<sup>52,56</sup> vasopressin also appears to be a "stress hormone" in equids, because substantially greater concentrations (tenfold greater than those induced by water deprivation) have been measured after application of a nose twitch, nasogastric intubation, or exercise.<sup>57,58</sup> Thus increases in plasma vasopressin concentration after water deprivation would be expected to vary in horses, and separating osmotic effects from stress effects may be difficult sometimes.

Once released, vasopressin acts on  $V_2$ -receptors on the basolateral membrane of collecting duct epithelial cells, leading to insertion of water channels (transmembrane proteins) in the apical membrane.<sup>48</sup> These channels increase the water permeability of the apical membranes and lead to increased water reabsorption. Action of  $V_2$ -receptors is mediated by activation of adenylyl cyclase and a stimulatory transmembrane G protein. Interestingly,  $V_2$ -receptor activation can be antagonized by activation of adjacent  $\alpha_2$ -adrenoceptors and by a prostaglandin  $E_2$ -mediated effect on an inhibitory G protein.<sup>59,60</sup> Although effects of these antagonists vary with species and have not yet been studied in horses, the diuresis associated with administration of  $\alpha_2$ -agonists to horses<sup>61,62</sup> likely may be attributable to vasopressin antagonism at the collecting duct.

As mentioned previously, most water drinking in equids occurs periprandially; thus feeding practices affect timing of water intake.<sup>46</sup> If a horse eats a large meal once or twice daily, then both increased plasma sodium concentration and decreased plasma volume (because of a shift of fluid into the bowel) stimulate thirst and vasopressin release. The result is a simultaneous increase in water intake and a decrease in urine output.<sup>63</sup> In addition, hypovolemia further stimulates activation of the renin-angiotensin-aldosterone system, which leads to enhanced renal sodium conservation as an additional means of restoring plasma volume. Although the increase in plasma sodium concentration with meal feeding is rather small

(1% to 3%), the decrease in plasma volume is much greater (5% to 25%). The magnitude of this fluid shift (and the degree of activation of the renin-angiotensin-aldosterone system) can be attenuated largely by feeding small meals four to six times throughout the day.<sup>64,65</sup> Thus more frequent feeding causes less perturbation of body fluids and likely has a protective effect against development of some forms of colic.

Although balance of daily water intake and output is critical for maintenance of homeostasis, it warrants mention that equids tolerate water deprivation well.<sup>66-72</sup> For example, after horses were deprived of water for 72 hours (which resulted in body weight loss in excess of 10%), most of the weight lost (90% of which was assumed to be water) was recovered within the first hour of being provided access to water.<sup>69</sup> Similarly, even greater body weight losses (approaching 20%) induced by water deprivation and desert walking in donkeys and burros were replaced largely within the first few minutes after water was provided.<sup>67,68</sup> Thus in terms of water balance, equids (especially donkeys and burros) truly can be considered desert-adapted animals.<sup>72,73</sup> An important reason for their ability to tolerate water deprivation appears to be a substantial intestinal reserve of water and electrolytes that they call on during periods of dehydration for the maintenance of plasma volume.<sup>74,75</sup> Despite rapid fluid replacement by equids that have been dehydrated by water deprivation, horses that become dehydrated because of prolonged exercise or diarrheal disease (colitis) often do not drink. This behavior can be attributed to the fact that these conditions produce loss of body water and osmoles in the form of sweat or diarrhea. As a result, plasma osmolality does not increase and osmotic thirst stimulus is not produced. In human endurance athletes this state of mild to moderate dehydration that does not induce thirst has been called *voluntary* and *involuntary* dehydration,<sup>76,77</sup> and although less well-documented, a similar response appears to occur in endurance horses.<sup>78</sup> Another form of involuntary dehydration, which may be accompanied by increases in plasma osmolality and protein concentration, also has been described anecdotally in mares after foaling.

## ELECTROLYTE BALANCE

Intake and loss of electrolytes also must be matched appropriately to maintain body content of electrolytes within narrow ranges. This balance is most important for the exchangeable ions (Na<sup>+</sup>, K<sup>+</sup>, and Cl<sup>-</sup>) because these have minimal tissue (skeletal) reserves that can be called on during times of need. An exception is the fluid and electrolyte reserve in the lumen of the gastrointestinal tract, which may be able to provide replacement of 10% or more of the body content of these electrolytes.<sup>75</sup> Three sources provide electrolytes: (1) feed, (2) water (usually minimal amounts), and (3) a number of dietary supplements. Electrolytes also can be lost by three routes: (1) in urine, (2) in feces, and (3) in sweat (insensible losses; see Table 19-3). Investigations of electrolyte balance have revealed that most horses that eat predominantly hay or pasture grass ingest excess potassium and chloride. In contrast, sodium intake varies and with some diets may be marginal.<sup>35,37,38</sup> A maintenance requirement for sodium of 0.4 to 0.8 mEq/kg/day or 200 to 400 mEq/day (6 to 12 g/day) for a 500-kg horse has been suggested<sup>38,54</sup>; however, exercising horses that may lose 500 to 1000 mEq of sodium per hour in sweat or are treated with furosemide have greater dietary requirements to replace such losses.<sup>37</sup> Thus addition of 50 to

75 g of common table salt (which provides 850 to 1275 mEq, because 1 g of NaCl provides approximately 17 mEq sodium) is a safe and economical method of providing daily supplemental sodium and chloride to athletic horses.

The data from the water and electrolyte balance studies performed by Tasker<sup>35</sup> and by Groenendyk, English, and Abetz<sup>38</sup> (see Table 19-3) provide a good illustration of the capacity of the equine kidneys to conserve sodium when dietary intake is low (see Tasker's data<sup>35</sup> at top) compared with when intake is unlimited (see Groenendyk, English, and Abetz's data<sup>38</sup> at bottom). Furthermore, these studies demonstrate that urinary excretion is the major route for loss of potassium and chloride. Although dietary intake of potassium is usually excessive, equine kidneys do not appear to have a great capacity to conserve potassium during periods of food and water deprivation or with anorexia associated with disease.<sup>35,37,77</sup> Thus urinary potassium concentration and total excretion can remain substantial in the face of decreased intake. Consequently, with decreased feed intake horses can develop significant total body potassium depletion and often benefit from supplemental dietary potassium (25 to 50 g per day of potassium chloride [KCl] provides 375 to 750 mEq, because 1 g KCl provides approximately 15 mEq of potassium).

In horses the stimuli for electrolyte intake (salt appetite) have received much less attention than stimuli for drinking. Houpt et al.<sup>54</sup> found that horses that had marginal sodium intake (250 mEq/day) and that were treated with furosemide ate more salt in the hours after treatment than did placebo-treated horses on the same diet; however, salt intake (which was comparable for eating salt from a block or drinking a 0.9% NaCl solution) was excessive in both treatment groups (in excess of 100 g). Thus salt appetite, unlike water intake, is less closely regulated to balance intake with losses. In fact, when salt is available *ad libitum*, horses appear to consume more than their maintenance needs. The excess is eliminated by increased urinary sodium excretion. Although this apparently excessive salt appetite may seem inappropriate, one could consider it advantageous for exercising horses, which have a much greater daily salt requirement.<sup>79</sup>

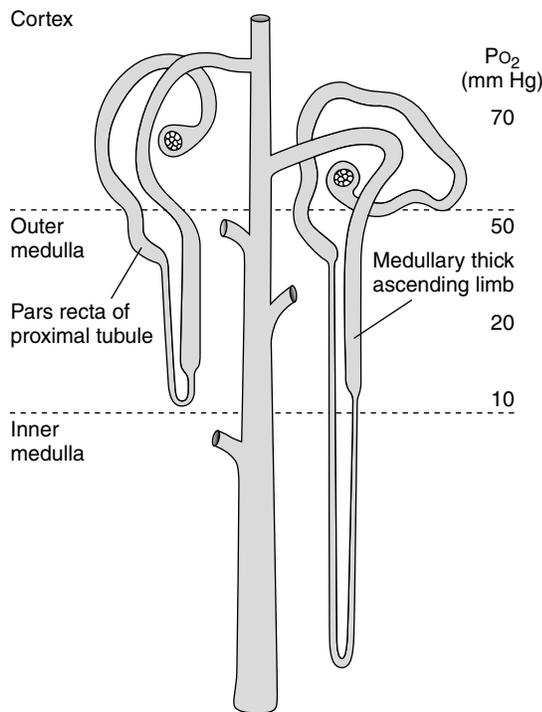

## RENAL REGULATION OF BODY WATER CONTENT AND ION COMPOSITION

The kidneys are the organs responsible for fine-tuning body water content and ion composition within narrow ranges. The important components of renal regulation of water and ion content include RBF, glomerular filtration, and tubular modification of glomerular filtrate to produce the final urine.

### RENAL BLOOD FLOW

At rest, the kidneys receive about 15% to 20% of the cardiac output, or about 7.5 to 10 L/min for an average-size horse.<sup>80,81</sup> This high tissue perfusion, 500 to 600 ml/min per 100 g of kidney compared with 50 to 100 ml/min per 100 g of brain tissue, is necessary for the kidney to function as an effective filter and as a regulator of extracellular fluid composition. Furthermore, tubular reabsorption of glomerular filtrate requires energy. Because more than 99% of the filtrate is reabsorbed, the metabolic rate of the kidney is high (second only to that of the heart), and despite the fact that the kidneys account for less than 1% of body weight, they are responsible for

about 10% of whole body oxygen use.<sup>1</sup> Next, RBF is distributed preferentially to the renal cortex. In fact, renal medullary blood flow, which is derived largely via the vasa recta that arise from the efferent arterioles of juxtamedullary glomeruli, accounts for less than 20% of total RBF.<sup>81</sup> Consequently, the renal medullary tissue normally functions in a hypoxic environment. Medullary hypoxia has been described as “an inevitable accompaniment of efficient urinary concentration” as a consequence of countercurrent exchange.<sup>82</sup> Although the latter mechanism would suggest that oxygen tension should decrease progressively toward the inner medulla, the lowest values, often no greater than 10 mm Hg, are found in the inner portion of the outer medulla, termed the *inner stripe* (Figure 19-9).<sup>83</sup> This finding can be explained by the substantial metabolic activity of epithelial cells lining the medullary thick ascending limb (mTAL) of the loop of Henle in the inner stripe. The sodium-potassium-adenosine triphosphatase pumps ( $\text{Na}^+, \text{K}^+ \text{-ATPase}$ ) in the basal membrane of these cells are responsible for the greatest adenosine triphosphate (ATP) use (and thereby oxygen consumption) in the medulla.<sup>84</sup> The combined effects of low oxygen delivery and a high rate of use produce the lowest oxygen tension in the inner stripe. Fortunately, several “protective” mechanisms exist to preserve medullary blood flow and tissue oxygenation during periods of renal hypoperfusion and include a preferential reduction in cortical blood flow along with redistribution of RBF to the corticomedullary region, accumulation of adenosine with depletion of ATP, and production of prostaglandin  $\text{E}_2$  ( $\text{PGE}_2$ )

**FIGURE 19-9** Schematic drawing of a nephron. In the outer medulla is the site of lowest intrarenal oxygen tension ( $\text{Po}_2$ ), in the final (straight) portion of the proximal tubule and the medullary thick ascending limb (mTAL) of the loop of Henle. Limited medullary blood flow and high metabolic rates make these outer medullary nephron segments the most susceptible to damage during periods of renal hypoperfusion.

and prostaglandin  $\text{I}_2$  ( $\text{PGI}_2$ ) and nitric oxide.<sup>82-84</sup> Of clinical importance is that the use of nonsteroidal anti-inflammatory drugs (NSAIDs) in patients with poor renal perfusion can exacerbate tissue hypoxia because  $\text{PGE}_2$  acts as a vasodilator and an inhibitor of  $\text{Na}^+, \text{K}^+ \text{-ATPase}$ . In fact, the earliest lesions of analgesic nephropathy include degeneration and necrosis of mTAL cells before development of overt papillary necrosis.<sup>84</sup>

RBF of horses has been measured by a variety of techniques including p-aminohippurate clearance ( $\text{Cl}_{\text{PAH}}$ ) by classic clearance techniques involving timed urine collections and by plasma disappearance curves, as well as clearance of radionuclides, microsphere injection, and use of ultrasonic Doppler flow probes placed around the renal artery (Table 19-4).<sup>80,81,85-101</sup> The latter technique does not provide absolute blood flow values but rather measures changes in RBF from a baseline value.<sup>98</sup> Recently, plasma disappearance curves for  $^{131}\text{I}$ -orthoiodohippuric acid and  $^{99\text{m}}\text{Tc}$ -mercaptoacetyltryglycine have been validated in normal horses in an attempt to establish radionuclide techniques for rapid and noninvasive measurement of RBF in hospitalized horses.<sup>96,101</sup> Although values for RBF determined by these radionuclide techniques compared well with previous data (Table 19-5), their future use in a clinical setting likely will remain limited because of moderate expense and the need to perform serial measurements to provide clinically relevant information in patients with reduced renal function.<sup>113</sup>

Intrinsic and extrinsic factors play a role in the control of RBF. The former include autoregulation and action of renal nerves; the latter include vasoconstrictors (catecholamines, renin-angiotensin system, arginine vasopressin) and vasodilators (prostaglandins, dopamine, atrial peptides, bradykinin, adenosine, and nitric oxide).<sup>1</sup> Although not unique to the kidney, autoregulation of blood flow is a physiologic response that maintains cortical RBF in the normal range through a rather wide range of perfusion pressures (75 to 180 mm Hg in human beings). This response is thought to be independent of neural or hormonal mechanisms and is attributed to a myogenic response to changes in arterial wall tension. The local action of renal nerves or release of vasoconstrictor substances leads to an increase in renal vascular resistance that may occur in response to disease states (hypovolemic or endotoxic shock), drugs (particularly anesthetic agents), or physical stress (exercise). RBF may or may not decrease, depending on the degree of vasoconstriction. For example, renal vascular resistance increases during low-intensity exercise to divert a greater portion of the cardiac output to the working muscles. Thus the fraction of cardiac output delivered to the kidneys decreases; however, because cardiac output also increases in response to exercise, total RBF remains unchanged.<sup>93</sup> In contrast, during halothane anesthesia in ponies, redistribution of cardiac output occurs without an increase in cardiac output. Under these circumstances, renal vasoconstriction is accompanied by a decrease in RBF to about 60% of the awake value at 1.0 to 1.5 minimal alveolar concentration of halothane. As the plane of anesthesia deepens (to 2.0 minimal alveolar concentration), a greater increase in renal vascular resistance (or degree of vasoconstriction) further decreases RBF to about 25% of the awake value, likely because of further vasodilatation of other vascular beds and a mild decrease in cardiac output.<sup>89</sup> Although RBF was not measured, results of a recent study of prolonged (18 hours) anesthesia with sevoflurane are of interest in terms of probable renal hypoperfusion and damage.<sup>114</sup> After 10 hours of anesthesia an increase in urine production

TABLE 19-4

<sup>a</sup>Cl<sub>Diodrast</sub>: Clearance of 3,5-diiodo-4-pyridine-N-acetic acid; Cl131<sub>I-o-HA</sub>: clearance of <sup>131</sup>I-o-iodohippurate; Cl<sub>PAH</sub>: clearance of *p*-aminohippurate; Cl99<sub>mTc-MAG3</sub>: clearance of 99mTc-mercaptoacetyltriglycine.

<sup>b</sup>RBF values presented have been calculated from effective renal plasma flow (ERPF) data using extraction ratios (ERs) of 0.80 for diodrast and 0.91 for <sup>131</sup>I-o-iodohippurate and *p*-aminohippurate: RBF = (ERPF/ER)/(1-hematocrit); hematocrit was assumed to be 0.35.

<sup>c</sup>Other horses and ponies also were studied after bolus injection of <sup>131</sup>I-o-iodohippurate and yielded ERPF values of 16.93 ± 6.05 and 10.65 ± 2.73 ml/min/kg for ponies and horses, respectively; these values corresponded to a RBF of 8.6 ± 10.2 ml/min/kg in ponies and 18.0 ± 4.6 ml/min/kg in horses.

<sup>d</sup>Values estimated from figure.

<sup>e</sup>Sex not reported.

<sup>f</sup>RBF values for microsphere studies are expressed in units of milliliters per minute per 100 g of kidney tissue; a value of 500 ml/min/100 g would correlate to an RBF value of 18 ml/min/kg (or 3.6 and 9 L/min for a 200-kg pony and a 500-kg horse, respectively).

<sup>g</sup>Values reported are for ponies under general anesthesia (halothane in oxygen); these authors also reported that renal medullary blood flow was 2.6% to 18.8% of total RBF in two ponies.

was accompanied by evidence of tubular dysfunction (e.g., glucosuria, enzymuria). Furthermore, microscopic lesions after anesthesia were limited to the more distal nephron (mTAL and distal tubule), providing support that these normally hypoxic nephron segments may be the first to succumb to prolonged hypoperfusion.

When RBF decreases, counteracting vasodilatory mediators usually are released in an attempt to ameliorate the decrease in RBF. The best studied of these vasodilatory mediators include renal prostaglandins (PGE<sub>2</sub> and PGI<sub>2</sub>) and dopamine. Although

the role of renal prostaglandins in the control of basal or resting RBF is thought to be insignificant, renal prostaglandins are important mediators of vasodilatation in response to a number of vasoconstrictive stimuli.<sup>115</sup> Furthermore, production of renal prostaglandins is several times greater in medullary tissue so that action of these mediators leads to a greater increase in inner cortical (region of juxtamedullary glomeruli) and medullary blood flow. As mentioned previously, one should not be surprised that the lesion associated with antagonism of prostanoid production by use of NSAIDs is medullary or

## Reported Values for Glomerular Filtration Rate in Horses and Ponies—cont'd

Number of Animals	Method <sup>a</sup>	Glomerular Filtration Rate (GFR) (Mean ± SD/SE ml/min/kg [Range])	Cl <sub>crend</sub> /Cl <sub>In</sub> Ratio <sup>a</sup>	Reference
30 Horses (7 ♂, 23 ♀)	Cl <sub>In</sub>	1.73	1.03 <sup>c</sup>	110
	Cl <sub>CRend</sub>	1.79		
6 Pony foals (3 ♀, 3 ♂)	Cl <sub>In</sub>	3.21 ± 0.36 (2.73-3.64)	0.60 <sup>c</sup>	99
	Cl <sub>CRend</sub>	1.92 ± 0.14 (1.60-2.14)		
5 Horses	Cl <sub>99mTc-DTPA</sub>	3.3 ± 0.4	—	111
6 ♀ Horses	Cl <sub>CRend</sub>	1.20-1.87	—	112 <sup>a</sup>

<sup>a</sup>Cl<sub>In</sub> ' Inulin clearance; Cl<sub>CRend</sub> ' endogenous creatinine clearance; Cl<sub>125I-iothalamate</sub> ' clearance of <sup>125</sup>I-iothalamate; Cl<sub>99mTc-DTPA</sub> ' clearance of 99mTc-diethylenetriamine pentaacetic acid (99mTc-DTPA); Cl<sub>14C-In</sub> ' clearance of <sup>14</sup>C-inulin; Cl<sub>CRex</sub> ' exogenous creatinine clearance; Cl<sub>99mTc-DTPA(cam)</sub> ' clearance of 99mTc-DTPA determined by serial imaging at the body surface with a gamma camera.

<sup>b</sup>Values taken from Knudsen.<sup>85</sup>

<sup>c</sup>Values presented have been calculated from original data.

<sup>d</sup>Low GFR values were attributed to rapidly declining plasma inulin concentrations (nonsteady state conditions) during the urine collection periods.

<sup>e</sup>Sex not reported.

<sup>f</sup>Other horses and ponies also were studied after bolus injection of <sup>125</sup>I-iothalamate and yielded GFR values of 5.39 ± 1.79 and 3.44 ± 1.11 ml/min/kg for ponies and horses, respectively.

<sup>g</sup>Attempts at measuring GFR by plasma disappearance after bolus injection of inulin were unsuccessful.

<sup>h</sup>Value presented is for control group; GFR was not different after phenylbutazone administration (1.36 ± 0.04 ml/min/kg) or phenylbutazone and furosemide administration (1.44 ± 0.12 ml/min/kg) but was reported to increase to 1.75 ± 0.16 ml/min/kg after water loading (25 L) and to 1.77 ± 0.18 ml/min/kg after water loading and phenylbutazone administration.

<sup>i</sup>Ponies were anesthetized during the studies.

<sup>j</sup>Mares studied before, during, and after 1.2 minimum alveolar concentration halothane anesthesia.

<sup>k</sup>Value calculated from urinary clearance values for inulin and creatinine (Cr).

<sup>l</sup>Despite correction for differences in depth (right kidney closer to lateral body surface than left kidney), the clearance of 99mTc-DTPA determined by serial imaging at the body surface with a gamma camera showed a greater (~60% total) GFR by the right kidney compared with the left kidney (~40% of total). Because similar differences have not been demonstrated in microsphere studies of renal blood flow (RBF) (in which both kidneys receive equal blood flow), this technique requires further refinement before it can be used to provide accurate measures of GFR in horses.

papillary necrosis.<sup>116,117</sup> With or without renal vasoconstriction, activation of dopamine receptors (DA<sub>1</sub> type) leads to renal vasodilatation. Because the receptors are located on most renal arterioles, blood flow increases in the renal cortex and the medulla. For this reason, dopamine infusions are touted to be of benefit in treating ARF because this catecholamine has been shown to increase RBF and urine output by 30% to 190% in normal horses.<sup>98</sup>

## GLOMERULAR FILTRATION

Approximately 20% of the blood entering the glomeruli passes through small pores in the filtration barrier into Bowman's capsule. The primary force driving filtration is glomerular capillary transmural hydraulic pressure. A relatively constant pressure across the glomerular capillary wall is maintained by greater resistance in the arteriole leaving the glomerulus (efferent arteriole) than in the arteriole entering the glomerulus (afferent arteriole). This difference in vascular resistance generates the hydraulic pressure that forces plasma water out of the glomerular capillaries.<sup>1</sup> The filtration barrier is made up of three layers: (1) endothelium of the glomerular capillaries, (2) basement membrane, and (3) foot processes of the epithelial cells (podocytes) lining Bowman's capsule. The pore size of the filtration barrier, about 8 to 10 nm in diameter, prevents filtration of cells and larger proteins. As a result, the fluid that enters Bowman's capsule is an ultrafiltrate that is essentially identical to plasma except that it has less than 0.05% of the protein content of plasma. Interestingly, the diameter of albu-

min is about 6 nm, so its size should not prevent filtration. Glycosaminoglycans containing heparin sulfate and sialic acid residues impart a significant negative charge to the filtration barrier. Thus charge repulsion of albumin (which is similarly negatively charged) may be more important than molecular size in preventing significant loss of albumin into the filtrate; however, metabolic disturbances (metabolic acidosis) can neutralize the glomerular charge barrier, and one can observe transient proteinuria in the absence of structural damage to the glomerular barrier.<sup>118</sup>

By definition, glomerular filtration rate (GFR) is the volume of plasma filtered per unit of time and commonly is described in milliliters per minute per kilogram of body mass. The GFR of horses and ponies ranges between 1.6 to 2.0 ml/kg/min, with some authors reporting slightly higher values for ponies. This range is similar to those of other animals and human beings. For a 500-kg horse this value equals 800 to 1000 ml per minute or about 1200 to 1400 L per day. This value represents filtration of the total plasma volume 60 to 70 times per day. Because urine production is about 10 L per day, more than 99% of the glomerular filtrate is reabsorbed.

Like RBF, GFR has been measured in horses by a variety of techniques, including Cl<sub>In</sub> by classic clearance techniques, Cl<sub>Cr</sub>, and clearance or plasma disappearance of radionuclides (see Table 19-5).<sup>\*</sup> Plasma disappearance curves for 99mTc-diethylenetriamine pentaacetic acid (99mTc-DTPA) have been

<sup>\*</sup>References 1, 25-27, 85-88, 91, 93, 96-110, 113-115, 119, 120.

documented to compare well in normal horses with  $Cl_{in}$  (the gold standard).<sup>96</sup> Although this technique is less expensive than  $^{131}I$ -orthoiodohippuric acid clearance for estimating RBF,<sup>113</sup> clinical use is limited by availability of nuclear medicine capabilities and expense (because one must take multiple measurements to assess disease progression or response to treatment). Recently, Gleadhill et al.<sup>120</sup> described use of a three blood sample technique to estimate GFR by plasma disappearance of  $^{99m}Tc$ -DTPA. Interestingly, rather than expressing GFR on the basis of per kilogram of body mass or a body surface area, they suggested that GFR should be compared with extracellular fluid volume. Because plasma activity of  $^{99m}Tc$ -DTPA also can be used to estimate extracellular fluid volume, one can make this estimate of GFR using  $^{99m}Tc$ -DTPA alone. Standardization of GFR based on extracellular fluid volume is attractive and warrants further consideration because it eliminates the effect of variable body composition (e.g., specifically differences in body fat) when expressing GFR based on body mass. The authors subsequently used this method to estimate the decrease in GFR accompanying exercise.<sup>111</sup>

The mechanisms responsible for control of RBF (autoregulation, neural input, hormonal factors) also play a role in control of GFR. In addition, GFR is affected further by factors such as plasma protein concentration (oncotic pressure) and alterations in the filtration barrier. As discussed previously, a balance exists between that action of vasoconstrictor and vasodilator substances during periods of decreased RBF. Interestingly, GFR decreases less than RBF with moderate to severe renal vasoconstriction. This sparing effect on GFR has long been attributed to greater vasoconstrictive effects of angiotensin II on efferent arterioles compared with afferent arterioles.<sup>121</sup> Such a response could increase the glomerular capillary transmural hydraulic pressure driving filtration and would be manifested by an increase in filtration fraction. In fact, the latter response has been documented in exercising horses.<sup>93</sup> More recently, however, other vasoconstrictors (endothelins) and vasodilators (endothelium-derived relaxing factors, nitric oxide) have been shown to play a role in the control of glomerular capillary hemodynamics and filtration so that a singular role for angiotensin II is likely an oversimplified explanation for the sparing effect on GFR.<sup>122</sup>

## RENAL TUBULAR FUNCTION

Once the glomerular filtrate enters the renal tubule, it is modified extensively in the process of becoming the final product excreted into the renal pelvis. A complete review of renal tubular function is beyond the scope of this text; however, a few general concepts warrant mention, and a number of specific aspects are addressed elsewhere in this chapter. First, most glucose, amino acid, electrolyte, and water reabsorption occurs across epithelial cells lining the proximal tubule; however, these substances are not all reabsorbed to the same extent. For example, this tubule segment is responsible for reabsorption of essentially all filtered glucose and amino acids, about 90% of filtered bicarbonate, about 70% of filtered sodium, and about 60% of filtered chloride.<sup>28</sup> Furthermore, at the end of the proximal tubule, fluid is no more concentrated than it was in Bowman's space. Tubular sodium concentration is unchanged, whereas tubular chloride concentration actually has increased (because of preferential bicarbonate reabsorption). Despite limited modification of these tubular fluid components, net reabsorption of between 60% and

80% of the total filtered load of sodium, chloride, and water occurs within the proximal tubule. Proximal tubular epithelial cells are also responsible for secretion of ammonium ions and a number of organic anions and cations, as described previously.

Tubular fluid passing into the loop of Henle becomes progressively more concentrated (hypertonic) as it travels to the inner medulla because the descending limb is permeable to water, urea, and electrolytes (the latter to a lesser degree).<sup>28</sup> In contrast, the ascending limb is relatively impermeable to water but actively reabsorbs sodium, chloride, and potassium via the apical  $Na^+/K^+/2Cl^-$  co-transporter (blocked by furosemide), which is coupled to  $Na^+,K^+$ -ATPase on the basolateral membrane. As a result, fluid leaving this nephron segment is actually less concentrated (hypotonic) than the original filtrate. The loop of Henle is responsible for reabsorption of an additional 15% to 20% of filtered sodium and chloride, along with addition of urea to the tubular fluid. More important, the loop of Henle is responsible for generation of the medullary osmotic gradient via countercurrent multiplication. This function results from the combined effects of different permeability characteristics of the descending and ascending limbs of the loop of Henle and active removal of sodium and chloride in the ascending limb.

The distal tubule is quantitatively less important in reabsorption of electrolytes and water; however, the distal tubule is the nephron segment in which the final qualitative changes in urine occur.<sup>28</sup> For example, the distal tubule is an important site of calcium, potassium, and acid excretion. The latter two typically are exchanged for sodium under the influence of aldosterone. Tubule fluid passes from the distal tubule into the outer or cortical collecting ducts, which are impermeable to urea. In addition to further modification of fluid in the cortical collecting ducts, tubular urea concentration increases steadily as water is removed (under the influence of vasopressin) as fluid travels to the inner medulla. In contrast, in the absence of vasopressin (as with diabetes insipidus), the collecting ducts are impermeable to water and produce hypotonic urine. The collecting ducts remain impermeable to urea (which accounts for up to 50% of the osmoles in urine) except for the innermost medullary segments, which allow urea to be recycled into the interstitium for maintenance of the medullary osmotic gradient.

Reabsorption of glomerular filtrate by renal tubules requires a close association with the vascular system that carries reabsorbed solute and water to the circulation. Proximal tubules are adjacent to peritubular capillaries, which have a tremendous capacity to accommodate the massive flux of solute and water across proximal tubule epithelial cells. Equally important in maintenance of the medullary osmotic gradient are the vasa recta, hairpin capillaries that travel deep into the renal medulla in association with loops of Henle derived from the population of juxtamedullary nephrons. Blood flow through these capillaries is typically slow, allowing for countercurrent exchange of solute in the medullary interstitium, which is necessary for generation and maintenance of medullary hypertonicity. Urea leaving the descending limb of Henle and being recycled across the innermost portion of the medullary collecting duct is responsible for about half of this medullary hypertonicity.

These basic aspects of tubular function have a number of important clinical implications. First, proximal tubule epithelial cells have a high metabolic rate. Although most of the

proximal tubule is in the more highly perfused renal cortex, renal hypoperfusion leads to a relative hypoxia surrounding these cells because of ongoing metabolic activity. Consequently, the proximal tubule is highly susceptible to injury when cortical blood flow is reduced (e.g., with hypovolemia or other states accompanied by a decrease in RBF). Second, as discussed previously, the renal medulla receives only a small fraction of the total RBF, leading to a normally hypoxic local environment. Thus any degree of renal hypoperfusion also is accompanied by exacerbation of medullary hypoxia, especially in the inner stripe because of the metabolic activity of epithelial cells lining the mTAL. In fact, in cases of ARF in human beings, histologic examination of renal tissue actually may show more severe lesions in the more distal nephron (mTAL) rather than in the proximal tubule.<sup>123</sup> Recognition of this more distal tubular damage has also led to consideration of therapeutic interventions to reduce damage to this nephron segment during periods of poor renal perfusion (e.g., continuous infusion of furosemide to decrease the metabolic activity of the mTAL). Third, despite the fact that the distal tubule and collecting ducts are responsible for reabsorption of less than 5% of the total glomerular filtrate, a decrease in reabsorption of only 1% to 2% can be quantitatively significant and can lead to dramatic polyuria (see Polyuria and Polydipsia, later in this chapter). Next, generation of a maximal medullary concentration gradient requires slow flow of tubular fluid for countercurrent multiplication and slow flow of blood through the vasa recta to maximize countercurrent exchange. Thus conditions that increase tubular flow rates (high-volume intravenous fluids) or increase vasa recta blood flow (endogenous PGE<sub>2</sub> and PGI<sub>2</sub> production consequent to renal hypoperfusion) compromise the medullary concentration gradient (partial medullary washout) and lead to production of more dilute urine with increased urinary sodium concentration (and excretion).

A final aspect of tubular function that appears to be unique to horses among the domestic species is excretion of calcium. Equine urine is well recognized as being cloudy and viscid. These qualities can be attributed to the large amount of calcium excreted in normal equine urine, largely in the form of calcium carbonate (CaCO<sub>3</sub>) crystals, and mucus secreted by glands in the renal pelvis and proximal ureter that acts to “lubricate” the lower urinary tract to minimize adherence of crystal to the epithelium lining the ureters, bladder, and urethra. Although the nature of this unique tubular calcium excretion has been studied little in horses, one report of the role of vitamin D in calcium and phosphorous homeostasis in horses suggested that this vitamin-hormone was less important in horses than in other species.<sup>124</sup> This fascinating difference between horses and other species evaluated by large animal internists clearly warrants further investigation.

## EXCRETION OF SOLUTE AND WATER

Renal function traditionally is thought of in terms of glomerular filtration, tubular modification of the filtered fluid, and excretion of the final urine. This concept accommodates excretion of nitrogenous and organic wastes and the major aspects of regulation of body water content and ionic balance. Urine concentration and volume also are affected by solute excretion, and another way to think about renal function is in terms of total solute and water excretion. For example, a horse

could produce 6 L of urine daily with an osmolality of 900 mOsm/kg to excrete 5400 mOsm of solute or, if the solute load were doubled to 10,800 mOsm, then the horse could produce 12 L of urine with an osmolality of 900 mOsm/kg to eliminate the additional solute. Thus urine osmolality reflects the ability of the kidney to dilute or concentrate the final urine but does not necessarily provide an accurate estimate of the “quantitative ability” to excrete solute or retain water. One assesses these functions by calculating osmolal clearance ( $C_{\text{osm}}$ ) and free water clearance ( $C_{\text{H}_2\text{O}}$ ).<sup>28</sup> Like other clearances, these calculations require measurement of urine flow (via timed urine collection) and measurement of plasma and urine osmolality.

These measures of renal solute and water handling are conceptualized by considering urine to have two components: (1) that which contains all the urinary solute in a solution that is isosmotic to plasma ( $C_{\text{osm}}$ , usually expressed in milliliters per minute or liters per day), and (2) that which contains free water without any solute ( $C_{\text{H}_2\text{O}}$ , also expressed in milliliters per minute or liters per day). The sum of these two components is the actual urine flow rate in milliliters per minute or liters per day. Because urine is typically more concentrated than plasma,  $C_{\text{H}_2\text{O}}$  typically has a negative value, indicating water conservation. In fact, the inverse of free water clearance is termed *renal water reabsorption*. Returning to the foregoing example, excretion of the 5400 mOsm would require production of 18 L of urine that is isosmotic with plasma (using a value of 300 mOsm/kg for plasma). However, because 6 L of concentrated urine actually was produced during the period measured, the kidneys quantitatively have reabsorbed 12 L of free water per day. In contrast, despite production of urine with an identical urine osmolality (900 mOsm/kg), excretion of 10,800 mOsm would require production of 36 L of urine isosmotic with plasma. Free water clearance would be 30 L per day (i.e., 30 L per day of free water would be reabsorbed by the kidneys). Thus although concentrated urine always will have a negative  $C_{\text{H}_2\text{O}}$  value, indicating renal water reabsorption, and dilute urine always will have a positive value for  $C_{\text{H}_2\text{O}}$ , indicating renal water excretion, quantitative assessment of renal solute and water handling requires measurement of osmolal and free water clearances.

Excretion of free water by the kidney occurs by generation of hypotonic tubule fluid in the ascending limb of the loop of Henle, and the amount or volume of free water produced depends on the amount of tubule fluid presented to that segment. Free water consequently is excreted by keeping the collecting ducts relatively impermeable to water (lack of vasopressin). Assessment of  $C_{\text{H}_2\text{O}}$  is most helpful in patients with hyponatremia and hypo-osmolality that cannot be attributed to another primary disease process (diarrhea or bladder rupture). For hyponatremia to develop, water excretion must be defective. For example, hyponatremia can develop with prerenal failure (hypovolemia) or with oliguric renal failure after a reduction in GFR and the amount of filtrate presented to the loop of Henle. Hyponatremia and hypo-osmolality may also develop with use of loop diuretics, because less free water is generated in the ascending limb of the loop of Henle because of blockade of the apical Na<sup>+</sup>/K<sup>+</sup>/2Cl<sup>-</sup> co-transporter (smaller amounts of solute are removed). A final cause of true hyponatremia may be the syndrome of inappropriate vasopressin secretion or syndrome of inappropriate antidiuretic hormone secretion. Although the latter condition has not been documented in horses, occasionally it may play a role in the development of hyponatremia in a foal.<sup>125</sup>

## EXAMINATION OF THE URINARY SYSTEM

Harold C. Schott II

### 🌀 HISTORY AND PHYSICAL EXAMINATION

To begin the evaluation of a horse with urinary tract disease, one should collect a complete history and perform a thorough physical examination. Important historical information includes duration and type of clinical signs, number of horses affected, diet, medications administered, and response to treatment. One also should assess water intake and urine output. For example, owners may mistake pollakiuria (frequent urination) for polyuria (increased urine production), and distinguishing between the two is helpful for forming a diagnostic plan. Pollakiuria frequently occurs in females during estrus or in either sex of horse with cystic calculi or cystitis. In contrast, polyuria more often accompanies renal disease, pituitary pars intermedia dysfunction (PPID), behavior problems (primary polydipsia), diabetes insipidus, or diabetes mellitus. Astute owners may note increased thirst after exercise or a change in urine character, such as a clearer stream, to support polydipsia and polyuria.

One can determine water intake over 24 hours by turning off any automatic-watering devices and providing a known volume of water to the horse.<sup>1</sup> Water intake can vary widely with environmental conditions, level of activity, and diet (see Renal Physiology) so that repeated measurements over several 24-hour periods may be more rewarding in documenting average daily water consumption. Urine output, which should range between 5 and 15 L in a horse with normal renal function, is more difficult to determine. One can apply a urine collection harness for 24-hour urine collections<sup>2-5</sup>; alternatively, one can use an indwelling Foley catheter attached to a collection apparatus to quantify urine output in mares. Although horses used for research tolerate these devices fairly well, the devices have limited application to clinical patients. One can construct a practical collection device for geldings and stallions by cutting off the bottom of a large plastic bottle, padding it, and fitting it over the prepuce. One covers the opening of the bottle with a rubber tube and clip; urine can be removed every few hours.<sup>6</sup> During the collection period, horses usually are tied or restrained in stocks to minimize interference with the collection device.

The most common presenting complaints for horses with urinary tract disease are weight loss and abnormal urination. Other clinical signs vary with the cause and site of the problem and may include fever, anorexia, depression, ventral edema, oral ulceration, excessive dental tartar, colic, or scalding or blood staining of the perineum or hindlimbs. Although lumbar pain and hindlimb lameness have been attributed to urinary tract disease, a musculoskeletal problem is the usual cause of these clinical signs. Decreased performance may be an early presenting complaint for renal disease, but poor performance likely results from changes associated with uremia (mild anemia and lethargy) rather than from renal pain. Occasionally a horse with urolithiasis or renal neoplasia may have a history of recurrent colic. Prolonged or repeated posturing to urinate and dysuria or hematuria would be important findings

to implicate the urinary tract as the probable source of abdominal pain in such patients.

In addition to a thorough physical examination, one should include rectal palpation in the evaluation of all horses with suspected urinary tract disease. One should palpate the bladder to determine size, wall thickness, and presence of cystic calculi or mural masses. If the bladder is full, then one should palpate the bladder again after bladder catheterization or voiding. One can palpate the caudal pole of the left kidney for size and texture. The ureters generally are not palpable unless enlarged or obstructed by disease, but one should palpate the dorsal abdomen (retroperitoneal course of ureters) and trigone to determine if they are detectable. Dilation of a ureter may occur with pyelonephritis or ureterolithiasis; in mares, palpation of the distal ureters through the vaginal wall may be more rewarding. One also should palpate the reproductive tract to assess whether a reproductive problem could be causing the clinical signs.

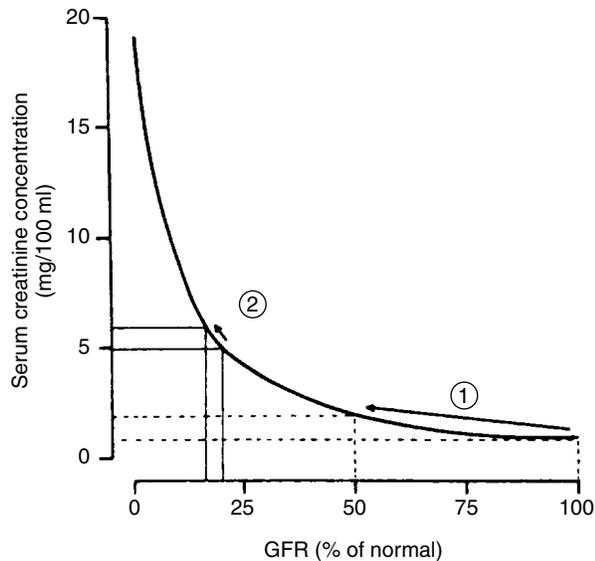

### 🌀 HEMATOLOGY AND SERUM BIOCHEMISTRY

A complete blood count (CBC) that reveals an elevated white blood cell count and total protein or fibrinogen concentration would support an inflammatory or infectious disease process. One may observe mild anemia (packed cell volume [PCV], 20% to 30%) consequent to decreased erythropoietin production and a shortened red blood cell (RBC) life span in horses with CRF.

BUN and Cr concentrations are the most commonly used indices of renal function, specifically GFR.<sup>7-9</sup> One must remember that BUN and Cr do not increase until the majority of nephrons (generally considered about 75%) become nonfunctional.<sup>10</sup> Although this commonly used percentage is based on studies of partially nephrectomized laboratory animals, several clinical reports in which unilateral nephrectomy was used successfully to manage disorders of the upper urinary tract support a similar renal reserve capacity in horses.<sup>11-15</sup> In addition, renal function remained within normal ranges, and animals maintained body weight after experimental unilateral nephrectomy in ponies<sup>16</sup> and in horses.<sup>17</sup> Thus measurement of BUN and Cr is of little use in evaluating early or minor changes in GFR. Once elevated, however, small increases in BUN and Cr are more sensitive indicators of further deterioration in GFR, because one can interpret doubling of BUN or Cr as a 50% decline in remaining renal function (Figure 19-10).

Urea can be measured by a variety of methods, categorized broadly as direct or indirect analyses.<sup>7,8</sup> The direct method is the diacetyl monoxime reaction, in which urea reacts with diacetyl after hydrolysis of diacetyl monoxime to diacetyl and hydroxylamine. One determines urea concentration spectrophotometrically by measuring the yield of the yellow diazine reaction product. Indirect analysis is based on enzymatic conversion of urea to ammonia and carbonic acid by urease. Several methods exist for subsequently determining ammonia concentration, and the one used most often is the enzyme-coupled reaction with glutamate dehydrogenase. Although the term *BUN* is widely accepted, one must remember that the actual measurement reported is the urea concentration in serum or plasma.

Cr can also be assayed by several methods, but the one used most often is the Jaffe's reaction, which is a colorimetric assay based on the formation of a complex between Cr and alkaline

**FIGURE 19-10** Relationship between glomerular filtration rate (GFR) and serum creatinine (Cr). When renal function is normal, a large decrease in GFR (as with acute renal failure) results in a minor increase in Cr (arrow 1). In contrast, when renal function is decreased (as with chronic renal failure [CRF]), a much smaller decrease in GFR results in a similar increase in Cr (arrow 2). (From Brenner BM, editor: Brenner and Rector's the kidney, ed 8, Philadelphia, 2008, WB Saunders.)

picrate.<sup>7-9</sup> Unfortunately, a number of other substances in plasma or serum contribute to the yellow color, which leads to a 20% overestimation of actual Cr in human beings and in horses.<sup>18</sup> These non-Cr chromagens include glucose, pyruvate, acetoacetate, fructose, uric acid, and ascorbic acid. Interference by non-Cr chromagens is greatest when Cr is in the normal range, which leads to a high coefficient of variation in repeated measurements of the same sample. With azotemia, Cr measurement by the Jaffe's reaction becomes more accurate because the contribution from non-Cr chromagens does not increase significantly (non-Cr chromagens are responsible for less than 5% of the color development when Cr is >5.0 mg/dl). Non-Cr chromagens do not interfere significantly with urine Cr measurement.

In addition to the factors discussed in the preceding section that influence urea and Cr metabolism (see Renal Physiology), spurious increases in Cr may be reported in various metabolic disorders or after administration of certain cephalosporin antibiotics.<sup>8</sup> When such increases in Cr are thought to be spurious, one can measure true Cr by several methods, which include use of an automated analyzer that distinguishes Cr and non-Cr chromagens by their different rates of color development or performance of the Cr imidohydrolase enzyme assay. The latter yields ammonia, which can be quantified by colorimetric methods. As an example, Cr measured by the Jaffe's reaction increased 16% after horses were fasted for 3 days; however, when serum was analyzed by the enzymatic method, no increase in Cr was detected.<sup>18</sup> In addition to spurious increases in Cr, other substances can cause spurious decreases in serum Cr. The most common one is bilirubin, which, when greater than 5.0 mg/dl, may decrease measured Cr by 0.1 to 0.5 mg/dl.<sup>8</sup>

The reporting of serum or plasma urea and Cr concentrations also varies between different countries. In the United States, BUN and Cr are reported in milligrams per deciliter, whereas in other parts of the world they are reported in standard international units of millimoles per liter and micromoles per liter, respectively. One can convert BUN from milligrams per deciliter to millimoles per liter and Cr from milligrams per deciliter to micromoles per liter by multiplying by 0.357 and 88, respectively.<sup>8</sup>

*Azotemia* is the term used to describe an elevation in BUN and Cr; thus it is strictly a laboratory abnormality. Azotemia can be prerenal in origin because of decreased renal perfusion, it may be attributable to primary renal disease, or may accompany obstructive diseases or disruption of the urinary tract (postrenal azotemia).<sup>10,19</sup> Thus one should interpret BUN and Cr in light of hydration status of the patient, presenting complaint, and physical findings. In general, animals with prerenal azotemia tend to have smaller increases in BUN and Cr than animals with intrinsic renal failure, whereas animals with postrenal failure may have the greatest degree of azotemia.<sup>20</sup> Unfortunately, BUN and Cr can cover a wide range of values for all three categories of azotemia; thus specific ranges do not identify the type of azotemia.<sup>20-23</sup> In an attempt to characterize azotemia better, use of the BUN-to-Cr ratio also has been examined. In theory the ratio should be higher for prerenal azotemia (because of increased reabsorption of urea with low tubule flow rates) and postrenal azotemia (because of preferential diffusion of urea across peritoneal membranes in cases of uroperitoneum) than for azotemia associated with intrinsic renal failure. As for categoric values for BUN and Cr, BUN-to-Cr ratios measured in azotemic dogs with naturally occurring diseases were distributed over wide, nondiscriminatory ranges for all three types of azotemia.<sup>20,21</sup> In horses the BUN-to-Cr ratio more often has been used to separate ARF from CRF. In the acute form of renal failure, Cr tends to increase proportionately more than BUN, leading to a BUN-to-Cr ratio of less than 10:1.<sup>24</sup> In contrast, with CRF, the BUN-to-Cr ratio often exceeds 10:1. Although a clear explanation for this difference has not been established, the difference may be related to different volumes of distribution for urea and Cr. Urea, a nonpolar molecule, diffuses freely into all body fluids, whereas Cr, a charged molecule, likely requires longer to diffuse out of the extracellular fluid space. Thus a sudden decrease in renal perfusion leads to a greater increase in Cr than in BUN. Muscle breakdown or damage, as with rhabdomyolysis, may be an additional factor contributing to the rapid increase in serum Cr. Furthermore, the BUN-to-Cr ratio value provides only a suggestion of the duration of azotemia in horses, because one can find exceptions for acute and CRF. Finally, the BUN-to-Cr ratio also may be useful in assessing adequacy of dietary protein intake in cases of CRF (see Chronic Renal Failure).<sup>25</sup>

The terms *prerenal azotemia* and *prerenal failure* describe the reversible increase in BUN and Cr associated with renal hypoperfusion.<sup>10,19,23,26</sup> Although these terms are entrenched firmly in human and veterinary medical literature, they likely contribute to the failure to recognize the renal damage that accompanies a number of medical and surgical conditions. Lack of recognition is attributable to the large renal functional reserve. In fact, in many cases of prerenal failure, one can demonstrate altered glomerular and tubule function by proteinuria and cast formation, impaired concentrating ability, and changes in electrolyte excretion.<sup>27,28</sup> Although such functional alterations are usually reversible, a degree of permanent

nephron loss can occur and could explain the finding of microscopic evidence of renal disease in as many as one third of equine kidneys examined.<sup>29</sup> Thus considering prerenal failure as a transient and reversible period of compromised renal function that can lead to permanent but clinically silent decreased renal functional mass may be more appropriate. Furthermore, periods of decreased RBF or prerenal failure are accompanied by a number of compensatory renal responses that are mobilized to preserve RBF (autoregulatory response of the afferent arterioles) and GFR (increase in filtration fraction because of angiotensin II-mediated efferent arteriolar constriction). In addition, increased intrarenal production of vasodilatory prostaglandins (PGE<sub>2</sub> and PGI<sub>2</sub>) is an important response to renal ischemia that maintains or even increases medullary blood flow (see Renal Physiology). Thus one also can consider prerenal failure as a period of decompensation from the numerous renal compensatory responses to hypoperfusion.<sup>30</sup>

Prerenal azotemia traditionally is differentiated from intrinsic renal failure by assessing urinary concentrating ability. With prerenal azotemia, maintenance of urinary concentrating ability is demonstrated by a urine specific gravity greater than 1.020 and urine osmolality exceeding 500 mOsm/kg. In contrast, urinary concentrating ability typically is lost with intrinsic renal failure, and urine specific gravity and osmolality are less than 1.020 and 500 mOsm/kg, respectively, in the face of dehydration.<sup>31</sup> Such assessment is challenging, however, because it is valid only when performed on urine collected before initiation of fluid therapy or administration of any of a number of medications ( $\alpha_2$ -receptor agonists, furosemide) that can affect urine flow and concentration.<sup>32-35</sup> In addition to these measures of urinary concentrating ability, urine-to-serum ratios of osmolality, urea nitrogen and Cr concentrations, and fractional sodium clearance may provide useful information to differentiate prerenal azotemia from intrinsic renal failure (Table 19-6).<sup>31,32</sup> For example, urine-to-serum Cr ratios exceeding 50:1 (reflecting concentrated urine) and fractional sodium clearance values less than 1% (indicating

adequate tubule function) would be expected in horses with prerenal azotemia, whereas ratios less than 37:1 and clearance values greater than 0.8% were reported in a group of horses determined to have primary renal disease.<sup>31</sup> Although these values can be helpful, the data in Table 19-6 illustrate that renal hypoperfusion is accompanied by a progressive loss of concentrating ability, because the ranges of these ratios tend to be lower for horses with prerenal azotemia than for clinically normal horses. Thus these data also support the concept that the progression from prerenal failure to intrinsic renal failure is associated with decompensation of the intrarenal responses to hypoperfusion.<sup>30</sup> Clinically, this decompensation is recognized as persistence of azotemia, whereas prerenal azotemia rapidly resolves (by 30% to 50% within 24 hours and completely by 72 hours) in response to fluid therapy and other supportive treatments.

In patients at risk for developing ARF, including horses with serious gastrointestinal disorders, or rhabdomyolysis and in those receiving nephrotoxic medications, serial assessment of urine specific gravity or osmolality, sodium concentration, and fractional sodium clearance may be useful in identifying significant changes in renal function before the onset of azotemia. Similarly, if one determines urine flow rate during a timed urine collection period, then assessment of renal water reabsorption ( $C_{H_2O}$ ; see Renal Physiology) can be a sensitive predictor of impending renal failure.<sup>36-38</sup> Unfortunately, monitoring of these parameters often is complicated by use of intravenous fluid support in such patients. Although intravenous fluids can complicate interpretation of many of these indexes of renal function, Roussel et al.<sup>32</sup> found that the urine-to-plasma osmolality ratio remained greater than 1.7:1 in healthy horses receiving 20 L of an intravenous polyionic solution over 4 hours. Thus serial measurement of urine specific gravity or osmolality may provide useful information for patients at high risk for ARF.

One usually considers a diagnosis of postrenal azotemia resulting from obstruction or disruption of the urinary tract based on clinical signs, including dysuria and renal colic. With bladder rupture, however, some affected foals and adult horses continue to void urine, although progressive abdominal distention usually accompanies development of uroperitoneum. One most often confirms urinary tract disruption by measuring a twofold or greater value for peritoneal fluid Cr concentration compared with Cr concentration. Occasionally in a foal with a urachal problem or a gelding with a disrupted urethra, postrenal azotemia may be accompanied by considerable swelling in the abdominal wall or in the prepuce, respectively.

In addition to screening for azotemia and concentrating ability, the laboratory database should include serum electrolyte, protein (albumin and globulin), and glucose concentrations, as well as muscle enzyme activity.<sup>8,19,22-26</sup> Hyponatremia and hypochloremia are common in horses with renal disease. Serum potassium concentration may be normal or may be elevated in cases of acute or CRF. Hyperkalemia is often most extreme and most serious with urinary tract disruption and uroperitoneum. Calcium and phosphorus concentrations vary in horses with renal disease. Hypercalcemia and hypophosphatemia often occur in horses with CRF, especially when they are fed alfalfa hay (see Chronic Renal Failure), whereas hypocalcemia and hyperphosphatemia are more common with ARF. With protein-losing glomerulopathies, albumin tends to be lost to a larger extent than the higher-molecular-weight globulin. One can find low total protein and albumin concentrations

TABLE 19-6

**Diagnostic Indices that may be Useful for Separating Prerenal from Renal Azotemia in Horses**

Diagnostic Index	Normal Horses	Prerenal Azotemia	Renal Azotemia
Urine osmolality (mOsm/kg)	727-145	458-961	226-495
Uosm/Posm	2.5-5.2	1.7-3.4	0.8-1.7
UUN/PUN	34.2-100.8	15.2-43.7	2.1-14.3
UCr/PCr	2.0-344.4	51.2-241.5	2.6-37.0
FCI <sub>Na</sub>	0.01-0.70	0.02-0.50	0.80-10.10

Modified from Grossman BS, Brobst DF, Kramer JW et al: Urinary indices for differentiation of prerenal azotemia and renal azotemia in horses, *J Am Vet Med Assoc* 180:284, 1982.

Uosm, Urine osmolality; Posm, plasma osmolality; UUN, urine urea nitrogen; PUN, plasma urea nitrogen; UCr, urine creatinine; PCr, plasma creatinine; FCI<sub>Na</sub>, fractional sodium clearance.

in severe cases of chronic renal disease, whereas other horses may have an increased globulin concentration consistent with a chronic inflammatory response. Hyperglycemia (values >150 to 175 mg/dl) after stress, exercise, sepsis, PPID, or diabetes mellitus can result in glucosuria.<sup>39,40</sup> Finally, when pigmenturia is a complaint, muscle enzyme activity measurements are helpful in differentiating myoglobinuria from hematuria or hemoglobinuria.

## URINALYSIS

One should perform urinalysis whenever one suspects urinary tract disease. One can collect urine as a midstream catch during voiding, via urethral catheterization, or via cystocentesis in foals. Unlike cows, horses cannot be stimulated easily to urinate, but they often urinate within a few minutes after being placed in a freshly bedded stall. Manual compression of the bladder during rectal palpation may stimulate urination after the rectal examination is completed. One should evaluate color, clarity, odor, viscosity, and specific gravity at the time of collection.<sup>41,42</sup> Normal equine urine is pale yellow to deep tan and often is turbid because of the large amounts of CaCO<sub>3</sub> crystals and mucus. Urine appearance commonly changes during urination, especially toward the end of micturition, when more crystals tend to be voided. If pigmenturia or hematuria is present, then noting the timing and duration of passage of discolored urine may help localize the source. Pigmenturia throughout urination is most consistent with myonecrosis or a bladder or kidney lesion, whereas passage of discolored urine at the start or end of urination more often occurs with lesions of the urethra or accessory sex glands (see Hematuria).

## ASSESSMENT OF URINE CONCENTRATION

Urine specific gravity is a measure of the number of particles in urine and is a useful estimate of urine concentration. Although determination of specific gravity with a refractometer is quick and easy (reagent strips should not be used to measure specific gravity in horses),<sup>41</sup> one must recognize that urine concentration is determined most accurately by measurement of urine osmolality, because the presence of larger molecules in urine, such as glucose or proteins, leads to overestimation of urine concentration by assessment of specific gravity. Clinically, overestimation is a problem in patients with diabetes or heavy proteinuria.<sup>43</sup> Urine specific gravity is used to separate urine concentration into three categories: (1) urine that is more dilute than serum (hyposthenuria or specific gravity <1.008 and osmolality < 260 mOsm/kg); (2) urine and serum of similar osmolality (isosthenuria or specific gravity of 1.008 to 1.014 and osmolality of 260-300 mOsm/kg); and (3) urine that is more concentrated than serum (specific gravity >1.014 and osmolality >300 mOsm/kg). Although urine of most normal horses is concentrated (three to four times more concentrated than serum with specific gravity of 1.025 to 1.050 and an osmolality of 900-1200 mOsm/kg), occasionally a normal horse produces dilute or highly concentrated urine. For example, in response to water deprivation for 24 to 72 hours, horses with normal renal function often produce urine with a specific gravity greater than 1.045 and an osmolality greater than 1500 mOsm/kg.<sup>44-46</sup> In contrast, foals typically have hyposthenuric urine consequent to their mostly milk diet.<sup>47</sup> Although the constant polyuria decreases the ability of the

neonate to generate a large osmotic gradient in the medullary interstitium, dehydrated foals still can produce urine with a specific gravity greater than 1.030. With chronic renal insufficiency the ability to produce concentrated (specific gravity >1.025) or dilute (specific gravity <1.008) urine is lost. Thus horses with CRF typically manifest isosthenuria. As discussed previously, urine specific gravity is helpful in differentiating prerenal from renal azotemia in horses that exhibit dehydration or shock after a number of disorders.

## REAGENT STRIP ANALYSIS

The pH of equine urine is usually alkaline (7.0 to 9.0 pH).<sup>41,42,48</sup> Vigorous exercise or bacteriuria can result in acidic pH. Bacteriuria can impart an ammonia odor to the urine secondary to breakdown of urea by bacteria with urease activity. Concentrate feeding generally decreases urine pH toward the neutral value.<sup>48</sup> Similarly, the more dilute the urine sample is, the closer the pH is to 7.0. The dilute urine produced by foals typically is neutral to mildly acidic and is relatively free of crystalline material. Interestingly, calcium oxalate crystals are more prevalent in urine of foals than in that of adults.<sup>49</sup> Occasionally, one detects aciduria in a dehydrated or anorectic horse. Although aciduria typically has been attributed to metabolic acidosis, many patients actually may have hypochloremic metabolic alkalosis accompanied by paradoxical aciduria. The mechanism for paradoxical aciduria is likely similar to that described in ruminants with abomasal outflow obstruction.<sup>50</sup> Briefly, after all chloride has been reabsorbed from the glomerular filtrate, further sodium reabsorption occurs by exchange with (excretion of) potassium or hydrogen ions. Thus paradoxical aciduria is most likely to occur with concomitant hypokalemia or whole-body potassium depletion.

Commercially available urine reagent strips can yield false-positive results for protein when one tests alkaline samples. Thus proteinuria can be assessed better by performing the semiquantitative sulfosalicylic acid precipitation test or by specific quantification with a colorimetric assay (e.g., the Coomassie brilliant blue dye method<sup>51</sup> or other assays that are used routinely on cerebrospinal fluid [CSF]). In normal mares a mean value of 3.2 mg/kg (1.6 g) per day and a range of 3.6 to 22.3 mg/kg (1.8 to 11.2 g) per day for urinary protein excretion have been reported by Schott, Hodgson, and Bayly<sup>52</sup> and by Kohn and Strasser,<sup>53</sup> respectively. These values translate into urinary protein concentrations of less than 100 mg/dl in most normal horses. Comparison of the quantitative protein result (milligrams per deciliter) to urine Cr concentration (milligrams per deciliter) in the form of a urine protein-to-Cr ratio also is recommended. This technique is more practical because it obviates timed urine collection. Although a normal range has not yet been reported for horses, values exceeding 1.0:1.0 and 3.5:1.0, respectively, are considered above normal for dogs<sup>54</sup> and indicate nephrotic range proteinuria in human beings.<sup>8</sup> Thus a urine protein-to-Cr ratio greater than 2:1 likely supports significant proteinuria in an equine patient. Proteinuria may occur with glomerular disease, bacteriuria, or pyuria or may transiently follow exercise.<sup>52</sup>

Normal equine urine should not contain glucose. Although the renal threshold for glucose has not been evaluated thoroughly in horses, an early study by Link<sup>55</sup> suggested that the threshold may be lower (about 150 mg/dl) than that of small animals and human beings. Thus glucosuria can accompany hyperglycemia associated with the causes described previously

or with administration of dextrose-containing fluids or parenteral nutrition products.<sup>39,40</sup> In addition, glucosuria may accompany sedation with  $\alpha_2$ -agonists or exogenous corticosteroid administration.<sup>33,34</sup> When one detects glucosuria in the absence of hyperglycemia, one should suspect primary tubule dysfunction. Glucosuria more often has been detected in horses with ARF (mostly in experimental models of nephrotoxicity) than in those with chronic renal disease. Unlike ruminants, ketones rarely are detected in equine urine, even in advanced catabolic states or with diabetes mellitus. A positive result for blood on a urine reagent strip can reflect the presence of hemoglobin, myoglobin, or intact RBCs in the urine sample. Evaluation of serum for hemolysis and of urine sediment for RBCs, combined with an ammonium sulfate precipitation test to detect myoglobin,<sup>56</sup> can be rewarding in differentiating between these pigments (see Hematuria). Finally, occasionally one detects bilirubinuria on reagent strip analysis of equine urine. Bilirubinuria is associated with intravascular hemolysis, hepatic necrosis, and obstructive hepatopathies. In most instances, one more commonly detects hemolysis and hepatic disease by abnormal biochemical data such as elevated serum bilirubin concentration and increased hepatic enzyme activity.

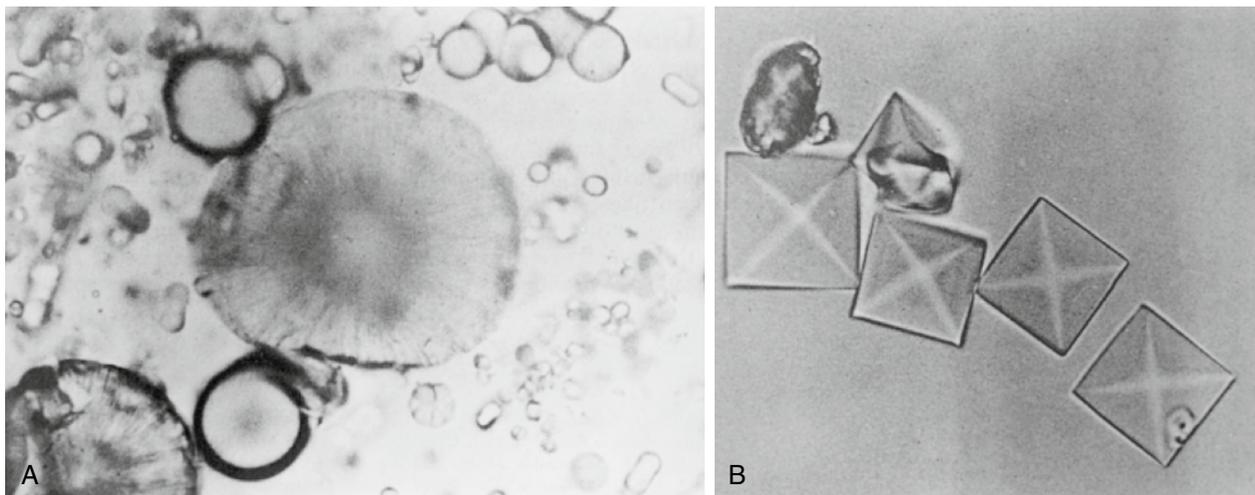

### SEDIMENT EXAMINATION

Sediment examination is probably the most underused diagnostic technique available for evaluation of urinary tract disorders in horses. In human beings, sediment examination has been demonstrated to be a useful predictor for occurrence and severity of ARF.<sup>57</sup> Unfortunately, a major limitation is that sediment should be examined within 30 to 60 minutes after collection. To perform sediment examination, 10 ml of fresh urine is centrifuged (usually in a conical plastic tube) at 1000 rpm for 3 to 5 minutes. The supernatant urine is discarded (or used for quantitative protein determination) and the pellet is resuspended in the few drops of urine remaining in the tube. A drop of sediment is transferred to a glass slide, and a

coverslip is applied. One first examines the sediment at low power to evaluate for casts and subsequently at high power to quantify erythrocytes, leukocytes, and epithelial cells, as well as to determine whether bacteria are present. Casts are molds of Tamm-Horsfall glycoprotein and cells that form in tubules and subsequently pass into the bladder. They are rare in normal equine urine but may be associated with inflammatory or infectious processes. Casts are unstable in alkaline urine; thus one should evaluate sediment as soon as possible after collection to ensure accurate assessment. Fewer than five RBCs per high-power field should be seen in an atraumatically collected urine sample. Increased numbers of urinary RBCs can result from inflammation, infection, toxemia, neoplasia, or exercise (see Hematuria). Pyuria (more than 10 white blood cells per high-power field) most often is associated with infectious or inflammatory disorders; normal equine urine should have few bacteria, if any. The absence of bacteria on sediment examination does not rule out their presence, however, and bacterial culture of urine collected by catheterization or cystocentesis (foals) should be performed when one suspects cystitis or pyelonephritis. Finally, equine urine is rich in crystals. Most of these are  $\text{CaCO}_3$  crystals of variable size, but calcium phosphate crystals and occasionally calcium oxalate crystals also are visible in normal equine urine (Figure 19-11).<sup>41,42,58</sup> Addition of a few drops of a 10% acetic acid solution may be necessary to dissolve crystals for accurate assessment of urine sediment.<sup>41</sup>

### ENZYMURIA

Renal tubules are metabolically active, being responsible for absorption or excretion of a wide range of substances. Transport of these compounds is facilitated by a number of enzymes, which are found in large amounts in lysosomes within or in the brush borders of tubular epithelial cells. Regular turnover of these cells and release of endocytotic vesicles and lysosomes into the tubular lumen results in activity of enzymes in urine (enzymuria).<sup>59</sup> A number of substances that are filtered

**FIGURE 19-11** Crystals commonly observed in equine urine sediment (original magnification,  $\times 160$ ). **A**, Large, round calcium carbonate ( $\text{CaCO}_3$ ) crystals (center and lower left) and smaller calcium phosphate crystals (oblong). **B**, Calcium oxalate dihydrate crystals. (Reproduced from Osborne CA, O'Brien TD, Ghobrial HK et al: Crystalluria: observations, interpretations, and misinterpretations, *Vet Clin North Am Small Anim Pract* 16:45, 1986.)

at the glomerulus (including bile acids, aminoglycoside and cephalosporin antibiotics, mannitol, dextrans, radiographic contrast media, and heavy metals) are taken up via endocytosis into proximal tubular epithelial cells. Endocytotic vesicles combine with lysosomes, and substances that are not broken down by lysosomal enzymes subsequently are extruded into the tubule lumen through evacuation of residual bodies.

Inflammation or necrosis of tubular epithelial cells results in elevated urinary activity of lysosomal and brush border enzymes. Because proximal tubular epithelial cells are the most metabolically active of all kidney cells, they are particularly susceptible to ischemic injury. Furthermore, they can be injured similarly by exposure to large quantities of nephrotoxins in glomerular filtrate. As a result, determination of the activities of certain urinary enzymes can provide evidence of tubular damage several days before azotemia may develop.<sup>60-63</sup> Additional contributors to increased urinary enzyme activity include (1) low-molecular-weight enzymes such as amylase that normally are filtered by glomeruli and reabsorbed in the proximal tubules, (2) postrenal genitourinary tract epithelia that usually contribute a negligible amount to the overall urinary enzyme activity (unless they become neoplastic), and (3) secretions from accessory sex glands. Contributions from the latter explain why intact males tend to have higher urinary activities of lactate dehydrogenase (LDH) and *N*-acetyl- $\beta$ -D-glucosaminidase (NAG).

Although more than 40 enzymes have been detected in urine of different species, only a few appear to be of diagnostic relevance. To be of clinical use, a urinary enzyme must have measurable activity in the kidney; its activity must lie within a fairly narrow range in urine of healthy animals; it must be sufficiently large (molecular weight >60,000) so as not to be filtered freely across the glomerulus; and its activity must increase early enough during the course of renal injury to permit institution of corrective treatment. Finally, the activity of the urinary enzyme should remain fairly stable in urine for several days without the need for special processing. In human beings and dogs, a number of enzymes, including NAG, LDH,  $\beta$ -glucuronidase, alanine aminopeptidase, alkaline phosphatase (ALP), leucine aminopeptidase,  $\gamma$ -glutamyltransferase (GGT), and kallikrein have been demonstrated to be sensitive indicators of renal damage.<sup>60-62,64,65</sup> With respect to horses, normal values have been established for activities of GGT, ALP, NAG, LDH, and kallikrein.<sup>66-70</sup> Attempts to assay aspartate aminotransferase and alanine aminotransferase activities were unsuccessful in normal horse urine.<sup>67</sup>

ALP and GGT are membrane-associated enzymes found primarily in the brush border of the proximal tubular epithelium.<sup>61-65,71</sup> Their activity in distal tubular epithelium is negligible.<sup>13</sup> These enzymes have activity in other tissues, but because they are not filtered by the glomerulus, elevated activity in urine in the absence of significant proteinuria is presumed to originate from the kidneys. Measurable activity in normal urine is attributed to cell turnover.<sup>61</sup> LDH is a more ubiquitous tubular epithelial enzyme, being as active in the distal tubules and medullary papillae as in proximal tubular epithelium.<sup>64-71</sup> NAG is a proximal tubular lysosomal enzyme.<sup>61-71</sup> Only GGT, ALP, LDH, and NAG have been assayed in the urine of horses known to have, or thought to have, some form of renal dysfunction. Determination of NAG activity can be difficult in normal equine urine because of its alkalinity, and normal values may be less than detectable assay limits when one uses a spectrophotometric, rather than a fluorometric, method.<sup>72-75</sup>

Published normal activities (expressed per gram of Cr) for these enzymes in equine urine are GGT: 0 to 25 IU/g Cr; ALP: 0 to 28 IU/g Cr; LDH: 0 to 12 IU/g Cr; and NAG: less than 1 IU/g Cr (<2 IU/L urine). Comparison with Cr concentration, which is relatively constant, results in less volume-related variation and allows interpretation of a randomly collected specimen (compared with a urine sample obtained during a timed collection period).<sup>66,76,77</sup>

Factors one must consider when measuring urinary enzyme activities include conditions under which the urine sample has been stored, urinary pH, diurnal variation, gender- and age-related variations, and other naturally occurring inhibitors or promoters of enzyme activity in urine (albumin, mucoproteins, proteolytic agents, amino acids, and ammonia). Although these factors have received limited study respecting equine urine, it has been documented that freezing can decrease activity of all enzymes, especially GGT. Furthermore, the colder the temperature, the more rapid the loss of enzyme activity.<sup>66</sup> To obtain the most accurate results, one should refrigerate samples (4° C) and assay them within 72 hours of collection. In species that have a slightly acidic or neutral urinary pH, assay of NAG is considered one of the most valuable diagnostic tests available. However, its activity appears to be susceptible to pH changes. In human beings receiving nephrotoxic medications, NAG activity in urine became undetectable at pH values greater than 8.<sup>78</sup> Similarly, NAG activities were undetectable (<2 IU/L) in urine of normal horses.<sup>79</sup> In a study of monensin toxicosis in horses, NAG activity increased as urinary pH decreased.<sup>68</sup> Certain amino acids and ammonia further act as inhibitors of lysosomal enzymes such as ALP and NAG in the urine of human beings, dogs, and rats,<sup>80,81</sup> and techniques have been developed to remove these agents from the urine by gel filtration before assay of their activity.<sup>82</sup>

Theoretically, assessment of changes in the urinary activity of selected enzymes may assist the clinician in identifying the segment of the nephron suffering the greatest dysfunction or damage. Although NAG, GGT, and ALP are associated primarily with proximal tubular epithelium, LDH usually is associated with distal tubular epithelial cells. Increases in urinary GGT and ALP activity have been induced experimentally in horses receiving gentamicin and neomycin for 5 to 10 days.<sup>83,84</sup> Increases also have been measured in horses with diarrhea, acute abdominal crises, and endotoxic shock. In the latter instances, enzymuria was assumed to indicate tubular damage after ischemia. Five consecutive days of furosemide administration also produced moderate increases in GGT and ALP activity, with ALP increasing more rapidly.<sup>79</sup> However, 48 hours of water deprivation failed to induce any changes in GGT, ALP, or LDH activity.<sup>70</sup> Similarly, no change in urinary LDH activity was observed in horses administered phenylbutazone (8.8 mg/kg PO) daily for 6 days.<sup>70</sup>

Although increases in urinary enzyme activities generally indicate acute tubular damage, one must interpret urine enzyme-to-Cr ratios carefully. Threshold values above which elevations are significant have not been well documented, although one study reported that a GGT/Cr value greater than 25 IU/g indicated tubular damage.<sup>66</sup> In contrast, in a study of gentamicin-induced nephrotoxicity in pony mares, Hinchcliff, McGuirk, and MacWilliams<sup>83</sup> measured GGT/Cr values exceeding 100 IU/g several days before measuring an increase in Cr concentration. Furthermore, one frequently may measure GGT/Cr values between 25 and 100 IU/g in horses receiving gentamicin at recommended doses. Similar to gentamicin

pharmacokinetics, enzymuria in these horses has been highly variable; these horses have not been recognized to be at risk of developing ARF. Although enzymuria likely reflects a degree of tubular damage in these patients, one should interpret increases in GGT/Cr values between 25 and 100 IU/g with caution, whereas increases greater than 100 IU/g are more likely to be clinically significant.

Horses with chronic renal disease may have normal or reduced enzyme activities that reflect cellular changes that occur in the nephron in response to chronic inflammation. Just as BUN and Cr concentrations may be normal during the early stages of renal disease, urinary enzyme activities may not accurately reflect renal dysfunction later in the disease course when results of blood tests and urinalysis are more likely to be abnormal. A possible reason for this phenomenon is that substantial destruction of tubular epithelium occurring early in the disease leaves fewer epithelial cells to be an ongoing source of elevated enzyme activities. Alternatively, regenerating tubular epithelial cells may be more refractory to the effects of the toxin.

All in all, determination of urinary enzyme activities has failed to gain acceptance as a routine measure of renal tubular damage in most equine hospitals. This lack of acceptance can be attributed to the high sensitivity for detection of subclinical renal tubular damage. For example, although a urine GGT/Cr ratio elevated to a value of 75 supports tubular damage, it does not provide the clinician a quantifiable risk for development of ARF. Thus as a single measurement, the ratio is of limited use in deciding whether one should discontinue use of a nephrotoxic medication (e.g., gentamicin). In contrast, more dramatic elevations of the GGT/Cr ratio may precede development of azotemia and could be a useful warning that one may need to discontinue a medication or, at a minimum, prolong the dosing interval. Until values for urinary enzyme activities are reported for a larger number of equine patients with various diseases, the true value of assessing urinary enzyme activity will remain unclear.

## FRACTIONAL CLEARANCE OF ELECTROLYTES

Urinary electrolyte losses, which reflect tubular function, can be expressed as excretion rates (total amount of electrolyte excreted during a given time period, expressed as milliequivalents per minute) or as clearance rates. Determination of clearance rates uses the same clearance concept to measure GFR. In brief, a clearance rate ( $Cl_A$ ) is a measure of the volume of plasma that is cleared completely of the substance in question (A) during a given time period. One calculates the  $Cl_A$  by performing a timed urine collection (to determine urine flow in milliliters per minute) and measuring the concentration of the desired substance in plasma and urine (Cr or inulin for determination of GFR):<sup>8</sup>

$$Cl_A = (\text{urine}[A]/\text{plasma}[A]) \times \text{urineflow}$$

As with protein, urinary clearance of many substances, including electrolytes, often is compared with that of Cr.<sup>8</sup> Basically, a substance that is filtered mostly across the glomerulus but is neither reabsorbed nor secreted by renal tubules (inulin) will have a clearance rate similar to that of Cr. In contrast, a substance that is poorly filtered (larger molecule) or reabsorbed to a great extent by renal tubules (sodium or chloride) will have a lower clearance value than that of Cr. Similarly, clearance values for substances that are eliminated by filtration and tubular secretion (potassium) may exceed that measured for Cr. An advantage of comparing the clearance of a substance (A) to  $Cl_{Cr}$  (expressed as a fraction of  $Cl_{Cr}$ ) is that it

obviates the need to perform a timed urine collection, because the urine flow factor is cancelled out in the calculation:

$$\frac{Cl_A}{Cl_{Cr}} = \frac{\frac{\text{urine}[A]}{\text{plasma}[A]} \times \text{urine flow}}{\frac{\text{urine}[Cr]}{\text{plasma}[Cr]} \times \text{urine flow}}$$

that, by rearrangement and expression as a percentage becomes

$$\frac{Cl_A}{Cl_{Cr}} = \left[ \frac{\text{plasma}[Cr]}{\text{urine}[Cr]} \times \frac{\text{urine}[A]}{\text{plasma}[A]} \right] \times 100$$

This calculation is called the *fractional Cr clearance value*.<sup>8,85</sup> More often, however, the term *fractional excretion* has been used to describe this value. Although most sources recommend that blood and urine samples be collected at the same time for determination of fractional clearance values, serum electrolyte and Cr concentrations are usually stable (except in patients with prerenal azotemia or ARF), so one can use blood values measured within a few days of the urine sample in the clearance calculations. Consequently, leaving a specimen cup for the client to use to collect a voided sample is acceptable and obviates bladder catheterization in many cases.

As previously discussed (see Renal Physiology), the equine kidneys function to conserve more than 99% of filtered sodium and chloride ions. In contrast, potassium ions are conserved poorly except during periods of whole-body potassium depletion (anorexia, prolonged exercise). Thus normal fractional clearance values are less than 1% for sodium but are considerably higher for potassium (Table 19-7).<sup>\*</sup> Increases in fractional sodium and chloride clearance values may reflect an appropriate renal regulatory response to dietary excess, as with psychogenic salt consumption.<sup>100</sup> Alternatively, increases in fractional clearance values specifically for sodium and phosphorus also can be early indicators of renal tubule damage<sup>31,83,97,101,102</sup>; however, one must interpret results of these calculations in light of fluid therapy because fractional clearance values can be increased artifactually in horses receiving intravenous polyionic solutions.<sup>31</sup> Similarly, medication (furosemide) or light exercise also can result in increased urine flow and fractional sodium and chloride clearance values.<sup>103</sup>

The kidneys play an important role in equine calcium and phosphorus homeostasis, and renal loss of these ions varies with dietary intake. Thus fractional clearances of calcium and phosphorus also have been used to assess adequacy of dietary intake.<sup>†</sup> Although diet is evaluated more appropriately on a herd basis by analyses of hay and concentrates, fractional clearances may be useful in individual animals or when feed analysis is impractical (e.g., forage consists of pasture). Determination of fractional calcium and phosphorus clearances has received limited study with a focus on young racing horses.<sup>92-94,104-106</sup> For example, excessive dietary phosphorus intake (which can lead to nutritional secondary hyperparathyroidism) leads to increased fractional clearance of phosphorus. Evaluation of fractional calcium clearance is hampered by the fact that most of the calcium in equine urine is in the form of  $CaCO_3$  crystals. To measure the urinary calcium concentration reliably, one must collect the entire contents of the bladder

<sup>\*</sup>References 31, 42, 46, 53, 86-90, 95-99.

<sup>†</sup>References 87, 88, 90, 92-94, 96, 97, 104-106.

during voiding or via catheterization to ensure collection of the initial crystal-poor and final crystal-rich fractions. Subsequently, one treats a well-mixed aliquot of urine with acetic acid or nitric acid to solubilize the crystals.<sup>97</sup> In one report, fractional calcium and phosphorus clearance values greater than 2.5% and less than 4% were considered consistent with adequate dietary intake (adequate calcium intake with phosphorus intake that was not excessive).<sup>93</sup> Unfortunately, because the ranges for fractional calcium and phosphorus clearances can be wide in normal horses (see Table 19-7), measurement of these clearances may not be sensitive enough to detect minor dietary imbalances.

Determination of fractional electrolyte clearance values also has been advocated in the evaluation of horses with recurrent rhabdomyolysis.<sup>91,107,108</sup> Low sodium and potassium clearances have been reported in some affected horses. Whether these low fractional clearance values reflected total body electrolyte depletion (as a consequence of repeated bouts of exercise in hot weather or repeated furosemide administration) or a true physiologic predisposition to rhabdomyolysis was not determined. Nevertheless, low fractional clearance values document the need for electrolyte supplementation in equine athletes. Harris and Snow<sup>107</sup> also described another population of horses that exhibited recurrent rhabdomyolysis that had increased fractional phosphorus clearance and was

reported to respond to dietary supplementation with ground limestone. Thus although determination of fractional electrolyte clearances may be helpful in the evaluation of horses with recurrent rhabdomyolysis, only a small portion of affected horses are likely to show significant clinical improvement in response to dietary electrolyte supplementation alone.

Finally, the methodology used to determine fractional electrolyte clearances should be standardized because several factors may lead to erroneous results. For example, a note of caution is warranted when ion-specific electrodes (instead of a flame photometer) are used to measure urinary potassium concentration, because components of animal urine can interfere with the ion-specific electrode and lead to spurious low values. One usually can avoid this problem by performing the analysis on urine diluted with water.<sup>109</sup> Next, as mentioned previously, light exercise may increase urine flow rate and sodium excretion.<sup>103</sup> Thus “spot” urine samples are best collected in the morning before feeding and exercise. Recently, McKenzie et al.<sup>99</sup> compared fractional electrolyte clearance values between single-sample spot urine collections to 24-hour volumetric urine collections over 3 days in horses receiving diets varying in cation-anion balance. They found substantial variation in fractional clearance values within individual horses over the 3-day study, despite feeding of a consistent diet. When they assessed the effect of the differing diets, fractional clearance

NR, Not reported.

\*Values calculated from data provided.

†Fractional clearance of potassium may exceed upper limit on high potassium diets; a fractional clearance of phosphorus exceeding 4% suggests excessive dietary intake; a fractional clearance for calcium should exceed 2.5% with adequate intake.

‡Low range attributed to low urine potassium concentrations determined by ion-specific electrodes.

§Fractional clearance value for magnesium reported at 7 to 30.

values for sodium, potassium, and chloride were generally similar when calculated using urine electrolyte concentrations determined in spot urine samples or well-mixed 24-hour collection samples. However, they found greater variability with fractional clearance values for calcium and magnesium. The fact that they detected considerable variability should not be surprising when one remembers that fractional clearance values are a calculation using four measurements (Cr and electrolyte concentrations in plasma-serum and urine). Thus small variations in each measured value have the potential to magnify error in the final calculation. All in all, this study should serve as a reminder that determination of fractional electrolyte clearances is only one of the diagnostic tools one should use to evaluate patients with renal disease or recurrent rhabdomyolysis or to assess diet in a group of horses.

## IMAGING TECHNIQUES

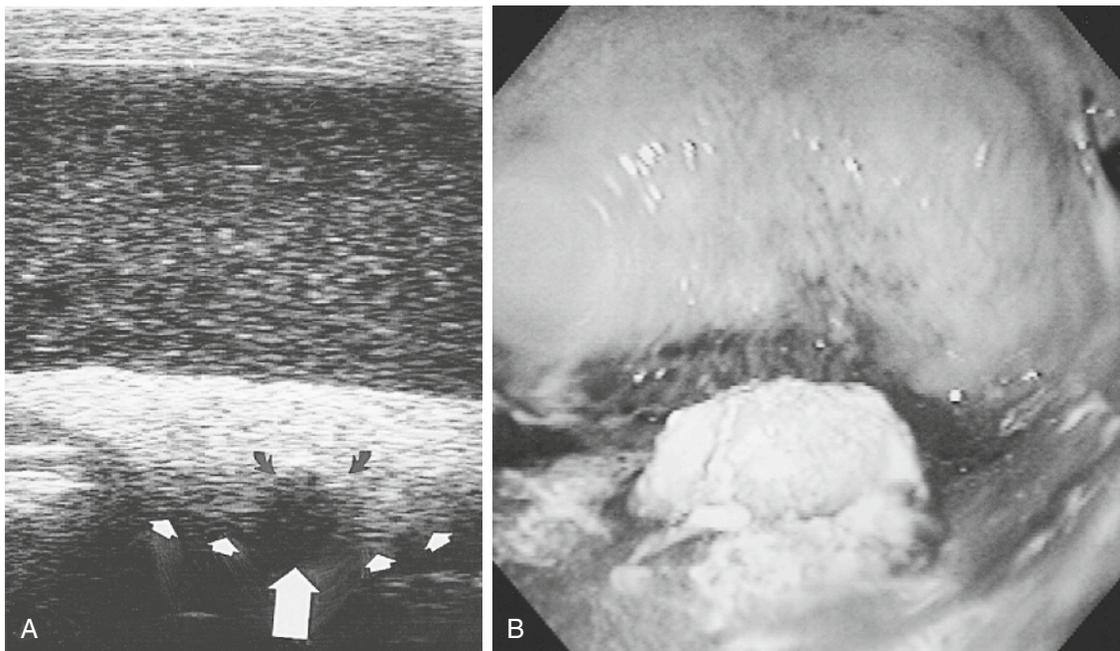

### ULTRASONOGRAPHY

One can perform ultrasonographic examination of the urinary tract transrectally or transabdominally.<sup>110-117</sup> Bladder imaging is performed best transrectally using a 5-MHz probe. One must remember the character of equine urine while imaging the bladder; the urine will be an inhomogeneous, echogenic fluid because of the presence of mucus and crystals. The latter can appear as echogenic sediment in the ventral aspect of the bladder, and balloting the bladder may cause this echogenic material to swirl. One also can confirm the presence of a cystic calculus because calculi have a highly echogenic surface and produce an acoustic shadow (Figure 19-12). Similarly, one

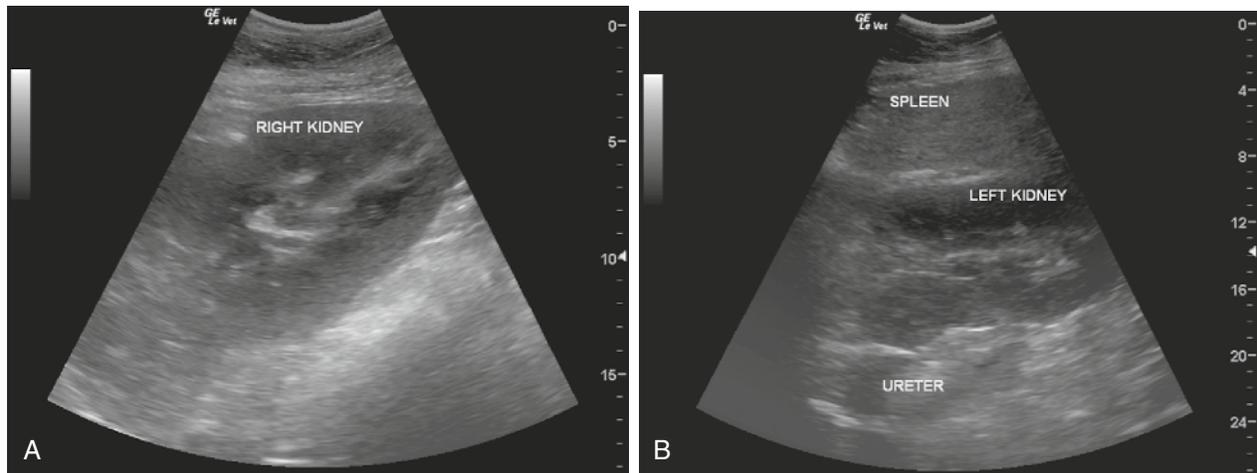

may image and palpate masses in the bladder wall during the examination.

The right kidney is triangular or horseshoe shaped and is imaged best transabdominally via the dorsolateral extent of the last two or three intercostal spaces (Figure 19-13, A). The left kidney is somewhat a more typical bean shape, lies deep to the spleen, and can be imaged via the last two intercostal spaces or via the paralumbar fossa. Because the left kidney is deeper than the right kidney, it can be difficult to image completely and is examined best with a 2.5- or 3-MHz probe (Figure 19-13, B). One should assess systematically the size and shape of both kidneys, architecture, and echogenicity of the parenchyma, including imaging the kidneys in dorsal, sagittal, transverse, and transverse oblique anatomic planes.<sup>115</sup> In a full-size horse the right kidney should not measure more than 15 cm in the longest axis, whereas the left kidney may measure up to 18 cm if imaged longitudinally.

In ARF the kidneys may be normal or enlarged, and abnormalities of parenchymal detail are not often detected. When present, abnormal findings may include perirenal edema, widening of the renal cortex, and loss of a distinct corticomedullary junction.<sup>111,112,114,116-118</sup> CRF can result in decreased kidney size, irregular surfaces, and increased echogenicity because of renal fibrosis. Cystic or mineralized areas in renal parenchyma can be associated with chronic renal disease or congenital anomalies. Although uncommonly recognized, distinct curvilinear hyperechoic bands in the outer renal medulla parallel to the corticomedullary junction have been imaged in foals and adult horses with renal disease attributable to acute or chronic phenylbutazone toxicity.<sup>117,119,120</sup> This finding, termed the *medullary rim sign*, is thought to result from

**FIGURE 19-12** Transrectal ultrasonographic and cystoscopic images of the bladder of a Miniature Horse mare with recurrent cystitis and urolithiasis. **A**, The ultrasonographic image shows a layer of echogenic crystalline material in the ventral aspect of the bladder (small, white arrows outline ventral bladder wall) and presence of a small cystolith (outlined by small black arrows and large white arrow). **B**, After lavage of the urine sediment, cystoscopy confirmed presence of a small urolith, which was amenable to removal by digital manipulation.

**FIGURE 19-13** Transabdominal ultrasonographic image of a normal, **A**, right kidney and, **B**, left kidney. The renal medulla is more hypoechoic than the renal cortex, except for the renal pelvis, which varies in echogenicity. The left kidney is imaged deep to the spleen.

**FIGURE 19-14** Transrectal ultrasonographic image of the left kidney of a mare with nephrolithiasis and hydronephrosis. The nephrolith has an echogenic surface and produces an acoustic shadow. The echolucent crescent moon-shaped structure is a fluid-filled remnant of the renal parenchyma, consistent with hydronephrosis.

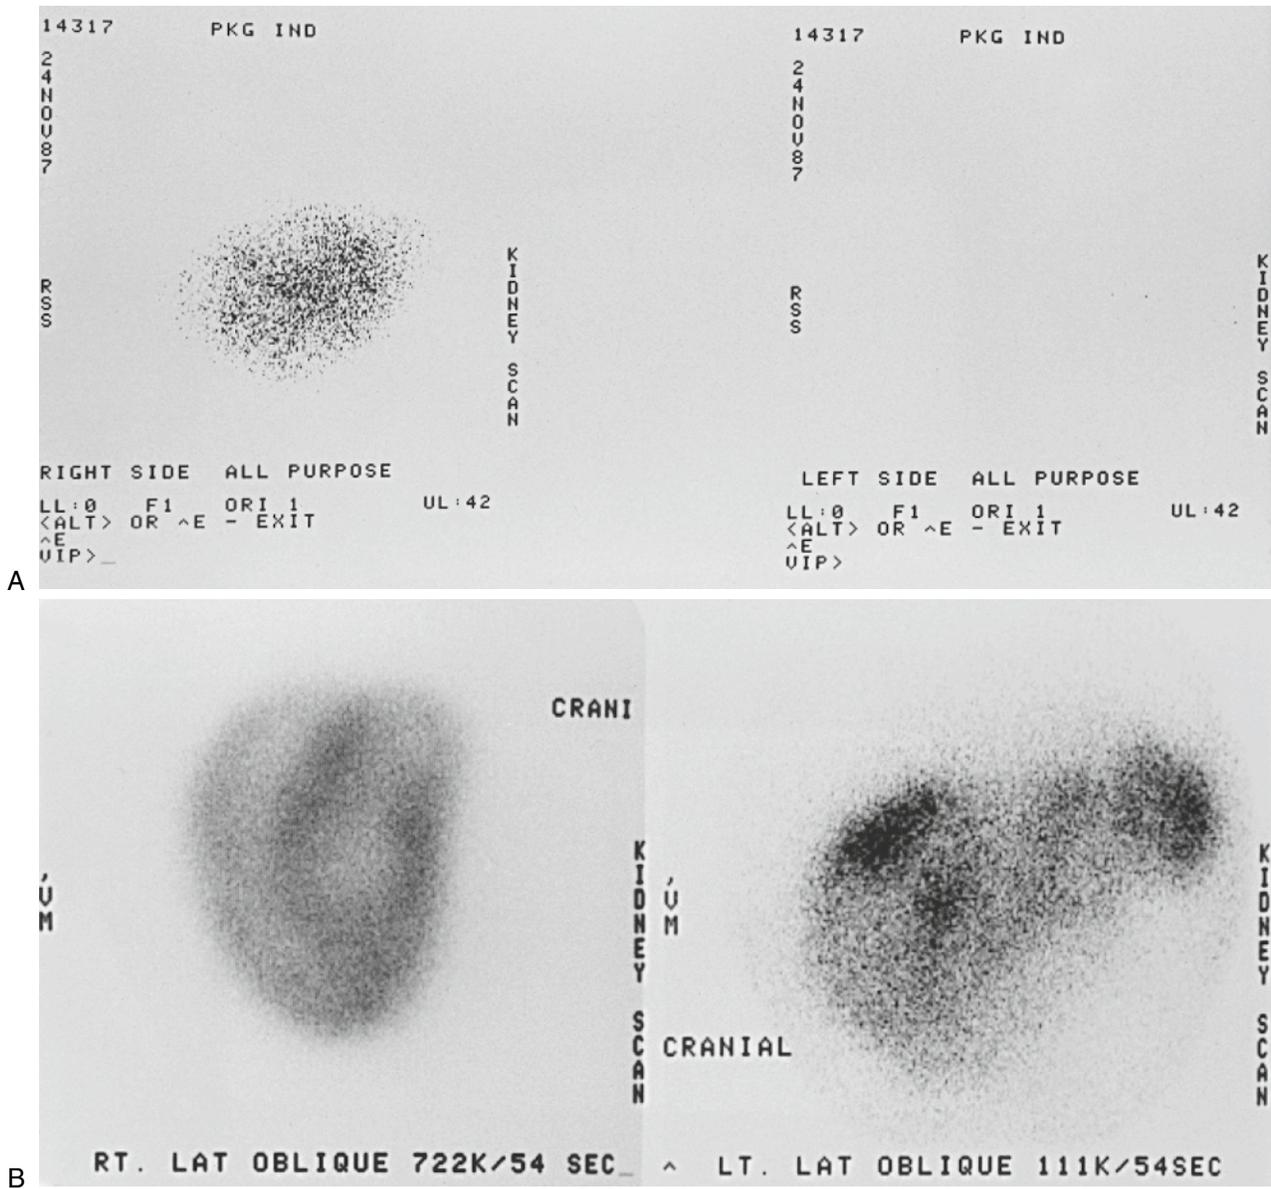

damage (and possible secondary mineralization) to the inner stripe of the outer medulla, the location of highly metabolically active nephron segments including the distal extent of the proximal tubule and the thick ascending limb of the loop of Henle. Calculi in the renal pelvis generally cast an acoustic shadow and can result in hydronephrosis of the affected kidney (Figure 19-14).<sup>111,112,114</sup> Occasionally, one cannot image one or both kidneys because of a gas-filled bowel between the kidney and abdominal wall. Re-examination at a later time generally is required for successful imaging in such cases. In addition, administration of high rates of fluid therapy, especially in foals, can lead to iatrogenic pyelectasia (fluid distention of the renal pelvis).<sup>117,121</sup> One should use caution so as not to interpret this mild distention of the renal pelvis falsely as evidence of ureteral or lower urinary tract obstruction.

## RADIOGRAPHY

Radiography rarely is used to evaluate urinary tract disease in adult horses. One usually can obtain diagnostic radiographs of the urinary tract only in foals or Miniature Horses. Excretory urography using intravenous contrast material or pyelography using contrast agent delivered into the renal pelvis under ultrasonographic guidance may be useful to identify a nonfunctional or hypoplastic kidney or an ectopic or torn ureter.<sup>122,123</sup> The latter procedure may be more rewarding, but both require general anesthesia to be performed safely. One also can use retrograde contrast studies to evaluate the ureters in mares<sup>124</sup>; however, they have been used most often in foals suspected of having an ectopic ureter or a ruptured bladder. Contrast radiographic studies also can help to identify strictures or masses in the urethra or bladder, but endoscopy is generally more useful for these problems. In small animals, abdominal survey radiographs are most useful for assessing kidney size and shape, whereas ultrasonography provides more information about parenchymal changes associated with renal disease.<sup>125</sup> Thus use of a standardized protocol for ultrasonographic evaluation of the equine kidneys should provide essentially the same amount of information as the combined use of survey radiography and ultrasonography in small animal patients.<sup>115</sup>

## NUCLEAR SCINTIGRAPHY

Nuclear scintigraphy is an additional imaging modality often used to assess renal anatomy and function in human beings and small animals. One can use various radionuclides and pharmaceuticals, depending on the type of scintigraphic examination being pursued.<sup>126-128</sup> In fact, scintigraphy is used routinely for quantitative measurement of GFR in these species. Walsh and Royal<sup>129</sup> compared use of renal scintigraphy (using <sup>99m</sup>Tc-DTPA, which is similar to inulin in that it is neither secreted nor reabsorbed after filtration) for measurement of GFR in horses but found greater variability compared with GFR values measured by plasma disappearance of inulin or the same radionuclide (<sup>99m</sup>Tc-DTPA).<sup>129</sup> Nevertheless, renal scintigraphy using <sup>99m</sup>Tc-DTPA can provide

**FIGURE 19-15** Renal scintigraphic images of horses with renal disease. **A**, Renal scintigraphic image using  $^{99m}\text{Tc}$ -diethylenetriamine pentaacetic acid ( $^{99m}\text{Tc}$ -DTPA) revealed absence of functional left renal tissue, compared with an image of the right kidney, in a stallion with chronic renal failure (CRF). A nonfunctional hypoplastic left kidney was found on necropsy examination. **B**, Renal scintigraphic image using technetium- $^{99m}$ -glucoheptonate ( $^{99m}\text{Tc}$ -GH) in a gelding with unilateral left-sided pyelonephritis revealed inhomogeneous uptake of the radionuclide and lesser count emission over the same time compared with the normal right kidney. The scintigraphic study, which provided anatomic and functional information, supported pursuit of unilateral nephrectomy, rather than prolonged antibiotic administration, as the treatment of choice for this horse.

qualitative information about renal function and is the only method currently available for assessing split renal function (assessing individual kidney function) in horses. Renal scintigraphy also has been performed with  $^{99m}\text{Tc}$  tagged to glucoheptonate (taken up by the proximal tubule epithelial cells to provide anatomic detail) or mercaptoacetyltriglycine ( $\text{MAG}_3$ , which is similar to p-aminohippurate because it is eliminated by proximal tubular secretion) to provide qualitative information about renal anatomy and function (Figure 19-15).<sup>130,131</sup> Thus one may use renal scintigraphy to document the presence of a functional kidney in horses when

multiple ultrasonographic examinations have been complicated by interfering bowel or when one desires information about individual kidney function.

## ENDOSCOPY

Endoscopy of the urinary tract is a useful diagnostic aid when the complaint is abnormal urination.<sup>41,132-134</sup> A flexible endoscope with an outside diameter of 12 mm or less and a minimum length of 1 m is adequate for examination of the urethra and bladder of an adult horse of either sex.

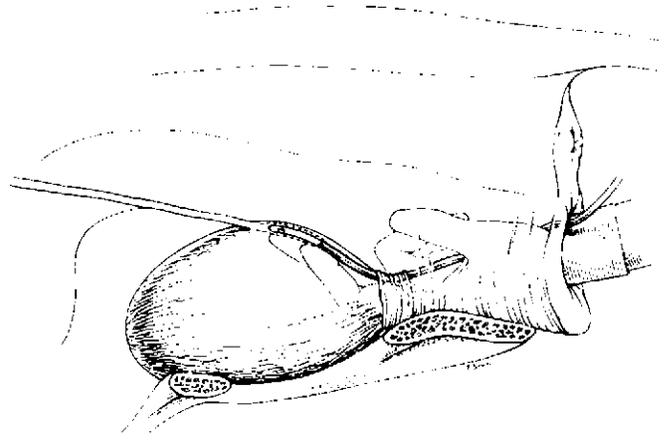

One should sterilize the endoscope before endoscopy of the lower urinary tract. Tranquilization of the patient is recommended, and one should clean the distal end of the penis or the vulva thoroughly. The endoscope is passed as one passes a catheter, using the air control intermittently to inflate the urethra or bladder. Normal urethral mucosa is pale pink with longitudinal folds. When dilated with air the mucosa flattens and may appear redder than normal, and a prominent submucosal vascular pattern may be apparent. Passage of a catheter before endoscopy (for sample collection or to empty the bladder) can produce mild irritation and erythema of the urethral mucosa; therefore one should not mistake these findings for abnormal findings. The regions of the ischial arch (where the urethra begins to widen into the ampullar portion) and of the colliculus seminalis (in the roof of the pelvic urethra just distal to the urethral sphincter) should be examined closely, because these are common sites of posturination or postbreeding hemorrhage in geldings or stallions (see Hematuria). Subsequent passage of the endoscope through the urethral sphincter and air distention allows evaluation of the bladder for calculi, inflammation, and masses (see Figure 19-12). Viewing the ureteral openings in the dorsal aspect of the trigone can help determine the source of hematuria or pyuria (see Hematuria). A small volume of urine should pass from each ureteral opening approximately once each minute or more frequently if the horse is well hydrated or has been sedated with an  $\alpha_2$ -agonist. One can perform ureteral catheterization to obtain urine samples from each kidney by passing sterile polyethylene tubing via the biopsy channel of the endoscope. Additionally, one can take biopsy samples of masses in the bladder or urethra.

## ☞ SPECIALIZED DIAGNOSTIC TECHNIQUES

### URETERAL CATHETERIZATION

With development of high-resolution videoendoscopic equipment, retrograde instrumentation of the bladder, ureter, and renal pelvis rapidly is replacing surgical exploration for diagnostic evaluation and therapeutic management of urinary tract disorders in human beings and dogs.<sup>126,135-137</sup> Similarly, retrograde ureteral catheterization and instrumentation can be a valuable technique for evaluation and treatment of horses with unilateral disorders of the upper urinary tract.<sup>138-140</sup> In addition to localization of unilateral renal hemorrhage, pyelonephritis, and neoplasia, ureteral catheterization further enables retrograde pyelography.<sup>124</sup> As mentioned previously, one may perform this technique successfully in male and female horses during cystoscopic examination.<sup>41,132-134</sup>

In mares, one also can catheterize the ureters manually without endoscopic guidance.<sup>141</sup> After preparation of the vulva, one catheterizes the bladder and drains the urine. One removes the bladder catheter and dilates the urethra manually until two fingers can be passed into the bladder. One can palpate the ureteral orifices dorsally as small, soft projections. When this is done, a catheter is placed between the fingertips, passed through the urethra, and directed into the ureter (Figure 19-16). A relatively rigid catheter with a rounded end (No. 8 to 10 French polypropylene catheter) facilitates passage into the ureter. After advancing the catheter 5 to 10 cm into the ureter, one attaches a syringe to the other end of the catheter and collects a urine sample. During sampling, the catheter is held in place and the ureteral opening is occluded with the fingertips to minimize loss of urine around the catheter.

**FIGURE 19-16** Manual placement of a polypropylene catheter into the ureter of a mare. (From Schott HC, Hodgson DR, Bayly WM: Ureteral catheterization in the horse, *Equine Vet Educ* 2:140, 1990.)

## WATER DEPRIVATION AND THE ANTIDIURETIC HORMONE CHALLENGE TEST

Water deprivation is a simple test to determine whether hyposthenuric polyuria is caused by a behavior problem such as primary (psychogenic) polydipsia or results from central or nephrogenic diabetes insipidus.<sup>6</sup> One should not perform a water deprivation test in an animal that is clinically dehydrated or azotemic. A baseline urinalysis should be performed (sample collected by catheterization to empty the bladder at the start of the test), and BUN, Cr, and body weight should be measured before removal of water (food does not necessarily need to be removed, but this may help prevent gastrointestinal complications of water deprivation). One measures urine specific gravity and weight loss after 12 (usually overnight) and 24 hours. Horses with normal renal function typically produce urine with a specific gravity greater than 1.045 and an osmolality greater than 1500 mOsm/kg in response to water deprivation of 24 to 72 hours in duration.<sup>44-46</sup> Practically, one can stop the test when urine specific gravity reaches 1.025 or greater. Furthermore, the test should be stopped if more than 5% of body weight is lost or clinical evidence of dehydration becomes apparent. With long-standing primary polydipsia, affected horses may not be able to concentrate urine fully (to a specific gravity > 1.025) because of partial washout of the medullary interstitial osmotic gradient. Extending the test period beyond 24 hours for such patients offers little benefit; however, affected horses should respond more favorably to water deprivation (producing urine with a higher specific gravity) after a period of partial water deprivation (termed a *modified water deprivation test*) during which daily water intake is restricted to 40 ml/kg for several days, which should allow time for restoration of the medullary interstitial osmotic gradient.<sup>6</sup> Horses with central or nephrogenic diabetes insipidus cannot concentrate urine in response to a water deprivation test.<sup>6,142-144</sup> When one suspects these problems, patients should be monitored every few hours because significant dehydration may ensue within 6 hours of water deprivation.

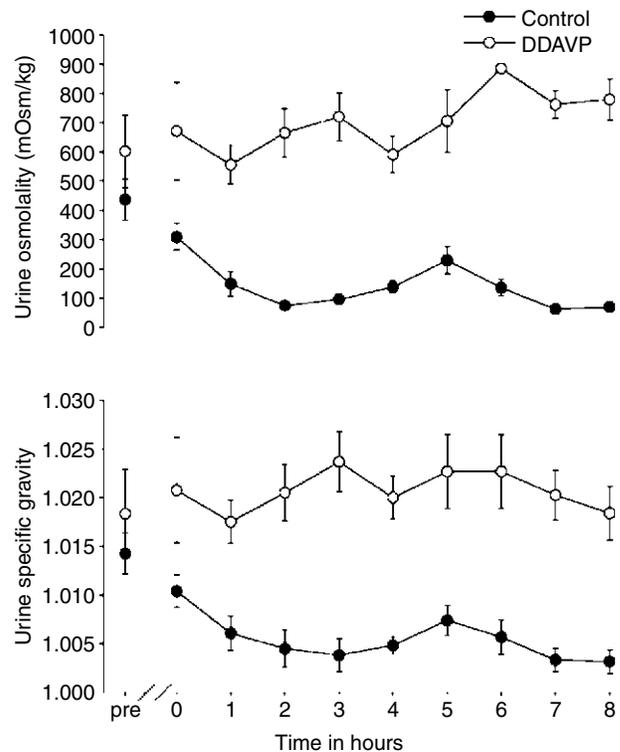

In the absence of azotemia or clinical signs of early renal failure, inability to concentrate urine in response to water deprivation supports a diagnosis of diabetes insipidus; however, the test does not distinguish between the neurogenic and

nephrogenic forms of the disorder. One can differentiate these by exogenous administration of vasopressin (antidiuretic hormone).<sup>142-144</sup> Currently, two approaches exist for performing an antidiuretic hormone challenge test. First, one can administer aqueous synthetic vasopressin (20 U/ml for intramuscular or subcutaneous injection) as an intravenous infusion (5 U [0.25 ml] added to 1 L of a 5% dextrose solution and administered IV at a rate of 2.5 mU/kg over 60 minutes [250 ml to a 500-kg horse]) or an intramuscular injection (0.5 U/kg). An increase in urine specific gravity to 1.020 or greater after 60 to 90 minutes would be the expected response, whereas failure to increase urine concentration would support nephrogenic diabetes insipidus. Second, one can use desmopressin acetate (DDAVP), a synthetic analog of arginine vasopressin. Administration of DDAVP is considered the safer diagnostic technique in small animals because the change in structure of this vasopressin analog has decreased pressor actions and less effect on visceral smooth muscle compared with an enhanced antidiuretic effect. One microgram of DDAVP has an antidiuretic activity of 4 U of arginine vasopressin. The author and co-workers recently validated the use of DDAVP as a replacement for the antidiuretic hormone challenge test in normal horses. In this study, the nasal spray form of DDAVP (0.1 mg/ml DDAVP) was diluted in sterile water and 0.05 µg/kg was administered intravenously (25 µg, equal to 100 U of antidiuretic activity, to a 500-kg horse) to horses that had polyuria induced by repeated nasogastric intubation with water for 3 days preceding DDAVP challenge. Urine was collected for 8 hours after DDAVP administration and an increase in urine specific gravity to values greater than 1.020 was observed from 2 to 7 hours after DDAVP administration (Figure 19-17).<sup>145</sup> Furthermore, DDAVP administration had no effect on heart rate or systemic blood pressures. These data demonstrate that intravenous administration of DDAVP is a safe and useful diagnostic tool for evaluation of horses with diabetes insipidus.

A final test for evaluating polyuria and polydipsia is an intravenous challenge with hypertonic saline (Hickey-Hare test).<sup>146</sup> The goal is to produce an increase in plasma osmolality, which should trigger release of endogenous vasopressin. One protocol for the test would be to measure plasma osmolality and endogenous vasopressin concentrations before and within 30 minutes after administration of 1 to 2 ml/kg of a 7.5% NaCl solution. A normal response, expected in horses with primary polydipsia, would be concurrent increases in plasma vasopressin concentration and urine specific gravity. Horses with nephrogenic diabetes insipidus also would respond with an increased plasma vasopressin concentration; those with neurogenic diabetes insipidus would not. Urine specific gravity would not be expected to increase in response to hypertonic saline administration with either form of diabetes insipidus. One could evaluate plasma vasopressin concentrations similarly before and at the end of a water deprivation test.<sup>147,148</sup> Unfortunately, however, assays for plasma vasopressin concentration are not currently available at commercial laboratories. Thus pursuit of this diagnostic test requires cooperation of a research laboratory.

## QUANTITATIVE MEASURES OF RENAL FUNCTION

As mentioned previously, azotemia does not develop until more than 75% of nephrons cease to function; therefore measurement of BUN and Cr, although readily available, provides

**FIGURE 19-17** Urine osmolality and specific gravity in six horses administered 0.05 µg/kg desmopressin acetate (DDAVP) (open circles) or placebo (filled circles) intravenously at time 0. The horses had polyuria induced by repeated nasogastric intubation with water (40 ml/kg) twice daily for 3 days preceding DDAVP challenge and again 4 hours after administration of DDAVP. Urine was collected for 8 hours after treatment, and an increase in urine specific gravity to values greater than 1.020 was observed from 2 to 7 hours after DDAVP administration.<sup>145</sup>

a poor reflection of smaller declines in renal function. A number of methods are available to quantitate renal function in horses.<sup>41,149</sup> Basically, these tests can be separated into plasma disappearance curves or clearance studies involving use of timed urine collections. Generation of plasma disappearance curves requires collection of an initial blood sample, intravenous administration of one of a number of compounds (inulin, Cr, sodium sulfanilate, phenolsulfonphthalein [phenol red], or radionuclides), and collection of another series of blood samples over the subsequent 60 to 90 minutes.<sup>129,150-155</sup> One can express results in terms of an elimination half-life in minutes or as clearance values in milliliters per kilogram per minute. Mean elimination half-lives of  $39.5 \pm 4.4$ ,  $32.8 \pm 4.1$ , and  $16.4 \pm 2.3$  minutes have been reported for sodium sulfanilate,  $^{99m}\text{Tc-MAG}_3$ , and phenolsulfonphthalein, respectively, in healthy horses.<sup>150,151,155</sup> The difference in these values can be explained in part by the fact that  $^{99m}\text{Tc-MAG}_3$  and phenolsulfonphthalein are eliminated mostly by tubular secretion and consequently are cleared more rapidly from plasma than is sodium sulfanilate (eliminated mostly by glomerular filtration). Plasma elimination half-times are most useful when measured sequentially throughout the course of renal disease; for example, Bertone et al.<sup>156</sup> reported a progressive increase in the sodium sulfanilate elimination half-time from 90 to 150 minutes during a 240-day course of CRF in a horse with PKD.

When one uses plasma disappearance curves of a substance to estimate GFR, the compound being used must meet all the requirements of a filtration agent<sup>152-154</sup>: (1) no significant binding to plasma proteins, (2) ability to be filtered freely across the glomerulus, and (3) absence of tubular reabsorption or secretion. The gold standard compound is inulin. More traditionally, GFR has been measured by timed urine collection periods (to measure urine flow rate) and measurement of plasma and urine concentrations of a test compound that meets the listed requirements.<sup>8,149</sup> Several protocols exist for performing urine clearance studies. Ideally, the urine collection period should span 24 hours, although for practicality, one may use shorter collection periods.<sup>6,149</sup> For all protocols, one documents the bladder as being empty at the start of the collection period by catheterization or observation of voiding. All urine produced during the study period is collected and pooled into one sample. At the end of the collection period, the bladder should be emptied again via catheterization, the total volume of urine produced should be recorded, and an aliquot of the pooled urine sample should be assayed for the test substance. Similarly, one measures the concentration of the test substance in a blood sample collected near the midpoint of the urine collection period. For urine collections of 12 to 24 hours, endogenous Cr is the test substance used because it is the only one that does not have to be given by steady intravenous infusion during the collection period. GFR is calculated as the  $Cl_{Cr}$ ,

$$GFR = \frac{\text{urine}[\text{Cr}]}{\text{plasma}[\text{Cr}]} \times \text{urine flow}$$

with the modification that the result usually is divided by body mass (in kilograms) to express GFR in term of milliliters per minute per kilogram. Although endogenous Cr is a convenient test substance, its use typically underestimates GFR because non-Cr chromagens in serum artifactually increase the value in the denominator.<sup>149</sup> Similarly, significant tubular secretion of Cr can be one of the compensatory responses to renal failure. This can lead to overestimation of GFR calculated using endogenous  $Cl_{Cr}$ . Despite these limitations, the endogenous  $Cl_{Cr}$  technique for measurement of GFR can provide useful information, especially when it is performed on several occasions during the course of renal failure (see Chronic Renal Failure).

To avoid the limitations of endogenous  $Cl_{Cr}$  as a measure of GFR, one can administer a number of filtration markers (inulin, Cr, radionuclides) as an intravenous infusion throughout the urine collection period.<sup>153,154,157-162</sup> One starts the infusion as a bolus to increase the plasma concentration of the test substance to the desired level (e.g., the desired plasma concentration for exogenous Cr is 5 to 10 mg/dl, to minimize the influence of non-Cr chromagens) and subsequently continues a steady infusion throughout the remainder of the collection period. One usually performs this type of study for a shorter period with the horse restrained in stocks. One should empty the bladder of the horse at the start of the study and collect urine after two or three 30-minute intervals. One should pass a catheter and empty the bladder completely at the end of each 30-minute period. Alternatively, an indwelling bladder catheter can be used for the entire collection. After urine volumes are measured, an aliquot of each urine sample is assayed and a blood sample is collected at the midpoint of each urine collection period for the test substance; then the GFR is calculated as the mean value for the two or three collection periods. For all

practical purposes, these types of GFR measurements (with the exception of exogenous  $Cl_{Cr}$ ) usually are limited to research studies, because commercial laboratories do not offer inulin assays. One also can use this shorter protocol for GFR determination using endogenous Cr as the test substance, without the need for an intravenous infusion. (The results of a number of studies measuring GFR in normal horses are presented in the previous section of this chapter; see Renal Physiology.)

## RENAL BIOPSY

Renal biopsy is a useful diagnostic technique for identifying the affected region of the nephron, the type of lesion, and the chronicity and severity of disease.<sup>8,163-166</sup> Although biopsy is a safe procedure when performed with ultrasonographic guidance, it has risks, including perirenal hemorrhage or hematuria and, less commonly, penetration of bowel. In human beings, perinephric hematomas are common and have been detected in 57% to 85% of patients the day after biopsy. Microscopic hematuria occurs in virtually all patients for the first couple of days after biopsy, and gross hematuria occurs in 5% to 10% of patients. Most of these complications are inconsequential, but in 1% to 3% of patients the complications have resulted in the need for postbiopsy transfusions.<sup>8</sup> Similarly, in a group of seven normal horses subjected to renal biopsy, postbiopsy macroscopic and microscopic hematuria occurred in five animals. Furthermore, perirenal hemorrhage was a prominent finding during necropsy examination of five of these animals (including one examined 27 days after biopsy tissue was collected).<sup>166</sup> Thus renal biopsies remain controversial in human and equine renal failure patients.<sup>167-169</sup> Renal biopsies should be approached with caution and are indicated only when the results would alter the therapeutic plan or prognosis. Information about the effect of renal biopsy results on therapy and outcome of renal disease in human beings is limited; however, in one prospective study, biopsy results were found to influence physicians' decisions on about half of cases when the technique was performed.<sup>170</sup> In general, renal biopsy is pursued more aggressively in human beings with acute renal insufficiency than in those with chronic renal insufficiency, especially when it is difficult to determine the type of renal disease based on results of urinalysis and sediment examination.<sup>8</sup> In the equine patient, one performs a renal biopsy with the horse sedated and restrained in a stocks. Penetration of the needle (a Tru-Cut biopsy needle or, preferably, a triggered biopsy device) into the renal parenchyma is imaged sonographically by triangulating the ultrasound beam with the biopsy instrument and the kidney or by determination of the site and depth of biopsy needle placement via ultrasonographic imaging immediately before biopsy. One should place the tissue collected in formalin for histopathologic and electron microscopic evaluation. Additional samples can be collected for bacterial culture and for immunofluorescence testing (placed in Michel's transport medium or quick-frozen after coating with a preservative such as Tissue-Tek). One should determine appropriate sample processing beforehand by contacting the pathologist who will examine the biopsy samples.

Although renal biopsy results could provide useful diagnostic and prognostic information about the type of renal disease in horses with ARF (e.g., glomerulonephritis, tubular necrosis, interstitial nephritis), they have been used more often to document the presence of chronic disease in horses with CRF. In most cases of CRF, one cannot detect the inciting cause unless

it can be associated with a historical event or immunofluorescence testing is pursued. This limitation can be attributed to the fact that significant renal disease develops before onset of azotemia. Pathologic lesions are widespread at this point, and involvement of all nephron segments and the interstitium often leads to the interpretation of end-stage kidney disease (ESKD). In occasional cases the results may help separate infectious (pyelonephritis) or congenital (renal dysplasia) causes from nonspecific causes of renal failure. Although such results could be useful in the therapeutic approach to these patients, one should consider the limitations and risks of renal biopsy before performing this technique in horses with CRF.

## URODYNAMIC PROCEDURES

Cystometry and urethral pressure profiles are used to evaluate detrusor and urethral muscle function, respectively. Both techniques involve measurement of intraluminal pressure during inflation of the bladder or urethra. These techniques have been useful for diagnosis of myogenic and neurogenic disorders of the bladder and urethra in dogs and human beings.<sup>171</sup> The procedures have been performed experimentally in normal horses and ponies,<sup>172-174</sup> but little information is available about use of these techniques in clinical cases (see Urinary Incontinence and Bladder Dysfunction).

## ACUTE RENAL FAILURE

Warwick M. Bayly

Acute renal failure is a clinical syndrome associated with abrupt reduction in GFR. Sustained reduction in GFR is associated with failure of the kidneys to excrete nitrogenous wastes causing azotemia and with disturbances in fluid, electrolyte, and acid-base homeostasis. The human medical literature is full of various terms and definitions for different forms of ARF. Veterinary medical definitions are simpler. Basically, ARF can result from decreased renal perfusion without associated cell injury (prerenal failure); obstruction or disruption of the urinary outflow tract (postrenal failure); or ischemic or toxic damage to the tubules, tubular obstruction, acute glomerulonephritis leading to a primary reduction in the filtering capacity of the glomeruli, or tubulointerstitial inflammation and edema. Any of these intrarenal causes can be associated with intrinsic renal failure. Prerenal azotemia and ischemic tubular insults or necrosis represent a continuum, the former resulting in the latter when perfusion is compromised sufficiently to result in death of tubule cells.<sup>1</sup> Classically, ARF has been associated with oliguria and occasionally with anuria, and these are certainly the most commonly noted clinical signs associated with this disease in horses; however, nonoliguric forms of ARF, particularly intrinsic renal failure, exist and are characterized by slower development of azotemia, lower peaks in Cr concentrations, more subtle increases in urinary sodium clearance, and a more rapid recovery of renal function in response to treatment. Nonoliguric renal failure seems to be diagnosed less commonly in horses, although it is not uncommon to recognize mildly azotemic horses that have apparently normal urine output. In some cases, localized proximal tubule damage and reduced solute reabsorption actually may lead to enhanced distal delivery of filtrate, which may result in polyuric ARF.

In horses, ARF is usually prerenal or renal in origin and most often is caused by hemodynamic or nephrotoxic insults.<sup>2</sup> With the exception of bladder rupture in the neonate, postrenal failure is uncommon in horses. Identification and correction of the cause of ARF is important, because in the early stages of failure renal dysfunction is frequently reversible, whereas established ARF often requires extensive supportive care and carries a guarded prognosis. By identifying patients at increased risk and attempting to interrupt the cycle of events leading to ARF, one possibly may reduce the incidence of this condition.

## CAUSES

Prerenal failure is associated with conditions that result in decreased cardiac output or increased renal vascular resistance (or in both) and is the most common cause of reversible azotemia. In horses the most common causes of reduced cardiac output (and therefore reduced renal perfusion) are associated with diarrhea, endotoxemia, acute blood loss, septic shock, and prolonged exercise. The resultant reductions in RBF, GFR, and urine output usually result in azotemia and retention of water and electrolytes. Anesthesia also may decrease cardiac output enough to result in a degree of prerenal azotemia. NSAIDs also can precipitate prerenal azotemia in patients with decreased RBF.<sup>3</sup> Although prostaglandins play only a minor role in maintenance of RBF in the normal state, PGE<sub>2</sub> and PGI<sub>2</sub> are important vasodilatory mediators of RBF under conditions of reduced renal perfusion. Thus administration of NSAIDs to dehydrated or toxemic patients may contribute further to renal hypoperfusion by exacerbating a decrease in RBF. In some cases this also may be sufficient to produce ischemic renal parenchymal damage, thus causing intrinsic renal failure. Generally, the parenchymal lesion associated with NSAID toxicity is medullary crest or papillary necrosis. Such lesions develop because the renal medulla normally receives much less blood flow than the renal cortex and consequently is much more susceptible to NSAID-induced changes in RBF.

In human beings, intrinsic renal diseases that lead to ARF generally are categorized according to the primary site of injury: tubules, interstitium, glomeruli, or vessels.<sup>1</sup> Acute tubular necrosis (ATN) is the form of intrinsic renal failure recognized most often in horses (interstitial and primary glomerular disease being recognized occasionally, and vascular disease almost never). Ischemia, especially when associated with microvascular coagulation (which often leads to irreversible cortical necrosis<sup>4</sup>), and nephrotoxins probably are the most common causes of equine ATN. Important nephrotoxins include aminoglycoside antibiotics and NSAIDs. Less commonly, ATN develops after exposure to endogenous pigments (myoglobin or hemoglobin), heavy metals such as mercury (contained in some counterirritants), or vitamin D or K<sub>3</sub>.<sup>5-8</sup> Use of aminoglycosides, particularly gentamicin, is a common cause of equine ATN.<sup>9</sup> Toxicity is a result of damage to proximal tubular epithelial cells that is mediated by impaired cell organelle function. Administration of potentially nephrotoxic agents such as NSAIDs or furosemide (which can exacerbate hypovolemia) can increase the risk of aminoglycoside nephrotoxicity.

Myoglobinuria and hemoglobinuria have been associated with development of ARF in horses (pigment nephropathy).<sup>10</sup> Myoglobinuric nephrosis can follow exertional rhabdomyolysis, heat stroke, or extensive crush injuries. Causes of

intravascular hemolysis and hemoglobinuria include incompatible blood transfusions, immune-mediated hemolytic anemia, fulminant hepatic failure, and toxicosis from ingesting onions (*Allium* spp.) or withered red maple leaves (*Acer rubrum*). Although the mechanism of pigment-induced renal injury is still not well understood, increased hydroxyl radical formation associated with reduction of ferrous iron compounds and tubular obstruction by casts of heme proteins are likely contributing factors. The fact that pigment nephropathy is uncommon in well-hydrated horses suggests a possible link to renal perfusion. Myoglobin and hemoglobin have been suggested to induce renal vasoconstriction.

Acute interstitial nephritis often is not recognized but is believed usually to result from an allergic reaction to drugs such as the  $\beta$ -lactam and sulfa antibiotics. Autoimmune and embolic or ascending bacterial infections also may be associated with the condition, which is characterized by edema and inflammatory cell infiltration of the interstitium. Tubules frequently contain white and RBCs, which pass into the lumen through the disrupted tubular basement membrane.

Glomerulonephritis often is identified post mortem in aged horses<sup>2,11</sup> and apparently is most often immune mediated. Glomerulonephritis often results in subacute or nonoliguric renal failure. Although the condition is theoretically reversible with immunosuppressive agents, in horses such undertakings are usually impractical and rarely are tried for long.

Postrenal obstructive failure can develop after disease of the renal pelves, ureters, bladder, or urethra. The severity of the failure depends on the extent of the obstruction. Frequently, problems are not recognized in horses until urine output obviously is reduced or renal function is impaired to the point that systemic problems are manifested. Although a neurogenic bladder can cause a functional obstruction, postrenal failure in horses most often results from intraluminal blockage by uroliths, which can cause obstruction anywhere in the urinary outflow tract.<sup>12,13</sup> Other possible intraluminal causes include neoplasia or stricture formation. Extraluminal obstructive lesions such as retroperitoneal tumors or adhesions or bladder displacements also occasionally are associated with development of postrenal failure.

## ☪ PATHOPHYSIOLOGY

The pathophysiology of equine ARF has received little study, and the mechanisms at work are assumed essentially to be the same as those identified in experimental studies of other animal species. Several mechanisms have been demonstrated to be involved in the development of ARF, the actual pathogenesis being complex and depending somewhat on the cause of the disease. Multiple factors probably operate in different combinations at different times and in different nephrons. These different mechanisms are discussed next in relation to the type of failure with which they are associated (i.e., prerenal, intrinsic, and postrenal failure).

The pathophysiology of prerenal failure and ischemic ARF tend to involve the same processes. Toxins that cause ATN also share many pathophysiologic features with ischemic ARF.<sup>14</sup> The heterogeneity of intra-RBF is an important factor in the development of this condition. The kidneys are particularly susceptible to ischemic and toxic injury because of their unique anatomic and physiologic features. Although they receive approximately 20% of the cardiac output, only about 10% to 20% of total RBF reaches the medulla via the vasa recta.

This low medullary blood flow is necessary to ensure a functional countercurrent mechanism in this region of the kidney; however, low blood flow also creates a large corticomedullary oxygen gradient and renders the renal medulla hypoxic and highly susceptible to ischemic injury. Conversely, the renal cortex receives 80% to 90% of total RBF and is particularly susceptible to toxins.

Hypovolemia triggers compensatory systemic and renal responses. The systemic responses include activation of the autonomic nervous system and renin-angiotensin system and release of antidiuretic hormone. Peripheral vasoconstriction is one of the effects of these responses. Renal responses to decreases in circulating blood volume have several phases. Initially, tubular reabsorption of sodium and water increases and is mediated by nerves and hormones. Reabsorption usually is associated with reduced clearance of urea and an associated increase in serum urea nitrogen concentration in the face of preservation of GFR, which in turn maintains the plasma Cr concentration in the normal range. More severe hypovolemia overcomes renal autoregulation, RBF being redistributed from the cortex to the medulla and GFR thus declining. The renal circulatory changes further enhance tubule solute reabsorption in the face of the decreased GFR. The net effect is production of small amounts of concentrated urine, a high urine-to-plasma Cr ratio, and low fractional sodium clearance.<sup>15</sup>

A further reduction in RBF results in a syndrome considered intermediate between the prerenal and intrinsic ischemic forms of ARF. Urine concentrating ability apparently is disrupted earlier than is sodium reabsorptive capability, with the result that urine osmolality decreases and output increases, but fractional sodium clearance stays low. Patients may appear to be mildly polyuric.<sup>16</sup> With more severe or prolonged renal hypoperfusion and ischemic insult, urinary sodium and fractional sodium clearance start to increase and the animal develops nonoliguric, and then oliguric, ARF. These changes are associated with progressively more severe tubule necrosis as the ARF progresses from prerenal to renal. The more severe the insult is, the poorer is the prognosis.

Intrarenal vasoconstriction is caused by an imbalance between vasoconstrictive and vasodilating factors (systemic or local) that act on small renal vessels in particular. These mediators include the vasodilator nitric oxide and the constrictor endothelin. Hypercalcemia is associated with increases in free calcium in the vascular smooth muscle and leads to enhanced vascular tone. Vasopressin and angiotensin II also have been shown to induce significant vasoconstriction under certain experimental conditions, as have endotoxins and myoglobin. Some nephrotoxins—gentamicin, heavy metals, and radiographic contrast agents—can cause renal vasoconstriction in addition to having direct toxic effects on the proximal tubules.<sup>17-19</sup>

Prostaglandins  $E_2$  and  $I_2$  are potent mediators that are responsible for a critical vasodilating response in the face of reduced RBF when activation of the renin-angiotensin system alone would result in further vasoconstriction. Increases in circulatory concentrations of angiotensin II stimulate synthesis of these renal prostaglandins. Consequently, the vasoconstrictive effects of stimulating the renin-angiotensin system usually are blunted somewhat by concomitant increases in  $PGE_2$  and  $PGI_2$ ; however, in the face of increased angiotensin II and simultaneous inhibition of prostaglandin synthesis (e.g., because of an NSAID), a significant increase in renal vascular resistance results.<sup>20</sup>

The reduction in GFR associated with reduced renal perfusion is associated with a number of mechanisms involving the glomeruli, vasculature, and tubules. In the initial phases a reduction in glomerular capillary hydrostatic pressure is associated with a net drop in RBF and a rise in renal vascular resistance. The latter phenomenon usually is associated with afferent arteriolar vasoconstriction and efferent arteriolar vasodilation and initially is reversible with volume expansion. Later (2 days or more), restoration of RBF does not necessarily improve GFR, and a drop in RBF is associated with a disproportionately greater drop in GFR.<sup>21</sup> Even when vasoconstriction is reversed, GFR may not improve; this reflects loss of RBF autoregulation. This disproportionate reduction in GFR suggests a fall in the ultrafiltration coefficient of the glomeruli after a reduction in total filtering area. The mechanism for this is unclear but may be associated with increases in angiotensin II concentration, because this agent is known to induce mesangial contraction and a drop in the ultrafiltration coefficient.<sup>22</sup>

In addition to the aforementioned vascular changes that can affect GFR, the possible effects on GFR in the juxtamedullary region of even mild changes in RBF warrant specific mention. The glomeruli and adjacent straight portion of the proximal tubule and thick ascending limbs of the loops of Henle in this region are apparently particularly susceptible to hypoxia (i.e., ischemia) because of their high oxygen requirements. Swelling of endothelial and tubule cells after prolonged ischemia in this region results in increased vascular resistance and continued compromise of the medullary circulation, even when cortical RBF has been restored.<sup>14,23</sup>

GFR also can be compromised significantly by obstruction of tubular lumina by casts of cellular debris and inflammatory cells. Increased intratubular pressure decreases the net driving pressure for glomerular filtration in the same way that obstruction of the urinary outflow tract ultimately can lead to a lower GFR. One of the reasons that agents that accelerate the solute excretion rate (e.g., furosemide, mannitol) may be therapeutic adjuncts has been that they are believed to help disperse these luminal blockages.

Tubuloglomerular feedback is a regulatory mechanism that lowers GFR whenever solute (most notably NaCl) concentrations at the macula densa are increased. In ARF, impaired transport in the thick ascending limb of the loop of Henle in the context of preserved glomerular response to signals from the macula densa results in a decrease in GFR. This feedback is a normal protective mechanism mediated principally by the renin-angiotensin system, although prostaglandin, intracellular calcium, and adenosine may play a role in signal transmission or regulation. In essence the mechanism serves to prevent massive fluid losses associated with a reduction of tubular reabsorptive capacity; however, in cases of renal hypoperfusion and ischemia, the effect is the opposite, because basically the feedback mechanism exacerbates the effects of already reduced RBF.

Proximal tubule cells undergo morphologic changes early in cases of ischemia. They lose their brush borders and polarity, and the integrity of their tight junctions is disrupted, probably after alterations in the actin and microtubular cytoskeletons.<sup>24,25</sup> Under these conditions the glomerular filtrate is able to leap back to the peritubular circulation, thus reducing the net (or effective) GFR. This mechanism is thought to be an important source of GFR reduction only in more severe cases of ischemia or nephrotoxin exposure.

Tubule cells involved in solute reabsorption have a high metabolic rate and a high demand for oxygen. The existence of the corticomedullary oxygen gradient makes these cells vulnerable to the effects of hypoxia and ischemia, the thick ascending limb of the loop of Henle in the outer medulla being most susceptible.<sup>26</sup> Early in ischemic and toxic ARF, decreases in ATP and adenosine diphosphate tissue levels occur with associated elevations in adenosine monophosphate and inorganic phosphate concentrations. Much of the adenosine monophosphate is broken down further to adenosine and then to xanthine. Adenosine is a potent constrictor of cortical blood flow and probably enhances the effect of the tubuloglomerular feedback system. Depletion of ATP in tubular cells inhibits cell volume regulation, and the resultant swelling probably contributes to luminal obstruction and increased vascular resistance. Redistribution of Na<sup>+</sup>,K<sup>+</sup>-ATPase from the basolateral to the apical membrane of the tubule cells reduces the ability of the cells to extrude sodium into the peritubular fluid and circulation.<sup>27</sup> Redistribution of integrins to the apical surface contributes to the breakdown of tight junctions.<sup>28</sup> Depletion of ATP in tubule cells also leads to an increase in cytosolic calcium concentration. In addition to being a vasoconstrictor, calcium activates proteases and phospholipases, interferes with mitochondrial energy metabolism, and can break down the cytoskeleton.<sup>1,29</sup> Administration of calcium channel blockers has helped ameliorate ARF in some experimental situations.<sup>30</sup>

Reperfusion of renal tissue after a period of ischemia is associated with rapid production of oxygen free radicals and with significant tissue damage. Xanthines, neutrophils, phospholipase A<sub>2</sub>, mixed-function oxidases, and mitochondrial electron transport are associated with the production of these oxidants.<sup>31</sup> Phospholipase A<sub>2</sub> hydrolyzes phospholipids in cell and mitochondrial membranes to free fatty acids and lysophospholipids and produces arachidonic acid. Arachidonate in turn is converted to eicosanoids that are vasoconstricting and chemotactic for neutrophils.<sup>32</sup> Cell membranes are particularly susceptible to phospholipase activity after reperfusion. Reperfusion injury is a major consideration in transplant surgery; however, the role it plays in the pathogenesis of prerenal and ischemic ARF is not clear.

Many of the cellular biochemical and structural changes that occur along with the ischemic form of ARF are also important parts of the pathogenesis of ATN associated with exposure to nephrotoxins. Toxin-associated dysfunction and necrosis of cells result in increased tubular pressure and a decreased glomerular capillary hydrostatic pressure gradient. Loss of reabsorptive capability triggers tubuloglomerular feedback and further reduces GFR by lowering RBF after vasoconstriction and a decrease in the glomerular ultrafiltration coefficient. Transepithelial backleak of solutes into the circulation further interferes with the excretory function of the kidneys.

## ACUTE TUBULAR NECROSIS

Many agents are recognized to have potential nephrotoxic effects. Aminoglycoside-induced renal toxicity results from accumulation of these agents within the renal cortex. Streptomycin is the least nephrotoxic of the aminoglycosides, whereas gentamicin and kanamycin are intermediate nephrotoxins. Neomycin is the most nephrotoxic. Most cases of aminoglycoside toxicity are associated with conditions that cause reduced renal perfusion because the healthy kidney

usually can tolerate some degree of aminoglycoside overdosing. After filtration at the glomerulus, aminoglycosides bind to phospholipase on the brush border of proximal tubules and subsequently are reabsorbed by pinocytosis. Accumulation of these antibiotics interferes with lysosomal, mitochondrial, and  $\text{Na}^+$ , $\text{K}^+$ -ATPase function by inhibiting phospholipase A activity. Binding to the brush border is saturable with the result that sustained exposure of the proximal cells to the drug (as with multiple daily-dosing) results in greater accumulation of the drug and increased nephrotoxicity. As a result, once-daily dosing may attenuate the risk of nephrotoxicosis while maintaining or improving therapeutic efficacy (because it results in higher peak concentrations).<sup>33,34</sup> Many mild cases of aminoglycoside toxicity notably are associated with nonoliguric ARF and therefore may go unrecognized in horses.

Some cephalosporins, such as cephaloridine, have considerable nephrotoxic potential. These agents cause necrosis because of mitochondrial toxicity after accumulation of the antibiotic in the cell.<sup>35</sup>

Not all cases of ATN are caused by direct toxic changes in tubule cells. For instance, whether myoglobin and hemoglobin are truly nephrotoxic is still debatable. The principal characteristics of pigment nephropathy caused by these agents are tubule obstruction and reduced RBF (caused by the direct vasoconstrictor effects of the pigment). Whether obstruction is physical, caused by pigment accumulation, or reflects aggregation of sloughed cells is not clear. Myoglobin tends to be associated with nephropathy more frequently than hemoglobin. Patients often quickly become oliguric, presumably because of the widespread tubule obstruction.

### ACUTE INTERSTITIAL NEPHRITIS

Distinguishing between drug-induced ATN and acute interstitial nephritis can be difficult, and the latter rarely is diagnosed in horses. Making a distinction may be a particular problem when continued use of antibiotics is indicated. With ATN one may alter the dosing regimen, whereas with interstitial nephritis, short-term corticosteroid therapy is often of benefit in human beings. Interstitial nephritis often is marked by eosinophiluria and eosinophilia and is more likely to be associated with the presence of red cells than is ATN. The exact immune mechanism by which interstitial nephritis develops is unclear, although it is thought most likely to be caused by delayed cell-mediated hypersensitivity or the presence of antitubule basement membrane antibodies.<sup>36</sup> The prognosis is usually grave in horses with acute interstitial nephritis.

### ACUTE GLOMERULONEPHRITIS

Acute glomerular nephropathy is rare in horses; however, when it occurs, it usually is manifested by the nephrotic syndrome, although hematuria and oliguria sometimes are apparent. Deposits of  $\gamma$ -globulin and complement are found along the basement membrane (global form) or in the mesangial area (mesangioproliferative form).<sup>37</sup> Group C streptococcal antigens have been identified along with equine glomerulonephritis, and equine infectious anemia (EIA) viral antigen-antibody complexes have been recognized in the glomeruli of horses that were not in renal failure.<sup>11,38</sup> Deposition of immune complexes activates the complement cascade. Formation of  $\text{C}_3\text{b}$  and  $\text{C}_5\text{a}$  causes platelet aggregation and attracts neutrophils.

Tissue damage results from deposition of complement *per se* and from inflammation associated with neutrophil activation and release of reactive oxygen radicals, proteases, elastases, and other lysozymes. These enzymes, plus platelet-activating factor and leukotriene  $\text{B}_4$ , increase vascular permeability and upregulate expression of adhesion molecules, thus promoting further inflammation.<sup>32</sup> Severe reduction in GFR results from large drops in the glomerular permeability coefficient, which is associated with the widening of Bowman's spaces after inflammation and deposition of immune complexes.

Basically, increases in ureteral pressure for any reason result in GFR reduction because of a drop in the glomerular capillary hydrostatic pressure gradient, some tubular backleaking, a decrease in the glomerular permeability coefficient, and ultimately, a reduction in RBF. (See previous discussion of the pathophysiology of postrenal ARF.)

### CLINICAL SIGNS

In most horses with hemodynamically mediated (i.e., prerenal, ischemic) ARF, clinical signs are usually referable to the primary problem, such as acute colic or enterocolitis, sepsis, coagulopathies, rhabdomyolysis, or heavy-metal poisoning, rather than to renal dysfunction. Therefore the predominant clinical signs are often dehydration (with or without diarrhea), depression, and anorexia. Other signs can include tachycardia, hyperemic mucous membranes, pyrexia, mild abdominal pain, and laminitis. Because clinical signs usually relate to the inciting problem, ARF may not be suspected or detected unless the veterinarian specifically evaluates renal function as part of the workup for a more obvious disease. In general, the clinical manifestations of ARF reflect the systemic effects of toxic substances usually excreted in the urine (i.e., uremia generally is reflected by anorexia and depression), urinary tract dysfunction, and derangements of fluid, electrolyte, and acid-base balance. One may observe signs of encephalopathy in horses with severe azotemia.

Although oliguria is considered the hallmark of ARF, urine production in horses varies. Oliguria frequently occurs in the early stages of hemodynamically mediated ARF and is the most frequently reported clinical sign that is related directly to urinary tract dysfunction. As outlined in the section on pathophysiology, however, nonoliguric and polyuric stages of prerenal and intrinsic ARF also can be associated with renal hypoperfusion. Anuria is rare. Nonoliguric or polyuric ARF also can be associated with exposure to nephrotoxins (ATN), and polyuria is common during the recovery phase of ARF, regardless of its cause. The magnitude of azotemia tends to be lower in nonoliguric than in oliguric ARF, possibly indicating less severe damage in the former condition. Similarly, nonoliguric ARF is associated with a more favorable prognosis.

Patients with ARF often are treated initially with large volumes of intravenous or oral fluids for the primary disease. In these cases, oliguria may progress to polyuria. When significant renal damage has been sustained, persistence of oliguria in the face of fluid administration usually is manifested as failure to produce a significant volume of urine in response to fluid therapy. The degree of change of azotemia also is minimal in the initial 24 to 36 hours of treatment. If one does not monitor these patients carefully, then fluid retention may lead to development of subcutaneous and pulmonary edema. Soft feces caused by fluid retention also may be apparent in patients with oliguric ARF.

Postrenal or obstructive uropathy usually is characterized by mild to severe abdominal pain and pollakiuria and stranguria (see Obstructive Disease of the Urinary Tract).

## DIAGNOSIS

Increases in plasma urea nitrogen and Cr concentrations (i.e., azotemia) are frequently the initial findings that suggest compromised renal function. Azotemia simply reflects a reduction in GFR; it has almost no differential diagnostic value. After establishing recent development of azotemia, the equine internist must proceed systematically to differentiate between six possible syndromes associated with ARF: (1) prerenal ARF, (2) ischemic ARF, (3) ATN, (4) acute interstitial nephritis, (5) acute glomerulonephritis, and (6) obstructive (postrenal) ARF. A useful way to go about this is first to try to rule out pre- and postrenal ARF. If this is possible, then the patient must have a type of intrinsic ARF; therefore one can direct further diagnostic efforts to identifying the disease subtypes.

As described in greater detail later (see Urolithiasis), the diagnosis of postrenal obstructive disease usually is based on a combination of clinical signs, history, and the results of rectal palpation, ultrasonography, and urinary tract endoscopy. The frequency and volume of urination can vary with these cases, and total obstruction causes anuria. Salt and water reabsorption often are impaired as the problem persists, which results in hyponatremia (i.e., plasma sodium concentrations in the low-normal range). Although the mechanisms for this sodium wasting are not completely clear, the wasting apparently is related to impaired function of the ascending limb of the loop of Henle and an increased medullary blood flow after prostaglandin release. Both of these events greatly diminish the magnitude and effect of the medullary countercurrent concentrating mechanisms. Prostaglandin also directly inhibits the effect of antidiuretic hormone.<sup>39</sup>

Measurement of specific gravity in the azotemic horse is a commonly practiced means of detecting prerenal ARF. In these cases the value is usually greater than 1.025 and often as high as 1.055. In human beings, one can use a number of reliable indexes to differentiate renal azotemia from prerenal azotemia<sup>40-42</sup> that are based on urine osmolality and the ratio of urine-to-plasma osmolality ( $U/P_{osm}$ ), urine sodium concentration and fractional sodium clearance, and ratios of urine-to-plasma urea concentrations ( $U/P_{UN}$ ) and urine-to-plasma Cr concentrations ( $U/P_{Cr}$ ). Fractional sodium clearance in particular is a good indicator of solute reabsorption and proximal tubule function, whereas  $U/P_{Cr}$ , and to a lesser extent  $U/P_{UN}$ , are useful indexes of the ability of the tubules to reabsorb water. The utility of these indexes in horses also has been investigated and has been shown to have considerable differential diagnostic value.<sup>15</sup> Although these tests are discriminatory, some degree of overlap occurs between them respecting prerenal and parenchymal or intrinsic problems. One also must bear in mind that these indexes do not allow differentiation between intrinsic and postrenal disease. A number of horses with prerenal (nonoliguric) ARF have urine osmolality less than 360 mOsm. A small percentage of horses in prerenal ARF have  $U/P_{Cr}$  less than 30 (usually >50) and fractional sodium clearance greater than 0.80% (usually <0.50%), most likely because of the unrecognized existence of tubule damage before volume depletion or because of a natriuretic effect of some treatments such as diuretics or intravenous fluids. Natriuresis is particularly

likely to be induced along with bicarbonate administration because sodium cations are lost with unreabsorbed bicarbonate anions. In these cases the determination of the fractional chloride clearance may be a better indicator of the response of the kidney to hypoperfusion.

No parameter reliably differentiates between prerenal and ischemic ARF because of the pathophysiologic continuum between these diseases. At one end is reduced GFR with preserved tubule function and concentrating mechanisms. This form of disease is readily reversible with appropriate therapy. Additional or more prolonged decreases in GFR lead to disturbances in tubule function and slower reversal of damage until the other end of the spectrum is reached, in which complete and irreversible loss of renal function occurs. Assessment of urine specific gravity before initiation of fluid therapy is helpful in differentiating prerenal failure from renal failure. As normally functioning kidneys would preserve salt and water maximally in response to a transient decrease in RBF with prerenal failure, so urine specific gravity and osmolality are greater than the values associated with serum, whereas the urine produced by horses with intrinsic ARF is often isosthenuric (specific gravity <1.020). In a clinical situation, assessment of the response to fluid therapy is the most practical way to differentiate prerenal failure from intrinsic forms of ARF. Azotemia caused by prerenal problems should resolve quickly with replacement of fluid deficits and restoration of renal perfusion. In prerenal failure, volume repletion also should restore renal function, with the result that the magnitude of azotemia should decrease by 50% or more during the first day of therapy. In contrast, fluid therapy usually does not lead to prompt resolution of azotemia associated with intrinsic problems. Application of the measurement of  $U/P_{Cr}$  and  $U/P_{UN}$  ratios is limited to use on urine samples collected before initiation of fluid therapy or the first urine sample voided after fluid therapy has been started.

In prerenal ARF, electrolyte and acid-base abnormalities generally reflect problems caused by a primary disease (e.g., enterocolitis, colic, blood loss). Most frequently, horses are mildly acidotic, hyponatremic, and hypochloremic. Plasma concentrations of potassium and calcium vary according to what disease is causing renal hypoperfusion. Potassium concentration also is affected to some extent by urine output, hyperkalemia being most common in association with oliguria and anuria.

The technique for biopsy of the left kidney has been well described.<sup>43</sup> The main indication of kidney biopsy is to help differentiate between types of intrinsic renal disease when one thinks that this distinction will have therapeutic and prognostic relevance. One often can diagnose ischemic failure and ATN without biopsy. The primary complication associated with the biopsy procedure is renal hemorrhage, which can be severe. Ultrasonographic guidance and use of a spring-loaded biopsy instrument may reduce the risk of complications. Ultrasonography also allows biopsy of the right kidney. As the knowledge of equine renal physiology and pathology improves, and advances in molecular genetics lead to techniques that supplant or supplement standard histopathologic methods, the diagnostic usefulness of renal biopsy may increase. For example, biopsy results may dictate the use of immunosuppressive agents in the treatment of some forms of renal parenchymal disease (e.g., interstitial nephritis).

Identification of subtypes of intrinsic ARF often depends on analysis of urine and urine sediment. The availability of

a history of exposure to ischemic insults or potential nephrotoxins such as aminoglycosides certainly helps in this regard, but determination of the severity of the condition and its prognosis still generally relies on the analysis of urine. Ischemic tubule disease is similar to ATN. In both cases a slight to moderate proteinuria with specific gravities usually less than 1.020 and urine osmolality less than 350 mOsm occurs. Fractional sodium clearance is nearly always greater than 1.0, regardless of urine output. Granular casts frequently are visible, particularly with ATN. Enzymuria and phosphaturia are frequently prominent early in the course of ATN.<sup>44,45</sup> Plasma sodium and chloride concentrations are usually low. Plasma concentrations of calcium and inorganic phosphate vary greatly: increases, decreases, and normal values are possible, depending on the diet of the horse, the nephrotoxin, and the location and severity of damage to the nephron.<sup>38,44,45</sup>

One must remember that GFR is reduced in cases of ATN and is most likely caused by the increase in presentation of sodium and chloride at the macula densa after dysfunction of proximal sodium reabsorption. Stimulation of the macula densa results in release of renin and local production of angiotensin II, thus increasing renal vascular resistance and lowering RBF. The low GFR may mask the absolute magnitude of the damage in tubule function; however, if one studies renal sodium reabsorption carefully over time in cases of ATN, then this defect appears to improve more rapidly than that of GFR.<sup>46</sup>

Acute interstitial nephritis often is not recognized in horses; however, in a study conducted about 20 years ago, the condition was diagnosed in approximately one eighth of all human patients who needed renal biopsy for diagnosis of unexplained ARF.<sup>47</sup>

Edema and diffuse or focal patches of interstitial inflammation characterize the disease. In human medicine, the number of drugs, toxins, and infectious agents known to induce this disease is growing. No reason exists to believe that similar agents are not capable of causing the same disease in equids. Inflammatory cells surround the tubules and can move between epithelial cells into tubule lumina. As a result, white blood cell casts are common. The leukocytes are also capable of disrupting the tubule basement membrane, making cell repair much less likely; this is an important distinguishing feature between ATN and interstitial nephritis. With the former disease the basement membrane usually stays intact. Reduction of GFR and azotemia probably result from the interstitial edema, intratubular obstruction, and release of vasoactive agents.

Acute interstitial nephritis and ATN have similar fractional sodium clearance,  $U/P_{Cr}$ , and  $U/P_{osm}$  values; however, the urine sediment may be different for each disease. Sterile pyuria and microscopic hematuria commonly occur with interstitial nephritis, although RBC casts are rare. Mild proteinuria and eosinophiluria are also common. Eosinophiluria generally seems to be limited to renal interstitial disease, mainly drug-induced interstitial nephritis but also chronic pyelonephritis and systemic lupus erythematosus.<sup>48,49</sup> Eosinophiluria may or may not be accompanied by eosinophilia. Eosinophils in equine urine should be easy to observe using Wright's stain, given the alkaline nature of the fluid. Occasionally, fevers are believed to be associated with the development of interstitial nephritis. This clinical sign is relatively nonspecific and might be misleading if the animal is being treated with antibiotics for an infection. What one might see

with close monitoring of the patient is an initial reduction or resolution of the fever after the onset of antimicrobial therapy followed by recurrence of the fever and development of azotemia. If this happens, then acute interstitial nephritis should be on the rule-out list.

The nephrotic syndrome usually characterizes acute glomerulonephritis. Proteinuria is moderate to severe, and the urine usually is concentrated. Urine osmolality and  $U/P_{osm}$  are comparable with the values with prerenal ARF and are higher than those values normally seen in ATN. Urinary sodium concentration and fractional sodium clearance tend to be much lower than with other intrinsic renal and postrenal causes of ARF. The ratios of  $U/P_{UN}$  and  $U/P_{Cr}$  are often similar to those associated with prerenal failure and higher than those in ischemic, tubular, interstitial, or postrenal disease. Renal tubular secretion of Cr is increased in glomerulonephritis, with the result that Cr concentrations may not rise quickly and urea nitrogen-to-Cr ratios stay high, as they frequently do with prerenal problems. Therefore although urinary indexes should make possible differentiation of acute glomerulonephritis from other parenchymal and postrenal diseases, they overlap much with those associated with prerenal ARF. One is going to differentiate ARF caused by acute glomerulonephritis from that caused by hypoperfusion based on the significant proteinuria and red cell numbers usually associated with the former disease. Red cell casts are more common with glomerulonephritis than with other intrinsic causes of ARF. Some causes of postrenal ARF also may manifest red cell casts, but the proteinuria is not normally as great in those situations.

## ☞ TREATMENT

Initially, treatment of horses with ARF should focus on reversing the inciting or underlying cause and correcting fluid and electrolyte imbalances. Early identification of patients at risk and prevention of problems by rapid restoration and accurate maintenance of intravascular fluid volume, glomerular filtration, and urine production (with fluids and possibly diuretics) is obviously preferable to treatment. The importance of prevention cannot be overstated. One should correct initial fluid deficits over the first 6 to 12 hours of treatment. Physiologic saline or a balanced electrolyte solution is the fluid of choice unless the patient is hypernatremic, as may be the case in prerenal ARF or acute glomerulonephritis. In the event of hypernatremia, solutions of 0.45% NaCl and 2.5% dextrose is recommended. The addition of 50 to 100 g of dextrose per liter of fluid to saline or polyionic fluids helps address the caloric needs of anorectic horses. If fluid administration is begun early in the course of the disease or if the problem is not severe, then diuresis should result. When this occurs, one should maintain intravenous fluid therapy at least at twice maintenance level (up to 100 ml/kg per day or more) until Cr concentration decreases dramatically. One then reduces the rate of fluid administration to 40 to 50 ml/kg per day until the Cr concentration is normal or the horse is eating and drinking adequately.

In the event that the horse remains oliguric 10 to 12 hours after starting fluid therapy, administration of dopamine in 5% dextrose slowly (3 to 5  $\mu$ g/kg/min) may improve RBF and urine output. One should monitor blood pressure during dopamine infusion because the drug can induce significant hypertension. Administration of dopamine should be discontinued if blood pressure starts to rise. One can attempt to restart the infusion

at a lower rate when pressure has returned to normal. Blood pressure also may increase because of overhydration of oliguric patients who are receiving isotonic fluids. Regular monitoring of body weight, hematocrit, and serum total protein concentration, central venous pressure, and lung sounds is important if one is to prevent problems caused by overhydration.

The use of diuretic agents such as mannitol and loop diuretics to treat ARF is controversial. Furosemide and ethacrynic acid are the loop diuretics most commonly used. Furosemide is a particularly potent short-acting agent that acts by blocking the Na/K/2Cl<sup>-</sup> co-transporter in the ascending limb of the loop of Henle. In addition to promoting diuresis, co-transporter inhibition also may protect these tubule cells by reducing their metabolic rate and thus oxygen demand in the face of limited oxygen availability after hypoperfusion. To be effective, loop diuretics must gain access to the tubule lumina. Therefore loop diuretics may be of limited value in prerenal or ischemic problems, although the potential protective effect of furosemide on the especially vulnerable cells of the thick ascending limb may warrant its administration. Loop diuretic administration also may exacerbate or induce volume depletion in cases of ARF that are characterized by isosthenuria or polyuria (e.g., early ATN), thus making the condition worse and rendering the patient more susceptible to the effects of nephrotoxins such as gentamicin. Loop diuretics appear to be most beneficial when used in cases characterized by tubule obstruction (e.g., pigmenturia) because the diuretic-induced increase in solute retention apparently helps flush these blockages and casts from the tubules.

Although loop diuretics have no direct effect on GFR, 20% mannitol (0.25 to 1.0 g/kg) given over 15 to 20 minutes may help combat oliguria by increasing RBF and GFR. The increase occurs after reductions in plasma protein concentration and oncotic pressure. These changes in turn result from the systemic effects of the increase in intravascular osmolality induced by the mannitol. Mannitol also may induce synthesis of the vasodilator PGE<sub>2</sub> and release of atrial natriuretic peptide, which also would increase RBF and GFR. Once filtered, the agent also acts as an osmotic diuretic, thus decreasing urine solute concentration and boosting urine volume. Consequently, mannitol also can be effective in treating conditions characterized by tubular obstruction and swelling of tubule cells.

Hyperkalemia is uncommon in equine ARF, except in some postrenal cases. When present, hyperkalemia is usually mild and responds to administration of potassium-free intravenous fluids. When hyperkalemia (>6.5 mEq/L) persists, correction of any associated acidosis with sodium bicarbonate or administration of glucose (up to 10% solution), or both, usually helps. In the worst or most refractory cases, insulin may be necessary. Potassium supplementation (KCl 20-40 mEq/L) may be necessary during the polyuric phase of recovery from ARF.

Calcium metabolism often is disrupted in cases of equine ARF, with hypocalcemia and hyperphosphatemia or hypercalcemia and hypophosphatemia having been reported variously. Hypercalcemia usually resolves with a switch to a grass or grass-hay diet and with time. Hypocalcemia probably occurs for a number of reasons, including skeletal resistance to parathyroid hormone during the early stages of ARF and deficiency of 1,25-dihydroxycholecalciferol, which results from downregulation of renal 1,25-hydroxylase by the hyperphosphatemia, dysfunction of this enzyme after renal parenchymal damage,

or both.<sup>45,50</sup> Hypoalbuminemia and enhanced deposition of calcium in injured tissues, as can occur in cases of rhabdomyolysis, are other factors to consider. Administration of a calcium salt as part of the intravenous fluid therapy protocol is usually sufficient to correct this.

Severe uremia often decreases RBC life span and induces platelet dysfunction. Consequently, anemia (possibly also caused by decreased production of erythropoietin) and bleeding tendencies may be associated with ARF. These conditions may require treatment with transfusions, synthetic erythropoietin, or conjugated estrogens.

Because aminoglycoside toxicity is one of the more commonly recognized causes of equine ARF,<sup>4,9,51</sup> continued aminoglycoside use in horses with ARF warrants specific attention. Gentamicin and amikacin are the aminoglycoside antibiotics most often used in equine practice, and their pharmacokinetics have been well studied in healthy animals. Large interindividual and age variations occur in the volume of distribution and clearance of these drugs in normal horses, and this variability is even greater in diseased horses. Therefore when a patient with ARF requires aminoglycoside antibiotics, monitoring serum trough concentrations of the drug to adjust the dosing interval is strongly indicated, because it provides the best protection against exacerbating renal damage. Renal dysfunction associated with aminoglycoside toxicity usually is indicated by an increase of at least 0.3 mg/dl in Cr concentration. When this occurs, discontinuing therapy or increasing the dosing interval should be considered. One must remember that changes in urine sediment and development of enzymuria, mild proteinuria, glucosuria, and decreased urine-concentrating ability develop a number of days before Cr concentration increases and are good indicators of the development of aminoglycoside nephrotoxicity. One usually can address the problem successfully by maintaining or increasing intravenous fluid therapy to guard against renal hypoperfusion and by appropriately adjusting the dosing interval with the antibiotic.

## ☞ PROGNOSIS

The prognosis for equine ARF depends on the underlying cause, the duration of renal failure, the response to initial treatment, and the development of secondary complications such as diarrhea, thrombophlebitis, and laminitis. Generally speaking, the duration of ARF before beginning therapy is the most important determinant of prognosis. Of the primary causes of ARF, severe ischemic failure and acute interstitial nephritis probably carry the worst prognosis in horses. ARF of any cause, however, should be associated with a reduced or poor prognosis in the event that early interruption of the pathophysiologic events leading to ARF is not achieved or that the animal displays prolonged oliguria or anuria (longer than 12 hours) after institution of vigorous therapy. Most cases of postrenal ARF carry a favorable prognosis, provided the initiating disease is treated successfully. When discussing prognosis with horse owners, practitioners always must bear in mind that a successful outcome is not always associated with complete return of normal function. Many horses live long after a bout of ARF but never fully regain the ability to concentrate urine as well as they did before the disease; in other cases they remain constantly polyuric. ATN, after nephrotoxicity in particular, carries a favorable prognosis when tubule basement membranes remain intact.

## CHRONIC RENAL FAILURE

Harold C. Schott II

### ☞ PREDISPOSING CONDITIONS

CRF is recognized infrequently in horses. For dogs and cats the prevalence of CRF has been reported to be 0.9% and 1.6%, respectively,<sup>1</sup> whereas the Veterinary Medical Data Base at Purdue University reported that only 515 of 442,535 horses admitted to participating veterinary teaching hospitals during the years 1964 through 1996 had CRF (prevalence of 0.12%). In actuality, this may be an underestimate, because when a diagnosis of CRF is established for a horse, the horse likely may be destroyed without presentation to a veterinary teaching hospital. As in dogs and cats, CRF appears to be a greater problem in older horses (the prevalence increased to 0.23% in horses older than 15 years). The 0.51% prevalence for intact males older than 15 years of age also suggests that stallions may be at greater risk.

Although the clinical syndrome of CRF is uncommon, one widely cited abattoir study revealed that 16% of 45 horses examined had glomerular lesions on light microscopic examination and 42% (22 of 53 horses examined) exhibited deposits of immunoglobulin or complement on immunofluorescence staining of tissue samples.<sup>2</sup> Although these findings suggest that as many as one third of horses may show microscopic evidence of renal disease, only one of the horses in this survey exhibited signs of CRF. This disparity can be attributed to a large renal reserve capacity, because clinical signs of renal failure do not become apparent until two thirds to three fourths of functional nephrons have been lost.<sup>3</sup> Although this rule of thumb is based on studies of partially nephrectomized laboratory animals, support for similar renal reserve capacity in horses is found in several clinical reports of unilateral nephrectomy used successfully to manage disorders of the upper urinary tract.<sup>4-8</sup> In addition, after experimental unilateral nephrectomy in ponies<sup>9</sup> and horses,<sup>10</sup> renal function remained within normal ranges and the animals maintained body weight.

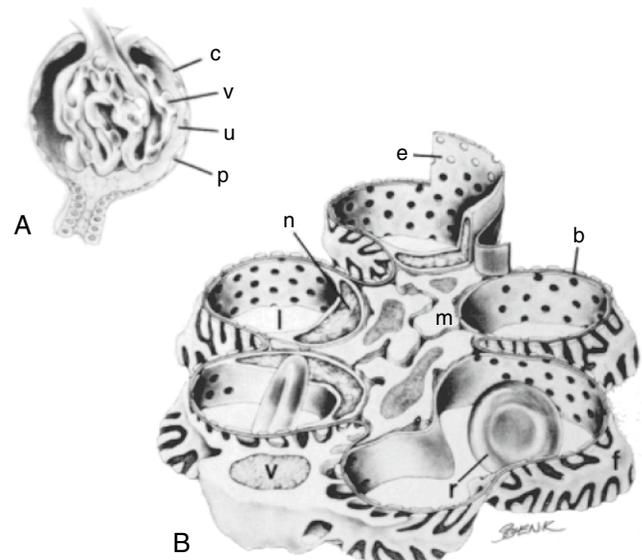

Disorders of the kidneys leading to CRF may be congenital or acquired. In horses younger than 5 years with a history that includes no event that might have been complicated by ARF, one should suspect a congenital renal disorder: renal agenesis, hypoplasia, dysplasia, or PKD.<sup>11-24</sup> Although each of these congenital abnormalities occasionally is recognized, acquired disease consequent to glomerular or tubular injury is more often the cause of CRF in horses.<sup>25-30</sup> Acquired disease is usually insidious in onset, and renal injury may have been initiated years earlier. Thus identifying the cause of CRF is challenging because many horses have evidence of advanced glomerular and tubular disease, termed *ESKD*, by the time clinical signs of CRF develop. Nevertheless, knowing the various causes of CRF affords a better overall understanding of CRF in horses.

### GLOMERULONEPHRITIS

Glomerular injury is a common precipitant of renal insufficiency and CRF in horses. Although immune-mediated glomerular injury is implicated most often in glomerulonephritis, glomerular integrity can be disrupted by a number of unrelated disease processes, including ischemia, toxic insults, and infection.<sup>31</sup> These mechanisms usually lead to significant vascular

and tubulointerstitial changes in addition to glomerular injury. Thus the designation glomerulonephritis typically is reserved to denote renal disease of which immune-mediated glomerular damage is suspected to be the initiating factor in development of renal failure. Until the last decade, glomerulonephritis was considered a rare cause of CRF in domestic animals; interstitial nephritis was implicated more often.<sup>32-34</sup> Refinement of histologic examination with immunofluorescence staining techniques and electron microscopic examination of renal tissues has led to increased recognition of subclinical and clinically significant glomerulonephritis.<sup>34</sup>

A brief review of the subgross anatomy of the glomerulus sheds light on the pathophysiology of glomerulonephritis. The renal corpuscle, or glomerulus, is comprised of a tuft of glomerular capillaries surrounded by epithelial cells that line Bowman's capsule. The root that supports the pedicle of the glomerular capillary network is similar to the mesenteric root that supports the intestinal tract, and Bowman's capsule is analogous to the peritoneum (Figure 19-18-1, A). On a microscopic level, components of the glomerulus include capillary endothelial cells, mesangium (cells and matrix), GBM, and visceral epithelial cells. At the vascular pedicle, the latter become contiguous with parietal epithelial cells that line Bowman's space, much as mesothelial cells covering bowel serosa and mesentery become contiguous with the peritoneum at the mesenteric root.<sup>31</sup> Glomerular capillary endothelial cells are unique in that they are fenestrated with pores that represent the initial barrier for passage of blood components into the urinary space (Figure 19-18, B). The mesangium, which lies between endothelial and epithelial cells, is the support

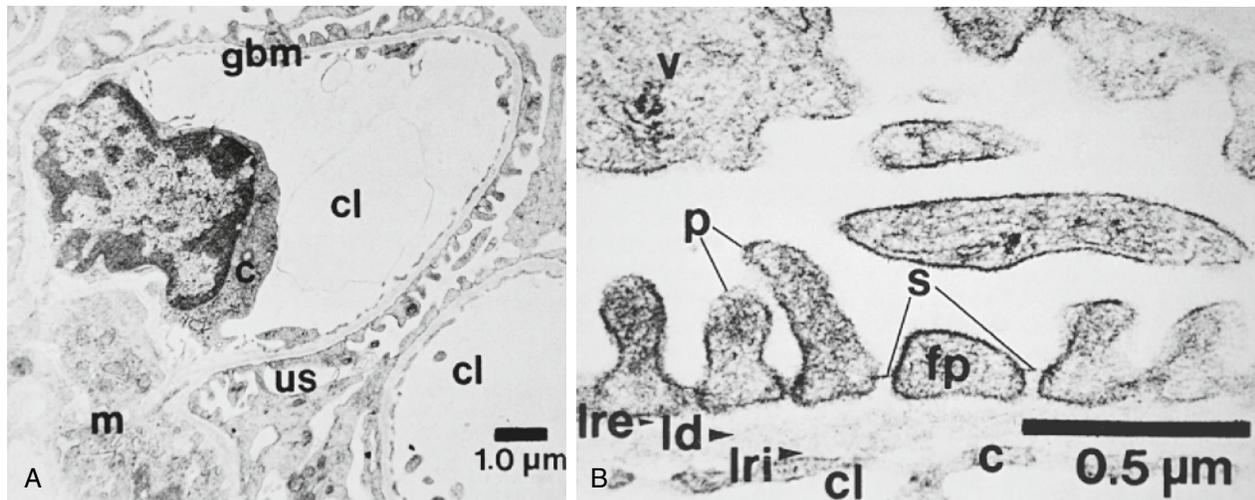

**FIGURE 19-18** Subgross anatomy of a renal corpuscle. **A**, A renal corpuscle with a tuft of glomerular capillaries surrounded by Bowman's capsule (**c**) shows visceral (**v**) and parietal (**p**) epithelial cells separated by the urinary space (**u**). **B**, Cross-section of a portion of a glomerulus shows the nucleus (**n**) and fenestrations (**e**) of capillary endothelial cells, the glomerular basement membrane (GBM) (**b**), mesangial cells (**m**) separated by mesangial matrix, and the nucleus (**v**) of a visceral epithelial cell. A red blood cell (RBC) (**r**) is in the lumen (**l**) of one of the glomerular capillaries. (From Osborne CA, Hammer RF, Stevens JB et al: The glomerulus in health and disease: a comparative review of domestic animals and man, *Adv Vet Sci Comp Med* 21:207, 1977.)

structure of the glomerular capillaries and is analogous to the mesenteric tissue supporting bowel. Mesangial cells are a component of the reticuloendothelial system and phagocytize macromolecular substances, among them are fragments of old GBM or larger molecules that pass through endothelial cell pores but cannot pass subsequently through the GBM. In addition, mesangial cells have contractile elements that allow them to participate in regulation of glomerular hemodynamics. Furthermore, these cells proliferate in response to glomerular injury and can release a number of cytokines that modulate the glomerular inflammatory response.<sup>35</sup> The GBM lies between endothelial and epithelial cells and surrounds glomerular capillaries, except where mesangium is present (Figure 19-19, A). Returning to the abdominal cavity analogy, the GBM would lie beneath bowel serosa except in the area of mesenteric attachment, which would contain mesangial cells and matrix. The GBM consists of a central electron-dense layer, the lamina densa, and two thinner, more electron-lucent layers, the lamina rara externa and the lamina rara interna (Figure 19-19, B).<sup>31,35</sup> The main components of the GBM are collagen-like molecules and matrix glycoproteins that are produced principally by visceral epithelial cells. Normal GBM undergoes steady turnover with removal of debris by mesangial cells. The visceral epithelial cells, also called *podocytes*, cover the uriniferous duct side of the GBM and have many cytoplasmic extensions called *foot processes* that form extensive interdigitations with foot processes of adjacent epithelial cells. The narrow gap between foot processes—the filtration slit or slit pore—is bridged by a thin membrane, the slit pore diaphragm.<sup>31,35</sup>

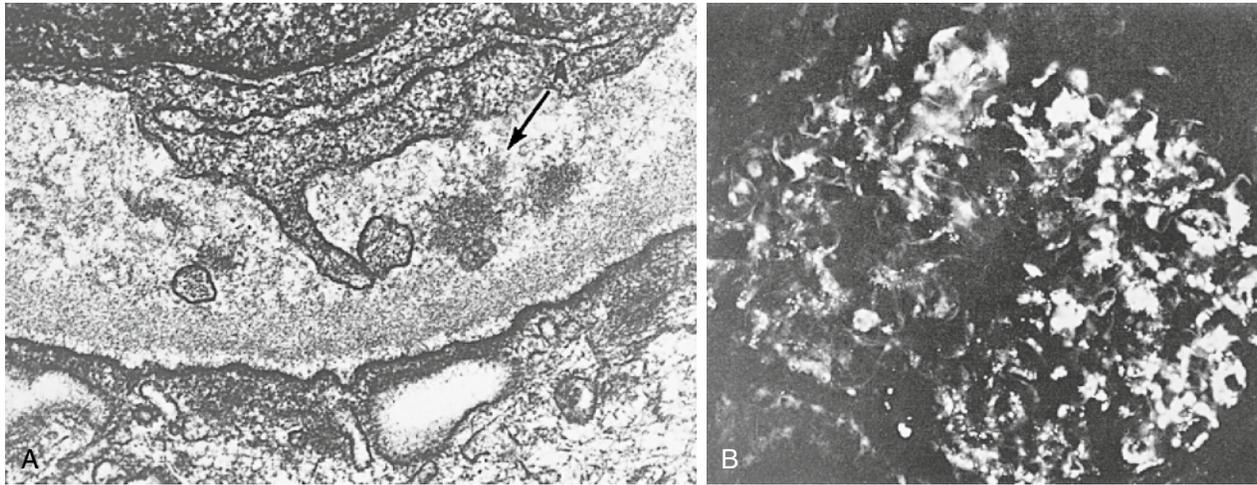

The filtration barrier of the glomerulus consists of fenestrated endothelial cells, GBM, and slit pores between epithelial cell foot processes. These structures constitute a size-selective and charge-selective filtration barrier. Although all components

of this barrier are anionic (i.e., they repel anionic macromolecules), the GBM is thought to be the principal agent of the permeability characteristics of the filtration barrier. The GBM is rich in glycosaminoglycans, containing heparin sulfate and sialic acid residues. These strongly anionic molecules are responsible for its negative charge barrier, which limits filtration of anionic macromolecules, predominantly albumin.<sup>1,35</sup>

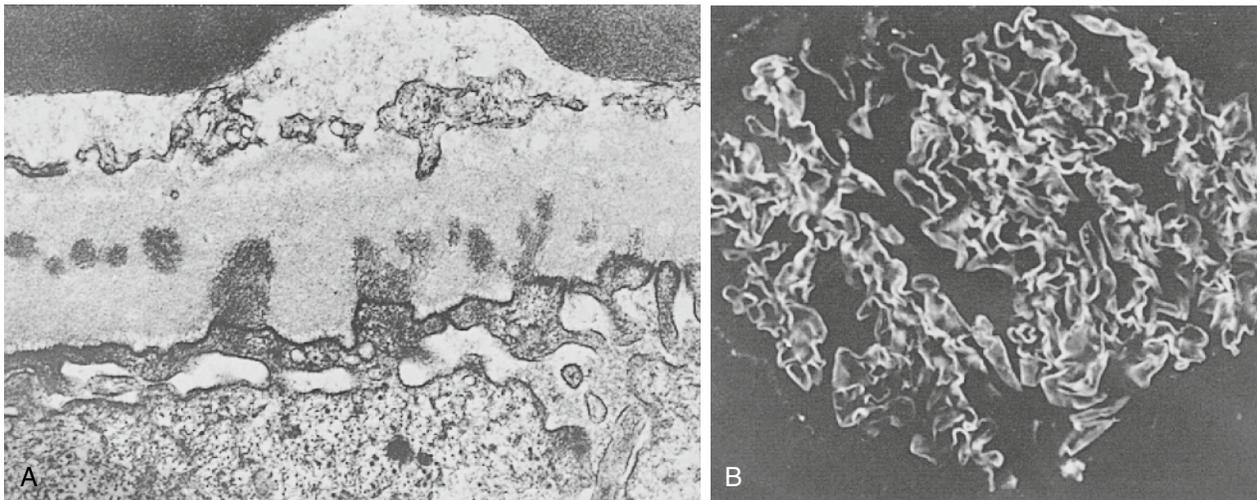

Glomerulonephritis is initiated by deposition of circulating immune complexes along the GBM and in the mesangium, leading to complement activation and leukocyte infiltration and adherence. Release of oxidants and proteinases by neutrophils and macrophages; production of eicosanoids, cytokines, and growth factors by macrophages and mesangial cells; and platelet aggregation and activation of coagulation factors lead to endothelial and epithelial cell swelling (with fusion of foot processes), formation of microthrombi in glomerular capillaries, and mesangial cell proliferation.<sup>1,31,36</sup> Immune complexes can be deposited in a subendothelial, intra-GBM, or subepithelial site, depending on their size and charge properties, but most tend to be found in the subendothelial space. On electron microscopic examination these immune complexes appear as electron-dense granular deposits (Figure 19-20, A), and staining with anti-immunoglobulin G and anticomplement (C3) antibodies reveals an irregular (granular or “lumpy bumpy”) immunofluorescence staining pattern (Figure 19-20, B).<sup>1,2,31</sup> The GBM proliferates to surround the immune deposits, leading to irregular thickening of the filtration barrier. Despite widening of the filtration barrier, the size-selective and charge-selective filtration properties are compromised, and microscopic hematuria and proteinuria result. In rare instances, glomerulonephritis may be attributed to a true autoimmune disorder in which autoantibodies directed against GBM components (e.g., type IV collagen) are produced. Electron

**FIGURE 19-19** Electron micrograph of a normal glomerulus. **A**, Low-power magnification illustrates patent capillary lumens (**cl**) separated from the urinary space (**us**) by fenestrated endothelial cell cytoplasm (**c**), the glomerular basement membrane (GBM) (**gbm**), and foot processes of visceral epithelial cells. Mesangial cells and matrix (**m**) are also apparent (bar = 1.0 µm). **B**, Higher-power magnification reveals the ultrastructural features of the filtration barrier including, from bottom to top, the capillary lumen (**cl**) and endothelial cell cytoplasm (**c**); the lamina rara interna (**lri**), lamina densa (**ld**), and lamina rara externa (**lre**) of the GBM; and cytoplasm (**v**), foot processes (**fp**), and slit diaphragms (**s**) of the visceral epithelial cells. Deposits of glomerular polyanion or glycosaminoglycans (**p**) are visible on the foot processes (bar = 0.5 µm). (From Osborne CA, Hammer RF, Stevens JB et al: The glomerulus in health and disease: a comparative review of domestic animals and man, *Adv Vet Sci Comp Med* 21:207, 1977.)

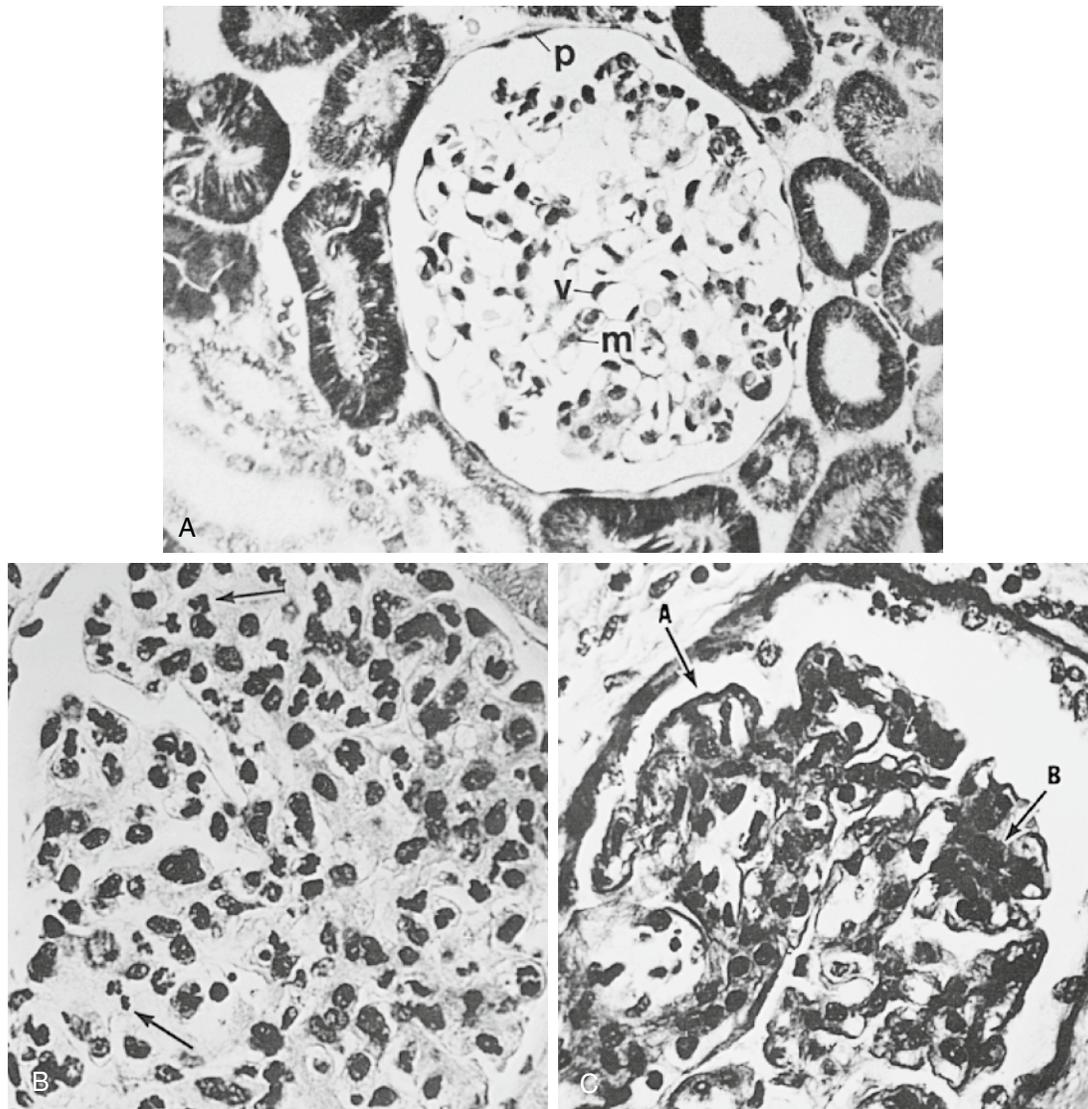

**FIGURE 19-20** Immune-mediated glomerulonephritis in a horse 165 days after experimental infection with equine infectious anemia virus (EIAV). **A**, An electron micrograph ( $\times 32,500$ ) shows endothelial cell swelling (*top*), thickening of the glomerular basement membrane (GBM) with electron-dense immune deposits in a predominantly subendothelial location (*arrow*), and fusion of foot processes of the visceral epithelial cells. **B**, Immunofluorescent staining with fluorescein-tagged antiequine immunoglobulin G antibody ( $\times 100$ ) demonstrates granular or "lumpy bumpy" deposits of immunoglobulin G along the GBM and in the mesangium. (From Banks KL, Henson JB, McGuire TC: Immunologically mediated glomerulitis of horses. 1. Pathogenesis in persistent infection by equine infectious anemia virus, *Lab Invest* 26:701, 1972.)

**FIGURE 19-21** Spontaneous immune-mediated glomerulonephritis in a horse. **A**, An electron micrograph ( $\times 22,750$ ) shows a RBC (RBC) in the capillary lumen (*top*), relatively normal fenestrated endothelial cytoplasm, thickening of the glomerular basement membrane (GBM) with electron-dense immune deposits in a predominantly subepithelial location, and fusion of foot processes of the visceral epithelial cells. **B**, Immunofluorescent staining with fluorescein-tagged antiequine immunoglobulin G antibody ( $\times 160$ ) demonstrates smooth, linear deposits of immunoglobulin G. (From Banks KL, Henson JB, McGuire TC: Immunologically mediated glomerulitis of horses. 2. Antiglomerular basement membrane antibody and other mechanisms of spontaneous disease, *Lab Invest* 26:708, 1972.)

microscopic examination in these cases also reveals GBM thickening with predominantly subepithelial electron-dense deposits (Figure 19-21, A), and immunofluorescence staining shows a more regular or smooth, linear pattern of immunofluorescence (Figure 19-21, B).<sup>31,37,38</sup> Autoimmune glomerulonephritis, accompanied by proteinuria, also has been described as one of the manifestations of systemic lupus erythematosus

in horses.<sup>39</sup> Another immune mechanism of glomerulonephritis in horses is production of mixed or monoclonal cryoglobulins and deposition of antibody-antibody immune complexes along the glomerular GBM.<sup>40,41</sup> Cryoglobulinemia is associated with a number of diseases in human beings<sup>35,40</sup> but has been described in only a few horses.<sup>41,42</sup> Deposition of antibody-antibody immune complexes along the GBM may be a more

**FIGURE 19-22** Histologic changes in equine glomerulonephritis. **A**, Photomicrograph of a normal glomerulus. Bowman's capsule is lined by flattened parietal epithelial cells (**p**). Visceral epithelial cells (**v**) are adjacent to the glomerular basement membrane (GBM), which is of uniform thickness. Mesangial cells (**m**) are surrounded entirely by glomerular capillaries (periodic acid–Schiff [PAS] stain,  $\times 100$ ). **B**, Photomicrograph demonstrates proliferative glomerulonephritis in a horse after experimental infection with equine infectious anemia virus (EIAV). A combination of neutrophil infiltration (*arrows*) and mesangial cell proliferation is apparent (hematoxylin-eosin stain,  $\times 160$ ). **C**, Photomicrograph demonstrates membranous glomerulonephritis in a horse after experimental infection with EIAV. The GBMs are thickened (**A**) and mesangial areas contain PAS-positive material (**B**) (PAS stain,  $\times 160$ ). (A from Osborne CA, Hammer RF, Stevens JB et al: The glomerulus in health and disease: a comparative review of domestic animals and man, *Adv Vet Sci Comp Med* 21:207, 1977; B and C from Banks KL, Henson JB, McGuire TC: Immunologically mediated glomerulitis of horses. 1. Pathogenesis in persistent infection by equine infectious anemia virus, *Lab Invest* 26:701, 1972.)

important precipitant of glomerulonephritis than was recognized previously because electron microscopic examination is required to demonstrate characteristic fibrillar or crystalline intracapillary and subendothelial deposits associated with the condition.<sup>40</sup> Regardless of what immune mechanism leads to glomerular injury, the end result is thickening of the filtration barrier, retarded GFR, and development of CRF in severe cases.

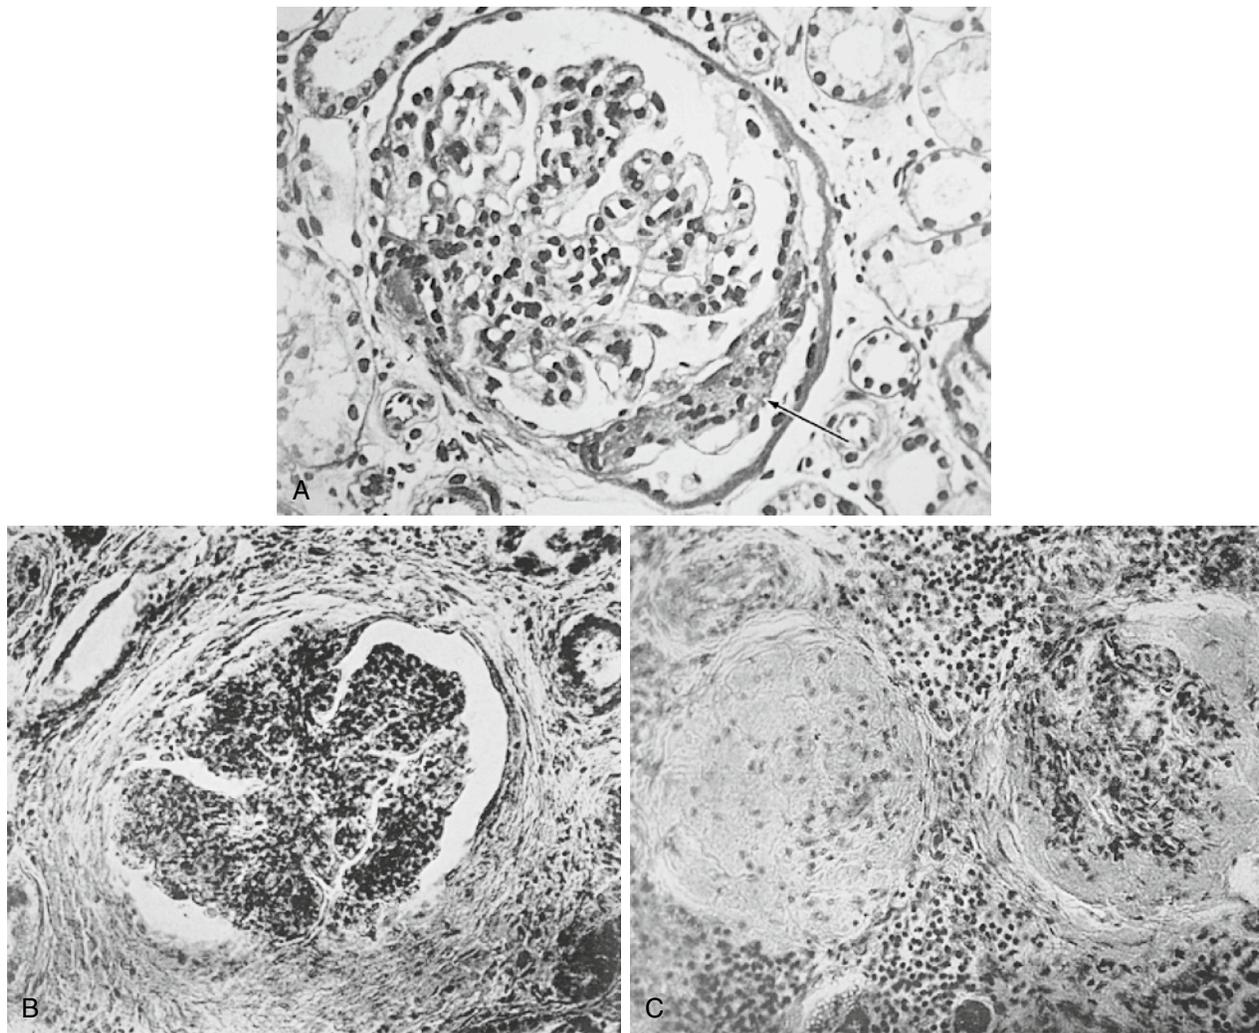

Although a number of terms are used to describe the specific morphologic changes associated with glomerular injury,

glomerulonephritis is categorized most broadly histologically as *proliferative* or *membranous*.<sup>1,31,34</sup> Proliferative (or mesangio-proliferative) glomerulonephritis describes glomerular injury associated with influx of inflammatory cells and proliferation of mesangial cells. The predominant histologic finding is increased cellularity in glomeruli (Figure 19-22, A and B). This lesion tends to be associated with the more acute stages of glomerulonephritis during which immune complexes are being deposited in a predominantly subendothelial site. Membranous glomerulonephritis describes glomerular injury

accompanied by significant thickening of the capillary wall and GBM; with periodic acid–Schiff (PAS) staining, the predominant histologic finding is increased in the mesangial area and on the GBM (Figure 19-22, C). Methenamine silver stain further enhances visibility of the thickening of the GBM.<sup>31,34</sup> Membranous glomerulonephritis tends to be associated with more soluble immune complexes or autoantibodies that can pass through the GBM and localize in a predominantly sub-epithelial site, resulting in less infiltration of inflammatory cells. As would be expected, a spectrum of lesions is visible in naturally occurring glomerulonephritis, leading to varying histologic descriptions of the disease (membranoproliferative glomerulonephritis). As glomerular injury progresses, proliferation of the parietal epithelium also occurs, likely in response to filtration of macromolecules and cellular debris. Lesions associated with parietal cell proliferation can include layering

of epithelial cells (termed *crescents*) on the inner aspect of Bowman's capsule (Figure 19-23, A), adhesion formation between the glomerular tuft and Bowman's capsule (Figure 19-23, B), and tuft collapse. Glomerulosclerosis describes the end stage of progressive, irreversible glomerular injury in which replacement of glomerular components with hyaline material is visible on histologic examination (Figure 19-23, C).<sup>31</sup>

Specific histologic categorization of glomerulonephritis provides causative and prognostic information for human beings with renal failure attributable to glomerular disease.<sup>35</sup> Subcategorization of glomerulopathies also has been done in a prospective study of naturally occurring chronic renal disease in canines. Although classifications—including focal glomerulonephritis, mesangioproliferative glomerulonephritis, endocapillary proliferative glomerulonephritis, crescentic glomerulonephritis, and sclerosing glomerulonephritis—could

**FIGURE 19-23** Progressive histologic changes in equine glomerulonephritis. **A**, Photomicrograph of a renal biopsy specimen illustrates membranoproliferative glomerulonephritis (an increase in cell numbers and thickening of the glomerular basement membrane [GBM]) and parietal epithelial cell proliferation resulting in crescent formation (*arrow*; periodic acid–Schiff stain [PAS],  $\times 100$ ). **B**, Photomicrograph demonstrates progressive glomerulonephritis resulting in adhesion formation between the capillary tuft and proliferating parietal epithelial cells. **C**, Photomicrograph of end-stage glomerulosclerosis shows replacement of glomerular components with hyaline material (more complete in glomerulus on the left). (A from Osborne CA, Hammer RF, Stevens JB et al: The glomerulus in health and disease: a comparative review of domestic animals and man, *Adv Vet Sci Comp Med* 21:207, 1977; B and C from Fincher MG, Olafson P: Chronic diffuse glomerulonephritis in a horse, *Cornell Vet* 24:356, 1934.)

be made, histologic findings were not prognostically useful.<sup>43</sup> This study also revealed that glomerular disease was responsible for 52% of canine CRF; however, an inciting disease (vegetative endocarditis) could be identified in only one of 31 dogs with glomerulonephritis.

Glomerulonephritis also appears to be an important cause of CRF in horses.<sup>27</sup> Of 60 reported cases of CRF attributable to acquired disease, glomerulonephritis was identified as the inciting cause of CRF in 32 (53%) (Table 19-8).<sup>25-27,36,40,41,44-56</sup> Glomerulonephritis also may be the initiating disease process in cases of ESKD for which gross and histopathologic changes are so extensive that a primary mechanism of renal injury cannot be identified. A number of systemic inflammatory and infectious disease processes in horses may be accompanied by glomerulonephritis, but progression to CRF appears to be a rare sequela. For example, experimental *Leptospira pomona* infection produced subacute glomerulonephritis characterized by hypercellularity and edema of capillary tufts,<sup>74</sup> but leptospirosis appears to be a rare cause of clinical renal disease in horses.<sup>75-77</sup> Similarly, experimental infection with equine infectious anemia virus (EIAV) produced histologic and immunofluorescent evidence of glomerulonephritis in 75% and 87% of infected horses, respectively.<sup>37</sup> Immunoglobulins with anti-EIA activity were eluted from glomeruli collected from experimentally infected horses, but none of the horses showed clinical signs of renal disease. Poststreptococcal glomerulonephritis is a well-recognized cause of renal disease in human beings,<sup>35,78</sup> and Roberts and Kelly<sup>79</sup> speculated that glomerulonephritis in a horse with chronic pleuritis and purpura hemorrhagica likely resulted from circulating immune complexes involving streptococcal antigens. Divers et al.<sup>56</sup> provided support for this hypothesis by eluting group C streptococcal antigens from immune complex deposits in

glomeruli collected from a horse with CRF. Finally, an occasional case of equine glomerulonephritis may result from true autoimmune disease, and in one instance, anti-GBM antibody was eluted from glomeruli with linear GBM immunofluorescent staining pattern isolated from a horse.<sup>2</sup> Little information is available about histopathologic subcategories of glomerulonephritis in horses, although several reports have attempted to make comparisons with glomerular lesions that have been better characterized in other species.<sup>40,54,80</sup> No reports have attempted to correlate histologic changes with the degree of renal failure in horses. Thus assessment of the severity of renal disease associated with glomerulonephritis in horses currently is based more on clinical findings (e.g., body condition, magnitude of azotemia) than on histologic changes in a renal biopsy sample.

### CHRONIC INTERSTITIAL NEPHRITIS

Tubulointerstitial disease usually results from ATN after ischemia, endotoxemia, sepsis, or exposure to nephrotoxic compounds. Hypovolemia associated with acute blood loss, colic, diarrhea, endotoxemia, or sepsis can lead to renal hypoperfusion and ischemic damage.<sup>81</sup> Severe localized infection (e.g., pleuritis, peritonitis) or septicemia also may be accompanied by tubule damage. Aminoglycoside antibiotics, NSAIDs, vitamin D, vitamin K<sub>3</sub>, acorns, and heavy metals such as mercury are potentially nephrotoxic.<sup>82</sup> Intravascular hemolysis or rhabdomyolysis also can lead to acute tubular damage after the nephrotoxic effects of hemoglobin and myoglobin (see Acute Renal Failure). In horses tubulointerstitial disease culminating in CRF also can be caused by ascending UTI resulting in pyelonephritis<sup>25,27,52,64-68,83</sup> or bilateral obstructive disease caused by ureteroliths or nephroliths.<sup>22,27,59-63,84</sup> In other cases

\*In many reports of acquired renal disease leading to chronic renal failure (CRF), histopathologic changes involve glomeruli and interstitium. Categorization in this table is based on the authors' conclusions in these reports. When severe lesions involved glomeruli and interstitium, a categorization of ESKD was made.

<sup>†</sup>ESKD and reports of oxalate nephropathy.

**FIGURE 19-24** Histologic changes in interstitial nephritis. The interstitium contains dense infiltrates of lymphocytes and plasma cells superimposed on moderate interstitial fibrosis and tubular atrophy (hematoxylin-eosin stain,  $\times 275$ ). (From Brenner BM, editor: *Brenner and Rector's the kidney*, ed 8, 2008, Philadelphia, WB Saunders.)

a cause of the tubule disease may not be identified.<sup>57,58</sup> Finally, although this has not yet been described in horses, immune mechanisms, including anti-tubular basement membrane disease, can lead to chronic interstitial nephritis (CIN) in human beings.<sup>35</sup>

CIN is defined most strictly by clinical signs of renal disease associated with histologic changes of tubular damage and an interstitial inflammatory cell infiltrate (Figure 19-24). Inflammatory cells include lymphocytes, monocytes, and occasionally plasma cells. Neutrophils are uncommon; however, eosinophilic infiltrates suggest drug reactions in human patients.<sup>35</sup> Major glomerular and vascular lesions are not apparent. The hallmark that distinguishes CIN from acute tubular and interstitial disease is interstitial fibrosis.

Although CIN has a fairly strict histologic definition, a number of disease processes can lead to tubular damage. For all practical purposes, *CIN* is a catchall term for extraglomerular causes of CRF in horses. As a consequence, gross findings in horses with CIN can vary dramatically. For example, analgesic nephropathy (NSAID toxicity, of which phenylbutazone has the greatest nephrotoxic potential<sup>85</sup>) can produce papillary necrosis<sup>69,86</sup> manifested by hematuria<sup>87</sup> in the early stages of disease, whereas chronic disease may be associated with nephrolithiasis and hydronephrosis. The area of papillary necrosis serves as a nidus for stone formation, and subsequent obstructive disease leads to hydronephrosis.<sup>61,84</sup> Similarly, upper UTI can lead to minor or major changes in the architecture of the kidneys and to variable histologic changes.

Using CIN as a broad category for nonglomerulonephritis causes of CRF in horses, this group of tubulointerstitial diseases was responsible for 38% (23 of 60) of the previously reported cases of CRF in horses (see Table 19-8). Although in theory one would expect CIN to be accompanied by greater evidence of tubular dysfunction (e.g., enzymuria, glucosuria, increased

fractional clearance of sodium), abnormal measures of tubule function have not been detected regularly. Similarly, microscopic hematuria and proteinuria, the hallmarks of glomerular disease, would not be expected.

## END-STAGE KIDNEY DISEASE

End-stage kidney disease describes the severe gross and histologic changes in kidneys collected from animals in the final stages of CRF. Grossly, the kidneys typically are pale, shrunken, and firm, and they may have an irregular surface and an adherent capsule. Histologically, severe glomerulosclerosis occurs along with hyalinization and extensive interstitial fibrosis. The end-stage lesions make determining the initiating cause of renal disease virtually impossible. In several cases with a pathologic description consistent with ESKD, the underlying cause of renal injury could not be established.<sup>58,70-73</sup>

## CHRONIC RENAL FAILURE OF OTHER CAUSES

Several early cases of CRF in horses were attributed to oxalate poisoning because oxalate crystals were observed in renal tubules.<sup>57,70</sup> Horses appear to be more resistant than other domestic species to oxalate-induced renal damage<sup>88</sup>; however, experimental administration of various forms of oxalate (in large doses) produced hypocalcemia and gastrointestinal signs rather than renal failure.<sup>89</sup> In fact, the early reports of oxalate nephropathy in horses failed to demonstrate that the affected horses had been exposed to oxalates.<sup>57,70</sup> Furthermore, long-term ingestion of plants containing oxalate produces fibrous osteodystrophy (oxalates bind calcium in the intestinal tract, decreasing intestinal calcium absorption), but renal damage in affected horses has been minimal.<sup>90</sup> Formation of oxalate crystals in diseased equine kidneys now is recognized as a secondary change likely related to stasis of urine in damaged renal tubules.<sup>50</sup>

Amyloidosis is an unusual cause of CRF in horses.<sup>88,91</sup> Amyloid deposits associated with systemic disease typically are composed of aggregates of the amino-terminal fragment of serum amyloid A protein, an acute phase protein.<sup>92-95</sup> Concentrations of serum amyloid A increase with many inflammatory disease processes, and chronic elevations can result in amyloid deposition (AA type) in a variety of tissues, a condition termed *systemic reactive amyloidosis*.<sup>96,97</sup> Incidence and tissue localization of amyloid exhibit considerable species variation. Dogs appears to be affected most often, but the fact that the disease is familial in Abyssinian cats implies a genetic basis for the disease.<sup>97</sup> Amyloid deposits accumulate as stacks of protein in a  $\beta$ -pleated sheet conformation and are identified in tissue samples by their extracellular location and homogeneous, eosinophilic appearance when stained with hematoxylin and eosin. They are birefringent when viewed under polarized light, and staining with alkaline Congo red solution imparts a characteristic green color.<sup>96,97</sup> Amyloid deposition in the kidney is most common in dogs and cattle, and renal amyloidosis is a significant cause of CRF in dogs.<sup>97</sup> In horses, localized amyloidosis of the upper airway or skin is more common than systemic amyloidosis.<sup>96</sup> In the localized form, amyloid deposits are composed of immunoglobulin light chains (AL type). Although reports describe systemic reactive amyloidosis consequent to heavy parasite infestation in horses, renal involvement was minimal or not apparent.<sup>98,99</sup> Systemic amyloidosis

has been recognized most often in horses hyperimmunized for antiserum production, and hepatic and splenic involvement may be more common than renal involvement in these horses.<sup>88,91,93</sup>

A final acquired cause of CRF, renal neoplasia, is discussed in greater detail elsewhere in this chapter. Although horses with renal neoplasia may have weight loss, the tumors are usually unilateral and development of CRF is uncommon.

## ☞ UREMIC TOXINS AND THE UREMIC SYNDROME

Regardless of the underlying cause of nephron loss, the ensuing renal insufficiency leads to development of azotemia and its clinical manifestation, the uremic syndrome.<sup>35,92-94,100</sup> The uremic syndrome is a multisystemic disorder that develops as a result of the effects of uremic toxins on cell metabolism and function. Although the uremic syndrome originally was attributed to the effects of increased BUN concentration, a number of nitrogenous compounds now are known to accumulate in CRF and contribute to alterations of cell metabolism and function. In fact, the correlation between the severity of the uremic syndrome and the magnitude of azotemia is poor. For example, urea administered to human beings with normal renal function results simply in fluid shifts, osmotic diuresis, and increased thirst.<sup>101</sup> Urea toxicity also has been studied in nephrectomized dogs and in human patients with CRF sustained by dialysis. Increasing the urea concentrations of the dialysate to maintain BUN at artificially higher values has produced variable results. For example, BUN values up to about 150 mg/dl were associated with few clinical signs, whereas lethargy, weakness, anorexia, vomiting, and a bleeding diathesis (caused by platelet dysfunction) were produced when BUN was increased to values exceeding 175 to 200 mg/dl. Excess circulating urea also can degrade spontaneously to ammonia, carbonate, or cyanate. Cyanate can react with the N-terminal amino groups on a number of proteins and by altering tertiary structure can interfere with enzyme activity and structural integrity of cell membranes.<sup>35</sup> Thus accumulation of urea is likely responsible for some of the signs of uremic syndrome.

Cr and other guanidino compounds also accumulate in renal failure. These compounds are strong organic bases that contain an amidino group ( $N - C = NH$ ).<sup>35</sup> With CRF, urinary excretion of Cr and other guanidino compounds actually may increase (because of tubular secretion) but not enough to prevent increases in blood concentrations. For example, the author has found that in naturally occurring cases of equine CRF (author's unpublished data), endogenous  $Cl_{Cr}$ , when measured simultaneously with  $Cl_{In}$ , overestimates GFR by 50% to 100%. These data indicate that tubular secretion of Cr, which Finco and Groves were unable to document in healthy ponies,<sup>102</sup> is initiated by or is quantitatively much greater with CRF. Although metabolic pathways have not been elucidated fully, guanidino compounds appear to be produced predominantly in the liver, and their concentration in blood and tissues increases with decreased renal function or increased dietary protein intake.<sup>101</sup> The relationship between guanidino compounds and the syndrome of uremia is also unclear. For example, administration of methylguanidine to healthy dogs resulted in weight loss, neurologic signs, and anemia, but only when blood concentrations were an order of magnitude greater than those in spontaneous cases of CRF.<sup>35</sup> In contrast, administration of another guanidino compound,

guanidinopropionic acid, led to hemolysis by depleting erythrocyte glutathione concentrations (supporting a role for this uremic toxin in the anemia of CRF).

Products of intestinal bacterial metabolism—including secondary methylamines (from metabolism of choline and lecithin), aromatic amines (from metabolism of tyrosine and phenylalanine), polyamines (from metabolism of lysine and ornithine), and tryptophan breakdown products (indole, skatole, indoleacetic acid, and others)—can contribute to the clinical signs associated with the uremic syndrome. Some of these compounds have been studied thoroughly (e.g., the inhibitory effect of the polyamine spermine on erythropoiesis), whereas others are ill understood but likely contribute to altered neuromuscular and neurologic function.<sup>35,100,101</sup>

Another group of larger uremic toxins have been termed *middle molecules*.<sup>35,101</sup> These compounds are higher-molecular-weight compounds (500 to 3000 D) that are removed more readily from uremic patients by peritoneal dialysis than by hemodialysis. These compounds are not well characterized, and their existence is supported more by the difference in clinical response to peritoneal dialysis and hemodialysis in uremic human patients awaiting renal transplantation.

In addition to nitrogenous compounds, abnormal metabolism of hormones and trace minerals also accompanies the decline in renal function associated with acute and CRF. Secondary hyperparathyroidism (leading to osteodystrophy) and insulin insensitivity are well-recognized endocrine contributions to the uremic syndrome in human and small animal patients.<sup>35,101,103,104</sup> Endocrine dysfunction can be attributed to several factors: (1) decreased production of renal hormones (erythropoietin, vitamin D<sub>3</sub>), (2) decreased hormone clearance prolonging plasma half-life (parathormone, gastrin), (3) decreased hormone production (testosterone), (4) tissue insensitivity (insulin, parathormone), and (5) hypersecretion to reestablish homeostasis (parathormone).<sup>35</sup> Regarding trace minerals, uremia may be accompanied by aluminum toxicity and zinc deficiency. Aluminum may contribute to some of the neurologic signs associated with azotemia (especially with ARF), whereas zinc has been implicated in testicular atrophy and abnormal taste in uremic human patients.<sup>35,101</sup> Presumed uremic encephalopathy has been reported in horses with CRF when neurologic dysfunction could not be attributed to other causes.<sup>105</sup> All five reported cases died or were euthanatized. Swollen astrocytes were observed histologically in all horses that were necropsied.

Clearly, because so many potential uremic toxins exert their effects as renal function declines, a single compound or even a few compounds likely will not ever be identified as the primary cause of the uremic syndrome in patients with CRF. Furthermore, these compounds together are more likely to impair basic cell function in a number of tissues, and the signs of uremia are more likely to reflect multisystemic organ dysfunction. Methylation of a number of membrane proteins recently has received considerable attention as one of the common mechanisms of cell dysfunction.<sup>106</sup> What is truly remarkable, however, is the tremendous adaptive capacity of the failing kidneys to maintain sodium and water balance within narrow ranges until GFR declines to 20% of the normal value or less.<sup>107</sup>

## ☞ CLINICAL SIGNS

Horses with CRF present relatively late in the disease course, when their owners note lethargy, anorexia, and weight loss. A history of months to years of polydipsia and polyuria in some

cases supports renal disease of long duration. In other animals, preexisting disease (e.g., colic, colitis, pleuropneumonia) or prolonged medication (e.g., aminoglycoside antibiotics, NSAIDs) may provide important information about the initiation and duration of renal failure. In most cases, however, the onset is insidious and identifying a precipitating event or gauging the duration of renal disease is not possible.

Chronic weight loss is the most common presenting complaint for horses with CRF.<sup>25-30</sup> Partial anorexia, ventral edema, polydipsia and polyuria, rough hair coat, lethargy, and poor athletic performance are other owner concerns. In addition, horses with advanced CRF may have a characteristic odor that likely reflects the combined effects of uremic halitosis and increased urea excretion in sweat. For the horses presented in Table 19-8, weight loss, ventral and peripheral edema, and polydipsia and polyuria, respectively, were reported in 53 of 63 (84%), 24 of 56 (43%), and 21 of 48 (44%) of the cases. Lethargy and weight loss can be attributed to several factors. An increase in the concentration of nitrogenous wastes in blood can have a direct central appetite-suppressant effect that can lead to partial or complete anorexia.<sup>35,101</sup> Next, as azotemia develops, excess urea diffuses across gastrointestinal epithelium and is metabolized to ammonia and carbon dioxide by bacterial urease. In the oral cavity, excess ammonia can lead to excessive dental tartar formation (Figure 19-25), gingivitis, and oral ulcers. In the gastrointestinal tract, excess urea and ammonia can lead to ulceration and mild to moderate protein-losing enteropathy, and severely uremic animals may produce soft feces.<sup>1,35,101</sup> The prolonged half-life of gastrin (eliminated through the kidneys) may contribute further to ulcer formation because of increased gastric acid secretion.<sup>35</sup> Finally, as the combined effects of uremic toxins render the affected patient catabolic, body mass declines as body reserves are tapped to meet basal energy requirements.<sup>35,101</sup>

Mild ventral edema with CRF may be attributable to three factors: (1) decreased oncotic pressure, (2) increased vascular permeability, and (3) increased hydrostatic pressure. Because albumin accounts for approximately 75% of plasma colloid oncotic pressure, decreases in albumin concentration (<2.0 g/dl)

**FIGURE 19-25** Excessive dental tartar on the canine tooth and lower corner incisor of a horse with chronic renal failure (CRF).

can decrease plasma oncotic pressure despite a normal total plasma protein concentration.<sup>108,109</sup> The effects of uremic toxins on endothelial cell membranes can alter vascular permeability, which contributes to edema.<sup>35,101</sup> Chronic renal insufficiency can lead to renal hypoxia and hypoperfusion, which stimulate renal juxtaglomerular cells to release renin. Activation of the renin-angiotensin system tends to elevate blood (and capillary hydrostatic) pressure and contributes to edema. Activation of the renin-angiotensin system also leads to increased sodium reabsorption in the proximal (direct effect of angiotensin II) and distal (effect of aldosterone) tubules.<sup>109</sup> Sodium retention leads to expansion of circulating volume, which is another factor in edema formation. Alterations in blood pressure in horses with CRF have not been evaluated routinely (as they have in small animal and human patients), and increased circulating concentrations of angiotensin II or aldosterone in horses have not been documented extensively. As a result the nephrotic syndrome (characterized by edema, hypoalbuminemia, and heavy proteinuria) is not as well documented in horses as in small animals and human beings with CRF. However, horses with CRF appear less at risk for the significant pleural effusion or ascites that can accompany the nephrotic syndrome in small animals.<sup>1</sup>

Polydipsia and polyuria are variable findings in horses with CRF. The magnitude of polydipsia and polyuria theoretically is related to the degree of tubulointerstitial damage; however, the degree of polyuria does not appear to correlate with the magnitude of azotemia in clinical cases. Typically, polyuria is not as severe with CRF as with diabetes insipidus or psychogenic water drinking and may not be noticed by an owner (see the Polyuria and Polydipsia section of this chapter). The wide variation in water intake in normal horses and common use of automatic waterers and large stock tanks also make observation of polydipsia more difficult. The mechanisms of polyuria with CRF can include (1) increased tubular flow rate in surviving nephrons, (2) decreased medullary hypertonicity, and (3) impaired response of collecting ducts to vasopressin (acquired nephrogenic diabetes insipidus). Although these mechanisms may contribute to the polyuria of CRF, which of them may be most important is not known.<sup>1,110</sup>

An early complaint for horses with CRF is poor performance, which may be related to mild anemia (PCV 25% to 30%) and lethargy. Although the anemia of CRF has been attributed to several factors—including blood loss, decreased erythrocyte survival time, nutritional deficiencies, and decreased erythropoietin activity—the latter clearly has emerged as the principal cause of anemia in human beings and small animals with CRF.<sup>1,35,111</sup> In fact, administration of recombinant human erythropoietin (rhEPO) to patients awaiting kidney transplant has been one of the most significant advances in management of human CRF because it has eliminated the need for blood transfusions, has improved exercise capacity, and has decreased morbidity associated with the uremic syndrome.<sup>35,111</sup> Administration of rhEPO has also benefited anemic dogs and cats with CRF, although both species may need iron supplementation to support erythropoiesis.<sup>1,35</sup> The response often has been only temporary because many small animal patients develop refractory anemia after production of anti-rhEPO antibodies within a few weeks to months after initiation of treatment.<sup>1</sup> Plasma concentrations of erythropoietin have been determined in normal horses,<sup>112</sup> and rhEPO administration (15 IU/kg IV, three doses per week for 3 weeks) has been reported to increase the hematocrit in

splenectomized horses<sup>113</sup>; however, no reports describe rhEPO administration to horses with CRF. Furthermore, moderate to severe anemia that may be fatal has been reported to develop after repeated rhEPO administration to racehorses.<sup>114-116</sup> The risks of adverse reactions outweigh the potential benefits of rhEPO, and its use in horses should be avoided.

## DIAGNOSIS AND LABORATORY EVALUATION

One establishes a diagnosis of CRF when persistent isosthenuria (specific gravity of 1.008-1.014) accompanies azotemia and typical clinical signs.<sup>26-30,117</sup> Rectal palpation of the left kidney may be normal or may reveal a kidney that is small or firm with an irregular surface. Less often, the kidneys and ureters may be enlarged if obstructed by uroliths or if infection or neoplasia is present. The ratio of BUN-to-Cr concentration (BUN-to-Cr ratio) in horses with CRF is typically greater than 10:1 (Table 19-9); that for horses with prerenal azotemia or ARF is often less than 10:1.<sup>27</sup> This difference can be attributed in part to different volumes of distribution for urea (all body fluids) and Cr (primarily the extracellular fluid space). As a consequence, with acute reductions in RBF, the increase in Cr concentration is usually greater, on a relative or percentage basis, than the increase in BUN. The point deserves emphasis, however, that BUN is influenced by dietary protein intake so that BUN-to-Cr values do not always distinguish ARF from CRF. In fact, one also can use the BUN-to-Cr ratio to assess adequacy of dietary protein intake in the management of horses with CRF because a value greater than 15:1 can reflect excessive protein intake.<sup>29</sup>

In addition to azotemia, further abnormal laboratory data accompanying CRF can include mild anemia, hypoalbuminemia, hyponatremia, hyperkalemia, hypochloremia,

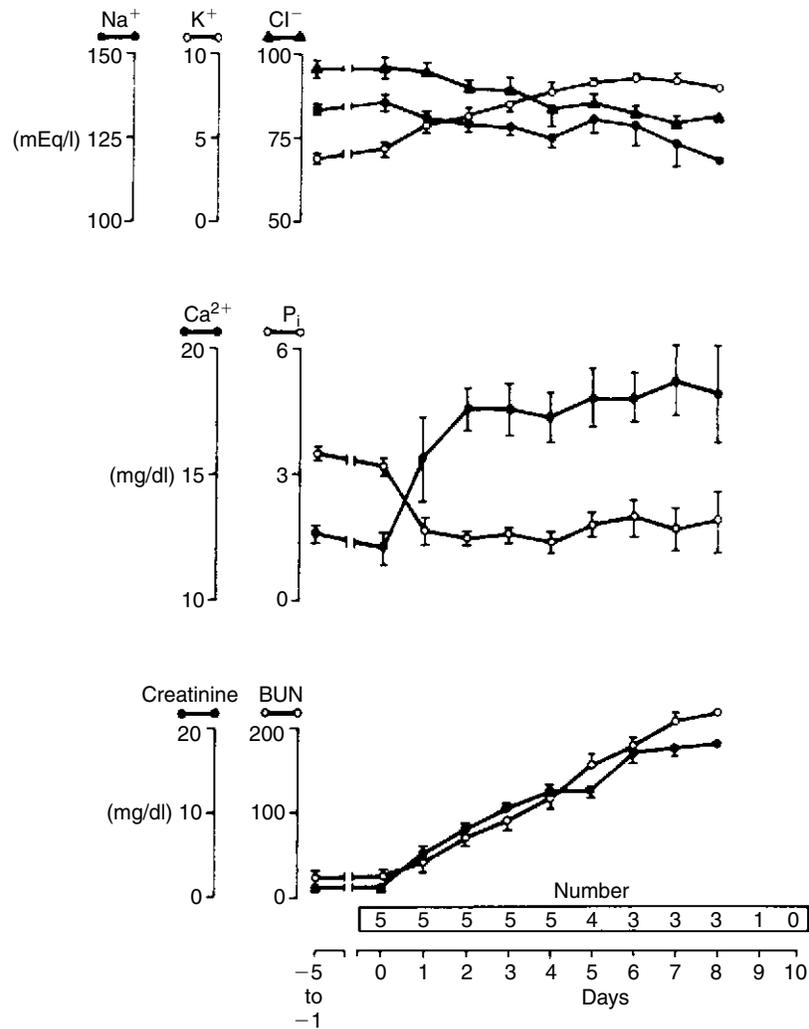

hypercalcemia, hypophosphatemia, and metabolic acidosis (see Table 19-9). A nonregenerative anemia is related largely to a deficient supply of the renally secreted glycoprotein erythropoietin; however, reduced erythrocyte life span may be another significant contributor to anemia. Normally, equine erythrocytes have a life span of 140 to 155 days.<sup>115</sup> With uremia, erythrocyte life span is shortened because excessive nitrogenous waste products alter the integrity of erythrocyte membranes and the function of ion channels, which regulate erythrocyte volume.<sup>102</sup> These less resilient erythrocytes are more likely to be removed from the circulation by the reticuloendothelial system.

The electrolyte alterations associated with CRF reflect loss of tubule function. Because sodium, chloride, bicarbonate, and phosphate are conserved by renal tubules, excessive urinary loss of these electrolytes accompanies CRF. Although fractional electrolyte clearance values (see Examination of the Urinary System) may remain within normal ranges or increase only slightly in horses with CRF, significant daily urinary loss of electrolytes still may occur. As an example, if a horse with CRF and Cr and sodium concentrations of 5.0 mg/dl and 130 mEq/L, respectively, is producing 20 L of urine daily with respective Cr and sodium concentrations of 50 mg/dl and 12.5 mEq/L, then the fractional clearance of sodium is 1.0% and daily urinary sodium loss is 250 mEq. An increase in urinary sodium concentration to 25 mEq/L after another decrease in tubular reabsorption would result in an increase in fractional sodium clearance to 2% but would represent an additional 250 mEq of daily sodium loss in the urine. The latter value would approach 1% to 2% of the exchangeable sodium in the body and would require an additional 15 g of salt intake daily to accommodate this loss. Hypercalcemia and hypophosphatemia (Williams-Smith syndrome) are fairly common findings in horses with CRF (see Table 19-9), and the degree of hypercalcemia appears to vary with the amount of calcium in the diet.<sup>25,49,52,118</sup> In human beings with ESKD, hypercalcemia is an occasional finding attributed to hyperparathyroidism, vitamin-D supplementation, or use of calcium-containing dialysate solutions. Furthermore, the osteodystrophy of CRF is associated with aluminum deposition in bone, which has been speculated to reduce skeletal buffering capacity for increases in serum calcium concentration and thereby contributes to hypercalcemia.<sup>35</sup> Because the equine kidney is an important route of calcium excretion (via CaCO<sub>3</sub> crystals), impaired tubular function in the face of continued intestinal absorption is the most common explanation for calcium accumulation in blood. This explanation is supported by the rapid development of hypercalcemia after experimental bilateral nephrectomy in ponies fed alfalfa hay (Figure 19-26).<sup>9</sup> In addition, parathormone concentrations have been found to be below the lower limit of detection in horses with CRF, indicating that hyperparathyroidism does not play a role in development of hypercalcemia.<sup>23,58</sup> However, parathormone clearance by the kidney also is reduced with CRF and may be associated with a change in the regulatory set point for serum calcium concentration in uremic human beings.<sup>35</sup> Whether hypercalcemia in horses with CRF leads to exacerbation of renal disease or tissue mineralization remains unknown. Nevertheless, one can demonstrate the effect of dietary calcium by changing the type of hay fed to horses with CRF. Horses with serum calcium concentrations exceeding 20 mg/dl on a diet of mostly alfalfa can have their serum calcium concentrations returned to the normal range within a few of days after changing the diet to

TABLE 19-9

Abnormal Laboratory Values Reported for Horses with Chronic Renal Failure		
Parameter	Number*	Percentage
Blood urea nitrogen/serum creatinine concentrations (BUN/Cr) >10	29/34	85%
BUN/Cr >15	17/34	50%
Anemia (packed cell volume [PCV] <30%)	12/30	40%
Hypoalbuminemia (<2.5 g/dl)	12/14	86%
Hypoalbuminemia (<2.0 g/dl)	7/14	50%
Hyponatremia (Na <sup>+</sup> <135 mEq/L)	26/40	65%
Hyperkalemia (K <sup>+</sup> >5.0 mEq/L)	23/41	56%
Hypochloremia (Cl <sup>-</sup> <95 mEq/L)	19/41	46%
Hypercalcemia (Ca <sup>2+</sup> >13.5 mg/dl)	26/39	67%
Hypophosphatemia (P <1.5 mg/dl)	17/36	47%
Acidosis (pH <7.35)	3/5	60%

**FIGURE 19-26** Changes in serum electrolyte concentrations, blood urea nitrogen (BUN) concentration, and serum creatinine (Cr) concentration after bilateral nephrectomy in Shetland ponies. (From Tennant B, Lowe JE, Tasker JB: Hypercalcemia and hypophosphatemia in ponies following bilateral nephrectomy, *Proc Soc Exp Biol Med* 167:365, 1981.)

grass hay.<sup>20,27</sup> Similarly, nephrectomized ponies fed grass hay did not become hypercalcemic.<sup>27</sup> The cause of hypophosphatemia in horses with CRF also remains undocumented, although it has been explained by the law of mass action, which leads to a decrease in serum phosphate concentration in association with hypercalcemia.<sup>35,118</sup> A similar response is not observable in horses that eat *Cestrum diurnum* (leading to a syndrome of hypervitaminosis D)—they develop hypercalcemia without hypophosphatemia.<sup>119</sup> Another possibility that has been suggested is that hypophosphatemia may result from long-standing anorexia associated with CRF.<sup>58</sup> Regardless of the cause, clinical problems associated with hypophosphatemia have not yet been recognized in horses with CRF.

A degree of metabolic acidosis accompanies CRF in human beings and small animals and is attributed to decreased ability of failing kidneys to excrete hydrogen ions and regenerate bicarbonate.<sup>1,35</sup> Normally, acid-base balance is maintained by reabsorption of filtered bicarbonate and excretion of hydrogen ions along with ammonia and phosphate. As renal function declines in the early stages of renal failure, hydrogen ion excretion via renal ammoniogenesis and ammonium

excretion increases. As renal failure progresses, compromised renal ammoniogenesis and decreased medullary recycling of ammonia caused by structural renal damage likely contribute to impaired ammonium excretion. Because hepatic glutamine synthesis is required for renal ammoniogenesis, the earlier increase in ammonium excretion may contribute to protein malnutrition in patients with CRF.<sup>1</sup> Metabolic acidosis also contributes to a number of the clinical signs of the uremic syndrome and may exacerbate some of the electrolyte alterations (e.g., hyperkalemia) of CRF. Metabolic acidosis has been reported in a limited number of horses with CRF (see [Table 19-9](#)); however, in the author's experience and that of others,<sup>26,58</sup> most horses with CRF have normal acid-base status or are alkalotic until the terminal stages of the disease, when metabolic acidosis typically develops. Metabolic alkalosis has been attributed to enhanced bicarbonate reabsorption and production, in association with hypochloremia and increased renal ammoniogenesis, respectively. In some instances, hypochloremic metabolic alkalosis may be accompanied by paradoxical aciduria.<sup>58</sup> The mechanism of paradoxical aciduria is likely similar to that of hypochloremic metabolic alkalosis

in ruminants with abomasal outflow obstruction.<sup>120</sup> Briefly, after all chloride has been reabsorbed from the glomerular filtrate, further sodium reabsorption occurs by exchange with (excretion of) potassium or hydrogen ions. Thus paradoxical aciduria is most likely to occur with concomitant hypokalemia or whole-body potassium depletion.

Horses with CRF also can develop hypercholesterolemia and hyperlipidemia (hypertriglyceridemia), and occasionally an animal has grossly lipemic plasma (hyperlipemia).<sup>27,29,117</sup> In fact, Naylor, Kronfeld, and Acland<sup>121</sup> reported a positive correlation between serum triglyceride and Cr concentrations in a group of azotemic horses. Twelve of 13 cases of hypertriglyceridemia in horses reviewed by Dunkel and McKenzie were azotemic.<sup>122</sup> With azotemia, hyperlipidemia can develop as a result of increased synthesis, decreased degradation, or increased mobilization of triglycerides from fat stores.<sup>35</sup> Lipoprotein lipase, which stimulates triglyceride uptake into cells, is inhibited by azotemia.<sup>123</sup> Heparin treatment (40 IU/kg subcutaneously every 8 hours) has been recommended to stimulate lipoprotein lipase in an attempt to clear the serum.<sup>27,29</sup> Hypercholesterolemia and hyperlipidemia increase the risk of atherosclerotic cardiovascular disease in human beings with CRF.<sup>35</sup> Furthermore, these conditions stimulate mesangial cell proliferation and matrix production in diseased glomeruli and thus accelerate progression to glomerulosclerosis.<sup>124</sup>

The failing kidneys have a tremendous adaptive capacity to maintain tubular function until GFR is low.<sup>107</sup> In the author's experience, tubular dysfunction resulting in significant sodium or phosphorous wasting (manifested by increased fractional clearance values), glucosuria, or enzymuria is more common with ARF than with CRF. When present, however, abnormal tubule function rarely leads to values for fractional sodium clearance in excess of 5%.<sup>62,73,125</sup> In contrast, loss of concentrating ability resulting in isosthenuria is a consistent feature of CRF that usually develops before azotemia. The associated polyuria may or may not be observed by the client, but the horse usually maintains water balance well through polydipsia. Polyuria typically results in urine that is clear and essentially devoid of crystals and mucus. Sediment examination is generally unremarkable, but increased numbers of red or white blood cells may occur with nephrolithiasis or ureterolithiasis or with pyelonephritis, respectively. Gross hematuria further supports lithiasis or neoplasia. One should include a quantitative urine culture in the diagnostic plan for all horses with CRF because bacteriuria may not always be accompanied by pyuria.

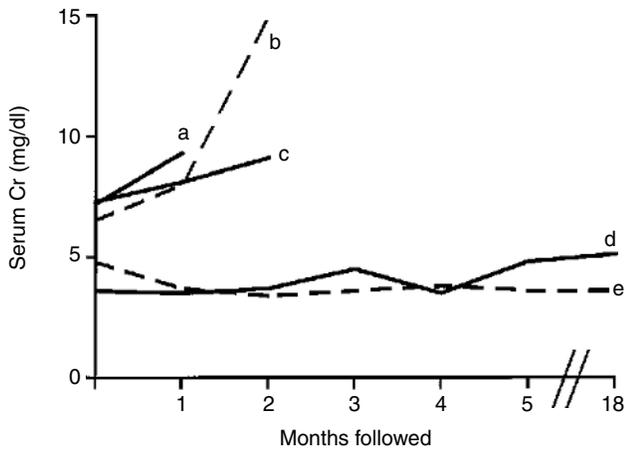

Alterations in the integrity of the highly anionic glomerular filtration barrier also can lead to loss of protein, predominantly albumin, in the urine. Few quantitative data are available on urinary protein loss in horses with CRF because in most previous reports proteinuria was assessed using urine reagent strips. Reagent strip results of +++ or ++++ correlate with protein concentrations of 100 to 300 and 1000 to 2000 mg/dl, respectively, depending on which reagent strip one uses. In a proteinuric horse that is producing 20 L of urine daily, these values would yield a wide range of urinary protein loss (20 to 400 g daily). The latter value would approach 25% of the total protein content of plasma and so is not realistic. In human beings with CRF, urinary protein loss exceeding 3.5 g per day (50 mg/kg per day for a 70-kg person) is classified as *nephrotic-range proteinuria*, and some patients with heavy proteinuria may lose in excess of 15 g per day (more than 200 mg/kg per day).<sup>35</sup> The upper limit of acceptable urinary protein

excretion in dogs is 20 mg/kg per day.<sup>126</sup> Using these values, estimates for the upper acceptable limits for urinary protein loss and nephrotic-range proteinuria in a 500-kg horse would be 10 g and in excess of 25 g per day, respectively. These values agree well with a mean value of 3.2 mg/kg (1.6 g per day) and a range of 3.6 to 22.3 mg/kg (1.8 to 11.2 g) per day in normal mares reported by the Schott, Hodgson, and Bayly<sup>127</sup> and by Kohn and Strasser,<sup>128</sup> respectively.

Another method to document proteinuria is to determine the ratio of urinary protein to urinary Cr (in milligrams per deciliter). This technique is more practical because it avoids a timed urine collection period. Although a normal range has not yet been reported for horses, values in excess of 1.0:1 and 3.5:1 are considered above normal and indicate nephrotic-range proteinuria in dogs<sup>126</sup> and human beings,<sup>35</sup> respectively. Thus a urine protein-to-Cr ratio greater than 2.0:1 likely supports significant proteinuria in a horse with CRF. Finally, a horse with CRF and heavy proteinuria (more than 200 mg/kg per day) could excrete as much as 100 g of protein daily (5% to 7% of total plasma protein). Proteinuria of this magnitude can increase urine specific gravity to 1.020 or greater and certainly would be great enough to lead to a decline in serum albumin (and total protein) concentration, despite increased hepatic albumin production. In some horses with CRF and a normal total plasma protein concentration, increased globulin concentration offsets mild hypoalbuminemia, whereas in other cases hyperglobulinemia actually can result in an increase in total plasma protein concentration.

One can use ultrasonography to determine kidney size in horses with CRF and to evaluate for the presence of cysts or nephroliths. Horses with ESKD typically have small kidneys that are more echogenic than normal (because of sclerosis and possible tissue mineralization).<sup>129-133</sup> Cystoscopy also can be a useful diagnostic aid to assess urine production qualitatively in each kidney and is particularly useful when ultrasonographic imaging fails to identify a kidney.<sup>131</sup> Renal scintigraphy is another imaging option to detect functional renal tissue that may not be apparent by ultrasonography.<sup>134</sup> One can perform renal biopsy using ultrasonographic guidance to document renal disease. Unfortunately, because most horses are presented for evaluation in the later stages of disease, biopsy results typically reveal glomerular, tubular, and interstitial lesions consistent with ESKD. Rarely do the lesions provide information about the inciting cause of the renal disease unless immunofluorescence testing and electron microscopy are pursued. These require placing samples in special fixatives, in addition to the sample placed in formalin for routine histopathologic examination. In some cases, renal biopsy results supporting pyelonephritis or a congenital anomaly (dysplasia) as the cause of CRF are useful in developing a therapeutic plan or providing a prognosis.

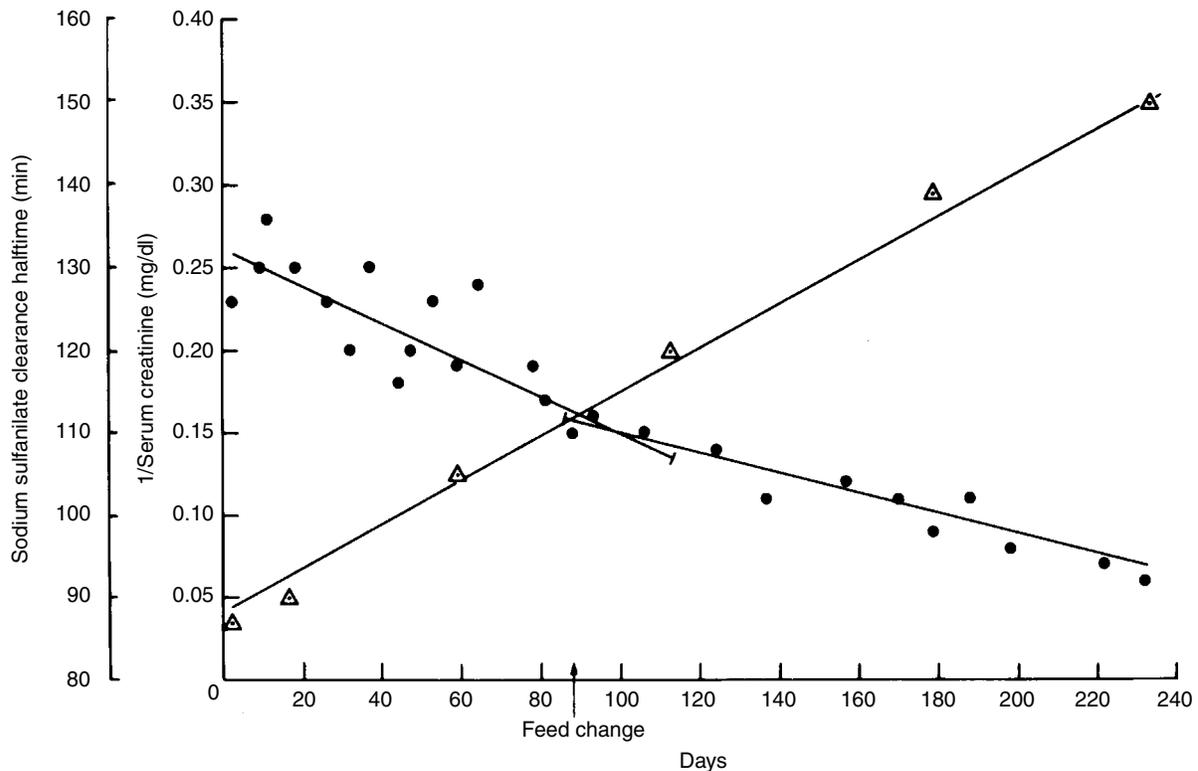

One can assess the severity of CRF in affected horses using available sophisticated techniques. The magnitude of azotemia is the most readily available and practical parameter but is an insensitive one.<sup>35</sup> Azotemia becomes apparent only after 75% or more of renal function is lost. Furthermore, the degree of azotemia can vary with nonrenal factors such as diet, body mass, and hydration. In general, Cr concentration is a more reliable measure than BUN, and doubling of Cr roughly correlates to a 50% decline in GFR (see Figure 19-6). Cr concentrations in the range of 5 to 10 mg/dl indicate a significant decline in renal function, and values exceeding 15 mg/dl are consistent with a grave prognosis. In contrast,

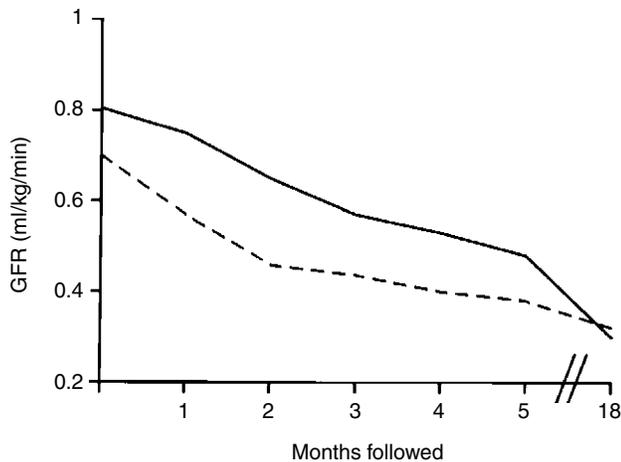

**FIGURE 19-27** Serum creatinine (Cr) concentrations in five horses with chronic renal failure (CRF). The three horses with an initial Cr concentration greater than 5 mg/dl (a to c) had rapid progression of renal disease over a 1- to 2-month period, necessitating euthanasia, whereas the two horses with an initial Cr concentration less than 5 mg/dl (d and e) were maintained with supportive care for longer than 18 months.

horses with a Cr concentration below 5 mg/dl may exhibit few clinical signs and can be managed for months or years (Figure 19-27). Plotting the inverse of Cr concentration ( $1/\text{Cr}$ ) over time also has been used to monitor progression of CRF in human beings<sup>135,136</sup> and in one horse<sup>20</sup> in an attempt to predict the end point of the disease process (Figure 19-28). Unfortunately, these plots are subject to considerable variation (because of changes in tubular secretion of Cr) and have not proved to be of any more value than monitoring Cr over time.<sup>135,136</sup>

Measurement of GFR provides the most accurate quantitative assessment of renal function but is pursued rarely because it is more time consuming and technically demanding than measurement of Cr concentration. Although a number of methods are available to measure GFR,<sup>137</sup> measurement of endogenous  $\text{Cl}_{\text{Cr}}$  or the plasma disappearance of exogenous Cr, sulfanilate,<sup>2,138</sup> or  $^{99\text{m}}\text{Tc-DTPA}$ <sup>139</sup> are the most practical methods in a clinical setting. The former requires timed urine collections, whereas the latter may require special assays or nuclear medicine capabilities (see Examination of the Urinary System). Horses in the earlier stages of CRF can develop tubular Cr secretion, which could lead to overestimation of GFR measured by the  $\text{Cl}_{\text{Cr}}$  technique. As renal disease progresses, however, Cr excretion decreases faster than GFR declines

**FIGURE 19-28** The inverse of the serum creatinine (Cr) concentration (filled circles) and the whole-blood sodium sulfanilate clearance half-time in a horse with chronic renal failure (CRF) associated with polycystic kidney disease (PKD). The slope of the line describing the reciprocals of Cr concentration from day 1 to day 98 was significantly different ( $P < 0.05$ ) from that from day 99 to 235, and the slope change was associated with a change from alfalfa to grass hay. (From Bertone JJ, Traub-Dargatz JL, Fettman MJ et al: Monitoring the progression of renal failure in a horse with polycystic kidney disease: use of the reciprocal of serum creatinine concentration and sodium sulfanilate clearance half-time, *J Am Vet Med Assoc* 191:565, 1987.)

**FIGURE 19-29** Glomerular filtration rate (GFR) as measured by endogenous creatinine clearance ( $Cl_{Cr}$ ) (solid line) and inulin clearance ( $Cl_{In}$ ) (dashed line) in a mare (see horse in Figure 19-28) with chronic renal failure (CRF). GFR declined steadily over the 18-month period, despite minimal change in serum creatinine (Cr) concentration. Compared with  $Cl_{In}$ , endogenous  $Cl_{Cr}$  overestimated GFR until the terminal stage of the disease process. This difference likely reflects tubule secretion of Cr in the earlier stages of CRF, which subsequently diminished during the final weeks of the disease course.

because of loss of compensatory secretion. Despite these limitations, repeated measurement of  $Cl_{Cr}$  in a single animal can be useful for monitoring progression of CRF over time (Figure 19-29).

## 🌀 DISEASE PROGRESSION

One of the hallmarks of CRF is the progressive nature of the disease,<sup>140-142</sup> and progression appears to be largely independent of the inciting cause because of the final common pathways of renal injury. The response to a decrease in renal functional mass is a compensatory increase in filtration (termed *single-nephron GFR*) and tubular function (e.g., Cr secretion, ammoniogenesis) by remaining nephrons. The increase in single-nephron GFR results from increased glomerular capillary blood flow and hydrostatic pressure leading to glomerular hyperfiltration. Hyperfiltration is associated with increased permeability of the GBM and proteinuria. Furthermore, increased filtration of macromolecules leads to activation and proliferation of mesangial and epithelial cells and eventually progression to glomerulosclerosis.<sup>35,108,140-142</sup> In addition to causing proteinuria, increased filtration of protein is accompanied by increased proximal tubular protein reabsorption. The latter leads to upregulation of genes encoding vasoactive and inflammatory mediators by tubular and interstitial cells and contributes substantially to injury of the renal interstitium.<sup>142</sup>

A number of studies investigating the mechanisms of glomerular hypertension have demonstrated that activation of the renin-angiotensin system and angiotensin II production are of considerable importance, because angiotensin II is a potent constrictor of glomerular efferent arterioles.<sup>143-145</sup> Activation of the intrarenal renin-angiotensin system can produce significant glomerular hypertension without producing increases in systemic angiotensin II concentration or blood pressure. In fact,

administration of specific angiotensin II receptor antagonists or angiotensin-converting enzyme inhibitors has been demonstrated to decrease glomerular capillary hydrostatic pressure and the magnitude of proteinuria in experimental studies of renal disease.<sup>143-146</sup> Angiotensin-converting enzyme inhibitors have helped to control hypertension and proteinuria in small animals,<sup>1,147</sup> but no reports describe use of angiotensin-converting enzyme inhibitors in horses with CRF.

The role of dietary protein in the progression of CRF has been the subject of a number of investigations in human beings and small animals with a variety of renal diseases.<sup>148-153</sup> A well-established fact is that one can ameliorate clinical signs of uremia by decreasing dietary protein content; however, whether decreasing dietary protein slows progression of renal disease remains controversial. Increased dietary protein has been demonstrated to increase activation of the renin-angiotensin system; therefore decreasing dietary protein could be protective for the reasons discussed in the preceding paragraph. Next, a decrease in protein intake leads to production of smaller amounts of urea and other nitrogenous wastes. In theory, the workload on the kidneys is similarly decreased. Because all work (aerobic ATP production and use) is associated with a degree of free radical production, greater protein intake would generate more free radicals. Free radicals appear to be especially injurious to diseased kidneys because their scavenging mechanisms are compromised. Increased dietary protein also requires increased ammoniogenesis by renal tubules to excrete the associated proton load; however, ammoniogenesis can lead to noninflammatory, nonimmune complement activation in proximal tubule epithelial cells. One can ameliorate this proinflammatory consequence of ammoniogenesis by supplementation with sodium bicarbonate. In summary, excessive dietary protein leads to a greater degree of uremia and has the potential to exacerbate renal damage in CRF by several mechanisms.

In contrast, protein-calorie malnutrition is associated strongly with increased morbidity and mortality in human CRF patients and can be attributed to increased protein catabolism when dietary protein intake is marginal to low. In human beings a number of serum components, including prealbumin, cholesterol, and insulin-like growth factor; plasma and muscle amino acid profiles; and body composition measurements have been studied as potential indexes of nutritional status. However, serum albumin concentration is the most practical and most extensively studied nutritional index. In addition to heavy proteinuria, hypoalbuminemia also can be attributed to protein-calorie malnutrition. Furthermore, a BUN-to-Cr ratio less than 10:1 may be another indication of inadequate protein intake. Thus current dietary recommendations call for dietary protein and caloric intake at levels that meet or slightly exceed predicted requirements, which should render nitrogen balance neutral.<sup>154</sup> Finally, a critically important but often overlooked aspect of nutritional management of CRF patients is provision of a palatable diet.<sup>1,154</sup> Feeding smaller meals more frequently and varying the diet help to increase food intake in CRF patients of all species.

Experimental studies of CRF in horses are limited to reports that describe the effects of prolonged daily dosing of horses with mercurial compounds.<sup>155-158</sup> In these four reports, each involving a single horse, the subjects were destroyed between 85 and 191 days after mercury administration began. Anorexia, weight loss, and nonpruritic urticaria were the major clinical signs. The renal lesion was CIN, which was accompanied by

a decrease in concentrating ability and an increase in water consumption. Additional tubular dysfunction included glucosuria in all four horses and a variable degree of proteinuria. Interestingly, the clinical signs and tubular dysfunction preceded the development of azotemia in all horses, and excretion of sodium or chloride did not increase. The final report focused principally on the effects on renal function, and azotemia did not develop until the final week of life; GFR (assessed by endogenous  $Cl_{Cr}$ ) decreased to 35% of the highest measured value on the day before euthanasia.<sup>158</sup> Aciduria and increased phosphate excretion, in addition to glucosuria and proteinuria, also were detected during the final week of life.

## TREATMENT

At the time of presentation most horses with CRF exhibit obvious weight loss and other clinical signs. Because of the progressive and irreversible nature of the renal disease, the long-term prognosis is grave. Specific corrective treatment for CRF (renal transplantation) is not available for horses, and maintenance by peritoneal dialysis or hemodialysis would only be practical for valuable breeding animals. Pyelonephritis could be considered an exception because antibiotic treatment in theory could lead to resolution of infection and improved renal function. Unfortunately, significant renal damage usually has occurred by the time the diagnosis is established in most cases of bilateral pyelonephritis, so the prognosis for a return to normal renal function is guarded to poor. In contrast, the short-term prognosis may be more favorable. Some horses with CRF may maintain Cr concentration of less than 5 mg/dl for months with minimal deterioration. To predict which patients will deteriorate more rapidly is difficult, but the recent history and initial ability to counteract weight loss with improved management are useful indicators. Laboratory analysis of blood samples at 2- to 4-week intervals to follow the degree of azotemia and serum electrolyte alterations may be useful in monitoring disease progression. In general, animals that are eating well and maintain reasonable body condition carry the best short-term prognosis and may still be able to perform some limited work. Their use as breeding animals may be reduced because azotemia and eventual weight loss would reduce the chance for normal conception and gestation. The goal in each case is to provide appropriate supportive care and to monitor the horse closely so as to provide humane euthanasia before the patient develops uremic decompensation.

As previously discussed, once significant renal disease is established, irreversible decline in GFR and progression of renal failure generally ensue.<sup>35,140-142</sup> Thus management of the equine patient afflicted with CRF involves palliative efforts to minimize further loss of renal function. The goals are to prevent complicating conditions (e.g., by providing plenty of water), to discontinue administration of nephrotoxic agents, and to provide a palatable diet to encourage appetite and minimize further weight loss.<sup>27-30,159</sup> Intravenous fluid therapy to promote diuresis, usually with 0.9% NaCl solution, is of much greater benefit in cases of acute, reversible renal failure but also may benefit patients that suffer a sudden exacerbation of CRF. One must administer intravenous fluid therapy cautiously because horses with CRF can develop significant peripheral or pulmonary edema.

Supportive care also can include supplementation of sodium bicarbonate (50 to 150 g per day) when serum bicarbonate concentration is consistently less than 20 mEq/L.<sup>159</sup>

One may need to add supplemental bicarbonate to a bran mash. If sodium bicarbonate supplementation aggravates ventral edema, then one should limit or discontinue supplementation. Edema is not usually a significant problem, and the horse should tolerate mild edema (rather than being treated with diuretics that could be ineffective or lead to further electrolyte wastage) unless the edema interferes with ambulation. In a previous edition of this text, the author also recommended supplementation with NaCl to replace potential loss of these electrolytes in urine in horses with CRF. However, a recent study<sup>160</sup> found that supplementation with NaCl (used in an attempt to increase water intake) in cats with preexisting renal disease led to progression of renal disease that remained after salt supplementation was discontinued. Thus one should approach salt supplementation in horses with CRF with caution and should consider it only for patients with hyponatremia and hypochloremia.

Substituting high-calcium and high-protein feed sources such as alfalfa hay with good quality grass hay and carbohydrates (corn and oats) may help control hypercalcemia and the magnitude of azotemia. Ideally, the hay and grain should contain an adequate but not excessive amount of protein (<10% crude protein), which should maintain the BUN-to-Cr ratio in a target range between 10:1 and 15:1.<sup>27</sup> Providing unlimited access to fresh water and encouraging adequate energy intake by feeding a variety of palatable feeds are important. In fact, if appetite for grass hay deteriorates, then offering less ideal feeds (e.g., alfalfa hay, increased amounts of concentrate) to meet energy requirements and reduce the rate of weight loss is preferable. Often horses continue to graze at pasture when their appetite for hay is diminished. Administration of B vitamins or anabolic steroids for their touted appetite-stimulating effects may benefit some animals. Although dietary fat is calorie dense, one must approach supplementation judiciously in patients with hyperlipidemia and hypercholesterolemia.

Administration of corticosteroids or NSAIDs can limit the intrarenal inflammatory response associated with renal failure and also may attenuate renal injury. For example, administration of meclufenamate limited proteinuria in a group of human patients with severe manifestations of the nephrotic syndrome<sup>161</sup>; however, nonspecific blockade of prostaglandin production by corticosteroids and most available NSAIDs has the adverse effect of decreasing production of important renal vasodilating agents (prostaglandin  $E_2$  and prostacyclin). Production of these prostanoids increases during periods of renal vasoconstriction or ischemia to maintain intra-RBF, particularly to the renal medulla. With excessive or long-term NSAID administration, renal papillary necrosis develops after medullary ischemia.<sup>61,62,69,86</sup> Thus the negative effects of corticosteroids and NSAIDs on RBF outweigh possible benefits, and they are not recommended routinely for the management of CRF in horses.

The progressive renal injury that occurs in CRF is associated with continued damage to glomerular and tubular membranes mediated by ongoing activation of the inflammatory cascade. In theory, treatment with antioxidant medications and free radical scavengers could be of benefit, but experimental data in horses do not bear this out. Similarly, interest in the role of dietary fatty acids as precursors of eicosanoids has been considerable. Specifically, dietary supplementation with sources rich in  $\omega$ -3 fatty acids (linolenic acid) compared with  $\omega$ -6 fatty acids (linoleic acid), appear to decrease generation of more damaging fatty acid metabolites during activation of the

inflammatory cascade. In horses, dietary supplementation with  $\omega$ -3 fatty acids (in the form of linseed oil) has been effective at ameliorating the effects of endotoxin in studies in vitro<sup>162-164</sup> and supplementation with fish oil (another rich source of  $\omega$ -3 fatty acids) slowed the progression of renal failure in laboratory animals.<sup>165,166</sup> Unfortunately, the effects of endotoxin in vivo were not ameliorated by feeding linseed oil in preliminary equine studies,<sup>167</sup> and the possible benefits of feeding  $\omega$ -3 fatty acids to horses with CRF are not known at this time.

Recently, control of hypertension and reduction of proteinuria have been recognized as the most successful interventions to limit progression of renal disease in human beings with CRF.<sup>142</sup> Thus monitoring the blood pressure and the level of proteinuria (urine protein-to-urine Cr ratio) in horses with CRF seems to be prudent. Treatment with angiotensin-converting enzyme inhibitors could be beneficial in horses with either of these problems but has not yet been pursued because of the expense of the available medications. Attention also has been directed to use of more specific anti-inflammatory or immunosuppressant medications to limit renal injury in immune-mediated glomerulonephritis. For example, inhibition of thromboxane synthetase activity (thromboxane A<sub>2</sub> is a potent vasoconstricting agent and platelet activator) was demonstrated to limit renal histologic and functional changes in a canine model of immune-mediated glomerulonephritis.<sup>168</sup> Similarly, cyclosporine was used as an adjunct treatment in a prospective study of naturally occurring canine glomerulonephritis. Unfortunately, renal function declined in cyclosporine-treated dogs, as it did in control dogs. The lack of any beneficial effect, along with the adverse reactions to cyclosporine, led to the conclusion that cyclosporine was of no use for treating CRF.<sup>169</sup> As these studies demonstrate, specific manipulation of the inflammatory or immune response can limit renal injury when one can administer medications before or early in the course of renal disease; however, with long-standing, naturally occurring disease, such treatments are much less likely to retard progression of renal failure significantly. Finally, other investigators are focusing on developing therapeutic strategies that may modulate or limit renal fibrosis. Their studies of the effects of cytokines, lymphokines, and proteoglycans on matrix synthesis and degradation by mesangial cells and on fibroblast activation in damaged glomeruli may lead to novel treatment options in the future.<sup>170,171</sup>

## URINARY TRACT INFECTIONS

Harold C. Schott II

In human beings, bacterial UTIs are among the most common infections.<sup>1</sup> In contrast, bacterial UTIs appear to be uncommon in horses.<sup>2-5</sup> As in other species, ascending UTIs are more common, although septic nephritis may be an occasional consequence of septicemia, especially in neonatal foals.<sup>6</sup> Mares are at higher risk for UTIs than geldings or stallions because of their shorter urethra.

Development of a UTI requires initial urethral colonization with pathogenic bacteria, entry of pathogens into the bladder, and subsequent multiplication in the bladder.<sup>1,9</sup> Urethral colonization involves adherence to uroepithelial cells, typically by fecal bacteria that possess fimbrial adhesins (pili) that bind to specific glycolipid receptors on uroepithelial cells. Not

surprisingly, pathogenic *Escherichia coli* are rich in these specific surface adhesins, whereas nonpathogenic *E. coli* have few specific surface adhesins. Further characterization of human pathogenic *E. coli* strains by their somatic (O), flagellar (H), and capsular (K) antigens has revealed that a small number of *E. coli* strains are responsible for a large percentage of UTIs.<sup>1,8,9</sup> Normal vulvar and preputial flora protect against urethral colonization by pathogenic bacteria, but any anatomic defect leading to turbulent urine flow compromises maintenance of normal flora and may increase the likelihood of colonization by pathogens.<sup>10,11</sup> Although broodmares have not been proved to be at greater risk, intercourse is a well-established risk factor for development of UTIs in women. In addition, human prostatic secretions contain a heat-stable cationic protein that has potent antibacterial activity.<sup>1</sup> Thus stallions may be at lower risk than geldings for UTIs.

Once a pathogen has colonized the distal urethra, rapid proliferation between micturitions allows invasion of the proximal urethra and bladder, which do not have a protective flora. Host defenses in the bladder include immunoglobulins in urine and a mucopolysaccharide layer rich in glycosaminoglycans covering the uroepithelial surface.<sup>8,9</sup> Production of protective glycosaminoglycans is under hormonal control by estrogen and progesterone in rabbits.<sup>12</sup> Thus lack of these hormonal effects has been suggested as an explanation for the increased risk for UTIs in prepubertal and postmenopausal women and in spayed dogs.<sup>7</sup> Furthermore, women with recurrent UTIs have been speculated to have decreased concentrations of secretory immunoglobulin A in their urine.<sup>13</sup> Although continued urine production dilutes proliferating bacteria, once pathogens have gained access to the bladder, the rate of replication far outweighs any dilution effect and allows the UTI to become established.<sup>1</sup> Although antibiotic therapy is highly effective in eliminating most UTIs, recurrent UTIs can be a challenge to manage. In addition to thorough evaluation to eliminate predisposing factors in these patients, one may consider additional approaches to prevention. For example, fimbrial vaccines are effective against experimental UTIs in monkeys.<sup>8</sup>

## ☞ URETHRITIS

Bacterial urethritis has been described as a cause of hemospemia in stallions<sup>14,15</sup>; however, with the exception of traumatic, parasitic (habronemiasis), or neoplastic conditions of the penis or urethra that interfere with urine flow, the author is unaware of documented cases of primary bacterial urethritis resulting in dysuria.<sup>16,17</sup> Furthermore, hemospemia likely attributable to urethritis in a number of previous cases probably resulted from proximal urethral defects, which have become easier to identify with high-resolution videorendoscopy (see Hematuria).<sup>18</sup> Bacterial infections of accessory sex glands or the prepuce also may cause dysuria. Accessory sex gland infections generally are limited to intact males and are more likely to cause infertility or hemospemia than dysuria.<sup>16,19</sup> Preputial infections can occur after trauma, presence of a foreign body, habronemiasis, or neoplasia, and affected horses typically have a malodorous, swollen sheath. Examination of the sheath and penis, along with biopsy of abnormal tissue, allows diagnosis of the primary problem. Occasionally, an older gelding may develop recurrent sheath swelling or infection that cannot be attributed to a primary disease process. The pathogenesis of this problem is not known,

although fat accumulation, poor hygiene, and inactivity may be contributing factors. Treatment involves repeated sheath cleaning, application of topical anti-inflammatory and antibacterial ointments, and when involvement is more severe, systemic antibiotic administration.

## ☪ CYSTITIS

Primary cystitis is uncommon in horses, and a predisposing cause should be ruled out whenever cystitis is suspected. Bacterial cystitis is usually a secondary problem that may accompany alterations in urine flow caused by urolithiasis, bladder neoplasia, bladder paralysis, an anatomic defect of the bladder or urethra, or instrumentation of the urinary tract (e.g., catheterization, endoscopy).<sup>2-5,10,11,20-24</sup> Dysuria may be manifested by pollakiuria, stranguria, hematuria, or pyuria. One may observe scalding and accumulation of urine crystals on the perineum of affected mares or on the front of the hindlimbs of affected male horses. One should not confuse these findings with normal estrous activity in the mare. Although nosocomial UTIs are a well-documented problem in hospitalized human<sup>1</sup> and small animal patients,<sup>25</sup> this complication has not been well-recognized in equine patients except for ill neonatal foals. Diagnostic evaluation includes physical and rectal examinations and collection of a urine sample for urinalysis and quantitative bacterial culture. In the absence of uroliths or other bladder masses, transrectal palpation of the bladder is usually within normal limits; however, endoscopic and ultrasonographic examination of the bladder may be helpful in assessing mucosal damage and wall thickening in horses with cystitis.<sup>26,27</sup> Because normal equine urine is rich in mucus and crystals, gross examination may be unrewarding, but sediment examination may reveal increased numbers of white blood cells (more than 10 leukocytes per high-power field) and presence of bacteria in some cases of cystitis. Normal sediment examination results do not rule out UTI. A definitive diagnosis requires quantitative culture results exceeding 10,000 colony-forming units (CFUs) per milliliter in a urine sample collected by midstream catch or urethral catheterization.<sup>3,5,28</sup> For best results, one should evaluate urine sediment within 30 to 60 minutes of collection and should cool samples for culture during transport because bacterial numbers may increase in samples left at room temperature. Organisms that may be recovered on culture include *Escherichia coli*, *Proteus* spp., *Klebsiella* spp., *Enterobacter* spp., *Streptococcus* spp., *Staphylococcus* spp., *Pseudomonas aeruginosa*, and rarely *Corynebacterium renale*.<sup>2-5,22</sup> Isolation of more than one organism is common. *Salmonella* spp. occasionally have been isolated from the urine of apparently healthy horses, and *Candida* spp. infections of the lower urinary tract also have been documented in sick neonatal foals receiving broad spectrum antibiotics.<sup>2,3</sup>

Successful treatment of bacterial cystitis requires correction of predisposing problems such as urolithiasis and administration of systemic antibiotics. Ideally, selection of an antibiotic is based on the results of susceptibility testing of isolated organisms, and the initial recommended course of treatment traditionally has been at least 1 week.<sup>2-5</sup> A trimethoprim-sulfonamide combination, ampicillin, penicillin, and an aminoglycoside, or ceftiofur can be initial choices. In human beings with uncomplicated cystitis, single-dose antimicrobial therapy, which is less costly and is associated with fewer adverse effects, has a success rate comparable with

that of longer-term conventional therapy (75% or greater). Furthermore, relapse after single-dose therapy is not accompanied by more severe clinical signs or more extensive urinary tract involvement<sup>1</sup>; however, if clinical signs recur after treatment is discontinued, then one should repeat urine culture along with additional diagnostic evaluation to determine a cause for altered urine flow or bacterial persistence.

Treatment of recurrent UTI usually requires long-term medication (4 to 6 weeks), and ease of administration and cost become additional considerations in antibiotic selection. Trimethoprim-sulfonamide combinations and the penicillins are excreted via the kidneys and concentrated in urine. Although results of in vitro susceptibility testing of isolated pathogens may reveal resistance, these drugs may have effective antimicrobial activity against the causative organisms because of the high concentrations achieved in urine.<sup>5</sup> Metabolism of the antibiotic is another consideration. For example, sulfamethoxazole is metabolized mostly to inactive products before urinary excretion, whereas sulfadiazine is excreted mostly unchanged in urine.<sup>29</sup>

Additional treatments for recurrent UTI can include supplementation with 50 to 75 g of loose salt to the diet<sup>7</sup> or provision of warm water during cold weather in an attempt to increase water intake and urine production. Administration of the urine-acidifying agent ammonium chloride (20 to 40 mg/kg PO daily) also has been recommended in cases of cystitis and urolithiasis.<sup>20</sup> Use of ammonium chloride at this dose, however, has not produced a consistent decrease in urine pH. Recently, use of larger oral doses of ammonium chloride (60 to 520 mg/kg/day),<sup>30-32</sup> methionine (1 g/kg every 24 hours), vitamin C (1 to 2 g/kg/day),<sup>33</sup> or ammonium sulfate (175 mg/kg/day)<sup>34</sup> were more successful in reducing urine pH to less than 6.0 in a limited number of horses; however, at these doses, medications were usually unpalatable and had to be administered by dose syringe or stomach tube. Adding grain to the diet is another simple way to decrease urine pH, although the decline is modest and urine pH typically remains greater than 7.0.<sup>33</sup> A final treatment aid is bladder lavage. This procedure most benefits horses with accumulations of large amounts of crystalloid material in the bladder, a condition that has been termed *sabulous urolithiasis*.<sup>34</sup> Whenever *sabulous urolithiasis* is present, neurologic control of bladder function should be assessed. Incomplete emptying of the bladder can result in excessive accumulation of urinary sediment. Although one can add a number of antiseptics to the sterile polyionic lavage fluid, the most important consideration is adequate volume to flush the crystalline debris completely from the bladder. Concurrent cystoscopy is a useful tool to assess the efficacy of bladder lavage.

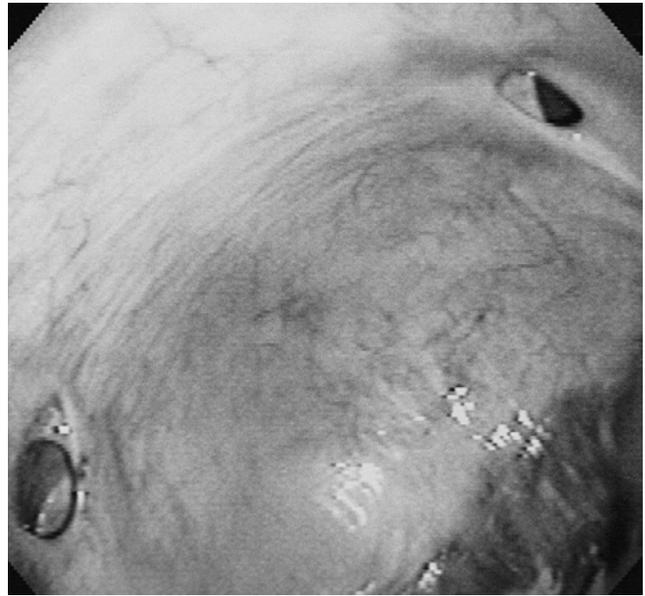

One report of experimental induction of cystitis in equids exists.<sup>35</sup> After chemical irritation of the bladder mucosa,  $2.5 \times 10^{13}$  CFUs of *Proteus mirabilis* were instilled into the bladders of nine female ponies. Three days later all ponies demonstrated stranguria, and culture results yielded 20,000 to 100,000 CFUs/ml of *P. mirabilis*. Sediment examination revealed increased numbers of white blood cells (more than 10 per high-power field) in seven of nine ponies, and bacteria were observed in all samples (although in low numbers of one to three per high-power field). In two untreated ponies, the cystitis resolved spontaneously between 2 and 4 weeks after inoculation; however, resolution was complete within 3 to 6 days in ponies treated with a trimethoprim-sulfadiazine combination.

Epizootics of cystitis also have been reported in the Southwestern United States<sup>22,36</sup> and in Australia.<sup>37</sup> In the former reports a syndrome of ataxia and urinary incontinence was associated with ingestion of Sudan grass and Johnson grass (hybrids of *Sorghum* spp.). Both problems were attributed to sublethal intoxication with hydrocyanic acid in the plants, which resulted in demyelination of the lower spinal cord and bladder paralysis. Pyelonephritis was often the cause of death in affected horses.<sup>36</sup> Another outbreak of cystitis, manifested by hematuria more than incontinence, occurred in the Northern Territories and Western Australia in 1963.<sup>37</sup> The kidneys and ureters were not affected, and ataxia was not observed in these horses. The problem, which resulted in loss of more than 200 horses, began shortly after the end of the wet season. Affected horses were on range pasture and, although this was not proved, a fungal toxin was suspected because sporidesmin (a toxin produced by *Pithomyces chartarum*) was known to cause bladder lesions in sheep and cattle. An environmental cause was substantiated further when no additional cases developed in 1964, after a “dry” wet season.

## 🌀 PYELONEPHRITIS

Upper UTIs involving the kidneys and ureters are rare in horses.<sup>2,3,5</sup> The course of the distal segment of the ureters in the dorsal bladder wall creates a physical barrier or valve to prevent VUR, a prerequisite for ascending pyelonephritis. VUR is more common in children because the intramural portion of the distal ureter lengthens with growth. Furthermore, congenital VUR often occurs in families, which suggests a genetic tendency for the problem, which has been associated with developmental anomalies of the intramural insertion of one or both ureters.<sup>1</sup> More obvious problems that interfere with this barrier and increase the risk for VUR and associated upper UTIs include ectopic ureter or bladder distention, which may occur with bladder paralysis or urethral obstruction. Over time, VUR leads to progressive ureteral dilation and renal scarring (Figure 19-30). This effect explains the common finding of ureteral dilation in young horses with ectopic ureters and provides further support for unilateral nephrectomy, rather than reimplantation of the ureter, as the treatment of choice for ectopic ureter.<sup>38,39</sup> In addition to VUR, intrarenal reflux also is required to initiate renal damage predisposing the parenchyma to ascending infection. The renal papillae contain collections of papillary duct openings. These are typically conical structures that protrude into the renal pelvis. Similar to the protective nature of the intramural ureteral segment against VUR, this morphology protects against intrarenal reflux; however, in human infants and young pigs, a second type of large, concave, “refluxing” papillae also have been described in the areas of the renal pelvis most often affected with renal scarring.<sup>1</sup> Thus VUR and intrarenal reflux are important in development of pyelonephritis.

The role of recurrent lower UTI in the development of pyelonephritis is less clear. For example, pyelonephritic scarring (without infection) can develop after high-pressure urinary tract obstruction (urethrolithiasis) and can predispose to future upper UTI. In contrast, many cases of recurrent cystitis never proceed to involve the upper urinary tract.<sup>1</sup> Because the kidneys are densely vascular organs, septic nephritis may develop in association with septicemia in neonatal or adult horses.<sup>6</sup> Unless renal involvement is extensive, the upper UTI may go undetected but could lead to development of

**FIGURE 19-30** Endoscopic image of the bladder of a pony mare with recurrent cystitis and pyelonephritis. The ureteral openings were distended easily by insufflation of the bladder with air. Ureteral dilation resulted from long-term vesiculoureteral reflux.

nephrolithiasis or CRF months to years later. As in the bladder, defense mechanisms within the normal kidney act to minimize bacterial colonization and proliferation. Efficacy of renal clearance varies with the species of bacteria entering the kidney. In addition, obstruction to urine flow (unilateral ureterolithiasis or nephrolithiasis) increases, rather than decreases, the risk of bacterial proliferation in the obstructed kidney.

Pyelonephritis in horses has been described in association with urolithiasis, recurrent cystitis, and bladder paralysis.<sup>2,3,5,21,36</sup> Other causes have included accidental amputation of the penis during castration,<sup>40</sup> foreign bodies in the bladder,<sup>41</sup> and lower urinary tract neoplasia.<sup>23,42</sup> With pyelonephritis, dysuria is manifested by hematuria or pyuria rather than stranguria and pollakiuria (as for cystitis). In addition, horses with upper UTIs generally have other clinical signs, including fever, weight loss, anorexia, or depression.<sup>2,3,5,41-49</sup> Upper UTIs also can be accompanied by nephrolithiasis or ureterolithiasis or both.<sup>49</sup> In such cases, whether lithiasis or infection develops first or whether both are consequences of VUR, intrarenal reflux, and renal parenchymal damage is unclear. In an occasional case, small uroliths may travel down the ureter and lead to recurrent urethral obstruction with renal colic as the presenting complaint.

As for cystitis, diagnostic evaluation includes physical and rectal examinations, urinalysis, and a quantitative urine culture. Careful palpation may allow detection of an enlarged ureter or kidney, although the kidney also may become shrunken in long-standing cases. In addition to the organisms causing cystitis, one also can isolate *Actinobacillus equuli*, *Streptococcus equi* subsp. *equi*, *Rhodococcus equi*, or *Salmonella* spp. from horses with hematogenous septic nephritis.<sup>3,6</sup> In horses with upper UTIs, one should perform a CBC and serum biochemistry profile to assess the systemic inflammatory response and renal function. Finally, cystoscopy (including watching for urine flow from each ureteral opening) and ultrasonographic imaging of the bladder, ureters, and kidneys are helpful adjunct

diagnostic procedures.<sup>26,27</sup> Ureteral catheterization (by passing polyethylene tubing via the biopsy channel of the endoscope or by using a No. 8-10 French polypropylene catheter, which can be passed blind in mares) may allow collection of urine samples from each ureter to distinguish unilateral from bilateral disease.<sup>50</sup>

Treatment for upper UTIs includes a prolonged course of appropriate systemic antibiotics (selected based on susceptibility testing results on isolated pathogens). In select cases with unilateral disease, one may consider surgical removal of the affected kidney and ureter.<sup>16,44,51</sup> Prerequisites for a nephrectomy include documentation of unilateral disease by normal laboratory results for renal function (absence of azotemia), recovery of insignificant numbers of bacteria (fewer than 10,000 CFUs/ml) from urine collected from the ureter leading to the nonaffected kidney, and ultrasonographic evidence of abnormal structure (e.g., fluid-filled structures, nephrolithiasis) in the affected kidney. Alternatively, poor response to several weeks of appropriate antimicrobial therapy and recurrence of clinical signs of pyelonephritis are additional indications for nephrectomy. Unfortunately, successful treatment of bilateral pyelonephritis is rare, but the poor prognosis likely is related to failure to establish the diagnosis until late in the disease course.

## ☉ PARASITIC INFECTIONS

One occasionally finds parasitic lesions associated with the nematodes *Strongylus vulgaris*, *Halicephalobus* (previously *Micronema*) *deletrix*, and *Diocotophyme renale* in equine kidneys.<sup>52</sup> Although larval migration of *S. vulgaris* in the renal artery and parenchyma is considered aberrant,<sup>53</sup> larval migration was found in more than 20% of horses in one abattoir survey. Passage through renal tissue may result in infarction or subcapsular or pelvic hemorrhage when parasites localize in these sites.<sup>54</sup> Although rare, *H. deletrix* infection is often life threatening because of CNS involvement leading to a variety of neurologic deficits that generally require euthanasia.<sup>55-59</sup> *Halicephalobus deletrix* has been suggested to be the most important cause of verminous meningoencephalomyelitis in horses.<sup>60</sup> Only the female parasite has been identified in equine tissues, typically in highly vascular organs. One usually finds large, granulomatous lesions that are full of the rhabditiform nematodes in the kidneys. The life cycle of *H. deletrix* is unknown, but the apparent saprophyte appears to have worldwide distribution. The finding of gingival lesions and oral granulomata in some horses suggests that ingestion is the likely route of infection. Attempts to find nematode larvae or eggs in urine have been unsuccessful, and whether the horse is an accidental host or is important for the life cycle of the parasite is unclear.<sup>55</sup> The free-living form is found in decaying organic debris (e.g., tree stumps) and also has been described to affect human beings.<sup>59</sup> Antemortem diagnosis has not been made, and CSF cytologic changes in affected horses cannot differentiate between nematodiasis and protozoal encephalomyelitis.<sup>58</sup> Renal involvement is typically inapparent, although one affected horse demonstrated a 2-week course of stranguria and polyuria before onset of neurologic deficits.<sup>56</sup> *Diocotophyme renale* is a large, bright-red nematode, and the female may reach 100 cm in length. The typical hosts are carnivorous species, but the parasite occasionally affects horses that ingest the intermediate host (annelid worm) while grazing or drinking from natural water sources.<sup>61</sup> Once

localized in the kidney, the parasite may live 1 to 3 years; eggs are shed in the urine. The parasite completely destroys the renal parenchyma, and death of the parasite leads to shrinking of the host kidney into a fibrous mass. Occasionally, hydronephrosis or renal hemorrhage may be a serious complication of parasitic infection.<sup>62,63</sup>

In contrast to the nematodes, infection with the coccidian parasite *Klossiella equi* appears common, yet no reports describe clinical disease associated with this coccidial infection.<sup>64-69</sup> Although disorders accompanied by immunosuppression have been suggested to increase its likelihood, *K. equi* infection is still considered an incidental finding in affected horses. The life cycle has not been elucidated fully, but one proposal is that ingested sporocysts (or sporozoites) enter the bloodstream and undergo schizogony in endothelial cells of the glomeruli. Merozoites are released into the urinary space and undergo one or more additional rounds of schizogony in tubular epithelial cells. Eventually, a population of merozoites develops into microgametes and macrogametes. Little evidence of an inflammatory response to parasite replication in renal tissues is apparent. Sporogony follows with the subsequent release of sporocysts into the urine.<sup>65,69</sup> Although *K. equi* has not been associated with clinical disease, it warrants mention that the organism has been found worldwide in horses, ponies, donkeys, burros, and zebras, and a recent postmortem survey of 47 horses in Australia revealed that six (12.8%) were infected.<sup>69</sup>

## OBSTRUCTIVE DISEASE OF THE URINARY TRACT

Harold C. Schott II

Most cases of obstructive urinary tract disease in horses are caused by urolithiasis. Urinary tract displacement, trauma, and neoplasia are other causes.<sup>1-3</sup> Urinary tract obstruction can result in a variety of clinical signs depending on the site and degree of obstruction. Incomplete obstruction can result in dysuria, incontinence, and mild abdominal pain, whereas complete obstruction usually results in moderate to severe pain termed *renal* or *kidney colic*. True “kidney colic” is an uncommon cause of abdominal pain, although horses may show signs of similar to signs of dysuria with gastrointestinal pain. Another complication of complete obstruction is rupture of the bladder or urethra. Signs of pain subside after rupture but are replaced by depression and inappetence, which accompany postrenal ARF. In some cases of disruption of the urinary tract, one also may observe progressive abdominal distention and enlargement of the penis and prepuce.

## ☉ EPIDEMIOLOGY OF UROLITHIASIS

The epidemiology of urolithiasis varies with species.<sup>4-7</sup> Lower urinary tract stones predominate in veterinary species, whereas upper urinary tract stones are more common in human beings. Historically, lower urinary tract stones were a more substantial problem in human beings as well, and they remain the more common form of urolithiasis in underdeveloped countries. The shift in prevalence from lower to upper urinary tract stones appears to have accompanied industrialization, but the reasons for the shift are not entirely clear.<sup>7</sup>

From 1970 to 1989, urolithiasis was responsible for 0.11% of equine admissions to 22 veterinary teaching hospitals and accounted for 7.8% of the diagnoses of urinary tract disease.<sup>4</sup> Male horses, especially geldings, are predisposed to urolithiasis (75% of all cases), but a breed predisposition has not been described. This sex predilection has been attributed to the shorter, distensible urethra of the mare, which likely permits voiding of small calculi.<sup>5</sup> Urolithiasis is typically an adult disease, and the mean age of affected horses is about 10 years.<sup>4</sup> Nevertheless, young horses can be affected, and the author has seen bilateral nephrolithiasis in a weaning foal (likely a consequence of neonatal septicemia) and dysuria in a 3-month-old colt caused by multiple cystoliths that formed on sutures used for repair of a ruptured bladder as a neonate. Uroliths are most common in the urinary bladder (60%), although they also may develop in the kidneys (12%), ureters (4%), and urethra (24%).<sup>4</sup> Interestingly, as many as 10% of affected horses have had uroliths in multiple locations.<sup>4</sup> Uroliths can vary greatly in size. In one mare a cystolith weighing more than 6 kg was detected as an apparently incidental finding in a horse destroyed for a limb fracture.<sup>8</sup>

## ☞ PATHOPHYSIOLOGY OF UROLITHIASIS

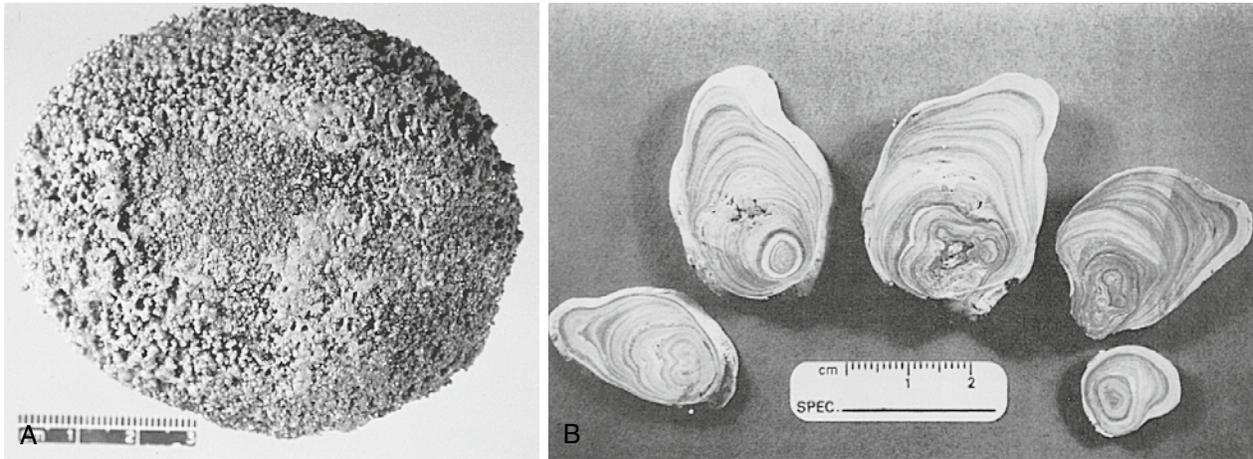

In general, two steps are required for calculus formation: (1) nucleation and (2) crystal growth.<sup>9-12</sup> Factors that contribute to precipitation of urinary crystals and nucleation include supersaturation of urine; prolonged urine retention; genetic tendencies to excrete larger amounts of calcium (hypercalciuria), uric acid (hyperuricosuria), or oxalates (hyperoxaluria); and inhibitors and promoters of crystal growth. For two or more ions in a solution to precipitate into a crystal, the product of their individual ion activities must exceed the equilibrium solubility product ( $K_{sp}$ ). A supersaturated solution is one in which the ion activity product exceeds the  $K_{sp}$ . A mildly supersaturated solution is termed *metastable*, because crystals tend to precipitate and dissolve at similar rates, so that crystal growth does not occur and the solution remains clear. However, once the ion activity product exceeds a critical value (formation product ratio), precipitation outpaces dissolution, rapid crystal growth occurs, and the solution becomes cloudy.<sup>9-12</sup> Normal human urine typically is supersaturated with one or more ion activity products; however, the formation product ratios are considerably higher in urine (10 times greater than  $K_{sp}$ ) than they are in an aqueous solution because of the presence of inhibitors of crystal growth.<sup>9</sup> This activity explains why observation of crystals in urine sediment examination is common, yet calculus formation is uncommon. Furthermore, although  $K_{sp}$  values are constant for each type of crystal, they vary with temperature and pH. Typically, cooling promotes crystal formation (as when samples are refrigerated), whereas effects of pH vary with the type of calculus (acidification leads to dissolution of calcium crystals but promotes crystallization of urate crystals).<sup>10</sup> Next, any problem resulting in urine retention or incomplete bladder emptying increases the chance of crystal growth. Although not described for horses, genetic variations in ion excretion rates are well-documented risk factors for human and canine urolithiasis. For example, hypercalciuria is inherited as an autosomal dominant trait in human beings and is responsible for 30% to 40% of nephroliths.<sup>9</sup> Similarly, dogs with cystine urolithiasis have an inherited defect in renal tubular transport of cystine, whereas

Dalmatians are afflicted with urate stones because of a defect in uric acid metabolism in the breed.<sup>6</sup>

Normal urine is rich in a number of inhibitors of crystal growth, including pyrophosphate, citrate, magnesium ions, glycosaminoglycans, and several glycoproteins including nephrocalcin.<sup>9,10,12</sup> The degree of inhibitory activity varies with crystal type; for example, pyrophosphate is responsible for 50% of the inhibitory activity against calcium phosphate stone formation in human urine but has a much less inhibiting effect on calcium oxalate stone formation.<sup>9</sup> Although poorly documented, inhibitors of crystal growth in equine urine, including its high mucous content, likely play an important protective role against calculus formation, which would seem especially true in light of the substantial urinary excretion of  $\text{CaCO}_3$  crystals by normal horses. Similar to the risk associated with increased ion excretion, one should not be surprised that defects in inhibitor activity also have been documented in syndromes of human urolithiasis.<sup>9,10</sup> Other urine components may act as promoters of crystal growth. These components principally include organic matrix components of calculi: matrix substance A, uromucoid, and a number of serum proteins.<sup>10,11</sup> Finally, some urine components may have inhibitor and promoter activity. For example, Tamm-Horsfall glycoprotein, a protein secreted in the ascending limb of the loop of Henle that forms the backbone of urine casts, has been shown to promote struvite crystal formation in feline urine.<sup>13</sup> In contrast, the glycoprotein also inhibits calcium oxalate crystal aggregation, and a group of human patients with calcium oxalate urolithiasis recently were demonstrated to have an abnormality in Tamm-Horsfall mucoprotein.<sup>14</sup>

Because normal urine of most species typically is supersaturated and is in balance between crystal precipitation and dissolution, spontaneous nucleation rarely initiates calculus growth. Rather nucleation generally requires stasis of urine flow, increasing the chance of contact between crystalline material and uroepithelium (as occurs in areas of the renal pelvis) or a damaged uroepithelial surface.<sup>10-13</sup> The latter results in local activation of inflammatory and clotting pathways, producing a nidus for local crystal adherence.<sup>15</sup> In addition, desquamated epithelial cells, leukocytes, or necrotic debris may provide a nidus for crystal growth at more distal sites in the urinary tract. Tissue damage from a variety of causes is likely the most important factor for the development of uroliths in horses. For example, after urinary tract instrumentation (e.g., catheterization, endoscopy), areas of traumatized uroepithelium are covered rapidly with a fine layer of crystalline material. This material usually resolves spontaneously unless infection develops. Similarly, nephroliths may form in the renal medulla or pelvis after papillary necrosis accompanying phenylbutazone toxicity. Once crystal growth begins around a nidus, equine urine has the disadvantage of being highly alkaline, favoring crystallization of most urolith components, especially  $\text{CaCO}_3$ .

Horses develop two basic forms of uroliths, and both are composed primarily of  $\text{CaCO}_3$ .<sup>5,16</sup> More than 90% are yellow-green, spiculated stones that easily fragment (type I urolith) (Figure 19-31, A). Less commonly, uroliths are gray-white, smooth stones that are more resistant to fragmentation (type II urolith; Figure 19-31, B). The latter stones often contain phosphate in addition to  $\text{CaCO}_3$ . The crystalline composition of normal equine urine sediment ( $\text{CaCO}_3$  crystals predominate, although calcium oxalate and phosphate crystals also occur) and uroliths is similar:  $\text{CaCO}_3$  in the form of calcite

**FIGURE 19-31** Equine cystic calculi. **A**, The more common flattened, spherical type of bladder calculus usually is spiculated. **B**, The less common form of gray, smooth-surfaced calculus may be more irregular in shape. (B from DeBowes RM: Surgical management of urolithiasis, *Vet Clin North Am Equine Pract* 4:461, 1988.)

(a hexagonal crystal form of  $\text{CaCO}_3$ ) is most common, followed by vaterite (a metastable, hexagonal crystal form in which  $\text{CaCO}_3$  is replaced partially by magnesium or to a lesser extent by manganese, strontium, and sulfur). Other less common components include aragonite (an orthorhombic crystal form of  $\text{CaCO}_3$ ), weddellite (calcium oxalate dihydrate), struvite (magnesium ammonium phosphate hexahydrate), hydroxyapatite, and uric acid (Table 19-10).<sup>16-21</sup> Neumann et al.<sup>16</sup> examined the cut surface of a number of equine uroliths by scanning electron microscopy and described a pattern of irregular, concentric bands around the core (Figure 19-32, A) that were separated by small spherules of crystalline material (Figure 19-32, B). This pattern suggested that calculus growth

occurs by accretion of preexisting microscopic spherules (the crystals already present in normal equine urine) on the surface of the growing urolith rather than by de novo crystal formation at the surface of the urolith. Furthermore, banding was speculated to represent growth through incorporation of organic matrix on the surface of the urolith at times when fewer spherules were present in urine. The gaps between adjacent spherules result in porosity to the urolith. Because precipitation and dissolution occur simultaneously during growth of urinary calculi, porosity allows exposure of inner aspects of the urolith to urine, which can lead to dissolution as urine composition changes. Neumann et al.<sup>16</sup> described two types of porosity observed by electron microscopy: (1) primary porosity, consisting of the original pores or gaps between spherules, and (2) secondary porosity, which developed after dissolution of inner areas of the uroliths. Greater dissolution or secondary porosity developed preferentially in areas of the urolith with higher magnesium content (vaterite). More extensive development of secondary porosity theoretically leads to increased urolith fragility, which has the therapeutic benefit of increasing the chance that the urolith can be crushed or fragmented before removal.

The role of UTI in the development of urolithiasis appears to vary with species.<sup>6,9,11</sup> Struvite urolithiasis in human beings and dogs appears to be almost exclusively a consequence of UTI, whereas most struvite uroliths in cats and sheep are not associated with infection.<sup>11</sup> In addition to contributing to uroepithelial injury and nidus formation, UTI with urease-positive bacteria (*Proteus* spp. and coagulase-positive staphylococci are most common) allows splitting of urea into two ammonia molecules, which are hydrolyzed rapidly to ammonium ions (a component of struvite crystals).<sup>9,11,12</sup> In a review of 68 horses with urolithiasis, Laverty et al.<sup>4</sup> reported positive urine culture results in only 2 of 19 horses in which urine culture was performed; however, culture of material from the centers of 30 calculi yielded positive results from 19 (63%), and a variety of different bacterial species were isolated. Only 1 of 28 calculi examined in this study contained struvite. The significance of finding bacteria in the center of equine  $\text{CaCO}_3$  uroliths is not known, especially for isolates other than

**FIGURE 19-32** Scanning electron microscopic appearance of the cut surface of equine cystic calculi. **A**, Lower-power micrograph reveals the intricate pattern of concentric banding around the core (bar = 500  $\mu\text{m}$ ). **B**, Higher-power micrograph reveals the ultrastructural features, including bands (1), spherules (2), and primary porosity in black (3) (bar = 50  $\mu\text{m}$ ). (From Neumann RD, Ruby AL, Ling GV et al: Ultrastructure and mineral composition of urinary calculi from horses, *Am J Vet Res* 55:1357, 1994.)

coagulase-positive staphylococci and *Proteus* spp.; culture of an appropriately collected sample of urine always is preferred over culture of a calculus.<sup>4,22</sup> Nephroliths and ureteroliths also are found in some cases of pyelonephritis.<sup>23-26</sup> Laing et al.<sup>26</sup> described a 2-year-old colt with bilateral nephrolithiasis and CRF. They recovered a *Proteus* spp. from urine, and the nephroliths were composed principally of  $\text{CaCO}_3$  but also contained lesser amounts of struvite. In contrast, Ehnen et al.<sup>27</sup> found evidence of infection in only one of eight horses with nephrolithiasis or ureterolithiasis (or with both) and CRF. In the author's experience, the presence of stones in the upper urinary tract or presence of multiple uroliths warrants concurrent evaluation for UTI, because the author has seen two horses with recurrent urinary tract obstruction with ureteroliths that were determined ultimately to be sequelae of unilateral pyelonephritis. Holt and Pearson<sup>28</sup> described a similar case in which a renal calculus and abscess were found 5 months after removal of a cystic calculus.

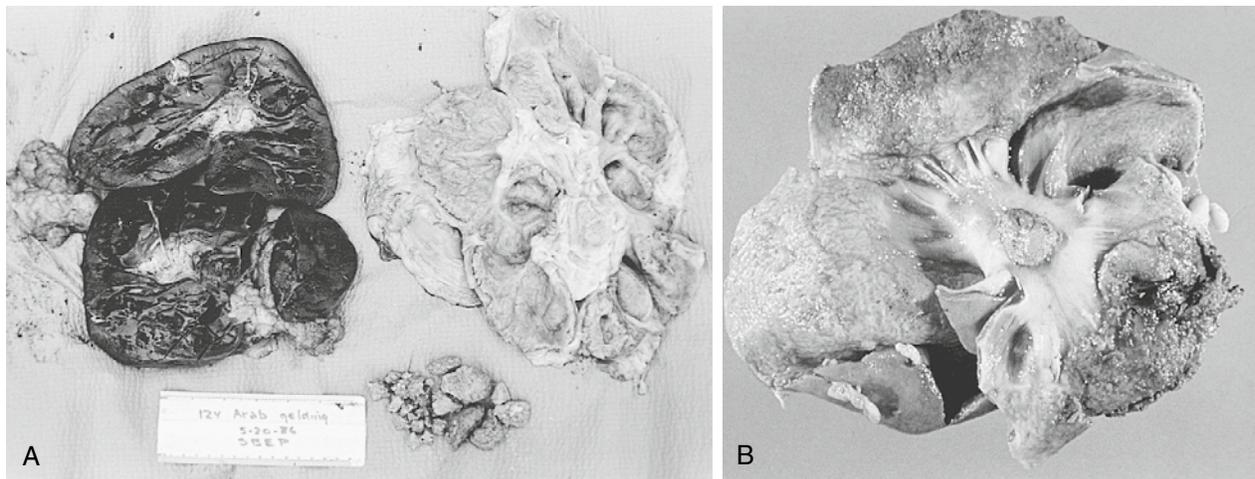

## NEPHROLITHIASIS AND URETEROLITHIASIS

Renal or ureteral calculi rarely were described as a cause of equine urolithiasis before the last decade<sup>29</sup>; however, a number of recent reports<sup>4,25-27,30-34</sup> have described nephrolithiasis and ureterolithiasis in horses. In a review of 68 horses with urolithiasis by Laverty et al.,<sup>4</sup> 16% had uroliths in the kidneys and ureters and a few horses with cystic calculi also had calculi in the upper urinary tract. Interestingly, 9 of 15 horses with nephroliths in this review were stallions; 3 of 15 were geldings, and 3 of 15 were mares. Whether a true increase in prevalence of nephrolithiasis and ureterolithiasis has occurred, or whether these conditions have become easier to document with the simultaneous development of ultrasonographic imaging as a diagnostic tool for equine medicine, is not clear. An undocumented speculation is that young racehorses may be at

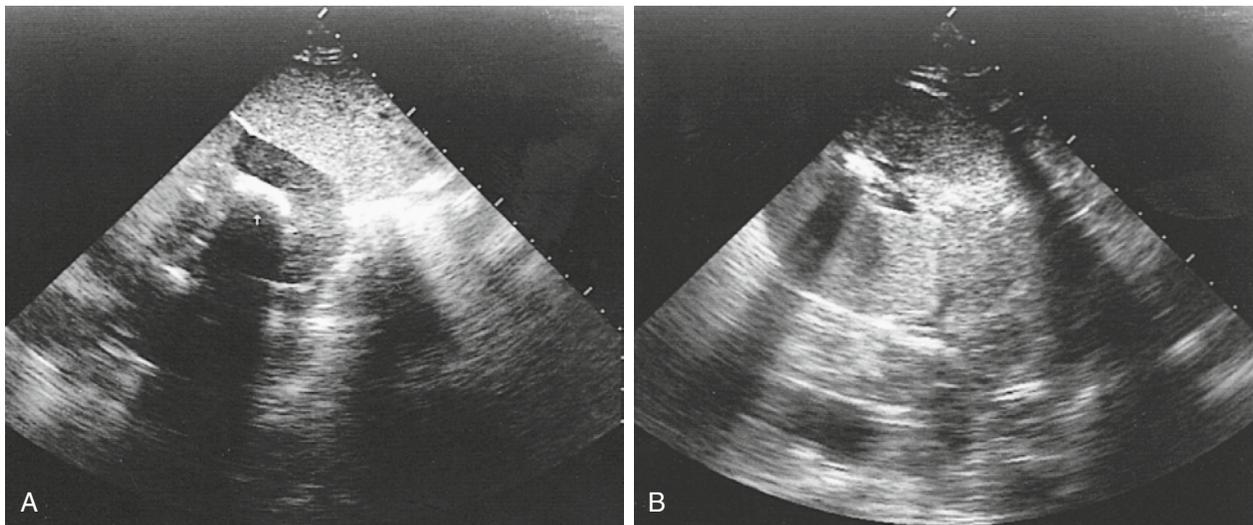

greater risk of developing renal calculi because of the common use of NSAIDs (and risk for development of papillary necrosis) in these athletes.<sup>27</sup> The important point is that one should not overlook upper urinary tract lithiasis in horses.

Nephroliths may develop around a nidus associated with a variety of renal diseases, including PKD (see Figure 19-6), pyelonephritis (Figure 19-33, A), papillary necrosis (Figure 19-33, B), or neoplasia. At present, data on upper urinary tract stones in horses are insufficient to know whether they develop spontaneously (in the absence of tissue damage) as in human beings or whether they differ significantly in mineral composition from cystic calculi. Although nephrolithiasis and ureterolithiasis are painful conditions in human beings, horses with nephroliths or ureteroliths often remain asymptomatic until bilateral obstructive disease leads to development of acute or CRF. Upper urinary tract stones also may be an incidental finding at necropsy.<sup>29</sup> When clinical signs are present, nonspecific presenting complaints consistent with uremia (poor performance, lethargy, inappetance, and weight loss) are more common than signs of obstructive disease (colic, stranguria, hematuria). Occasionally in the horse, a stone or nidus may pass down the ureter and lead to urethral obstruction and signs of acute obstructive disease. Rectal palpation may reveal an enlarged kidney or ureter (or bladder with urethral obstruction), and ureteral calculi may be palpable in an enlarged ureter. Because normal ureters are not palpable on rectal examination, one should palpate the entire course of the ureters (retroperitoneally along the dorsal abdominal wall to the dorsolateral aspects of the pelvic canal to their insertion at the dorsal bladder neck) because an enlarged ureter is easy to overlook.

One usually diagnoses renal and ureteral calculi during rectal or ultrasonographic examination (Figure 19-34). Although ultrasonographic imaging may provide information on the presence, number, and location of calculi, one can miss stones smaller than 1 cm in diameter despite complete examination.

**FIGURE 19-33** **A**, Multiple nephroliths developed in association with unilateral pyelonephritis in a gelding that was presented for repeated urethral obstruction. **B**, A small nephrolith lodged in the renal pelvis resulted in ureteral obstruction and development of hydronephrosis in a Standardbred gelding that had a 4-year history of phenylbutazone therapy.

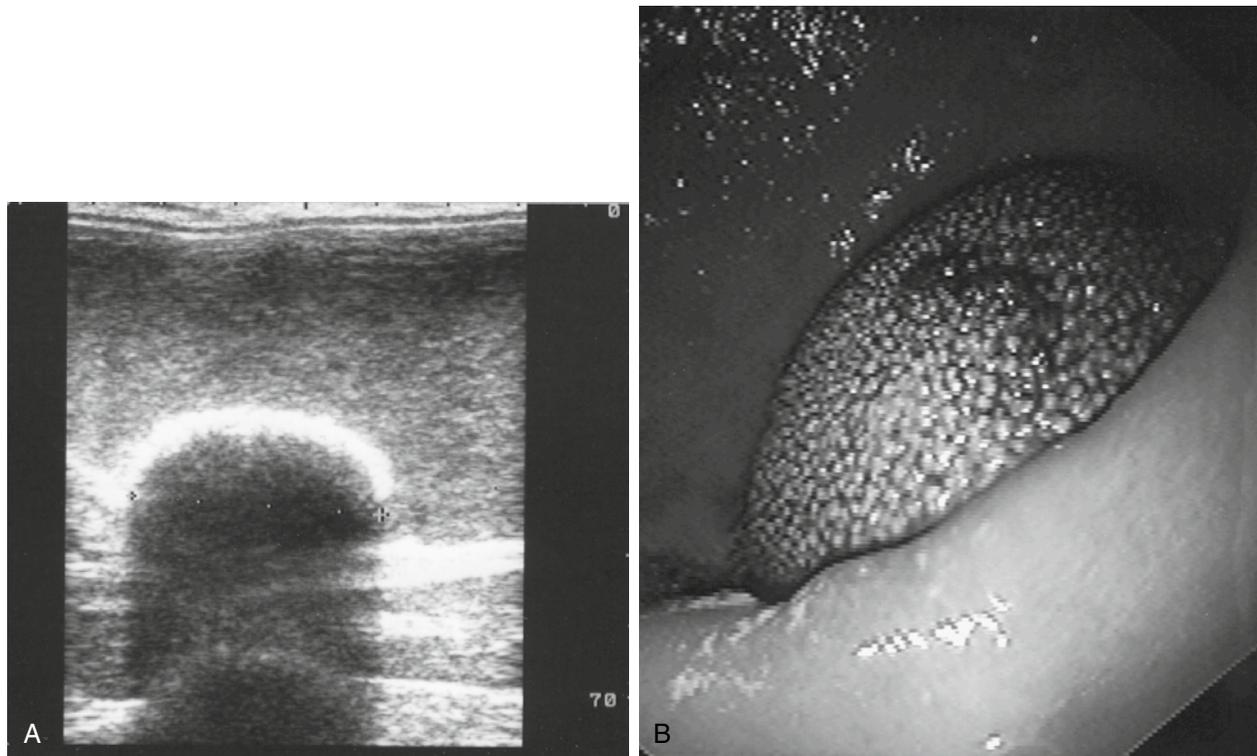

**FIGURE 19-34** Ultrasonographic images of the left, **A**, and right, **B**, kidneys of a 10-month-old Arabian filly that developed bilateral nephrolithiasis and chronic renal failure (CRF) as sequelae of neonatal septicemia. The nephroliths are highly echogenic and cast acoustic shadows in both kidneys.

Other ultrasonographic findings to support upper tract lithiasis include dilation of the renal pelvis or proximal ureter and, in long-standing cases, hydronephrosis.<sup>35,36</sup> Although azotemia generally accompanies bilateral disease, horses with unilateral disease often maintain normal renal function. For reasons detailed previously, one should perform a quantitative urine culture in all horses with nephrolithiasis or ureterolithiasis to assess possible intercurrent UTI.

Because most horses with nephrolithiasis or ureterolithiasis are in CRF by the time the diagnosis is established,<sup>27,37,38</sup> few cases are amenable to treatment. Thus reports of successful management of horses with renal and ureteral calculi are few. Removal of the calculus, limited to horses with unilateral disease or mild azotemia, has been the only effective means of treatment.<sup>30,32,34</sup> In the absence of azotemia, nephrectomy is the preferred technique for management of unilateral renal

calculi.<sup>32</sup> Furthermore, removal of the affected kidney and ureter should eliminate any associated upper UTI or chance of recurrence. The approach involves a dorsal flank incision, rib resection, and blunt retroperitoneal dissection to expose the kidney.<sup>3,39,40</sup> In one horse with mild azotemia, nephrotomy (via an approach similar to nephrectomy) was performed successfully to remove obstructing calculi in the renal pelvis and proximal ureter. Unfortunately, little improvement in azotemia occurred, and the horse was destroyed a few weeks later.<sup>27</sup> Ureteral calculi also have been removed by ureterolithectomy via ventral celiotomy and paralumbar approaches.<sup>30,33</sup> A basket stone dislodger (Dormia Stone Dislodger, V Mueller Co, McGow Park, Ill.), introduced through a vestibulourethral approach and guided by rectal palpation, also has been used for removal of distal ureteral calculi in the mare.<sup>30</sup> Medical management (antibiotics, grass hay, and salt to promote diuresis)

**FIGURE 19-35** **A**, Transrectal ultrasound examination of the bladder using a 5 MHz linear array probe. A single large calculus is present with acoustic shadowing ventral to the urolith. **B**, A type I urolith within the bladder as seen during cystoscopy.

of bilateral ureterolithiasis was attempted in a 3-year-old Thoroughbred filly with incomplete ureteral obstruction and mild azotemia.<sup>33</sup> After 4 weeks, deterioration of clinical signs and more severe azotemia prompted ureterolithectomy to remove stones from the left ureter. Percutaneous nephrostomy was used successfully for placement of a catheter in the right renal pelvis (to establish percutaneous urine flow) for short-term management of azotemia in the postoperative period. Unfortunately, the filly was destroyed after developing cecal impaction 6 days later, and necropsy examination revealed a shrunken, nonfunctional left kidney and a previously undetected nephrolith in the right kidney. This case demonstrated the feasibility and potential benefits of accessing the renal pelvis of the horse via percutaneous nephrostomy.<sup>41,42</sup>

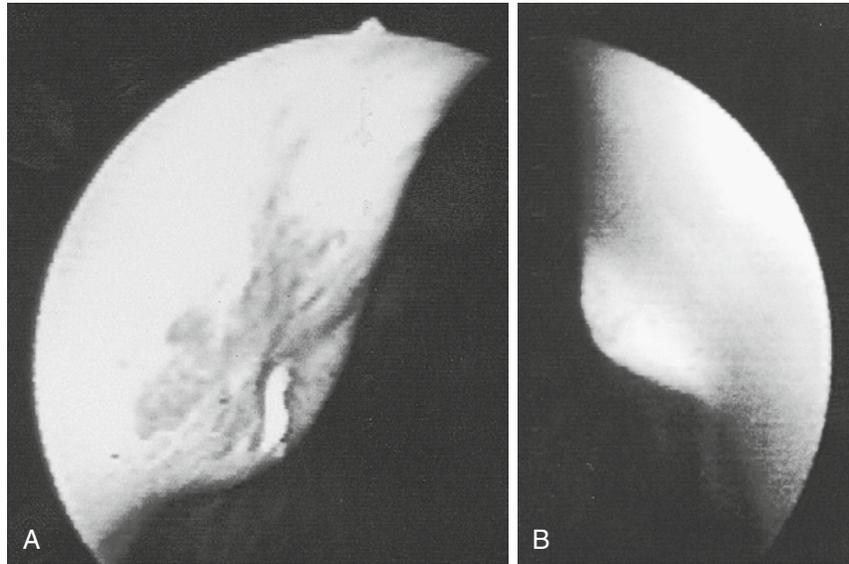

Rodger et al.<sup>34</sup> recently described the successful use of electrohydraulic lithotripsy through a ureteroscope to disintegrate a single, unilateral ureterolith in a horse with evidence of bilateral renal disease. Electrohydraulic lithotripsy is a means of converting electric energy into mechanical energy that can be directed to fragment the urolith.<sup>34,43,44</sup> Basically, the device produces an electric discharge arc (a spark) between two electrodes at the tip of the instrument. The heat associated with the discharge causes a small amount of the liquid medium (urine) to burst into gas bubbles, and the associated shock wave fractures the urolith. One must keep the end of the instrument adjacent to the urolith yet away from the mucosa, which could be disrupted by the same shock waves that destroy the calculus. Although the technique has not been highly successful for treatment of canine uroliths,<sup>45</sup> equine uroliths may be more amenable to its use because they are commonly porous (and fragile). Although electrohydraulic lithotripsy has been effective in treating selected equine cystoliths<sup>43,44</sup> and one

ureterolith,<sup>34</sup> the expense of the equipment and availability of other surgical options likely will limit its use to selected cases that are not amenable to routine surgical treatments. A more recent development in upper tract stone removal for human beings and dogs is extracorporeal shock wave lithotripsy.<sup>42</sup> This noninvasive technology uses a reflector to focus the energy from a shock wave generated outside the body on a nephrolith in situ and has proved efficacious in treating human nephrolithiasis. Although extracorporeal shock wave lithotripsy and laser technology have not yet been attempted in horses, they provide future treatment options for equine nephrolithiasis and ureterolithiasis.

## ☪ CYSTIC CALCULI

Cystic calculi are the most commonly recognized form of equine uroliths.<sup>1-5,28</sup> Cystoliths typically are flattened, spherical stones with a spiculated or smooth surface. Dysuria resulting from cystoliths may include hematuria, stranguria, pollakiuria, pyuria, or incontinence. Hematuria may be more apparent after exercise. An affected male horse may demonstrate stranguria by repeatedly dropping its penis and posturing to urinate but voiding little or no urine. An affected mare also may posture repeatedly to urinate and demonstrate winking, and these signs could be confused with estrous activity. Less common signs include an irritable attitude, recurrent colic, and loss of condition; one burro was presented for recurrent rectal prolapse.<sup>46</sup>

One usually diagnoses cystic calculi by palpation and ultrasound examination of the bladder per rectum (Figure 19-35). Bladder uroliths are usually large enough to be detected easily; however, if the bladder is distended, then one may need to

**FIGURE 19-36** View of the abnormal left, **A**, and normal right, **B**, ureteral openings of a horse with unilateral pyelonephritis and recurrent cystic calculi. The diagnosis was confirmed by culture of urine samples collected from each ureter.

empty it by passing a catheter to facilitate palpation of the stone. Bladder catheterization also allows assessment of urethral patency and collection of samples for urinalysis and quantitative culture. One should perform a CBC and serum biochemical profile to document whether anemia, inflammation, or azotemia has developed. Cystoscopic examination is helpful in assessing the size and number of cystic calculi and the severity of damage to the bladder mucosa, as well as any asymmetry in appearance or function of the ureteral openings (Figure 19-36, *A* and *B*).<sup>47,48</sup> Because one may find calculi in multiple sites in the urinary tract, thorough evaluation of the upper urinary tract is warranted for all cases of cystic urolithiasis.

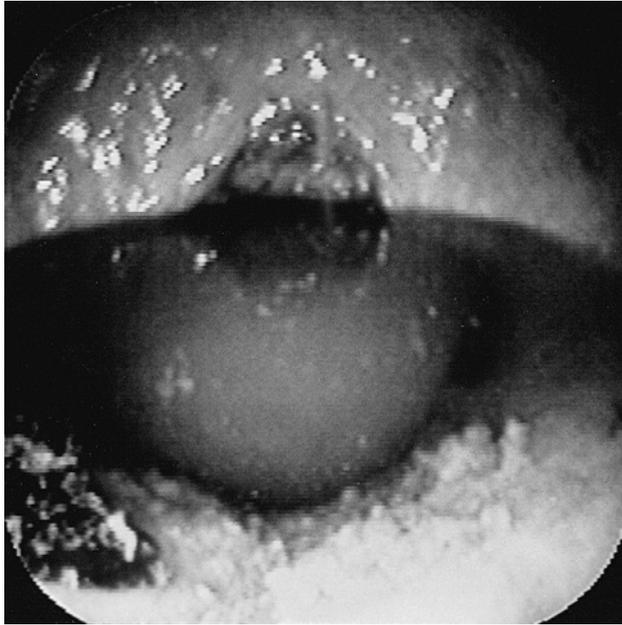

In contrast to upper urinary tract lithiasis, many reports<sup>43,44,46,49-64</sup> and several reviews detail the clinical signs and surgical options for management of cystic calculi.\*

The size of the calculus, gender of the horse, and surgeon's preference play a role in treatment selection. The preferred technique in males, especially for larger stones, is laparocystotomy through a ventral midline or paramedian incision with the horse in dorsal recumbency under general anesthesia. Laproscopic-assisted cystotomy may also be used for urolith removal in geldings.<sup>67</sup> For removal of smaller cystoliths, one can perform a perineal urethrotomy in the standing male horse with the use of local or epidural anesthesia. One catheterizes the urethra to facilitate identification of the urethra and makes an incision at the level of the ischial arch. After incising the urethra, forceps are used to grasp and remove the calculus and the bladder is lavaged to remove remaining debris. One may attempt removal of larger calculi via this approach by using a lithotrite to crush the urolith into smaller fragments. The urethral incision can be closed, but it usually is allowed to heal by second intention. Although this approach can be performed less expensively and the risks associated with general anesthesia can be avoided, doing so increases the risk of complications, including urethral trauma and stricture formation,<sup>28,68,69</sup> urethrolith formation at

the surgical site,<sup>4,70</sup> development of a urethral diverticulum,<sup>70</sup> and persistent urine passage through a fistula at the surgical site.<sup>69,71</sup> The distensible urethra of the mare allows retrieval of cystic calculi via this route in many cases. Using sedation and epidural anesthesia, one can remove the stone intact with forceps or by direct grasping if the surgeon has small hands. One may crush a spiculated urolith with a lithotrite to ease removal. Spiculated stones or urolith fragments can be manipulated further into a sterile plastic bag or palpation sleeve to minimize trauma to the urethral mucosa during removal. If necessary, then one also can enlarge the urethral lumen by performing sphincterotomy in the dorsal aspect of the urethra.<sup>72</sup> A pararectal (Gökels) approach for a dorsal cystotomy<sup>39,64</sup> and electrohydraulic lithotripsy,<sup>43,44</sup> as described for ureterolithiasis, also have been used in male and female horses to treat cystic calculi. Successful laser lithotripsy in horses depends on the composition of the urolith and type of laser.<sup>73</sup> Pulsed dye lasers may be more efficacious for fragmentation of equine uroliths. However, reports of laser lithotripsy in horses are limited, and it appears that certain lasers cannot be assumed to be uniformly successful against all types of equine uroliths.

After surgical removal of cystoliths, one administers systemic antibiotics and an anti-inflammatory agent for a minimum of 1 week. As for cystitis, antibiotic selection should be based on susceptibility testing of recovered isolates. If culture results are negative, then a sulfonamide-trimethoprim combination is an appropriate selection. An early report by Lowe<sup>70</sup> described excellent long-term results—and no recurrence—after removal of cystic calculi by laparocystotomy in four horses. Similar low rates of recurrence have been echoed in several reviews of equine urolithiasis.<sup>5,28,39,65</sup> In contrast to these favorable reports (most of which do not provide supporting data), Laverty et al.<sup>4</sup> reported that clinical signs of urolithiasis recurred in 12 of 29 horses (41%) for which follow-up data were available. The interval between episodes of recurrence was 1 to 32 months (mean: 13 months). As Lowe initially described in 1965,<sup>70</sup> Laverty et al.<sup>4</sup> also found greater recurrence of cystic calculi after treatment by perineal urethrotomy (7 of 15 horses)

\*References 4, 5, 28, 39, 65, 66.

**FIGURE 19-37** A large urolith is present in the bladder below the surface of the pool of urine. The cystolith was accompanied by bacterial cystitis and squamous cell carcinoma of the bladder.

compared with laparocystotomy. Other complications of cystic calculi unrelated to the surgical approach have included VUR and renal failure<sup>74</sup> and concurrent urolithiasis at other sites.<sup>4</sup> A more common complication of urethral obstruction,<sup>68</sup> bladder rupture, also may occur after cystic urolithiasis. The author also has seen a case of squamous cell carcinoma of the bladder that was associated with a large cystic calculus and development of uroperitoneum after bladder rupture (Figure 19-37).

Postoperative recommendations that may help prevent recurrence include control of UTI and use of urinary acidifiers, although the benefits of the latter are not well-documented (see Cystitis in the Urinary Tract Infections section of this chapter).<sup>5,62,65,66,75</sup> Other considerations for decreasing recurrence include dietary modifications to decrease calcium excretion and to promote diuresis. Changing the diet from a high-calcium hay (e.g., alfalfa) to grass or oat hay would decrease dietary calcium and thus should decrease urinary calcium excretion because fecal calcium excretion is relatively constant in horses.<sup>76</sup> This dietary change should decrease total calcium excretion and may decrease urinary nitrogen excretion and daily urine volume.<sup>77</sup> The latter changes could enhance supersaturation of urine. In theory, the addition of 50 to 75 g of loose salt daily to the concentrate portion of the diet should promote diuresis; however, in a study of ponies fed NaCl as 1%, 3%, or 5% of the total dry matter of the diet (1% approximates 75 g of NaCl for a 500-kg horse), no differences in water intake, urine production, or calcium excretion were observed.<sup>78</sup> Another factor that affects urine pH and urine calcium excretion is dietary cation-anion balance (DCAB = [Na + K] - [Cl + S]). A lower DCAB has been associated with a decrease in urine pH and an increase in urinary calcium excretion.<sup>79-81</sup> Increasing the amount of grain in the diet, changing to lower-quality hay, or adding one or more minerals to the diet (e.g., ammonium chloride, calcium chloride, ammonium sulfate) usually lowers DCAB. Not surprisingly, supplements that decrease DCAB are familiar as urinary acidifying agents. Because a diet low in calcium and DCAB

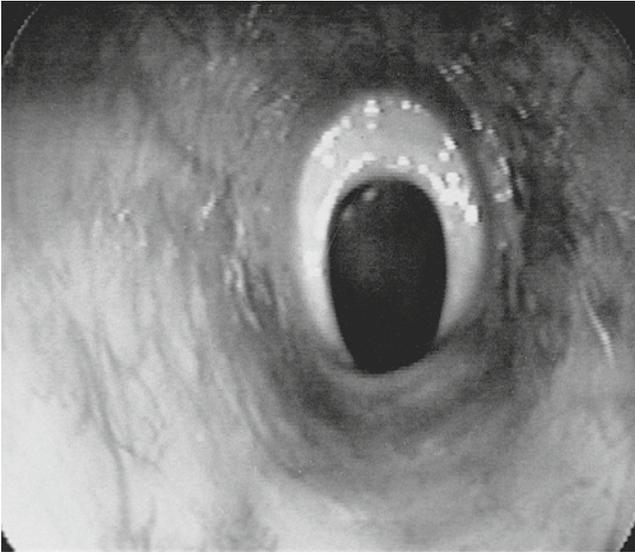

could result in a negative calcium balance, a possible long-term effect could be decreased skeletal calcium content.

Despite the success of dietary management (low-protein, phosphorous, and magnesium) for medical dissolution of canine<sup>82</sup> and feline<sup>83</sup> uroliths, dietary management is unlikely to replace surgical treatment of cystic urolithiasis in horses. This problem can be attributed to the fact that dietary management for small animals has been directed at struvite urolithiasis and that such stones are not common in horses. Nevertheless, one should not overlook dietary management as one of the postoperative recommendations for urolithiasis, because it could decrease the risk of recurrence. At the least, legume hays and dietary supplements containing calcium should be avoided, and the diet could be supplemented with 50 to 75 g of loose salt daily. Remillard et al.<sup>84</sup> used these dietary manipulations effectively, along with administration of ammonium sulfate as a urine-acidifying agent, to manage one recurrent case of equine urolithiasis.

## ☞ URETHRAL CALCULI

Urethral calculi are primarily a problem of male horses,<sup>1-5,68,70,85,86</sup> although they have been detected in a few mares.<sup>4</sup> In the absence of predisposing urethral damage or stricture formation, urethroliths are usually small cystoliths passed into the urethra. Thus most urethroliths initially lodge where the urethra narrows as it passes over the ischial arch. They may pass slowly farther down the urethra, until complete obstruction produces signs of renal colic. One should consider an obstructing urethral calculus when male horses show colic signs and frequently posture to urinate. Occasionally, one may see blood on the end of the urethra. Palpation of the penis may reveal repeated urethral contractions or a firm mass in the urethra. Rectal palpation reveals a distended bladder that is turgid, unlike the flaccid bladder distention of bladder paralysis. If the bladder ruptures, then colic signs are supplanted by progressive depression and anorexia after the development of postrenal ARF.<sup>4,68,85,86</sup> The diagnosis is confirmed by passage of a urinary catheter that is then obstructed by the urolith or by endoscopic examination of the urethra. One can confirm suspected bladder rupture by measuring a twofold or greater increase in peritoneal fluid Cr concentration compared with serum Cr concentration.

One can remove calculi lodged at the ischial arch through a perineal urethrotomy. Passage of a catheter into the bladder, if that is not achieved before surgery, is necessary to ensure a patent urinary tract after stone removal. The urethrotomy is allowed to heal by second intention, and temporary use of an indwelling bladder catheter usually is not necessary. One often can remove calculi lodged in the distal urethra from a sedated horse by gentle transurethral crushing of the urolith with a hand or forceps. For a calculus lodged distal to the ischial arch and unpalpable in the distal portion of the penis, general anesthesia and positioning the horse in dorsal recumbency are generally necessary for surgical removal of the stone. One may close the urethra or allow it to heal by second intention. Follow-up endoscopic examination of the urethra allows assessment of urethral healing and possible stricture formation (Figure 19-38). Further treatment includes administration of antibiotics and anti-inflammatory agents until dysuria resolves. Although initial treatment of urinary tract obstruction caused by a urethrolith is straightforward, the prognosis for affected horses should remain guarded because a number of potential complications of

**FIGURE 19-38** Stricture formation in the urethra at the level of the ischial arch formed as a complication of a perineal urethrotomy.

perineal urethrotomy (described previously) may occur. Furthermore, a substantial number of horses have had poor outcomes because of associated bladder rupture and peritonitis<sup>4,68,85</sup> or upper urinary tract lithiasis or pyelonephritis.<sup>4,28</sup>

### ☞ SABULOUS UROLITHIASIS

Another form of equine urolithiasis termed *sabulous urolithiasis* also has been described in a limited number of horses.<sup>28,87</sup> *Sabulous* (Greek for *sand*) *urolithiasis* refers to the accumulation of large amounts of crystalloid urine sediment in the ventral aspect of the bladder. This condition is a secondary problem resulting from bladder paralysis or other physical or neurologic disorders interfering with complete bladder emptying.<sup>88-90</sup> Affected horses usually are presented for evaluation of urinary incontinence or hindlimb weakness and ataxia, and one may detect accumulation of urine sediment in a distended bladder during rectal palpation. A complete neurologic examination should be performed on horses with *sabulous urolithiasis* or bladder dysfunction. Common differential diagnoses for bladder paresis or paralysis include equine herpesvirus-1 (EHV-1), polyneuritis equi, illicit tail block, equine protozoal myeloencephalitis, and sacral fracture or osteomyelitis. Symptomatic treatment includes repeated bladder lavage, medications that promote bladder emptying, and broad spectrum antibiotics, but the condition carries a poor prognosis unless the primary problem resulting in bladder paralysis can be resolved (see Urinary Incontinence and Bladder Dysfunction).

### ☞ BLADDER DISPLACEMENT

Displacement of the urinary bladder is a rare cause of obstruction and dysuria.<sup>1,91-94</sup> In mares, two types of bladder displacement can occur: (1) extrusion through a tear in the floor of the vagina or (2) true prolapse with eversion of the bladder.<sup>95</sup> Urethral obstruction also may occur with vaginal or uterine prolapse. In male horses, scrotal herniation of the bladder has been described, but this type of bladder displacement is

rare.<sup>96</sup> Bladder displacements typically result from repeated abdominal contractions or straining. Thus they most often are associated with parturition and to a lesser extent with colic. Perineal lacerations after trauma or foaling may lead to extrusion, whereas excessive straining without laceration leads to prolapse and eversion. Because the bladder turns inside out with the latter problem, one establishes the diagnosis by recognizing the appearance of the bladder mucosa and ureteral openings. Eversion does not always result in obstruction.

With urethral obstruction, one should pass a catheter into the bladder before correction of the displacement. In the absence of obstruction, one corrects extrusions during repair of the perineal or vaginal laceration. One should institute a course of broad spectrum antibiotics and an anti-inflammatory agent because pelvic abscess and peritonitis are potential complications. Manual reduction of bladder eversions may be successful in some cases, but more often than not one may need to perform urethral sphincterotomy to replace the bladder.<sup>94</sup> In some cases, reduction via laparotomy may be necessary because the everted bladder may be filled with the pelvic flexure, complicating manual reduction.<sup>93</sup> A purse-string suture placed in the area of the external urethral sphincter may be of benefit to prevent recurrence of the prolapse, and medical treatment should include broad spectrum antibiotics and an anti-inflammatory agent because UTI is a potential complication.

### ☞ PENILE TRAUMA

Urinary tract obstruction is an occasional complication of penile trauma or paraphimosis, and one should consider the patency of the urethra in all cases of penile injury. Causes may include blunt trauma, breeding injuries, use of stallion rings, sedation with phenothiazine tranquilizers, or laceration during castration.<sup>1,97-99</sup> In addition to preputial swelling, injury may result in a penile hematoma or possible paraphimosis.<sup>100,101</sup> In one report, hematoma formation in the corpus spongiosum penis (CSP) of a Quarter Horse stallion resulted in complete obstruction and bladder rupture.<sup>102</sup> In addition to ensuring patency of the urinary tract, treatment includes administration of antibiotics and anti-inflammatory agents until most of the swelling resolves. One may close lacerations of the urethra or leave them to heal by second intention depending on location and condition of the wound. Because stricture formation is a possible complication, some wounds may be treated better by phallectomy than by urethral repair.<sup>98</sup>

## HEMATURIA

Harold C. Schott II

Hematuria can be a presenting complaint for a variety of disorders of the urinary tract, including vascular malformation, UTI, urolithiasis, and neoplasia.<sup>1</sup> In addition to these problems, which are discussed elsewhere in this chapter, several other specific causes of hematuria exist. These causes range from microscopic hematuria accompanying exercise to more severe conditions that can result in life-threatening urinary tract hemorrhage. In addition, normal equine urine may contain pyrocatechin, an oxidizing agent that can cause urine

to turn red to brown after exposure to air, snow, or bedding (especially wood shavings).

Although values have not been determined in horses, normal human urine contains about 5000 (range: 2000-10,000) RBCs per milliliter.<sup>2</sup> This range of RBC excretion should yield negative results on reagent strip analysis and a report of not more than five RBCs per high-power field on sediment examination. Increases in RBC excretion may lead to microscopic or macroscopic hematuria. Microscopic hematuria, which implies an increase in RBC excretion that is not visible grossly, usually is associated with increases in the range of 10,000 to 2.5 million RBCs per milliliter of urine. On sediment examination at least 10 RBCs per high-power field should be apparent. Reagent strip analysis results can range from trace to +++. One must realize that reagent strip results, which use the peroxidase-like activity of hemoglobin and myoglobin to oxidize a chromogen in the test pad, do not differentiate between hemoglobin and myoglobin.<sup>3</sup> Thus positive results are not specific for hematuria and may be more appropriately termed *pigmenturia*. Despite this limitation, one can use reagent strips to differentiate hematuria from hemoglobinuria or myoglobinuria when the color change is limited to scattered spots on the test pad. This pattern implies that intact RBCs were adsorbed onto the pad, underwent lysis, and produced a localized color change caused by hemoglobin activity on the chromogenic substrates. Ability to differentiate hematuria from excretion of the heme pigments is limited to a threshold of 250,000 to 300,000 RBCs per milliliter of urine, unless urine samples are diluted with normal saline. Other limitations of reagent strip analysis include false-positive reactions when urine samples are contaminated with oxidizing agents (e.g., disinfectants) or false-negative reactions when urine samples contain vitamin C or have been preserved with formalin.<sup>3</sup>

Macroscopic or gross hematuria indicates RBC excretion in excess of 2.5 to 5 million RBCs per milliliter of urine (or about 0.5 ml of blood per liter of urine).<sup>2-5</sup> One can differentiate macroscopic hematuria from other causes of pigmenturia by centrifuging a sample of urine to produce a red cell pellet and yellow supernatant urine. Quantification of erythrocyte numbers in macroscopic hematuria is of little clinical value. In contrast, urinary RBC numbers may provide diagnostic and prognostic information in cases of microscopic hematuria in human beings.<sup>2</sup> However, variations in urine concentration complicate accurate counts. In concentrated urine (specific gravity >1.020), RBCs tend to become crenated because of the osmotic shift of water out of the cells. In urine with a specific gravity less than 1.010, osmotic swelling and dilution of hemoglobin lead to "ghost cell" formation.<sup>2,6</sup> Furthermore, many RBCs lyse in dilute urine (especially alkaline urine) so that RBC excretion is vastly underestimated. Reagent strip analysis can be useful in dilute urine samples to detect hemoglobin released from lysed erythrocytes.<sup>5</sup>

Microscopic examination of urine sediment in cases of hematuria is helpful in distinguishing glomerular from nonglomerular bleeding. The hallmark of glomerular bleeding is a substantial variation in RBC size, shape, and hemoglobin content (termed *dysmorphism*), whereas bleeding from other sites produces a more uniform population of urinary erythrocytes.<sup>2,5,7</sup> Dysmorphism is attributed to membrane deformation, which occurs as erythrocytes traverse the glomerular filtration barrier.<sup>7</sup> Urinary RBCs in normal persons are typically dysmorphic, indicating glomerular origin, but the excretion rate is low.<sup>2</sup> Thus one must interpret urinary RBC morphologic characteristics along with urinary RBC numbers to determine significance.<sup>7,8</sup>

The volume of dysmorphic cells tends to be lower than that of erythrocytes of nonglomerular origin, so that measurement of mean corpuscular volume (MCV) also has been used to separate glomerular from nonglomerular bleeding.<sup>9</sup> The presence of RBCs or hemoglobin casts is also pathognomonic for glomerular bleeding.<sup>2,5,7</sup> These casts form when urinary RBCs and hemoglobin from the proximal portion of the nephron (glomerulus) combine with Tamm-Horsfall mucoprotein secreted in the ascending limb of the loop of Henle. Because urinary RBCs and casts deteriorate rapidly in urine samples, other methods of detecting glomerular hematuria, such as immunocytochemical staining for Tamm-Horsfall glycoprotein, have been developed but have not gained widespread use.<sup>10</sup>

Noting the timing of hematuria is usually a more practical means of initially localizing the site of urinary tract hemorrhage.<sup>6</sup> Hematuria throughout urination is consistent with hemorrhage from the kidneys, ureters, or bladder, whereas hematuria at the beginning of urination often is associated with lesions in the distal urethra. Hematuria at the end of urination usually results from hemorrhage from the proximal urethra or bladder neck. A thorough diagnostic evaluation, including physical examination, rectal palpation, analyses of blood and urine, endoscopy of the lower tract, and ultrasonography, usually is rewarding in establishing the source and cause of urinary tract hemorrhage.<sup>1</sup>

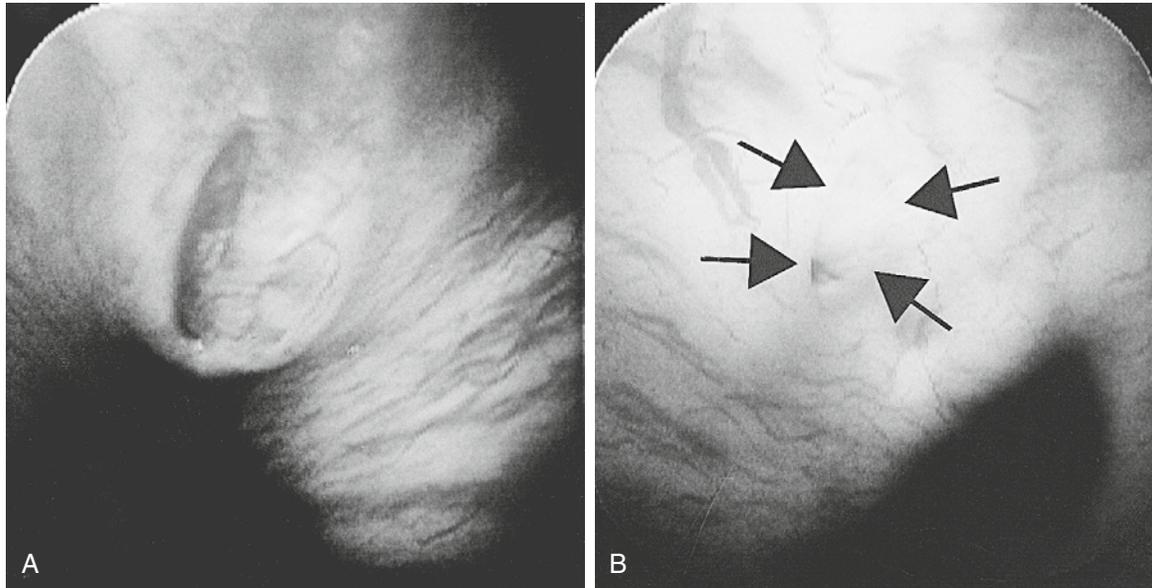

UTI, although uncommon in horses, may result in hematuria. With infection of the upper urinary tract, partial anorexia, weight loss, and fever may be additional presenting complaints, whereas horses with cystitis generally manifest stranguria and pollakiuria; however, hematuria has been the presenting complaint in several reports of cystitis and pyelonephritis.<sup>11-15</sup> The presence of uroliths at any level of the urinary tract may cause mucosal irritation and hemorrhage, resulting in hematuria.<sup>16-18</sup> Typically, affected horses also show signs of renal colic or painful urination (stranguria or pollakiuria), especially with uroliths in the bladder or urethra. Finally, neoplasia of the kidneys, ureters, bladder, or urethra may result in hematuria as the presenting complaint.<sup>19-22</sup> These conditions are discussed in detail in other sections in this chapter.

## ☪ TOXICITIES

Nephrotoxicity, particularly after administration of NSAIDs (especially phenylbutazone), may result in microscopic or gross hematuria.<sup>23-27</sup> Historical or current use of nephrotoxic medications supports this diagnosis, and discontinuation of the nephrotoxic agent and supportive care are the appropriate treatments. Horses that consume alfalfa hay containing blister beetles (equine cantharidiasis) may void red urine. Cantharidin is excreted in urine and is very irritating to the lower urinary tract, resulting in cystitis and hemorrhage from the urinary bladder mucosa.<sup>28</sup>

## ☪ URETHRAL DEFECTS

Although a recognized cause of hemospermia in stallions, rents or tears of the proximal urethra at the level of the ischial arch are a more recently described cause of hematuria in geldings.<sup>1,29-31</sup> Because the defects are difficult to detect without high-resolution videoendoscopic equipment, the lesions likely may have been missed in previous reports of urethral bleeding.<sup>32,33</sup> Consequently, hematuria has been attributed to urethritis or hemorrhage from "varicosities" of the urethral vasculature.<sup>29,33</sup> Because the vasculature underlying the urethral mucosa becomes prominent when the urethra is distended with air

**FIGURE 19-39** Endoscopic images of urethral defects or tears at the level of the ischial arch. **A**, A more acute lesion (hematuria for 2 weeks) is surrounded by a raised rim of tissue. **B**, A chronic lesion (hematuria for 6 months) is flat to recessed (*between arrows*). Evidence of inflammation around both lesions is minimal.

during endoscopic examination, especially in the proximal urethra (to the point that blood can be seen flowing in the submucosal vasculature), one easily would suspect that hemorrhage could arise from apparent urethritis or urethral varicosity.

Urethral rents or tears in geldings typically result in hematuria at the end of urination in association with urethral contraction.<sup>1,29,30</sup> Affected horses generally void a normal volume of urine that is not discolored. At the end of urination, a series of urethral contractions results in squirts of bright-red blood. Occasionally, the horse may pass a smaller amount of darker blood at the start of urination. In most instances the condition does not appear painful or result in pollakiuria. Interestingly, most affected stallions with hemospermia and geldings with hematuria have been Quarter Horses or Quarter Horse crosses that have been free of other complaints.<sup>30,33</sup> Treatment with antibiotics for suspected cystitis or urethritis routinely has been unsuccessful, although hematuria has resolved spontaneously in approximately half of the cases seen by the author.

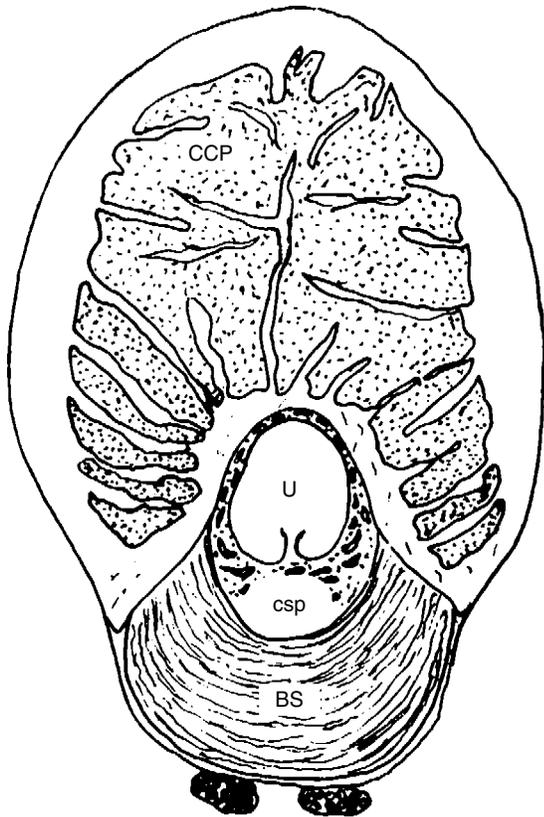

Examination of affected horses is often unremarkable. In comparison, horses with hematuria caused by neoplasms involving the distal urethra or penis usually have additional complaints such as pollakiuria, a foul odor to the sheath, or presence of a mass in the sheath or on the penis.<sup>34</sup> With urethral rents, laboratory analysis of blood reveals normal renal function, although mild anemia can be an occasional finding. Urine samples collected midstream or by bladder catheterization appear grossly normal. Urinalysis may have normal results, or the number of RBCs may be increased on sediment examination (a finding that also would result in a positive reagent strip result for blood). Bacterial culture of urine yields negative results.

One makes the diagnosis via endoscopic examination of the urethra, during which one typically sees a lesion along the dorsocaudal aspect of the urethra at the level of the ischial arch (Figure 19-39, A). With hematuria lasting several weeks, the lesion appears as a fistula communicating with the vasculature of the CSP (Figure 19-39, B). External palpation of the urethra in this area is usually unremarkable but can help

localize the lesion, because external digital palpation is visible via the endoscope as movements of the urethra.

Although the complete pathophysiology of this condition remains unclear, the defect has been speculated to result from a “blowout” of the CSP into the urethral lumen (Figure 19-40).<sup>30</sup> Hemorrhage from urethral rents occurs with higher pressure within the CSP during urination in geldings and ejaculation in stallions.<sup>31</sup> Pressure in the CSP during urination is higher in geldings because of their smaller CSP diameter as compared with stallions. Hematuria at the end of urination in geldings with urethral rents is speculated to occur when a sudden decrease in intraluminal urethral pressure occurs while pressure in the CSP is still high. Once created, the lesion is maintained by bleeding at the end of each urination, and the surrounding mucosa heals by formation of a fistula into the overlying vascular tissue.<sup>30</sup> An explanation for the consistent location along the dorsocaudal aspect of the urethra at the level of the ischial arch has not been documented but may be related to the anatomy of the musculature supporting the base of the penis and an enlargement of the CSP in this area. Furthermore, a narrowing of the lumen of the urethra at the distal extent of the ampullar portion of the urethra occurs that also may contribute to the location of the defects. However, histologic studies in both geldings and stallions have shown that no differences exist in the urethral mucosa, lamina propria, or CSP between the ischial arch and other sites in the penis.<sup>31</sup> An anatomic predisposition in Quarter Horses has not been documented but could be speculated to be based on an apparently increased risk in this breed. In addition, some of the affected horses have asymmetry to the musculature under the tail in this area, supporting a possible developmental defect (Figure 19-41).

Because hematuria may resolve spontaneously, no treatment may be required initially. If hematuria persists longer than 1 month or if significant anemia develops, then a temporary subsischial urethrotomy has been successful in a number of affected geldings. With sedation and epidural or local

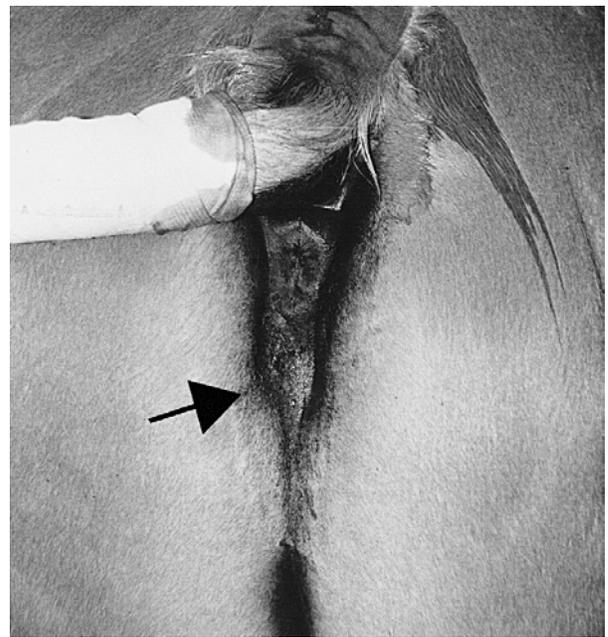

**FIGURE 19-40** Cross-sectional diagram of the equine penis at the level of the ischial arch shows a defect between the corpus spongiosum penis (CSP) (**csp**) and the urethral lumen (**U**). The CSP is a cavernous tissue surrounding the urethra that is distinct from the corpus cavernosum penis (**CCP**); the CSP is also adjacent to the bulbospongiosus muscle (**BS**) caudally. (From Schumacher J, Varner DD, Schmitz DG et al: Urethral defects in geldings with hematuria and stallions with hemospermia, *Vet Surg* 24:250, 1995.)

anesthesia, one makes a vertical incision down to a catheter placed in the urethra. The surgical wound requires several weeks to heal, and moderate hemorrhage from the CSP is apparent for the first few days after surgery. Additional treatment consists of local wound care and prophylactic antibiotic treatment (typically a trimethoprim-sulfonamide combination) for 7 to 10 days. Hematuria should resolve within 1 week after this procedure. Limiting the incision to entry of the CSP but not into the urethral lumen also has been a successful treatment and is now the preferred surgical treatment.<sup>30</sup> This treatment option provides support for the blowout cause and lessens the risk of urethral stricture formation. Furthermore, the treatment decreases the chance of a permanent fistula forming at the site, a surgical complication that has occurred in geldings.

## ☞ IDIOPATHIC RENAL HEMATURIA

Idiopathic renal hematuria is a syndrome characterized by sudden onset of gross, often life-threatening hematuria.<sup>35,36</sup> Hemorrhage arises from one or both kidneys and is manifested by passage of blood clots in urine. Endoscopic examination of the urethra and bladder usually reveals no abnormalities of these structures, but one may see blood clots exiting one or both ureteral orifices. Although a definitive cause of renal hemorrhage may be established in some horses (e.g., renal

**FIGURE 19-41** Perineum of Paint gelding with hematuria associated with a proximal urethral defect. The asymmetry of the perineal musculature is visible at the level of the ischial arch. (Arrow shows where asymmetry is more prominent on left side.)

adenocarcinoma, arteriovenous or arterioureteral fistula),<sup>37,38</sup> the disorder is termed *idiopathic* when a primary disease process cannot be determined. Both sexes, a wide age range, and several breeds of horses (including a mammoth donkey and a mule) have been affected. However, more than 50% of animals with idiopathic renal hematuria have been Arabians.

Use of the term *idiopathic renal hematuria* to describe this syndrome of horses was adopted from its use in human patients and dogs with severe renal hemorrhage.<sup>2,38-45</sup> *Benign essential hematuria* and *benign primary hematuria* are other terms that describe less severe hematuria that is not associated with trauma or other obvious causes of hematuria. In the latter species, hematuria is more commonly a unilateral than a bilateral problem, similar to what has been observed in the few affected horses. The pathophysiology remains poorly understood, but macroscopic hematuria has been associated with immune-mediated glomerular damage (e.g., acute postinfectious glomerulonephritis, membranoproliferative glomerulonephritis, immunoglobulin A nephropathy, Berger's disease), thin basement membrane nephropathy, and the loin pain-hematuria syndrome in human patients.

Although hematuria and pigmenturia can accompany a number of systemic diseases in horses,<sup>46-48</sup> patients affected with idiopathic renal hematuria appear to have spontaneous, severe hematuria in the absence of other signs of disease. Although one report suggested that severe renal hemorrhage resulted from pyelonephritis,<sup>15</sup> supportive data were lacking. In cases managed by the author, neither UTI nor lithiasis has been detected; the magnitude of hematuria often resulted in the need for repeated blood transfusions. As with hemorrhage associated with guttural pouch mycosis, the syndrome may produce episodic hemorrhage. Initially, one notes hemorrhage by finding a large amount of clotted blood in stall bedding or in the pasture. However, other client complaints (e.g., depression, anorexia, weight loss) are typically absent. Examination

**FIGURE 19-42** Endoscopic image of a large blood clot exiting the right ureteral opening of a gelding with idiopathic renal hematuria.

may reveal dried blood at the end of the penis or in the sheath of males or on the vulvar lips and between the hindlimbs of mares. In both sexes, neoplasia of the external genitalia or urinary tract is an important differential diagnosis, whereas in mares, one also must consider varicosities in the area of the vestibulovaginal sphincter, especially in multiparous mares. When blood is not detected in the sheath or vulvar areas, further evaluation may be unrewarding because the renal bleeding may cease spontaneously. Bleeding has been attributed anecdotally to cystitis and pyelonephritis in the absence of positive urine culture results, because hemorrhage stops during a course of antimicrobial therapy. More likely, spontaneous resolution has occurred. Furthermore, the magnitude of hematuria is considerably greater with idiopathic renal hematuria than with most UTIs, pyuria is absent, and urine culture results are negative. In the author's experience, one or two initial episodes of hemorrhage are followed by a more severe hemorrhagic crisis within months to several years after observation of the initial bleeding episode. Interestingly, renal colic has been notably absent in the history of affected horses.

One diagnoses idiopathic renal hematuria by exclusion of systemic disease, other causes of hematuria, and alterations in hemostasis. Physical examination may reveal tachycardia, tachypnea, and pale membranes consistent with acute blood loss. Rectal palpation may reveal an enlarged, irregular bladder because of the presence of blood clots. Azotemia is inconsistent. Endoscopic examination is important to document that hematuria is originating from the upper urinary tract and to determine whether hemorrhage is unilateral or bilateral (Figure 19-42). Repeated examinations may be required to answer the latter question. Ultrasonographic imaging is necessary to rule out nephrolithiasis or ureterolithiasis and occasionally may reveal a distended vascular space or renal vascular anomaly as the cause of hematuria. Renal scintigraphy can be a useful technique in affected horses

because it may provide semiquantitative information about renal function when a nephrectomy is being considered. Renal biopsy and immunofluorescent staining may assist in documenting immune-mediated glomerular injury, but the significance of such results is not well understood at this time.

Treatment for idiopathic renal hematuria consists of supportive care for acute blood loss, including blood transfusions. Medications intended to promote hemostasis (e.g., aminocaproic acid, formalin) also have been administered, but their efficacy has not been validated. Treatment with corticosteroids may be useful in cases with potential immune-mediated mechanisms as the cause of bleeding. Because the condition may be self-limiting in some patients, supportive care is warranted. With severe and recurrent hematuria of unilateral renal origin, a nephrectomy may be indicated, but one should warn owners of the risk of hematuria developing in the contralateral kidney. In the author's experience, risk of contralateral renal bleeding appears to be greater in the Arabian breed.

### ☞ EXERCISE-ASSOCIATED HEMATURIA

Exercise is accompanied by increased filtration of RBCs and protein across the glomerular barrier in a large percentage of human and equine athletes.<sup>4,49</sup> Typically the hematuria is microscopic, but occasionally one may observe gross discoloration of urine. Gross hematuria more often may result from bladder erosions, which may be induced traumatically by the abdominal contents pounding the bladder against the pelvis during exercise.<sup>50</sup> Detection of focal bladder erosions or ulcers with a contrecoup distribution and a history of emptying the bladder immediately before the exercise bout would be characteristic for this problem. A diagnosis of exercise-associated hematuria should be one of exclusion after diagnostic evaluation has ruled out other causes of hematuria such as presence of a cystolith.

### ☞ PIGMENTURIA ASSOCIATED WITH SYSTEMIC DISEASE

With any systemic disease that may lead to hemolysis, thrombocytopenia, coagulopathy, or alterations in vascular permeability, hematuria or hemoglobinuria may develop. Discolored urine has the potential to be accompanied by a degree of nephrotoxicity because of interaction of iron ions of the heme molecules with surface molecules on proximal tubular epithelial cells. With transient pigmenturia (as with exercise-associated hematuria), changes in renal function may not be apparent, but with more severe disease processes, ARF may develop. In human beings, a syndrome of hemolytic anemia and thrombocytopenia leading to development of ARF has been termed the *hemolytic-uremic syndrome*.<sup>51</sup> The syndrome is recognized more commonly in children than in adults and is the most common cause of ARF in children. Similar syndromes have been described in a limited number of horses.<sup>46-48</sup> Furthermore, hemolysis and hemoglobinuria may be recognized with liver disease, medications, or intoxications (e.g., ingestion of red maple leaves). Finally, conditions accompanied by extensive rhabdomyolysis also may result in pigmenturia and ARF.<sup>52</sup> Assessment of muscle enzyme activity in these cases usually is rewarding in establishing myoglobin as the most likely cause of pigmenturia. In addition, one can use the Blondheim test (ammonium sulfate precipitation) to differentiate myoglobinuria from hemoglobinuria.<sup>53</sup>

**POLYURIA AND POLYDIPSIA***Harold C. Schott II*

For small animals, polyuria and polydipsia have been defined as urine output exceeding 50 ml/kg/day and fluid intake of more than 100 ml/kg/day.<sup>1,2</sup> These values would equate to 25 L of urine production and 50 L of water consumption for a 500-kg horse. Compared with normal values for daily urine production and water consumption of 5 to 15 L and 20 to 30 L, respectively,<sup>3-10</sup> these definitions of polyuria and polydipsia appear applicable to horses as well. One must remember that urine production and water consumption vary with age, diet, workload, environmental temperature, and gastrointestinal water absorption. For example, urine production increases by 50% to 100% when the diet is changed from a grass to a legume hay.<sup>11</sup> Although this increase in urine production has been associated with higher dietary protein intake and urinary nitrogen excretion,<sup>12</sup> increases in calcium intake and urinary calcium excretion may be another contributing factor. Similarly, horses that are exercised heavily, are stabled in hot climates, or have chronic diarrhea may have a water intake exceeding 100 L per day yet produce normal volumes of urine.<sup>13</sup>

A brief review of water turnover by the equine kidneys provides insight into how a small change in renal water reabsorption can lead to a dramatic increase in urine production (polyuria). In normal horses, GFR exceeds 1000 L per day, a volume that is 10 times greater than the total extracellular fluid volume; however, approximately 99% of this water is reabsorbed in the renal tubules and collecting ducts, resulting in production of between 5 and 15 L of urine daily. The result is urine that is three to four times more concentrated than plasma (urine osmolality of 900-1200 mOsm/kg and a specific gravity of 1.025 to 1.050). Furthermore, urea (in urine) has replaced sodium (in plasma) as the most important solute. If only 98% of water is reabsorbed, then urine volume would double and the additional water would result in more dilute urine (urine osmolality of 450 to 600 mOsm/kg and a specific gravity of 1.015 to 1.025). If water reabsorption decreased to 96% of filtered water, then the horse would produce approximately 40 L of urine with a urine osmolality of 225 to 300

mOsm/kg and a specific gravity of 1.005 to 1.010 (Table 19-11). In the latter case, urine is more dilute than plasma (hyposthenuria) and the kidneys are excreting or losing water actively. Under certain conditions, active water excretion by the kidneys is important for maintenance of plasma osmolality in the normal range. The best example is a neonatal foal that may ingest a volume of milk exceeding 20% of its body weight daily.<sup>14</sup> This ingestion equates to a fluid intake approaching 250 ml/kg/day, and failure to produce a large volume of hyposthenuric urine could result in water retention, decreased plasma osmolality, and clinical hyponatremia (manifested by neurologic signs).

Determining that a horse is producing more urine than normal is often difficult, especially in horses kept at pasture. Owners may report that a horse is polyuric when in fact the frequency of urination has increased (pollakiuria) rather than the volume. Pollakiuria occurs with conditions such as cystitis and urolithiasis or during estrus in the mare. Horses housed in stalls bedded with straw are difficult to evaluate because excessive urine may not be obvious to the casual observer. For those bedded on shavings or sawdust, excessively wet bedding may be easier to recognize, but this is a subjective impression. Occasionally in a horse the polyuria may be so severe that urine may flow from the stall into the barn aisle. When doubt exists as to whether a horse has polyuria and polydipsia, documentation of water consumption over one or more 24-hour periods may be necessary.<sup>6</sup> One can quantify urine production by collecting urine over a 12- or 24-hour period. For geldings and stallions, one can construct a collection device by cutting off the bottom of a large plastic bottle, padding it, and fitting it over the prepuce. One covers the opening of the bottle with a rubber tube and clip to allow removal of urine every few hours. In mares, one can place an indwelling Foley catheter in the bladder or apply a urine collection harness.<sup>15-19</sup> During the collection period, horses usually are tied to minimize interference with the collection device.

The major causes of polyuria in horses include renal failure, PPID (Cushing's disease), and primary or psychogenic polydipsia.<sup>15,20</sup> Less common causes include excessive salt consumption, central and nephrogenic diabetes insipidus, diabetes mellitus, sepsis and endotoxemia, and iatrogenic causes (sedation with  $\alpha_2$ -agonists, corticosteroid therapy, or diuretic use).

TABLE 19-11

**Relationship of the Percentage of Water Filtered that is Reabsorbed to Daily Urine Output and Renal Water Absorption**

Glomerular Filtration Rate (GFR) (L/day)	Percentage of Filtered Water Reabsorbed	Urine Production (L/day)	Urine Osmole Excretion (mOsm)	Urine Osmolality (mOsm/kg)	Renal Water Reabsorption* (L/day)
1000	99%	10	10,000	1000	23.3
1000	98%	20	10,000	500	13.3
1000	96%	40	10,000	250	-6.7

\*Renal water reabsorption (the inverse of free water clearance) is a calculated volume of water that is retained or lost by the kidney. Renal water reabsorption is calculated from actual urine volume and the calculated volume of urine required to excrete all osmoles in urine that is isosmotic with plasma. In this table a urine osmolality value of 300 mOsm/kg is assumed to be isosmotic to plasma, 1 kg of water is assumed to equal 1 L of water, and a total of 10,000 osm is assumed to be excreted daily. Thus when 98% of filtered water is reabsorbed, the 20 L of urine produced (if isosmotic) would contain 6000 mOsm. Because an additional 13.3 L of water would be needed to excrete the remaining 4000 mOsm (as isosmotic urine), the kidneys are considered to be actively reabsorbing 13.3 L of water.

## ☞ RENAL FAILURE

Horses with ARF usually have a transient period of anuria or oliguria. If horses survive the acute phase of renal disease, then tubule damage results in a subsequent period during which impaired concentrating ability results in polyuria.<sup>15,21</sup> Urine is frequently hyposthenuric during this period of tubular repair. Owners should provide horses recovering from ARF with adequate water, salt, and a low-nitrogen (protein) and low-calcium diet. Such a diet consists of good quality grass hay or nonlegume pasture. Repair of tubules and return of concentrating ability may take several weeks. Although these animals appear to have normal renal function after this recovery period, a permanent reduction in total renal function likely persists because most animals can maintain apparently normal health with only about 30% to 50% of functioning nephrons.

CRF may develop after damage from nephrotoxins. In addition, immune-mediated mechanisms, chronic infection, and nephrolithiasis may give rise to CRF.<sup>21-23</sup> Horses that do not recover from the ischemic renal damage occurring with hypovolemic or endotoxic shock also may progress to CRF. Signs vary and include polyuria and polydipsia in some cases. When present, polyuria and polydipsia are usually moderate compared with the dramatic increases in urine production observed with primary polydipsia or diabetes insipidus. Most horses with CRF also exhibit other signs, including poor performance, weight loss, and ventral edema. A variable degree of azotemia is present, and urinalysis reveals isosthenuria (urine is isosmotic with plasma [260 to 300 mOsm/kg] with a specific gravity of 1.008 to 1.014).

The mechanisms of polyuria after acute and CRF are not entirely clear.<sup>24</sup> Increased tubular flow rate in surviving nephrons is one possible mechanism that would result in less time for water removal from tubular fluid. Next, medullary hypertonicity may decrease because of diminished transport of sodium and chloride out of tubular fluid passing through the ascending limb of the loop of Henle (diluting segment of the nephron) along with increased blood flow through the remaining medullary tissue. A third possibility is impaired response of collecting ducts to vasopressin (acquired nephrogenic diabetes insipidus). Although all these mechanisms may contribute to the polyuria of renal failure, which particular mechanism may be the most influential is not known. Furthermore, because the horse can produce hyposthenuric urine during the recovery phase of ARF, the mechanisms of polyuria differ somewhat for acute and CRF.

## ☞ PITUITARY PARS INTERMEDIA DYSFUNCTION

PPID is a common disorder of older horses that is often referred to as *equine Cushing's disease* because of its similarity to Cushing's disease in dogs and humans.<sup>20,25-32</sup> The clinical syndrome of PPID in horses is associated with hirsutism, laminitis, weight loss, and polydipsia and polyuria. The disorder is discussed in detail elsewhere in this text.

In one review of 17 horses with PPID, polyuria and polydipsia were found in 13 (76%)<sup>32</sup>; however, in another series of 21 horses with PPID, polyuria and polydipsia were not a historical complaint in any of the affected horses.<sup>31</sup> Thus the polyuria and polydipsia associated with Cushing's disease are generally less severe than that observed with primary polydipsia or diabetes insipidus. PPID may lead to polyuria by several mechanisms. First, polyuria may result from actions of hormones derived from proopiomelanocortin, most specifically adrenocorticotropin.

Hyperadrenocorticism resulting from excessive adrenocorticotropin activity on the adrenal cortex can lead to hyperglycemia, which may exceed the renal tubular threshold for reabsorption. The renal threshold for glucose in horses appears to be lower than in small animals (about 150 mg/dl).<sup>33</sup> When plasma glucose concentrations exceed this threshold value, the resultant glucosuria can lead to an osmotic diuresis. Although commonly implicated as the cause of polyuria in horses with PPID, glucosuria was found in only one of five affected horses in a recent clinical report.<sup>31</sup> Furthermore, horses with hyperglycemia and glucosuria still may be able to concentrate their urine in response to water deprivation.<sup>28</sup> A second mechanism implicated in the development of polyuria is cortisol antagonism of the action of vasopressin on the collecting ducts. Although frequently cited as the mechanism of polyuria in canine hyperadrenocorticism, experimental evidence to support this mechanism is lacking in dogs and horses. Furthermore, considerable species heterogeneity exists in the effects of corticoids on vasopressin activity, and in some species a primary dipsogenic effect may be more important. Next, growth of the pars intermedia may lead to impingement on the posterior pituitary and hypothalamic nuclei (located immediately dorsal to the pituitary gland), the sites of vasopressin storage and production, respectively. Decreased vasopressin production and release would result in a partial central diabetes insipidus as a third mechanism for polyuria.<sup>25</sup> Central diabetes insipidus, however, is not the cause of polyuria in all cases because some affected horses can concentrate their urine when deprived of water.<sup>28</sup> Consequently, polyuria and polydipsia seen in many horses with PPID is likely the combined result of several mechanisms.

## ☞ PRIMARY POLYDIPSIA

Although rare, primary or psychogenic polydipsia is probably the most common cause of polyuria and polydipsia in adult horses for which clients have a primary complaint of excessive water consumption and urination.<sup>15,20</sup> Primary polydipsia can be attributed to the fact that horses that exhibit this problem are generally in good body condition and are not azotemic. Furthermore, the magnitude of polyuria typically is much greater than that observed with renal failure or PPID. Owners may report that horses with primary polydipsia drink two to three times more water than their stablemates and their stalls often are flooded with urine. In some instances, primary polydipsia appears to be a stable vice that reflects boredom in affected horses, whereas in other cases it may develop after a change in environmental conditions, stabling, diet, or medication administration. Anecdotally, primary polydipsia is reported to be more common in Southern states during periods of high temperature and humidity. In human beings, primary polydipsia can be a compulsive behavior associated with mental illness or may be caused by a primary abnormality in the osmoregulation of thirst, in which case it is referred to as *dipsogenic diabetes insipidus*.<sup>34</sup> The latter may be idiopathic or may occur after neurologic disease involving the hypothalamic osmoreceptors regulating thirst. Excessive water consumption causes expansion and dilution of body fluids, leading to a decrease in plasma osmolality and suppression of vasopressin release. With low plasma vasopressin concentrations, collecting ducts become impermeable to water and hyposthenuria is induced to allow rate of water excretion to balance intake. In human beings, the magnitude of polydipsia and resultant polyuria vary considerably between affected persons, and

similar variation, although undocumented, likely occurs in affected horses as well.

One diagnoses primary polydipsia by exclusion of renal failure and hyperadrenocorticism. In addition, other factors, such as salt supplementation and medication administration, must be excluded. One excludes diabetes insipidus and confirms the diagnosis of primary polydipsia by demonstrating urine-concentrating ability after water deprivation.<sup>7,9</sup> Specific gravity should exceed 1.025 after water deprivation of sufficient duration (12-24 hours) to produce a 5% loss in body weight. In cases of long-standing polyuria, the osmotic gradient between the lumen of the collecting tubule and the medullary interstitium may be diminished (medullary washout). In these cases, vasopressin activity may not lead to an increase in urine specific gravity to values greater than 1.020. Consequently, horses with primary polydipsia lasting several weeks that fail to concentrate their urine after 24 hours of water deprivation may be given a modified water deprivation test. One performs the test by restricting water intake to approximately 40 ml/kg/day for 3 to 4 days. By the end of this time, urine specific gravity should exceed 1.025 in a horse that has had medullary washout. If the urine specific gravity remains in the isosthenuric range (1.008-1.014), then one should evaluate the polyuric horse further for early CRF, in which urine-concentrating ability may be compromised before the onset of significant azotemia. In theory, CRF could occur when between two thirds and three fourths of functional nephrons have been lost. Subtle signs of decreased performance and mild weight loss also would support early renal failure. Finally, horses with primary polydipsia typically produce hyposthenuric urine. Although such dilute urine would be an unlikely finding in the early stages of CRF, it could be found in the polyuric recovery phase after ARF. In the latter instance a thorough history should reveal whether any event that may have been complicated by ARF may have affected the horse recently.

Management of horses with primary polydipsia is empiric. Because the diagnosis is one of exclusion, once one establishes that the horse is not suffering from a significant renal disease, one may safely consider restricting water intake to meet maintenance, work, and environmental requirements of the horse. In addition, one should take steps to improve the attitude of the horse by reducing boredom. Increasing the amount of exercise or turning the horse out to pasture are possible options, as is providing a companion or toys in the stall. Increasing the frequency of feedings or the amount of roughage in the diet also may increase the time spent eating and thus reduce the habitual drinking.

## ☞ EXCESSIVE SALT CONSUMPTION

In an occasional case of apparent primary polydipsia, polyuria and polydipsia may be attributed to excessive salt consumption and are manifested by increased fractional sodium clearance. Such psychogenic salt eaters appear to be less common than psychogenic water drinkers, because the former would have to consume a substantial amount of salt to develop polyuria. In fact, the authors are aware of only one well-documented report of psychogenic salt eating in which a yearling Paint filly drank in excess of 500 ml/kg/day and had excessive urination when provided free access to salt.<sup>35</sup> The fractional clearances of sodium (3.4%) and chloride (2.6%) were increased and supported excessive intake. Although salt intake was not quantified for this filly, it may have exceeded 10% of the dry matter intake and appeared to be associated causally with muscle fasciculations and a stilted gait. Such a high intake is suggested

because no increases in water consumption or urine volume were detected in one study in which ponies were fed diets containing 1%, 3%, and 5% of NaCl.<sup>36</sup> The 5% NaCl diet contained 5 to 10 times the daily requirement of NaCl and was similar to feeding about 350 g NaCl daily to a 500-kg horse. Similar to cases of primary polydipsia, the filly described in this report was able to concentrate urine in response to water deprivation, and the problem was managed successfully by limiting water intake to 50 ml/kg/day and preventing access to salt.

## ☞ DIABETES INSIPIDUS

Diabetes insipidus results in polyuria and polydipsia because of vasopressin deficiency or insensitivity of the renal collecting duct epithelial cells to vasopressin. In human beings, vasopressin deficiency, or neurogenic diabetes insipidus, is the more common form, with hereditary and acquired forms being described. The hereditary form appears to result from decreased numbers of neurosecretory neurons in the supraoptic nuclei of the hypothalamus and is inherited in an autosomal dominant fashion. However, polyuria and polydipsia do not develop until after the first few years of life in affected persons, suggesting progressive loss of neurosecretory tissue. The acquired form of neurogenic diabetes insipidus results from degeneration of neurons in the supraoptic nuclei after trauma, vascular abnormalities, infection, or a variety of tumors.<sup>34,37,38</sup> As with the hereditary form, polyuria and polydipsia usually are not manifested until 80% to 90% of the neurosecretory neurons are destroyed.

In equids, two well-documented cases of neurogenic diabetes insipidus have been described.<sup>39,40</sup> Neither animal could concentrate urine in response to water deprivation, but administration of exogenous vasopressin resulted in an increase in urine concentration and a decrease in urine volume. In a Welsh pony in which the condition was considered idiopathic, the absence of an increase in plasma vasopressin concentration after water deprivation (compared with control ponies) further supported a diagnosis of neurogenic diabetes insipidus.<sup>39</sup> Acquired neurogenic diabetes insipidus after encephalitis was confirmed histologically in the other horse.<sup>40</sup> Two other reports of diabetes insipidus in horses more likely described cases of primary polydipsia because both animals demonstrated an ability to concentrate urine during water deprivation or had random urine specific gravities greater than 1.020.<sup>41,42</sup>

Nephrogenic diabetes insipidus results from resistance of the cortical and medullary collecting ducts to the antidiuretic action of vasopressin.<sup>34,37,38</sup> In the absence of systemic disease, nephrogenic diabetes insipidus is most commonly a familial disorder in human beings with an X-linked semirecessive mode of inheritance. As such, the disorder is carried by females and expressed in male offspring.<sup>43</sup> Nephrogenic diabetes insipidus has been reported in three colts, two of which were sibling Thoroughbreds, suggesting that an inherited form of nephrogenic diabetes insipidus also may occur in horses.<sup>44,45</sup> Two of the three colts were underweight for their age. Affected colts could not increase urine concentration in response to water deprivation, although they did show appropriate increases in plasma vasopressin concentration. Furthermore, minimal response to exogenous vasopressin administration in all three colts confirmed resistance of the cortical and medullary collecting ducts to the antidiuretic action of vasopressin.

Nephrogenic diabetes insipidus also may be acquired after drug therapy or a variety of metabolic, infectious, or mechanical

(postobstruction) disorders. Anomalous or neoplastic disorders resulting in structural deformation of the kidneys are another potential cause of nephrogenic diabetes insipidus.<sup>34,37,38</sup> Necropsy and histopathology revealed no lesions in one colt and few focal interstitial aggregates of lymphocytes, plasma cells, and rare areas of interstitial fibrosis in the kidneys with focal necrosis of the renal pelvis and ureteral epithelium in another.<sup>44</sup> Histopathologic lesions found in renal biopsies from one case<sup>45</sup> included severe vacuolization and intracytoplasmic eosinophilic granular changes in distal collecting duct epithelium and occasional slightly increased cellularity of glomeruli. However, these lesions were apparently reversible and not observed in repeat biopsies performed later, after dietary and supportive therapy for diabetes insipidus.

Neurogenic and nephrogenic forms of diabetes insipidus share some similarities in pathogenesis. Polyuria because of a lack of vasopressin activity results in net water loss and an increase in plasma osmolality. As plasma osmolality increases, stimulation of thirst results in a compensatory increase in water consumption. In normal individuals and those with nephrogenic diabetes insipidus, the osmoreceptors in the hypothalamus sense the increase in plasma osmolality and subsequently signal for vasopressin release. As little as a 1% increase in plasma osmolality (about 3 mOsm/kg) results in a 1 pg/ml increase in plasma vasopressin concentration. In normal individuals, this small change is substantial enough to increase urine osmolality and decrease urine flow. With greater increases in plasma osmolality, more vasopressin is secreted. In human beings, urine osmolality approaches a maximum after an increase in vasopressin concentration to about 5 pg/ml (from a resting value of about 1.0 pg/ml).<sup>34,38</sup>

Limited studies in ponies and horses suggest that a similar degree of vasopressin release occurs in response to minor increases in plasma osmolality<sup>46-48</sup>; however, vasopressin also appears to be a "stress hormone" in horses because substantially greater concentrations (tenfold higher than those induced by water deprivation) have been measured after application of a nose twitch, nasogastric intubation, or exercise.<sup>49</sup> Thus increases in plasma vasopressin concentration after water deprivation would be expected to vary in horses, and separating osmotic effects from stress effects in an individual horse may be difficult. A word of caution also is warranted about subjecting horses suspected of having diabetes insipidus to water deprivation. Because urine-concentrating ability may show minimal improvement with either form of diabetes insipidus, affected horses may continue to excrete excess water in the face of water deprivation. As a result, they may become substantially dehydrated (10% to 15%) within the first 12 hours of water deprivation. Thus one carefully should monitor horses suspected of having diabetes insipidus during the period of water deprivation to decrease the risk of inducing serious hypertonic dehydration.

The Hickey-Hare test to diagnose diabetes insipidus involves infusion of hypertonic (2.5%) saline (0.25 ml/min/kg IV for 45 minutes) to stimulate vasopressin release and water retention.<sup>45</sup> Normal animals will respond with concentrated urine and reduced urinary volume after sodium infusion. Horses with diabetes insipidus did not concentrate urine after hypertonic saline administration.<sup>44,45</sup>

In addition to assessing the effects of water deprivation on urine-concentrating ability and plasma vasopressin concentrations, the final diagnostic manipulation is often administration of exogenous vasopressin (2.5 mU/kg in 5% dextrose

[5 U vasopressin/l] constant rate infusion over 60 minutes or 0.5 U/kg IM).<sup>50</sup> In normal horses, urine specific gravity should increase to at least 1.020 60 to 90 minutes after vasopressin administration. Alternatively, DDAVP, a synthetic vasopressin analog, may be used. DDAVP is available as a nasal solution (0.1 mg/ml) for humans with central diabetes insipidus. The nasal spray can be diluted in sterile water and administered (0.05 µg/kg IV) for the diagnosis of diabetes insipidus in horses. Normal horses that underwent experimentally induced diuresis by repeated dosing of water via nasogastric tube increased urine specific gravity to greater than 1.020 from 2 to 7 hours after administration of DDAVP.

The medullary interstitial osmotic gradient develops as a result of countercurrent exchange, and the magnitude of the gradient is related inversely to tubular flow. Medullary washout may occur with the high tubular flow rates that can accompany renal disease. Although partial medullary washout may contribute to the concentrating defect in diabetes insipidus, the rapid response to exogenous vasopressin administration in cases of neurogenic diabetes insipidus (increase in urine osmolality to 900 mOsm/kg or greater) indicates that the medullary concentration gradient is not severely compromised.<sup>34,51</sup> This response further explains why in some cases of diabetes insipidus urine osmolality can be greater than plasma osmolality after water deprivation. The mechanism for this response is thought to be a decrease in tubule flow rate that allows more time for passive water extraction from the hypo-osmotic tubular fluid. With nephrogenic diabetes insipidus, one also may observe mild improvement in urine-concentrating ability (an increase in urine osmolality up to 500 mOsm/kg) in response to exogenous vasopressin administration. This response has been attributed to partial sensitivity of the collecting ducts to vasopressin and to vasopressin activity at other portions of the renal tubule.<sup>34,37</sup>

Treatment of diabetes insipidus should aim to manage polydipsia and polyuria. With neurogenic diabetes insipidus, recovery of vasopressin secretion is rare once the secretory neurons have degenerated to the degree that polyuria and polydipsia become apparent. Consequently, treatment consists of hormone replacement. In the past, intramuscular injection of Pitressin tannate in oil every 2 to 3 days was successful in limiting polyuria; however, development of resistance or allergic reactions was an occasional problem, and long-acting vasopressin formulations are no longer available. Vasopressin has relatively short antidiuretic effects and a short plasma half-life, which makes replacement therapy in horses difficult.<sup>52</sup> With the development of potent vasopressin analogs (desmopressin), effective treatment by nasal insufflation is now available.<sup>34</sup> The use of desmopressin for diagnosis and treatment of neurogenic diabetes insipidus in small animals has been described.<sup>51,53</sup> Largely by chance, other oral medications, including chlorpropamide and clofibrate, have been found efficacious in treating neurogenic diabetes insipidus. The mechanism of action of these drugs is uncertain, but they are thought to potentiate the effect of vasopressin on the collecting ducts.<sup>34,51</sup>

With nephrogenic diabetes insipidus, replacement hormone therapy is ineffective, and the only practical form of treatment for many years has been to restrict sodium and water intake or to administer thiazide diuretics. The latter treatment may reduce polyuria by 50% in many cases.<sup>34</sup> Thiazide diuretics inhibit sodium reabsorption in the distal tubule (diluting segment of the nephron) and increase solute delivery

to the collecting duct. The mechanism by which such therapy paradoxically benefits patients with nephrogenic diabetes insipidus is ill understood. Explanations include enhanced proximal tubular fluid reabsorption (via glomerulotubular balance) and decreased glomerular filtration and tubular flow (via a greater osmotic stimulus to the macula densa and subsequent tubuloglomerular feedback).<sup>34,38</sup> Recently, treatment with prostaglandin inhibitors or amiloride has decreased polyuria in patients with nephrogenic diabetes insipidus. The former agents probably work by decreasing RBF and glomerular filtration, whereas the latter drug, a sodium channel blocker, is thought to act in a manner similar to the thiazide diuretics.<sup>34</sup> One horse clinically improved with only dietary salt restriction (no additional salt other than what was contained in feed) and limited but regular access to water.<sup>45</sup>

## ☞ DIABETES MELLITUS

Diabetes mellitus is a state of chronic hyperglycemia usually accompanied by glucosuria.<sup>54,55</sup> The resultant osmotic diuresis is an occasional cause of polyuria and polydipsia in horses that has been described to result in a water intake exceeding 80 L per day.<sup>56,57</sup> Type I (insulin dependent) diabetes mellitus results from a lack of insulin that in human beings is usually attributable to viral or autoimmune disease. Those with type II (noninsulin dependent) diabetes mellitus have normal to high insulin concentrations but their tissues are insulin insensitive. Thus the response to an oral carbohydrate load or an intravenous glucose challenge is impaired, resulting in prolonged hyperglycemia.<sup>54</sup> The mechanism of insulin resistance is not well documented for horses but may result from decreased numbers of insulin receptors or lack of insulin receptor activation in response to insulin binding. The most common causes of equine noninsulin-dependent diabetes mellitus are equine metabolic syndrome and PPID, both of which are discussed in detail elsewhere in this text.<sup>26-30</sup>

Although uncommon, a few reports describe insulin-dependent and noninsulin-dependent diabetes mellitus that were not caused by PPID or equine metabolic syndrome and that resulted in polyuria and polydipsia as one of the presenting complaints.<sup>56-61</sup> Diagnostic evaluation reveals consistent hyperglycemia but negative dexamethasone suppression test results (a normal decrease of plasma cortisol to low concentrations). Treatment in most instances is supportive, although replacement insulin therapy may be helpful in cases in which measured serum insulin concentrations are low (insulin-dependent diabetes mellitus). In one case of pancreatic  $\beta$ -cell failure,<sup>57</sup> treatment with glyburide (0.02 mg/kg) and metformin (1.9 mg/kg) lowered interstitial fluid glucose concentrations to normal ranges. Insulin therapy may be of some benefit in horses with elevated serum insulin concentrations because pharmacologic doses in part may overcome the insulin insensitivity. In such cases, synthetic insulin products may be preferable over protamine zinc insulin, because one horse with PPID and secondary diabetes mellitus developed anti-insulin antibodies and had a relapse in clinical signs after 7 weeks of insulin therapy.<sup>30</sup>

## ☞ SEPSIS AND ENDOTOXEMIA

Polyuria and polydipsia also have been reported as clinical signs in horses with sepsis or endotoxemia, although other clinical signs such as fever, abdominal pain, and weight loss

predominate.<sup>62</sup> The mechanism is unclear but may result from endotoxin-induced prostaglandin production. Prostaglandin  $E_2$  is a potent renal vasodilating agent in laboratory animals, and it antagonizes the effects of antidiuretic hormone on the collecting ducts.<sup>63</sup> Some horses with chronic gram-negative bacterial infections (e.g., peritonitis, pleuritis) may have low-grade or intermittent endotoxemia as a mechanism for polyuria, similar to the polyuria observed with canine pyometra.<sup>64</sup>

## ☞ IATROGENIC POLYURIA

Finally, polyuria can be iatrogenic, occurring after a number of management practices or medical treatments. The most obvious iatrogenic cause is fluid therapy, for which polyuria is a desired response. Polyuria also has been observed with exogenous corticoid administration, although as for PPID the mechanism remains unclear. Human beings and dogs appear to experience a potent thirst response to exogenous corticoids; thus polydipsia may be an important cause of the polyuria observed. In horses receiving long-term dexamethasone treatment for immune-mediated disorders, one may observe profound glucosuria (2 to 3 g/dl) that leads to osmotic diuresis in these patients. Finally, transient diuresis or polyuria accompanies sedation with the  $\alpha_2$ -agonists xylazine and detomidine.<sup>65,66</sup> Although these agents cause hyperglycemia, and occasionally glucosuria, a more likely mechanism for the transient polyuria is the existence of  $\alpha_2$ -adrenoreceptors on collecting duct epithelial cells. Activation of these receptors is another mechanism of vasopressin antagonism.<sup>67</sup>

## RENAL TUBULAR ACIDOSIS

*Warwick M. Bayly*

The veterinary profession recognizes well that horses with acute or CRF are frequently acidotic. These animals are almost invariably azotemic, hypochloremic, and normo- or hyperkalemic and frequently have significant abnormalities on urinalysis. A less frequent renal disease associated with acidosis is renal tubular acidosis (RTA). RTA is a clinical syndrome of impaired renal acidification characterized by a hypokalemic, hyperchloremic acidosis without azotemia. Affected horses frequently have normal urinalysis. The condition has been well-described in human beings,<sup>1-3</sup> and several case reports documenting its existence in horses have appeared since the mid-1980s.<sup>4-12</sup>

The causes and pathogenic mechanisms responsible for the development of RTA are ill understood. In human beings RTA may be primary (genetic or idiopathic) or secondary, occurring after a variety of conditions, including hyperglobulinemia, various autoimmune disorders, kidney disease such as polyneuropathy and obstructive uropathy, cirrhosis, drug- or toxin-induced nephropathies (including amphotericin B toxicity), metabolic disorders involving nephrocalcinosis, and a number of genetically transmitted diseases. All reported equine cases apparently have been idiopathic, because no signs of primary renal, hepatic, or autoimmune disease or disturbance of calcium metabolism have been evident, and the horses have

had no history of access to toxins. In some cases, however, low-grade renal tubular disease has been suspected because of mild proteinuria.

General agreement is that three types of RTA exist.<sup>13</sup> Type 1, also known as *distal* or *classic* RTA, arises from the inability of the cells of the distal tubule to establish a steep hydrogen ion gradient between the blood and the urine. This inability results from failure of normal H<sup>+</sup> from the distal tubules. In many cases, this gradient may be less than 10:1. Whether or not this low ratio is caused by an insufficient number of proton-secreting pumps in the distal nephron or by H<sup>+</sup> diffusing back across the luminal membrane after being secreted is not clear. Accelerated K<sup>+</sup> secretion occurs because of the existing electrochemical driving forces in the distal nephron and the lack of protons to offset them. In addition to having high urinary K<sup>+</sup> clearances, patients may be hypercalciuric and hyperphosphaturic, although in horses this may be difficult to assess. Equine urinary concentrations of K<sup>+</sup> and Ca<sup>2+</sup> in particular are high. In human beings, about 70% of adults with distal RTA develop some form of urolithiasis.<sup>14</sup> This condition has not been recognized in the few reported equine cases and may not be, given the significant differences between the two species.

Type 2, or proximal, RTA is caused by a failure of HCO<sub>3</sub><sup>-</sup> resorption in the proximal tubule. This part of the nephron usually reabsorbs the bulk of the filtered HCO<sub>3</sub><sup>-</sup> via Na<sup>+</sup> and H<sup>+</sup> exchange and the subsequent breakdown of carbonic acid to carbon dioxide and water under the influence of carbonic anhydrase. Disruption of normal Na<sup>+</sup> and H<sup>+</sup> exchange or carbonic anhydrase activity therefore results in excess flow of HCO<sub>3</sub><sup>-</sup> to the distal tubule where the ability to resorb the anion is poor. This bicarbonaturia also results in accelerated K<sup>+</sup> secretion and hypokalemia. In human beings with this form of the disease, the suggestion is that a reduction occurs in the threshold concentration at which HCO<sub>3</sub><sup>-</sup> is reabsorbed from the proximal nephron. As a result, reabsorption resumes once serum HCO<sub>3</sub><sup>-</sup> concentration drops below this threshold, and a new steady state is said to develop. More likely because of the urinary HCO<sub>3</sub><sup>-</sup> loss, plasma HCO<sub>3</sub><sup>-</sup> concentration decreases, as does glomerular filtration of HCO<sub>3</sub><sup>-</sup>. Eventually the distal tubule reaches a point at which it can handle the amount of HCO<sub>3</sub><sup>-</sup> presented. Urine pH may start to decrease because of the lower amount of HCO<sub>3</sub><sup>-</sup> being excreted. A new steady plasma HCO<sub>3</sub><sup>-</sup> concentration is established, albeit considerably below

the normal range, and acid-base homeostasis may return gradually. Consequently, the type 2 condition often appears to be self-limiting in human beings.<sup>15</sup> This form of the disease occurs rarely by itself in human beings and almost always is associated with other signs of proximal tubule dysfunction such as defective resorption of glucose, amino acids, and phosphate (Fanconi syndrome). Type 2 RTA has been reported in two horses.<sup>4</sup>

Type 4 RTA is characterized by hyperkalemic, hyperchloremic acidosis and is common in human beings, but it has not been reported in horses. Type 4 RTA apparently is associated with hypoaldosteronism or resistance of the distal nephron cells to the effects of aldosterone. As a result the renal clearance of K<sup>+</sup> and H<sup>+</sup> is reduced. The associated natriuresis ultimately may lead to a reduced ability to concentrate urine because of “washout” of the medullary concentrating gradient, if the condition becomes chronic. Another form of RTA (type 3), which formerly had been described as having characteristics of type 1 and type 2 RTA, now is considered to be a variation of type 1.<sup>13</sup>

Differentiating between the distal (H<sup>+</sup> retention) and proximal (HCO<sub>3</sub><sup>-</sup>-wasting) forms of RTA is theoretically important if the approach to the human form of the disease is any guide, because in human beings the two types differ with respect to clinical severity, treatment, and prognosis.<sup>16</sup> The ability to differentiate between the forms of the disease in horses appears to be less critical, because treatment does not seem to differ much according to the suspected type of RTA. Table 19-12 summarizes some differential characteristics of the two types of the disease. In human beings with type 2 RTA, plasma HCO<sub>3</sub><sup>-</sup> concentrations tend to be higher than those associated with the distal form of the disease; but this does not appear to be the case in horses, because all the horses the author has seen, plus those that have been described in the literature, have been severely acidotic (HCO<sub>3</sub><sup>-</sup> concentrations of 10 mmol/L or less). In horses, differentiation between the distal and proximal types of the condition has been based on measurement of the urine pH. Evaluation of urine ammonium excretion, urine net charge or anion gap, and urinary PaCO<sub>2</sub> have not been reported in horses, although they are regarded as critical to the specific differentiation of RTA in human beings.<sup>17-19</sup> Because of the alkalinity of normal equine urine, measurement of urine PaCO<sub>2</sub> is probably of little benefit. With type 1 RTA, urine pH tends to stay high (i.e., in the normal

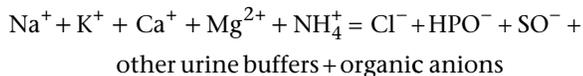

TABLE 19-12

Features Used to Differentiate Type 1 and Type 2 Renal Tubular Acidosis

Variable	Type 1	Type 2
Acidosis	Severe	Less severe, self-limiting
Hypokalemia	Severe	Mild to moderate
Glycosuria, proteinuria	Absent	Often present
Urine pH during mild/moderate acidosis	Inappropriately high	Inappropriately high
Severe acidosis	Inappropriately high	Normal
Effect of alkali administration	Decreases or worsens hypokalemia, depending on stage of disease	Worsens hypokalemia
Amount of HCO <sub>3</sub> <sup>-</sup> needed to correct acidosis	Low	High
Ammonium chloride challenge	Failure to excrete acid (urine does not acidify)	Urine pH decreases
Bicarbonate loading	Filtered bicarbonate is reabsorbed	Bicarbonate is lost in the urine

to alkaline range). In type 2, urine pH is generally neutral or slightly acidic. A suggested way of making this differentiation is to assess the urinary response to the administration of the urine-acidifying agent ammonium chloride (0.1 g/kg). Typically, one gives this solution orally, and it should lower the urine pH to less than 7.0, which it supposedly does in normal horses and those with type 2 RTA. In cases of distal (type 1) RTA, the urine pH remains high in the face of the increased acid load. Because the administration of such acidifying agents potentially could worsen the degree of acidosis in cases of type 2 RTA (as a result of reduced buffering capacity), performance of this test is not recommended until one has attempted at least partial replacement of the  $\text{HCO}_3^-$  deficit. In the author's experience, the ammonium chloride challenge test has proved unreliable, having failed to acidify the urine of normal healthy horses even when given intravenously in a 4-L solution. The dose and rate of administration may need to be increased before the test can be considered worthwhile. A more suitable alternative may be to infuse sodium sulfate as is done sometimes in human beings.<sup>1</sup> The author could find no reports of the use of this test in horses.

Another diagnostic option that may be worthy of investigation in horses is calculation of the urine net charge. As in any body fluid, the sum of urinary cations must equal the sum of its anions. Therefore in urine,

In human beings,  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  tend to be present in urine in small, constant quantities. Excretion of  $\text{HPO}^-$ ,  $\text{SO}^-$ , titratable buffers, and organic anions is also constant and exceeds the  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  by an amount that is referred to as the *urine anion gap* ( $\text{AG}_u$ ). Thus

The expression ( $\text{Na}^+ + \text{K}^+ - \text{Cl}^-$ ) is referred to as the *urine net charge* and reflects the excretion of  $\text{NH}_4^+$ .<sup>18</sup> Given the aforementioned plasma electrolyte and acid-base abnormalities, type 2 RTA has been shown likely to exist when the urine net charge is negative (i.e.,  $\text{Cl}^- > [\text{Na}^+ + \text{K}^+]$ ) because  $\text{NH}_4^+$  is greater than  $\text{AG}_u$ . In other words,  $\text{H}^+$  continues to be secreted normally from the distal tubule, and plenty of  $\text{NH}_4^+$  is being produced. When ( $\text{Na}^+ + \text{K}^+$ ) is greater than  $\text{Cl}^-$ , the net charge is positive, indicating that  $\text{NH}_4^+$  excretion is low because of failure to excrete  $\text{H}^+$  (i.e., type 1 or distal RTA exists).

No breed or sex predilection exists for RTA in horses, and the average age for 16 affected horses was 7 years.<sup>11</sup> The most common clinical signs in affected horses are depression, poor performance, weight loss, and anorexia. Various other signs such as chronic weight loss, ataxia, dysphagia, and periodic collapse also have been reported. The latter three signs may be manifestations of severe weakness, which probably is caused by the severe hypokalemia. The reduced  $\text{K}^+$  concentration also may be associated with bradycardia.

On clinical examination, affected horses are usually afebrile. Mild icterus is common, presumably because of the anorexia, although significant indirect hyperbilirubinemia and increases in serum concentrations of GGT and ALP have been observed. Although cirrhosis of the liver has been associated with the development of RTA in human beings, the

equine cases of which the author is aware have demonstrated no clinicopathologic changes compatible with severe liver disease. Sulfobromophthalein clearance half-time was normal in the one case in which it was measured.<sup>5</sup>

One should suspect RTA whenever a horse has a severe hyperchloremic metabolic acidosis in the absence of any obvious cause of extrarenal hypovolemia such as diarrhea or small intestinal ileus. In such cases the plasma anion gap usually is widened, whereas with RTA it remains normal. (However, hypoalbuminemia may mask widening of the anion gap because albumin is normally responsible for much of the normal anion gap.<sup>20</sup> Therefore the anion gap value should be smaller in hypoalbuminemic horses.) Azotemia has not been recognized in horses with RTA, although signs of tubular dysfunction, such as mild proteinuria and increases in fractional  $\text{K}^+$  clearance and urine GGT activity, have been observed. The results from renal biopsy and ultrasonic examination of the kidneys are normal.

Definitive diagnosis of RTA is based on the demonstration of severe hypokalemia (2.3 mmol/L or less) and a urine pH that is generally neutral or alkaline in the face of a severe acidosis (venous blood pH <7.15), although theoretically one could observe a slight aciduria with type 2 RTA. Hypokalemia in the face of severe acidosis is uncommon. Classically, the reverse is expected because of intracellular buffering of  $\text{H}^+$  and the reciprocal role of  $\text{H}^+$  and  $\text{K}^+$  in maintaining the electric neutrality of the extracellular fluid. Occasionally, serum chloride concentrations are in the high normal range rather than being increased. Blood gas measurement usually reveals some degree of compensatory respiratory alkalosis ( $\text{PaCO}_2 = 25$  to 35 torr).

The differential diagnosis of RTA includes those of any animal that has sudden weakness, depression, and possible collapse: cardiovascular failure, neurologic disease (including rabies), hypoglycemia, and peracute toxemia or endotoxemia. One usually can rule out all of these based on a thorough physical examination that finds nothing to support their possible existence. These findings, plus demonstration of the aforementioned electrolyte and acid-base abnormalities, suggest RTA. Conditions such as hypokalemic periodic paralysis, Addison's disease, PPID, and chronic corticosteroid or diuretic abuse could cause some of these clinicopathologic disturbances, but not the combination of hyperchloremia, acidosis, hypokalemia, and a normal plasma anion gap.

Prompt recognition of the disease and quick institution of therapy are important because the untreated condition is potentially fatal. All reported equine cases of RTA have responded satisfactorily to treatment, as have the cases the author has seen. Although the ability to differentiate between type 1 and type 2 RTA may be important in human beings from a therapeutic perspective, the distinction has not seemed to be essential in horses. Regardless of the suspected type of the disease, treatment of the condition in horses is associated with  $\text{HCO}_3^-$  and  $\text{K}^+$  replacement therapy. Although the administration of  $\text{KHCO}_3$  would seem to be ideal, the lack of ready availability of this substance and the need for prompt therapy means that treatment usually involves a combination of orally administered KCl and intravenously administered  $\text{NaHCO}_3$  and KCl. That one should not give  $\text{NaHCO}_3$  without some form of potassium supplementation deserves emphasis, to ensure that the hypokalemia does not get worse. Generally, a steady improvement in the condition of the patient occurs

after 12 to 24 hours of treatment. Oral fluids usually are given four to six times per day for the first 48 hours, whereas intravenous fluids frequently are given at a slow but steady rate. Inclusion of glucose or dextrose in the latter helps to promote uptake of  $K^+$  by the cells. The serum chloride concentration usually decreases as  $HCO_3^-$  concentration increases. In the author's experience, a steady improvement occurs in  $HCO_3^-$  values, and these tend to improve more rapidly than the  $K^+$  concentrations. Serum concentrations of the latter appear to be slower to return to normal, possibly because intracellular stores are replaced first. Estimating the total potassium deficit before the onset of treatment is impossible because of the huge intracellular deficit these animals suffer. In the author's experience, total deficits of this cation frequently exceed 4000 mmol.

With the correction of the acid-base and electrolyte disturbances, muscle strength and appetite generally return within 48 hours of the onset of treatment. At this point, one usually can reduce potassium supplementation and subsequently discontinue it once the forage intake of the horse has returned to normal. Obviously, giving the horse a diet that includes ample amounts of good quality hay is important because of the high potassium content of this feedstuff. Bicarbonate therapy generally continues longer, although one usually discontinues intravenous assistance in the horse with return of the appetite. Long-term oral supplementation with sodium bicarbonate is often required for the maintenance of normal acid-base status. Periodic rechecking of the animal is advised until it becomes clear that its condition is stable. Long-term follow-up of cases the author has seen and those that have been reported in the literature suggest that the prognosis is favorable but horses with evidence of renal disease may be more likely to relapse.<sup>11</sup>

## NEOPLASIA OF THE URINARY TRACT

Harold C. Schott II

Although neoplasia of the urinary tract is uncommon in horses,<sup>1-6</sup> reports exist of tumors involving the upper and lower urinary tract in this species. Renal neoplasms, which represent fewer than 1% of all equine tumors, include adenomata, renal cell carcinomata, and nephroblastomata.<sup>7</sup> Renal adenomata are small, well-circumscribed lesions in the renal cortex, that are usually incidental necropsy findings.<sup>8</sup> The best-described renal tumor in the horse is renal cell carcinoma or adenocarcinoma.<sup>9-19</sup> These lesions arise from epithelium of the proximal convoluted tubules in most cases. In human beings, renal cell carcinomata are known as the *internist's tumor* because of their diverse and often obscure presenting signs. Although a classic triad of symptoms including flank pain, gross hematuria, and palpable renal mass has been described, these symptoms occur in fewer than 10% of affected human beings at presentation.<sup>20</sup> Similarly, affected horses usually have nonspecific presenting complaints, including poor performance, depression, weight loss, and recurrent colic (Table 19-13). A paraneoplastic process leading to severe hypoglycemia has been reported in two cases of equine renal cell carcinoma, probably caused by production of an insulin-like factor, an abnormal variant of insulin-like growth factor II, or less likely from excessive

glucose use by the tumor.<sup>17,18</sup> Signs that increase suspicion of a primary urinary tract problem include hematuria (7 of 15 cases in Table 19-13) and detection of a palpable mass on rectal examination (9 of 15 cases in Table 19-13). Renal cell carcinomata are typically unilateral, and the contralateral kidney maintains normal renal function. Therefore indices of renal function such as BUN and Cr concentration are usually normal. Although nephrectomy is the treatment of choice in human beings, tumors are typically large and adherent to surrounding organs by the time they are detected in horses. Thus surgical removal usually is not possible. Furthermore, frequent metastases (10 of 15 cases in Table 19-13) are another indication that renal adenocarcinoma is usually not a treatable disease. The poor prognosis can be attributed to the fact that clinical signs of intra-abdominal neoplasia in horses often are not apparent until the disease is advanced.<sup>21</sup> In one report of renal carcinoma, clinical signs of the tumor were absent until the horse was anesthetized for laryngeal surgery. After an uncomplicated surgery, the horse was repositioned for recovery but died shortly thereafter. Compression of the caudal vena cava by a large renal carcinoma was suspected to have led to a decrease in venous return as the cause of sudden death.<sup>22</sup> In another horse, clinical signs were not observed until bony metastasis to the olecranon caused lameness.<sup>19</sup> Other neoplastic diseases that may affect the kidneys include nephroblastoma,<sup>23-25</sup> transitional cell carcinoma,<sup>21,26</sup> and squamous cell carcinoma.<sup>27</sup> Nephroblastoma (Wilms' tumor) is an embryonal tumor that arises in primitive nephrogenic tissue or in foci of dysplastic renal tissue, whereas the latter tumor types arise from the uroepithelium of the renal pelvis or ureter.<sup>8</sup> Papillary renal adenoma of distal nephron differentiation has been described as an incidental finding during necropsy of an aged mare.<sup>28</sup> Neoplastic involvement of the upper urinary tract also may occur with dissemination of lymphosarcoma, hemangiosarcoma, melanoma, or adenocarcinoma arising from other tissues in the abdomen.<sup>2,7,8,21,29</sup> Finally, although they are not truly cancerous disease processes, mucinous hyperplasia of the renal pelvic and proximal ureteral uroepithelium or ureteropelvic polyp formation can lead to development of a tissue mass in either kidney, ureteral obstruction, and hydronephrosis.<sup>30,31</sup> Renal mucous gland cystadenomas have been found incidentally at necropsy.<sup>32</sup> Mucous gland hyperplasia of the renal pelvis or proximal urethra are differentiated from cystadenomas by their thin fibrous connective tissue capsule, compression of adjacent renal parenchyma, multiple proliferative intraluminal papillary projections, and large mucus-filled cystic lumens.

In addition to rectal palpation for a mass in the area of either kidney and examination of urine for RBCs (hematuria), ultrasonographic evidence of a tissue mass destroying the normal architecture of the kidney would support renal neoplasia. Unfortunately, attempts to establish a definitive antemortem diagnosis were successful in only two previous reports. In the first case, neoplastic cells were detected on analysis of a sample of peritoneal fluid,<sup>12</sup> whereas percutaneous biopsy of the tissue mass in a second horse demonstrated neoplastic tissue. Thus these procedures are warranted in all horses with a mass consistent with a renal neoplasm. In addition to analyzing urine for hematuria, cytologic examination of urine for neoplastic cells is also warranted.<sup>33</sup>

The most common presenting complaint for bladder neoplasia is hematuria.<sup>33-35</sup> Unlike dogs, in which transitional cell carcinoma is the most commonly described bladder neoplasm,

TABLE 19-13

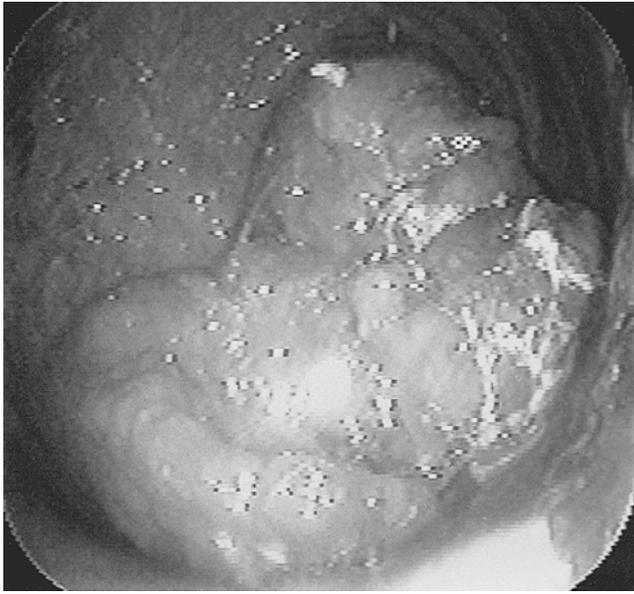

Clinical Features of Fifteen Horses with Renal Cell Carcinoma											
Breed	Age (Years)	Sex	Unilateral or Bilateral	Presenting Complaint	Weight Loss	Pain/Colic	Hematuria	Palpable Mass on Rectal Examination	Azotemia	Postmortem Findings	Reference
American Saddlebred	15	G	Bilateral	Recurrent colic	Yes	Yes	No	Yes	No	25-cm diameter renal calculus, metastases to liver and other kidney	9
Albino	10	F	Unilateral, left	Abortion and ascites	No	No	No	Yes	Mild	75-cm diameter, 31-kg mass, metastases to peritoneum	11
Standard-bred	16	F	Unilateral, right	Weight loss, hematuria	Yes	No	Yes	Yes	No	30-cm diameter, 8-kg mass, adhesions to liver and bowel, no metastases	11
Thoroughbred	16	F	Unilateral, left	Weight loss	Yes	No	Yes	Yes	Mild	35-cm diameter, 20-kg mass, hemoperitoneum, no metastases	12
Thoroughbred	16	F	Unilateral, right	Weight loss, soft feces	Yes	No	No	No	Mild	Metastases to liver and lungs	13
Pony	15	G	Unilateral, left	Weight loss, hematuria	Yes	No	Yes	Yes	No	6.6-kg mass, metastases to liver and lungs	14
Pony	10	G	Unilateral, right	Weight loss, back pain, colic, polyuria/polydipsia	Yes	Yes	Yes	No	No	6-cm diameter mass hemoperitoneum, no metastases	14

\*Paraneoplastic syndrome (hypoglycemia).  
G, Gelding; F, mare; NR, not reported.

**FIGURE 19-43** Leiomyosarcoma of the urinary bladder resulted in hematuria. (Courtesy R. MacKay, University of Florida.)

squamous cell carcinoma has been reported most frequently in horses.<sup>33,34</sup> Other types of bladder neoplasms affecting horses include transitional cell carcinoma, lymphosarcoma, leiomyosarcoma, and fibromatous polyps. In contrast to cattle, which develop bladder neoplasia in association with chronic ingestion of bracken fern and other plants (enzootic hematuria), dietary factors have not been incriminated in development of bladder cancer in horses.<sup>8</sup> One can establish diagnosis of bladder neoplasms by palpation or ultrasonographic imaging of a bladder mass, endoscopic examination and biopsy (Figure 19-43), and urine cytologic examination. Treatment has included partial bladder resection or intravesicular instillation of 5-fluorouracil, but successful outcomes have not been reported.<sup>33</sup> Doxorubicin (30 mg/m<sup>2</sup> IV) therapy was unsuccessful for the treatment of an extensive and poorly differentiated bladder leiomyosarcoma in one case.<sup>36</sup> Again, a poor prognosis likely is related to the extensive bladder involvement by the time clinical signs are apparent.

Tumors of the urethra and external genitalia are the most common urinary tract neoplasms of horses. Although reports describe a paraurethral lipoma<sup>37</sup> and fibrosarcomata<sup>38</sup> resulting in frequent urination or dribbling and UTI, respectively, tumors of the external genitalia are more common than urethral tumors.<sup>39-41</sup> Tumors affecting the external genitalia include squamous cell carcinoma, sarcoid, melanoma, mastocytoma, hemangioma, and papillomata or warts. Habronemiasis used to be a significant cause of genital lesions before the widespread use of ivermectin, and the disease should remain on the differential list because it can be distinguished from squamous cell carcinoma or sarcoid only by examination of a biopsy sample. Biopsy or simple impression smear of *Habronema* lesions will reveal extensive infiltration of eosinophils, which distinguishes habronemiasis from neoplasia. Breeds with nonpigmented genitalia (Appaloosas and Paints) appear to be predisposed to squamous cell carcinoma. Similarly, a predilection for geldings and stallions has been associated with a carcinogenic potential of smegma.<sup>42</sup> Affected horses may have a malodorous sheath or hematuria if the distal urethra is involved. Urinary tract obstruction is uncommon unless the tumors are large. Diagnosis is by

visual examination and collection of a biopsy sample. Collection of the latter often is by complete excision of the lesion. In addition to surgical excision, a rather high rate of recurrence has led to use of a number of adjunct therapies, including immunotherapy, cryotherapy, hyperthermia, and radiation therapy. Some squamous cell carcinomas may respond well to adjunctive treatment with piroxicam (80 mg PO every 24 hours).<sup>43</sup> Tumor response is likely dependent on expression of cyclooxygenase-2 (COX-2) and not all equine squamous cell carcinomas produce COX-2 equally. Piroxicam is a selective COX-2 inhibitor in other species. Inhibition of COX-2 may induce apoptosis in neoplastic cells, inhibit angiogenesis, or act as an immunostimulant. Adverse gastrointestinal effects are possible during piroxicam therapy and may be avoided by administering every 48 to 72 hours. Piroxicam administration has also been recommended in the treatment of transitional cell carcinoma in small animals.<sup>44</sup> Because all treatment combinations have had variable success, some authors recommend aggressive surgical treatment early in the course of the disease.<sup>45</sup> Most recently, local injection of cisplatin, a cytotoxic antineoplastic agent, has been used with a high success rate to treat equine sarcoid and squamous cell carcinoma.<sup>46,47</sup> Topical 5% 5-fluorouracil cream (every 24 hours in mares; every 14 days in males) with or without surgical debulking may be effective for treatment of noninvasive squamous cell carcinoma of the external genitalia.<sup>48</sup>

## URINARY INCONTINENCE AND BLADDER DYSFUNCTION

Warwick M. Bayly

Loss of control of bladder function is an infrequent problem in horses. When the condition is recognized, it is usually because a degree of incontinence develops, which by definition means that intravesicular pressure exceeds resting urethral pressure. Although a number of recognized abnormalities of bladder emptying can afflict human beings, dysfunctions of equine bladder control and micturition tend to fall into one of three categories, with the extent to which they are recognized depending on clinical signs. Basically, the three types of problems are (1) the reflex or upper motor neuron (UMN) bladder (also known as *spastic* or *autonomic bladder*), (2) paralytic or lower motor neuron (LMN) bladder, and (3) the myogenic or non-neurogenic bladder. Either of the last two conditions can be associated with the atonic bladder syndrome, which is probably appropriate given the similarity of clinical signs and subsequent treatment once either of the two types of conditions is recognized. In fact, although signs of UMN bladder problems are initially different from those of the other two groups, this condition in horses also usually is not recognized until a degree of incontinence develops. A final form of bladder neuropathy that has been described in human beings and dogs, but not in horses, is reflex dyssynergia. In this condition, loss of coordination of detrusor contraction and urethral relaxation occurs, with the result that the animal may make efforts to urinate but fail to do so. Such cases frequently appear similar to those of urethral obstruction, and one must distinguish between them.

Although treatment options are limited and tend to be the same, regardless of what type of condition is responsible for the incontinence, determining the origin of the problem

is prognostically important. To accomplish this, the internist needs to have a good working knowledge of how micturition normally is controlled.

## ☞ CONTROL OF MICTURITION

From a neurologic perspective, one can regard the bladder as having a body and an outlet, which can be divided further into the neck (or trigone) and the proximal urethra. Functionally, the bladder alternates between filling and storage and emptying and elimination phases.<sup>1</sup> Dysfunction in any of these areas or phases may result in clinical problems. Somatic innervation is primarily to the striated muscle of the urethra via a branch of the pudendal nerve, which originates from the sacral cord (S1 to S2). Other branches of this nerve go to the anal sphincter and perineum. The sympathetic nerve supply is provided via the hypogastric nerve, with the preganglionic fibers arriving from L1 to L4 and synapsing in the caudal mesenteric ganglion. From there, postganglionic fibers supply the bladder ( $\beta_2$ -receptors) and proximal urethra (primarily  $\alpha_1$ - and some  $\alpha_2$ -adrenergic receptors).<sup>2</sup> Parasympathetic innervation also originates in the sacral cord, with neurons combining to form the pelvic nerve. Many complex interneuronal connections exist between sympathetic and parasympathetic nerves in the wall of the bladder, as well as small adrenergic cells that facilitate contact between sympathetic and parasympathetic pathways.<sup>3</sup> As a result, complete denervation of the bladder is virtually impossible. During the filling phase, the tone of the smooth and striated muscles that together comprise the external and internal urethral sphincters increases. The pudendal nerve and the sympathetic nerves, respectively, innervate these muscles. Contraction of these muscles during filling maintains continence. Although the striated muscle forms a definite sphincter around the pelvic urethra, the anatomic existence of a bona fide internal sphincter is debatable.<sup>4</sup> However, the restriction to urine outflow that follows stimulation of the  $\alpha$ -adrenergic receptors at the neck of the bladder has a sphincterlike effect. The smooth muscle of the bladder, referred to as the *detrusor muscle*, is innervated by the parasympathetic pelvic nerve and  $\alpha_2$ -adrenergic postganglionic fibers.

The storage or filling phase is dominated by sympathetic nerve activity and provides an excellent example of the effects of reciprocal innervation.<sup>5</sup> During filling, the detrusor muscle relaxes because of  $\alpha$ -receptor-mediated inhibition of pelvic nerve afferents and stimulation of sympathetic  $\beta_2$ -receptors in the smooth muscle of the bladder body. The latter is a reflex response that involves sensory input from bladder stretch and pressure receptors via the afferent pelvic nerve fibers to the sacral cord, interneurons in the cord, and pre- and postganglionic sympathetic axons in the hypogastric nerve. Relaxation of this muscle allows accumulation of large volumes of urine with little or no increase in intravesicular pressure.

Intravesicular pressure starts to rise once detrusor muscle fibers are stretched fully. Receptors in the bladder wall detect these increases, and impulses are transmitted via the pelvic nerve and ascending spinoreticular cord tracks to the pons, cerebrum, and cerebellum, where they are interpreted as the sensation of bladder fullness. Signals responsible for voluntary micturition originate in the cerebrum and exert their influence via the brainstem, from which UMNs descend in reticulospinal tracts to the sacral parasympathetic nuclei. This triggers the emptying phase. From these sacral segments, pelvic nerve impulses stimulate detrusor muscle contraction, action

potentials traveling via parasympathetic ganglia in the pelvic plexus or bladder wall to postganglionic fibers that stimulate the smooth muscle. Depolarization waves spread throughout the bladder via tight junctions, resulting in a strong, coordinated, contractile process. Simultaneous inhibition of the pudendal nerve and hypogastric  $\alpha$ - and  $\beta_2$ -sympathetic activity further facilitates detrusor muscle activity and relaxation of the external and internal urethral sphincters, respectively. Part of this inhibitory activity represents reflex neuronal activity linking pelvic and pudendal nerve axons in the sacral cord and inhibiting internuncial connections between sacral segments and the sympathetic neurons in the lumbar cord. Urethral sphincter relaxation also is coordinated centrally in a number of areas, including the cerebellum. Detrusor muscle contraction pulls the bladder neck open, and micturition occurs. The emptying phase ends when the bladder stretch receptors sense that the bladder is empty and afferent parasympathetic (pelvic nerve) impulses cease. Pelvic nerve efferent activity also stops, and pudendal motor and sympathetic nerve activity resumes (because it is no longer inhibited), with the result that the detrusor muscle relaxes, restoring external and internal urethral sphincter tone.

## ☞ CLINICAL SIGNS OF BLADDER DYSFUNCTION

Control of bladder function obviously is complex, and many sites exist from which disruption of normal micturition could originate. In reality, problems are usually detectable in horses only when a degree of incontinence develops, which usually is manifested as constant or periodic dribbling of urine from the vulva or penis. In chronic cases, one frequently finds evidence of scalding and associated depilation of the perineum in mares and of the ventral abdomen in males, as well as the insides of the rear limbs in all animals. Any activity that results in increased intra-abdominal pressure, such as coughing or exercise, may exacerbate signs or else be associated with their initial observation. Adult horses develop these problems much more frequently than do foals.

Academically, being able to differentiate between the different neurogenic forms of bladder dysfunction and those of myogenic origin may seem important. In reality, the clinical signs and treatments tend to be the same, regardless of cause. UMN disease is characterized by increased urethral resistance, despite the presence of a full bladder, and may make catheterization or manual emptying of the bladder via rectal compression difficult. The condition usually occurs in association with broad, deep spinal cord lesions. In horses, these problems rarely are recognized in such cases because of the severe nature of associated clinical problems such as recumbency and myopathies. Frequently, such situations are deemed incompatible with life. (Possibly, a focal lesion caused by a disease such as equine protozoal myeloencephalopathy or an aberrant parasite migration could result in the development of spastic bladder without associated neurologic signs.)

If horses suffering from this type of problem are able to stand, are kept in a sling, or have an isolated problem, then in time they may develop the ability to urinate reflexively. This reflex develops because of the stimulation of pressure receptors connected to pelvic nerve afferents, which reflexively activate pelvic (parasympathetic) nerve efferents and the pudendal nerve. This activation results in detrusor muscle contraction and relaxation of the striated urethral muscle

(external sphincter) leading to frequent urination, especially if the increases in abdominal pressure are regular, as may occur with any movement. These patients usually have some residual volume in the bladder after these voiding episodes. In such cases, urine dribbling usually is reported to occur intermittently, which is an important part of differentiating this type of dysfunction from paralytic (i.e., LMN) causes of incontinence.

As for the LMN bladder, lumbosacral trauma, EHV-1 myeloencephalitis, and cauda equina neuritis are probably the most common causes of this type of dysfunction, although in some parts of the world Sudan grass toxicity<sup>6</sup> and sorghum cystitis-ataxia (enzootic ataxia cystitis)<sup>6,7</sup> are major problems. Tumors of the lumbosacral spinal cord, such as lymphosarcoma and melanomas, are also capable of inducing paralytic bladder. Finally, iatrogenic paralysis after epidural administration of alcohol occasionally has been reported in show horses. Because this practice is taboo, how frequently the procedure leads to this problem is impossible to know.

With a paralytic (LMN) bladder, one usually sees other signs of LMN and lumbosacral dysfunction, including all or some of the following: loss of anal sphincter tone, tail paralysis, analgesia or hypalgesia over the perineum, atrophy of the muscles of the hip and hindlimb, and hindlimb weakness. Damage to the pudendal nerve and loss of external urethral sphincter integrity are therefore particularly important in the development of this problem. The bladder is atonic and distended with the urethral muscles relaxed, which results in urine dribbling because of overflow from the bladder. This incontinence may appear continuous, which helps to differentiate it from spastic (UMN) dysfunction. Sometimes the penis or vulva also may appear paralyzed. The prognosis is usually poor because of the development of secondary cystitis and general damage to the bladder wall and the detrusor muscle.

Myogenic problems occur mainly in geldings. Although myogenic problems can occur after the obstructive effects of cystic calculi and cystitis, the problem generally lacks a specific identifiable cause. The condition generally develops slowly, in association with the accumulation of large amounts of sabulous or mucoid urinary sediment or sludge in the bladder, which mainly is comprised of CaCO<sub>3</sub> crystals. In time, the weight and volume of this material, when coupled with that of normal urine accumulation, progressively stretch the detrusor muscle. Incontinence is not normally notable until the cranial aspect of the bladder begins to protrude over the edge of the pubis, which results in cranial and ventrad displacement of the sediment, with the result that the bladder muscle is stretched beyond its normal modulus of elasticity and normal contraction and micturition is no longer possible. Severe distention and stretching also lead to a breakdown in tight junctions that prevents depolarizing waves from passing from muscle fiber to muscle fiber. Eventually, overdistention becomes so significant that the ability to maintain sphincter function is lost and incontinence develops. These cases usually occur without any other signs of neurologic disease; however, because of the lack of any identifiable cause or specific pathophysiologic mechanism, specific focal lesions of a peripheral nerve such as the hypogastric nerve in fact could lead to a similar syndrome. Certainly, retention of urine in the bladder for any period results in the deposition of large quantities of sediment that in turn exacerbate the problem. One must recognize that part of the problem in cases of myogenic atony may stem

from secondary cystitis, which develops after retention of urine for any period. The urea in retained urine breaks down to ammonia, which is irritating to the mucosal wall. Subsequent inflammation helps to damage the bladder musculature further.

Cystitis and chronic urethritis per se can be non-neurogenic, nonmyogenic causes of apparent incontinence. Irritation of stretch receptors in the bladder wall apparently causes regular stimulation of stretch receptors in parasympathetic afferents and stimulates detrusor contractions that cannot be inhibited voluntarily. This effect results in an apparent increase in the frequency of urination (pollakiuria) and an inability to control when it occurs. The condition frequently is referred to as *urge incontinence* and also may occur in association with a unilateral ectopic ureter in which the bladder is much smaller than usual (because of disuse) and incapable of storing a normal volume of urine. The frequency of micturition again is increased.

Hypoestrogenism also has been reported as a cause of non-neurogenic incontinence in an 18-year-old female Shetland pony.<sup>8</sup> A similar condition has been noted in older spayed bitches. The pathophysiologic mechanism of the condition is not known but probably is linked to a modulating effect of estrogen on the effects norepinephrine exerts on  $\alpha$ -adrenergic receptor activity in the internal urethral sphincter.<sup>9</sup> In the documented case, the patient responded well to small doses (2 mg) of estradiol cypionate given intramuscularly every other day.

A transient postoperative condition that results in urine retention after abdominal or perineal operations has been noted in human beings.<sup>10</sup> The cause has not been explained, although the hypothesis is that a reflex depression of parasympathetic nerves may be responsible for detrusor muscle stimulation. This condition is distinct from that which may be associated with pain and reluctance to contract abdominal muscles after surgery. Whether such a condition exists in horses is unknown.

## ☞ DIAGNOSIS

Careful general physical and neurologic examinations are the basis for characterization of the type of bladder dysfunction that exists in the equine patient and the basis for any efforts aimed at identifying a cause. Although never good, the prognosis appears to be most positive in cases in which the horse still can generate significant increases in intravesicular pressure. Therefore performance of tests aimed at evaluating bladder and urethral pressure-generating capacities may be diagnostically useful. Cystometry, which involves the inflation of the bladder with volumes of sterile water, isotonic saline, or carbon dioxide, has been described in horses and pony mares.<sup>11,12</sup> Briefly, one introduces a large-gauge (No. 30 French) catheter into the bladder and connects it via a three-way stopcock to an infusion pump and pressure transducer. The pressure transducer is connected to a chart recorder. One fills the bladder until micturition occurs. Intravesicular pressure is recorded continuously. Usually a gradual increase in pressure is related to the infusion of fluid until the pressure suddenly rises, reflecting the onset of detrusor muscle contraction. The pressure at the point of this sharp increase is regarded as the contraction threshold. In normal horses, this threshold is about  $90 \pm 20$  cm H<sub>2</sub>O.<sup>11</sup> One determines the urethral pressure profile in the same test by using a catheter with

multiple side openings and positioning the tip at the urethral sphincter. One then fills the catheter with fluid and withdraws it at a constant rate while recording the intraurethral pressure. Normal values are usually greater than 50 cm H<sub>2</sub>O. Pressures were significantly lower in recordings of three incontinent mares.<sup>12</sup> Although these tests have not been used widely, they have considerable prognostic potential. Put simply, the higher the pressures are, the better the prognosis is. One also can determine the distance over which high pressure is present in the urethra from these tests. Such determination also may be important, because it gives some further information on the integrity of the urethral sphincters.

## TREATMENT

Some horses with UMN disease recover gradually, especially if one can determine and treat a specific cause. A major complication with paralytic and myogenic forms of bladder dysfunction is that cases often are not recognized until the atonia is irreversible. By that time the prognosis tends to be poor and identification of an initiating cause is difficult—and likely irrelevant. In such cases, the treatment is often futile; however, one often can determine this definitively only by assessing the response to attempted treatment. Regardless of whether dealing with UMN, LMN, or myogenic disorders, treatment tends to be the same concerning the bladder.

If a definitive cause such as EHV-1 myeloencephalitis or equine protozoal myeloencephalopathy is identified, then one should institute the specific treatment for that disease. Concerning bladder dysfunction, the basic aim is to provide support while hoping for spontaneous recovery, which may take a long time (e.g., months in cases of pelvic nerve damage). A basic aim of therapy is to prevent retention of urine because of the secondary problems that this entails. Therefore promotion of bladder emptying is an important goal that one may attempt to reach by regular catheterization or the use of an indwelling catheter. (In male patients, one normally inserts such catheters via a perineal urethrostomy.) Although facilitating drainage, intermittent or indwelling catheterization appears to predispose the horse to secondary bacterial cystitis and therefore should not be used without some forethought. Some horses that are chronically incontinent seem to survive comfortably without any catheterization.<sup>7</sup> Antimicrobial therapy is important for treating any incontinence cases but is especially critical when one uses indwelling or regular catheterization.

One may give the  $\alpha$ -adrenergic blocker phenoxybenzamine (0.7 mg/kg PO every 6 hours) to eliminate any urethral resistance, thus facilitating emptying in the reflex UMN problem or in situations of great atonic overdistention. Bethanechol chloride is a parasympathomimetic agent resistant to the action of acetylcholinesterase and apparently has a selective effect on the smooth muscle of the gastrointestinal tract and bladder. The drug is used principally to stimulate detrusor muscle activity, and it acts by stimulating postganglionic parasympathetic effector cells rather than motor end plates. The recommended dosage ranges between 0.25 to 0.75 mg/kg subcutaneously three times a day. Starting the horse on the smallest dose is recommended. This drug reportedly has varying results.<sup>13</sup> Bethanechol has no effect when the bladder is completely atonic or areflexic. If the muscle is capable of generating weak contractions, then bethanechol may be useful. One could determine whether contractions are possible by cystometry. Although bethanechol can increase intravesicular pressure, whether it

helps evacuate the bladder also depends on the status of the urethral sphincter and striated muscle. One must remember that drugs such as phenoxybenzamine and bethanechol can have undesired side effects on other body systems. The use of general muscle relaxants and an  $\alpha$ -adrenergic blocker may be useful for achieving urethral muscle relaxation. Diazepam (0.2 to 0.5 mg/kg IV) and dantrolene are the most commonly used relaxants. Diazepam is effective in large doses, which also usually result in sedation. Dantrolene (10 mg/kg PO loading dose; 2.5 mg/kg PO maintenance every 6 hours) slows release of calcium from the sarcoplasmic reticulum and has been tried in dogs with varying effects.

Surgical removal of the sabulous sludge found in a number of these horses has been tried via perineal urethrostomy or cystotomy, with poor results.<sup>14</sup> Removal via cystotomy is not recommended because of difficulties in evacuating the material without contaminating the peritoneal cavity. Perineal urethrotomy, combined with irrigation with large volumes of fluid while the horse is anesthetized, seems to be the most effective way of removing this material. Five affected horses were managed for up to 3 years by repeatedly emptying the bladder through a urinary catheter and using saline lavage with cystoscopic guidance to remove residual sabulous material.<sup>15</sup> The cystitis was treated with antimicrobial and anti-inflammatory medications, and bethanechol chloride was also administered. Frequent catheterization resulted in a urethral stricture in one horse. Four horses returned to work and one was retired because of persistent incontinence.<sup>15</sup> The prognosis for most affected horses is poor because of chronic irreversible changes in the bladder wall, which seem to prohibit any possible return of normal detrusor muscle function.

# DISORDERS OF THE ENDOCRINE SYSTEM

## CHAPTER 20

### ADRENAL GLANDS

Ramiro E. Toribio

In horses, the adrenal glands lie retroperitoneally and embedded in the fat on the medial cranial pole of each kidney. They are red-brown, 7.0 to 8.0 × 3.0 to 3.5 cm, and weigh 15 to 20 g each. Blood supply to the adrenal gland is from the adrenal artery, which arises from either the aorta or the renal artery. Innervation involves sympathetic fibers from the splanchnic nerve. Accessory adrenal cortical tissue may be found in the adrenal gland capsule, periadrenal or perirenal adipose tissue, mesorchium, and in the vicinity of the equine testis.

The adrenal gland comprises two different organs, the *medulla* and the *adrenal cortex*, which differ in their embryologic origin, type of secretion, and function. The medulla is of neuroendocrine origin (neural crest), functionally related to the sympathetic nervous system, and secretes epinephrine and norepinephrine in response to sympathetic stimulation. The adrenal cortex derives from the mesoderm and secretes a different type of hormone, glucocorticoids, which are synthesized from cholesterol. The adrenal gland cortex consists of three zones: (1) the outermost zona glomerulosa, which secretes mineralocorticoids (aldosterone) in response to the renin-angiotensin system and changes in extracellular fluid osmolality; (2) the zona fasciculata, which secretes glucocorticoids (cortisol) in response to adrenocorticotropic hormone (ACTH, corticotrophin) stimulation; and (3) the zona reticularis, which secretes androgens.

Adrenocortical function (glucocorticoids) is controlled by the hypothalamus-pituitary-adrenal (HPA) axis. The hypothalamus secretes corticotrophin-releasing hormone (CRH) and arginine vasopressin (AVP) to stimulate pituitary ACTH secretion, which in turn stimulates the zona fasciculata to secrete cortisol. Subsequently, cortisol inhibits CRH and ACTH secretion as part of a negative-feedback control mechanism.

The adrenal gland cortex is involved in a wide variety of body functions, including maintenance of fluid and electrolyte balance, immunity, defense, and energy metabolism. Removal or destruction of the adrenal glands leads to death unless exogenous adrenocortical hormones are administered. Aldosterone increases renal sodium reabsorption and excretion of potassium. Hyperkalemia and increased activity of the

renin-angiotensin system are the most important factors to stimulate aldosterone secretion. Hyponatremia decreases aldosterone secretion. Cortisol increases gluconeogenesis, causes mobilization of amino acids from extrahepatic tissues to enter the gluconeogenesis, decreases glucose use, increases glucose concentrations, and inhibits insulin actions on glucose uptake and lipogenesis. Cortisol increases fat and amino acid mobilization to make them available during stress. Endogenous glucocorticoids are anti-inflammatory and immunosuppressors; increased cortisol concentrations result in eosinopenia and lymphopenia.

Unlike other species, maturation of the equine fetal adrenal glands occurs in late gestation and continues in the early postnatal period.<sup>1</sup> Diurnal variations in cortisol concentrations are noted in adult horses<sup>2,3</sup> and foals.<sup>4</sup>

### ☞ ADRENAL INSUFFICIENCY

Adrenal insufficiency, also known as *adrenal exhaustion*, *hypoadrenocorticism*, *turnout*, or *steroid letdown syndrome*, is a poorly documented condition in horses. Horses with adrenal insufficiency have low cortisol concentrations and do not respond appropriately to the ACTH stimulation test. Adrenal insufficiency also occurs in critically ill horses (colic, enterocolitis, endotoxemia, sepsis) and septic foals because the adrenal gland is a shock organ, and adrenal hemorrhage, thrombosis, and cortical necrosis may lead to adrenal atrophy and dysfunction.

In adult horses, adrenal insufficiency is often associated with the discontinuation of glucocorticoids or anabolic steroid treatment.<sup>5,6</sup> The adrenal gland response to exogenous ACTH in Thoroughbred horses was not altered by training,<sup>7</sup> and low serum cortisol concentrations were not found in stressed racehorses with a history of poor performance.<sup>8</sup> High plasma cortisol and ACTH concentrations were found in horses after maximal exercise.<sup>9-12</sup> Endurance horses in a 160-km ride had significantly higher midride plasma cortisol concentrations than preride concentrations.<sup>13</sup> A sixfold increase in cortisol secretion rate and a threefold increase in plasma cortisol concentrations was also found in exercising horses.<sup>14</sup>

Horses are suspected of having adrenal insufficiency when they display a history of depression, anorexia, exercise intolerance, weight loss, poor hair coat, lameness, and serum electrolyte derangements. Therefore it is critical to obtain a complete history, including performance, previous diseases, drug administration, and stressing conditions.

Endogenous and exogenous glucocorticoids suppress the HPA axis and induce atrophy of the zona fasciculata. The zona glomerulosa is minimally affected, although electrolyte abnormalities may be present in some cases.

Clinical signs include depression, anorexia, exercise intolerance, weight loss, mild abdominal discomfort, poor hair coat, lameness, and seizures.<sup>5,6,15,16</sup> Serum biochemical analysis may be normal, or hyponatremia, hypochloremia, hyperkalemia, and hypoglycemia may be present.<sup>5,6,15</sup>

Some of the clinical features of equine hypoadrenocorticism (hyponatremia and hyperkalemia without evidence of renal disease) resemble Addison's disease in human beings and small animals; however, Addison's disease has not been documented in the horse.

Adrenal insufficiency is rarely diagnosed in equine practice; however, it should be suspected in any horse with a history of anorexia, lethargy, poor body condition, poor exercise performance, glucocorticoid administration, electrolyte imbalances (hyponatremia, hypochloremia, hyperkalemia), and hypoglycemia. Baseline cortisol and ACTH concentrations, as well as the ACTH stimulation test, are critical to achieve a diagnosis. Cortisol has daily fluctuations, and single measurements do not provide enough information to make a diagnosis of hypoadrenocorticism. Therefore the ACTH stimulation test is more useful in assessing adrenal gland function.<sup>15,16</sup> Horses with adrenal insufficiency have decreased cortisol concentrations and do not or minimally respond to the ACTH stimulation test.<sup>15,17</sup> In addition, measuring ACTH concentrations is important to determine other causes of hypoadrenocorticism (iatrogenic, adrenal, pituitary). It is anticipated that exogenous glucocorticoids decrease ACTH concentrations (secondary hypoadrenocorticism), whereas adrenal gland dysfunction (primary hypoadrenocorticism) is associated with increased ACTH concentrations from decreased endogenous glucocorticoid negative feedback. In horses with increased plasma ACTH concentrations, the clinician must rule out pars intermedia dysfunction.

To perform an ACTH stimulation test, one administers 1 IU/kg of natural ACTH gel intramuscularly between 8 and 10 AM.<sup>17</sup> Immediately before ACTH injection, a blood sample is obtained in heparinized or plain tubes. One obtains additional blood samples 2 and 4 hours after ACTH administration. Horses with a functional adrenal gland should have two- to threefold increases in plasma cortisol concentrations after ACTH stimulation as compared with baseline values.<sup>6,17</sup> To perform the cosyntropin stimulation test, one administers 100 IU (1 mg) of synthetic ACTH (cosyntropin; Cortrosyn) intravenously (IV) between 8 AM and noon.<sup>18</sup> One obtains a baseline, preinjection blood sample and a postinjection sample 2 hours later. As with the ACTH stimulation test, plasma cortisol concentrations should be at least twice baseline in the second sample. ACTH<sub>1-24</sub> (25 IU) can also increase cortisol concentrations to twice baseline in horses.<sup>19</sup>

Necropsy findings of horses with hypoadrenocorticism include adrenocortical hemorrhages and necrosis, as well as adrenal atrophy and fibrosis.

Treatment of hypoadrenocorticism involves rest and glucocorticoid supplementation. The duration and dosage of exogenous steroid treatment that induces adrenocortical atrophy in healthy horses is unknown. However, information on the doses that inhibit adrenocortical function in horses is available. Doses of dexamethasone as low as 4 mg suppress the HPA axis for up to 24 hours.<sup>6</sup> Dexamethasone dosages of

0.044 to 0.088 mg/kg every 5 days for six treatments reduced cortisol concentrations for up to 4 days but did not change the response to ACTH stimulation.<sup>20</sup> Toutain et al.<sup>21</sup> found that dexamethasone (50 µg/kg, IV or IM) suppressed adrenocortical function for up to 4 days, prednisolone sodium succinate (0.6 mg/kg, IV or IM) for less than 24 hours, and prednisolone acetate suspension (0.6 mg/kg, IM) for up to 21 days. Dexamethasone (0.044 mg/kg, IM) and triamcinolone (0.044 mg/kg, IM) produced HPA axis suppression for 7 and 14 days, respectively.<sup>22</sup> A single intra-articular dose of methylprednisolone acetate (200 mg) suppressed adrenocortical function for up to 10 days.<sup>23</sup> Based on this information, prednisolone sodium succinate (up to 300 mg daily) is the first choice to treat hypoadrenocorticism; low doses of dexamethasone are the second option (triamcinolone and prednisolone acetate must be avoided). Alternatively, oral prednisolone (200-400 mg/horse) can be used. A case of hypoadrenocorticism secondary to prolonged anabolic steroid administration was successfully treated with 300 mg of oral prednisone for 9 months.<sup>5</sup> Prednisone (40 mg, PO, b.i.d., or 50 mg, IV) was also used to treat a foal diagnosed with adrenal insufficiency.<sup>15</sup> The efficacy of prednisone as a therapeutic agent in horses is questionable because prednisone is poorly absorbed from the equine intestinal tract and the active metabolite, prednisolone, is rarely produced.<sup>24</sup> In contrast, oral prednisolone has excellent bioavailability and may be more useful as a therapeutic agent in horses. Like with any long-term glucocorticoid therapy, slow withdrawal is recommended.

## ☪ ADRENAL INSUFFICIENCY IN CRITICALLY ILL FOALS

A substantial amount of information on the HPA axis of healthy and critically ill foals has been generated in recent years.<sup>1,4,25-28</sup> In foals, HPA axis dysfunction has been defined as an inappropriately low basal serum cortisol concentration (absolute adrenal insufficiency), an inadequate cortisol response to the ACTH stimulation test (low delta cortisol), and an abnormally high ACTH/cortisol ratio (relative adrenal insufficiency [RAI]).<sup>4,25-27</sup> For an accurate diagnosis of HPA dysfunction, results should be compared with values from healthy age-matched controls or to values generated in the same laboratory.

For many years it was proposed that adrenal insufficiency was a problem in premature and septic foals; however, not until recently was it demonstrated that dysfunction of the pituitary and adrenal glands is a frequent and serious problem in septic foals.<sup>25-27</sup> Hart et al.<sup>26</sup> found that 40% of septic foals had HPA axis dysfunction. Gold et al.<sup>25</sup> determined the ACTH/cortisol ratio in septic foals and found that RAI was common, with nonsurviving foals having the highest ratio. In a similar study, Hurcombe et al.<sup>27</sup> determined the AVP/ACTH and ACTH/cortisol ratios in septic foals and showed that HPA axis dysfunction at the pituitary and adrenal level was frequent in these foals. AVP is a major secretagogue for ACTH in the horse,<sup>29</sup> and a high AVP/ACTH ratio suggests a decreased ACTH response to AVP stimulation (pituitary insufficiency). Similarly, a high ACTH/cortisol ratio indicates decreased adrenal response to ACTH (RAI). The low cortisol concentrations observed in premature foals do not appear to be the result of ACTH insufficiency because high ACTH concentrations have been measured in these foals,<sup>30</sup> supporting adrenal insufficiency as a major problem in premature foals. A number of

studies have found that septic foals with high baseline cortisol concentrations are more likely to die.<sup>25-27</sup>

To assess RAI in sick foals, a cosyntropin stimulation test was recently validated in healthy foals.<sup>4</sup> A baseline blood sample is obtained for cortisol analysis. One then administers 10 µg (low-dose protocol) or 100 µg (high-dose protocol) of IV cosyntropin, and additional blood samples are collected at 30, 60, 90, and 120 minutes. Blood samples for cortisol concentrations can be collected in heparinized tubes or in tubes with no additives. With the 10-µg test, cortisol should peak at a value twice baseline at 30 minutes; with the 100-µg test, cortisol should peak at 90 minutes at two to three times the baseline value. The time of the day did not affect the results of this test.<sup>4</sup> A simplified protocol would be to obtain a baseline blood sample, administer 100 µg of IV cosyntropin, and collect a second blood sample 90 minutes later. With this test it was found that a poor response to 100 µg of cosyntropin (0- and 90-minute samples) was associated with foal mortality.<sup>26</sup>

## ☞ PHEOCHROMOCYTOMA

Pheochromocytomas are tumors that arise from the chromaffin cells of the adrenal medulla, which are part of the sympathochromaffin system (together with the sympathetic nervous system). During fetal life the chromaffin cells are associated with the sympathetic ganglia; after birth most of them degenerate, and the few remaining cells constitute the adrenal medulla. In human beings, approximately 90% of pheochromocytomas arise from the adrenal medulla, and often times are associated with a condition known as *multiple endocrine neoplasia* (MEN).<sup>31</sup> Extra-adrenal pheochromocytomas have been described in human beings but not in horses. In horses these tumors have a low incidence of malignancy and predominantly are unilateral.<sup>32,33</sup> Pheochromocytomas may be functional or nonfunctional. Functional pheochromocytomas secrete catecholamines at a rate sufficient to cause clinical signs.<sup>33</sup> Thus functional pheochromocytomas are diagnosed with more frequency than nonfunctional pheochromocytomas.<sup>34</sup> It is speculated that most equine pheochromocytomas are nonfunctional and go undiagnosed.<sup>35</sup> Both epinephrine and norepinephrine have been identified as the catecholamines produced by equine pheochromocytomas.<sup>36</sup>

Functional pheochromocytomas in horses have no breed or gender predilection<sup>33</sup> and have been described in horses older than 12 years.<sup>34,37</sup> Because clinical signs are of acute onset and of rapid progression from intense adrenergic stimulation, the clinical signs resemble those of colic, rhabdomyolysis, acute laminitis, enterocolitis, and hyperkalemic periodic paralysis. Clinical signs include abdominal pain from large hematomas or gastrointestinal distension secondary to ileus, anxiety, tachycardia, tachypnea, profuse sweating, muscle tremors, hyperthermia, dry and pale mucous membranes, increased capillary refill time, ataxia, and mydriasis.<sup>33,34,37</sup> Abortion has been documented. Clinical signs from nonfunctional pheochromocytomas in general are consistent with abdominal pain.<sup>33,35,37</sup>

Hematologic abnormalities of functional pheochromocytomas include hemoconcentration, stress leukogram (mature neutrophilia with lymphopenia),<sup>37</sup> and leukopenia with neutropenia.<sup>34</sup> Hemoconcentration likely results from epinephrine-induced splenic contraction rather than dehydration.<sup>34,35,37</sup> Epinephrine and epinephrine-induced steroid release may be responsible for the stress leukogram. Serum

biochemical abnormalities are nonspecific and include azotemia, metabolic acidosis, hyperglycemia, hyponatremia, hyperkalemia, hypocalcemia, and hyperphosphatemia.<sup>33,37</sup> Hyperglycemia is likely a consequence of increased  $\alpha$ - and  $\beta$ -adrenergic activity.<sup>31</sup> Hyponatremia with hyperkalemia, hypocalcemia, and hyperphosphatemia suggests acute renal failure; however, renal function in most reported cases was normal.<sup>34,35</sup> Hyperkalemia, hypocalcemia, and hyperphosphatemia could be the result of prolonged muscle activity and ischemia.<sup>33-35,37</sup> Hyperkalemia is unlikely to be from increased catecholamine concentrations because catecholamines induce hypokalemia by shifting potassium to the intracellular compartment ( $\beta$ -receptor mediated) and by increasing the activity of the renin-angiotensin system.<sup>38</sup> Glucosuria is also a frequent finding. Pheochromocytomas may secrete other hormones of neuroendocrine origin (calcitonin [CT], parathyroid hormone [PTH], ACTH, corticotropin-releasing hormone, somatostatin (SST), vasoactive intestinal peptide, leu-enkephalin);<sup>34,39-41</sup> however, this remains to be determined in horses.

The clinician should be aware that this condition carries a poor prognosis, and euthanasia may be a reasonable decision. Measurement of blood catecholamines or their metabolites in urine is valuable in establishing a diagnosis; however, this assessment can be a challenge, and most laboratories do not measure these hormones.<sup>33,34,37,42</sup> Ultrasonography and measurement of blood pressure (BP) can support the diagnosis.

If a diagnosis is reached, adrenalectomy can be attempted; however, the location of the adrenal glands, as well as the proximity of major blood vessels, tumor size, and arrhythmias (interaction between catecholamines and anesthetic agents),<sup>35</sup> make this a difficult decision.<sup>33,35,37</sup> Hypotensive  $\alpha$ -adrenergic antagonists such as phentolamine, phenoxybenzamine hydrochloride, and prazosin hydrochloride are used in human beings with functional pheochromocytomas before surgery.

Functional pheochromocytomas in horses do not appear to metastasize, are unilateral, tend to bleed, and at necropsy the tumor is frequently found to be ruptured. Myocardial infarction and degeneration may be present, probably the result of increased concentrations of catecholamines.<sup>33-35</sup>

Malignant pheochromocytomas have been documented in young and old horses.<sup>43,44</sup> A malignant pheochromocytoma was reported in a 6-month-old filly with a history of hindlimb lameness and spinal cord disease.<sup>44</sup> Both adrenal glands had multiple and well-circumscribed yellow masses, and metastases were found in the liver, lungs, vertebral canal, left scapula, and azygous vein. A malignant pheochromocytoma was also diagnosed in a 22-year-old mare that died of massive intrauterine hemorrhage.<sup>43</sup> This mare also had a thyroid C cell medullary adenoma and bilateral nodular hyperplasia of the adrenal medulla, findings that were consistent with MEN. This was the first documented case of MEN in the horse, although previous reports have been consistent with MEN.<sup>45</sup>

## ☞ HYPERADRENOCORTICISM

Hyperadrenocorticism from pituitary pars intermedia dysfunction (PPID; equine Cushing's disease) is discussed elsewhere in this text. Iatrogenic and adrenal hyperadrenocorticism are less common than pituitary-dependent hyperadrenocorticism (PDH) but have been described in horses.<sup>46-48</sup>

Iatrogenic hyperadrenocorticism was induced in a horse treated for a pruritic skin condition, after injecting 12 mg of triamcinolone acetonide followed by two injections of 200 mg of the same compound, all within 6 weeks.<sup>46</sup> Clinical signs included depression, polyuria-polydipsia, weight loss, and laminitis. Blood and urinalysis abnormalities (neutrophilia, lymphopenia, hyperglycemia, glucosuria) were similar to those of PPID. However, this horse also had increased serum activity of  $\gamma$ -glutamyltransferase (GGT), aspartate transaminase, and bile acid concentrations, indicating steroid-induced hepatopathy.

The diagnosis of iatrogenic hyperadrenocorticism is based on clinical history, low baseline ACTH and cortisol concentrations, and a low cortisol response to the ACTH stimulation test. Treatment consists of discontinuing exogenous steroids.

One case of pituitary-independent (adrenal dependent) hyperadrenocorticism has been documented in the literature.<sup>48</sup> In this case, a 12-year-old gelding displayed clinical signs of PDH. Baseline cortisol and ACTH concentrations were within the normal range, and the cortisol response to the ACTH stimulation test was normal. The horse was treated with bromocriptine with no improvement; over the next 11 months the clinical signs worsened. On necropsy, an adrenocortical adenoma associated with pituitary gland and contralateral adrenal gland atrophy was present.

## ADRENOCORTICAL NEOPLASIA

Adrenocortical tumors are rare in horses,<sup>19,48-50</sup> and the few cases reported in the literature were nonfunctional tumors. One case of a 12-year-old Dutch Warmblood gelding with a functional adrenocortical adenoma and clinical signs consistent with Cushing's disease (hyperadrenocorticism) was recently reported.<sup>48</sup>

## THYROID GLAND

Ramiro E. Toribio

The thyroid gland has two embryological origins: the *endoderm of the primitive larynx* that will give rise to the follicular cells that secrete thyroid hormones (THs) and the *ultimobranchial body of the fourth pharyngeal pouch* that contains neuroendocrine cells that will give rise to the C cells (parafollicular cells) that secrete CT.

In the horse, the thyroid glands are two discrete, firm lobes located in the dorsolateral aspect of the third to sixth tracheal rings.<sup>1,2</sup> The two lobes are connected by a narrow isthmus that contains fibrous tissue. In most healthy horses the thyroid glands are not visible but can be palpated as firm and movable structures. The weight of the thyroid glands relative to body weight is largest for fetuses and foals (mean, 0.28 g/kg; range, 0.12 to 0.67) and decreases with age; the ratio for adults is 0.08 g/kg (range, 0.01 to 0.15).<sup>3</sup> The normal total gland weight for newborn foals is around 15 g.<sup>4</sup> The glands are very vascular, receiving blood supply from two major arteries that arise from the external carotid and subclavian arteries. Thyroid gland blood supply is relatively greater (4 to 6 ml/min/g) than other highly vascular organs. Gland size does not parallel function, and functional tests must be used to establish an accurate diagnosis of thyroid dysfunction.

### BOX 20-1

#### COMMON ABBREVIATIONS ASSOCIATED WITH THE THYROID GLAND

TH	Thyroid hormone
HPT axis	Hypothalamus-pituitary-thyroid axis
TSH	Thyroid-stimulating hormone
DA	Dopamine
SST	Somatostatin
NIS	Na <sup>+</sup> /I <sup>-</sup> symporter
MIT	Monoiodotyrosine
DIT	Diiodotyrosine
T <sub>4</sub>	Thyroxine
T <sub>3</sub>	Triiodothyronine
TBP	Thyroid-binding proteins
TBG	Thyroid-binding globulin
TBPA	Thyroid-binding prealbumin
NTIS	Nonthyroidal illness syndrome
MEN	Multiple endocrine neoplasia
TRH	Thyrotropin-releasing hormone

## THYROID HORMONE FUNCTION

Understanding TH functions is important for the diagnosis and treatment of thyroidal and nonthyroidal diseases (Box 20-1). THs (triiodothyronine-T<sub>3</sub>, thyroxine-T<sub>4</sub>) are important in cell growth, differentiation, and metabolism in nearly all tissues.

The synthesis and secretion of THs is regulated by a negative-feedback system that includes the hypothalamus, the pituitary gland, and the thyroid gland (hypothalamus-pituitary-thyroid [HPT] axis). TH synthesis and secretion is stimulated by thyroid-stimulating hormone (TSH, thyrotropin), which is a glycoprotein with two subunits ( $\alpha$  and  $\beta$ ) secreted by the thyrotropes of the anterior pituitary gland. The  $\alpha$  subunit of TSH is shared with other pituitary hormones (luteinizing hormone, follicle-stimulating hormone). TSH secretion is controlled by hypothalamic neurons that release a tripeptide, thyrotropin-releasing hormone (TRH).<sup>5</sup> TSH synthesis and secretion is also under the control of the negative feedback of THs.<sup>6</sup> The hypothalamus can also inhibit TSH secretion through dopamine (DA) and SST.<sup>7</sup> In the pituitary, T<sub>3</sub> decreases the TSH response to TRH stimulation, and in the hypothalamus, T<sub>3</sub> decreases the mRNA expression and secretion of TRH.<sup>8-10</sup> In the pituitary gland and central nervous system (CNS), a type II deiodinase converts T<sub>4</sub> to T<sub>3</sub>. For T<sub>4</sub> to gain access to hypothalamic neurons it must be transported through the choroid plexus to the lateral ventricles bound to transthyretin (T<sub>4</sub>-binding protein). In various species, including the horse, TRH induces prolactin release.<sup>11-14</sup>

## THYROID HORMONE METABOLISM

A major function of the thyroid gland is to actively trap and conserve iodine against a large concentration gradient.<sup>1,7,15</sup> Iodine can be absorbed in its soluble form, iodide (I<sup>-</sup>), via the intestinal mucosa or any moist body surface or broken skin.<sup>1</sup> Iodide is actively transported and concentrated into the thyroid by a Na<sup>+</sup>/I<sup>-</sup> symporter (NIS).<sup>16</sup> The trapped iodide is oxidized by a thyroid peroxidase and incorporated into the tyrosine residues of thyroglobulin to form the inactive precursors, monoiodotyrosine (MIT) and diiodotyrosine (DIT). Coupling of these precursors results in the synthesis of thyroxine (T<sub>4</sub>) and triiodothyronine (T<sub>3</sub>). The iodinated thyroglobulin containing MIT, DIT, T<sub>3</sub>, and T<sub>4</sub> is stored as an extracellular polypeptide in the colloid of the thyroid follicles.<sup>17</sup> When needed, T<sub>4</sub> and T<sub>3</sub> are cleaved from the thyroglobulin, picked up by the follicular cells via endocytosis, and transported into the circulation.<sup>1,7</sup> Most of the TH released into circulation is T<sub>4</sub>, because total serum T<sub>4</sub> concentrations are 20 times higher than serum T<sub>3</sub>. Hormone synthesis and release are controlled by TSH and iodine availability. The feedback regulation of TSH secretion is closely related to the circulating concentrations of unbound (free) THs (fT<sub>4</sub> and fT<sub>3</sub>).<sup>1,7</sup>

The circulating THs are T<sub>4</sub>, T<sub>3</sub>, and reverse T<sub>3</sub> (rT<sub>3</sub>). Free T<sub>4</sub> and T<sub>3</sub> are the biologically active hormones. T<sub>3</sub> and rT<sub>3</sub> are both deiodination products of T<sub>4</sub>. All of the circulating T<sub>4</sub> is directly derived from the thyroid gland, whereas only 10% to 20% of the circulating T<sub>3</sub> is directly secreted from the thyroid gland. The major pathway for the production of T<sub>3</sub> is the 5'-monodeiodination of T<sub>4</sub> by a type I deiodinase (a selenoprotein) in peripheral tissues. This is referred to as *T3 neogenesis*. In the fetus, type I deiodinase activity is delayed, so T<sub>3</sub> neogenesis is low, and most deiodinase activity results in high concentrations of rT<sub>3</sub>. A switch in enzymatic activity near birth, partly the result of the influence of glucocorticoids, leads to high T<sub>3</sub> concentrations in newborns, including foals.<sup>7,18-22</sup> THs circulate bound to plasma proteins (thyroid-binding proteins [TBP]). Thyroxine-binding globulin (TBG) is the major protein (70% of T<sub>4</sub> and T<sub>3</sub> are bound to TBG); transthyretin (thyroid-binding prealbumin [TBPA]), and albumin bind to a lesser degree. In horses, the percentages of circulating T<sub>4</sub> bound to TBG, TBPA, and albumin is 61%, 22%, and 17%, respectively.<sup>23</sup> T<sub>3</sub> is bound to TBG and albumin but not to TBPA. Transthyretin is important to transport T<sub>4</sub> into the CNS. As THs are reversibly bound to transport proteins they act as TH reservoirs. T<sub>4</sub> has much greater protein-binding affinity and is considered a prohormone. Only free, unbound hormones cross the capillary endothelium to exert their biologic functions.<sup>24</sup> T<sub>3</sub> is much more potent than T<sub>4</sub>, and it has a shorter half-life. The half-life of T<sub>4</sub> in horses is approximately 50 hours.<sup>25</sup> Because a large fraction of THs are bound to plasma proteins, changes in protein concentrations may change total TH concentrations.

The enzymes responsible for the production of T<sub>3</sub> and rT<sub>3</sub> are also responsible for their inactivation. Three classes of 5'-deiodinases exist. *Type I deiodinase* is predominantly found in peripheral tissues such as thyroid, kidney, and liver, and is responsible for the conversion of most of T<sub>4</sub> to T<sub>3</sub> and rT<sub>3</sub>, and is inhibited by propylthiouracil (PTU). Type I deiodinase activity is increased by TSH and T<sub>3</sub>, and in hyperthyroidism, and it is decreased in hypothyroidism. *Type II deiodinase* is found in brown fat tissue, brain, and pituitary gland, is not affected by PTU,<sup>7</sup> and its primary function is to convert T<sub>4</sub> to T<sub>3</sub>

in the intracellular compartment.<sup>17</sup> Type II deiodinase activity is increased in hypothyroidism, and is likely to sustain intracellular T<sub>3</sub> concentrations despite low peripheral T<sub>4</sub> concentrations, especially in the nervous system. *Type III deiodinase* is found in the placenta, developing brain, and skin, and its primary function is to inactivate T<sub>4</sub> and T<sub>3</sub> (converts T<sub>4</sub> to rT<sub>3</sub>, inactivates T<sub>3</sub>) to regulate T<sub>3</sub> availability during development. The generation of inactive rT<sub>3</sub> by type I and III deiodinases is essential in the regulation of TH function. Metabolites are excreted via the urine, and some are conjugated and enter the enterohepatic circulation. Most iodide is returned to the thyroid gland.

The thyroid gland is also the site of production of CT, secreted by the parafollicular cells (C cells). CT is involved in calcium homeostasis.<sup>1,7,26</sup>

## MOLECULAR ACTIONS OF THYROID HORMONES

The TH receptors belong to the superfamily of nuclear receptors that work as transcription factors. Two types of TH receptors exist (TR- $\alpha$  and TR- $\beta$ ). T<sub>3</sub>, directly transported into the cell or derived intercellularly from T<sub>4</sub>, is the effector hormone. TH receptors interact with specific DNA sequences to regulate gene expression. Growth, thermogenesis, and energy metabolism depend on THs. T<sub>3</sub> stimulates thermogenesis, oxidative phosphorylation, oxygen consumption, protein synthesis, metabolic rate, carbohydrate absorption, glucose metabolism, lipid metabolism, lipoprotein lipase, lipolysis, and the conversion of cholesterol into bile salts. T<sub>3</sub> is also important for growth, maturation, and erythropoiesis, stimulation of heart rate, cardiac output, and blood flow, as well as critical for cerebral and neuronal development in young animals.<sup>1,15</sup> T<sub>3</sub> decreases the expression and synthesis of TSH and TRH.

## ☞ FACTORS THAT AFFECT THYROID GLAND FUNCTION AND TESTING

Many endogenous and exogenous factors can affect thyroid function and test results. Being aware of these factors is important in the interpretation and establishment of an accurate diagnosis and treatment.

### AGE

Age-related differences exist in TH concentrations in horses. Late in gestation a powerful central drive exists to stimulate the HPT axis.<sup>24</sup> Serum concentrations of T<sub>3</sub> and T<sub>4</sub> in foals are very high at birth and decrease with age,<sup>18-22,27,28</sup> with most of the decline occurring in the first 3 to 4 months of life.<sup>20,29</sup> Total T<sub>4</sub>, fT<sub>4</sub>, total T<sub>3</sub>, and fT<sub>3</sub> concentrations in the umbilical cord blood of newborn foals were found to be 14, 5, 7, and 3 times the adult concentrations, respectively.<sup>24</sup> At birth, plasma rT<sub>3</sub> declined rapidly as T<sub>3</sub> concentrations rose for the first 24 to 48 hours after birth.<sup>24</sup> Another study found that plasma T<sub>3</sub> concentrations decreased from 7.9 ng/ml at birth, to 0.9 ng/ml at 6 months, to 0.7 ng/ml at 9 months old.<sup>22</sup> Plasma T<sub>3</sub> concentration in mares was 0.5 ng/ml. In the same study, T<sub>4</sub> concentrations decreased from 233 ng/ml at birth to 49 ng/ml at 14 days and to 35 ng/ml at 6 months. Thus TH concentrations in newborn foals are ~10-fold higher than in adult horses, and TH concentrations in the range of adults may indicate a hypothyroid state.

## GENDER AND BREED

A clear association does not exist between gender and TH concentrations. Various studies have found higher concentrations in male horses,<sup>18,30,31</sup> lower concentrations in stallions and geldings,<sup>28,32</sup> or lower concentrations in mares than in stallions,<sup>30</sup> whereas others have found no differences.<sup>29,33-35</sup> No evidence indicates that TH concentrations differ among breeds.<sup>18,35</sup>

## PHYSIOLOGIC STATUS

Mares tested at all stages of the estrous cycle had no differences in TH concentrations.<sup>34</sup> T<sub>4</sub> concentrations, however, were lower after ovulation, which is the opposite pattern seen in other species. Higher TH concentrations have been reported in pregnant mares,<sup>36</sup> which is similar to other species.<sup>7</sup> This may be due in part to the increased TBG concentrations during gestation.<sup>7</sup> T<sub>4</sub> concentrations were statistically higher between days 49 and 55 of gestation as compared with mares in advanced pregnancy; however, T<sub>3</sub> did not vary with gestation.<sup>37</sup> Other studies found no differences between pregnant and nonpregnant mares.<sup>25,32</sup>

## HORMONES

Exogenous and endogenous glucocorticoids suppress pituitary TSH secretion, decrease the response of TSH to TRH, inhibit deiodination (except in the perinatal period where the conversion of T<sub>4</sub> to T<sub>3</sub> is enhanced), and decrease TH release.<sup>7,38</sup> Glucocorticoids decrease serum T<sub>4</sub> and T<sub>3</sub> concentrations, with the effect being more profound on T<sub>3</sub>.<sup>6</sup> Dexamethasone administration to healthy horses for 5 days did not change total T<sub>3</sub> and total T<sub>4</sub> concentrations, but it increased serum rT<sub>3</sub> and fT<sub>3</sub> concentrations and blunted the fT<sub>3</sub> response to TSH stimulation.<sup>39</sup> Catecholamines enhance the rate of deiodination of T<sub>4</sub> to T<sub>3</sub>, and have potentiating effects.<sup>40</sup> Estrogen enhances TBG production, whereas androgens tend to suppress it.<sup>7</sup> Oral administration of levothyroxine to healthy horses blunts the TSH and TH response to TRH stimulation.<sup>41</sup>

## SEASON AND DAILY RHYTHM

Cold temperatures stimulate and high temperatures inhibit the HPT axis.<sup>25,42,43</sup> A daily rhythm in TH concentrations has been identified in horses.<sup>44,45</sup> In geldings, T<sub>4</sub> peaked around 4 PM (2.4 ± 0.8 µg/dl), with the lowest T<sub>4</sub> values around 4 AM (1.8 ± 0.6 µg/dl). T<sub>3</sub> peaked between 8 AM and 4 PM (54 ± 13 ng/dl), with the lowest T<sub>3</sub> values around midnight (38.7 ± 10.8 ng/dl).<sup>44</sup> Higher T<sub>4</sub> concentrations between 5 and 8 PM, with lowest concentrations at 8 AM were reported in another study.<sup>45</sup> Diurnal variations in glucocorticoid concentrations appear to control the diurnal variations in TH by suppressing the pituitary response to TRH.<sup>46</sup>

## DISEASES: NONTHYROIDAL ILLNESS SYNDROME

Stress, illnesses, systemic inflammation, and starvation suppress the HPT axis. Because no clinical evidence indicates that low TH during disease is directly associated with hypothyroidism, this condition has been called the *low T3 syndrome* or the *euthyroid sick syndrome*. The designation *nonthyroidal illness*

*syndrome* (NTIS) has been proposed because it does not presume the metabolic status of the patient.<sup>47</sup> In this syndrome, T<sub>3</sub> concentrations are decreased, whereas T<sub>4</sub> concentrations can be low, normal, or elevated. In critically ill human patients, a significant decrease in T<sub>4</sub> and T<sub>3</sub> or an increase in rT<sub>3</sub> concentrations is associated with increased mortality rate.<sup>47</sup> Low TH concentrations were found in premature and septic foals,<sup>48</sup> confirming that NTIS occurs in newborn foals. Low TH concentrations are a common finding in obese horses with insulin resistance (IR) (metabolic syndrome). Hypothalamic and pituitary dysfunction appears to be the proximal cause of NTIS,<sup>47</sup> because administration of TRH to patients with NTIS increases TSH, T<sub>4</sub>, and T<sub>3</sub> release.<sup>49</sup> Although NTIS is a hypothyroid state, no evidence indicates that target tissues are chemically hypothyroid.<sup>47</sup>

Cytokines, glucocorticoids, and more recently, leptin are the key candidates in the pathogenesis of NTIS. Cytokines such as IL-1, IL-6, and TNF-α suppress TSH, T<sub>4</sub> and T<sub>3</sub> synthesis and secretion. IL-1 impairs TH synthesis, whereas IL-6 and TNF-α decrease T<sub>4</sub> and T<sub>3</sub> concentrations and increase rT<sub>3</sub> concentrations. Glucocorticoids are negative regulators of thyroid function; increased cortisol concentrations can be present in horses under different conditions, including stress, sepsis, obesity, IR, and pituitary gland dysfunction (Cushing's disease), and low TH concentrations can be measured in the same animals. The role of leptin in the pathogenesis of NTIS relates to caloric intake. A decline in energy intake decreases leptin concentrations, which reduces the hypothalamic synthesis of TRH.<sup>50</sup> No clear evidence indicates that TH replacement therapy in human beings or animals with NTIS is either beneficial or harmful. Some believe that replacement therapy may be harmful because exogenous TH may inhibit the HPT axis. The only clear indication for exogenous supplementation of THs in horses is to induce weight loss and enhance insulin sensitivity in obese animals, in particular those with metabolic syndrome.<sup>51</sup>

## ACTIVITY

Several studies have found increased T<sub>4</sub> concentrations in horses in training.<sup>19,52,53</sup> Another investigator documented increases in T<sub>4</sub> within 30 minutes after exercise, with no differences in T<sub>3</sub>.<sup>33,36</sup> Five minutes after a maximal speed race (1200 m), serum T<sub>3</sub> concentrations increased in Thoroughbred racehorses (from 55.6 ± 2.9 to 81.0 ± 3.7 ng/dl); however, T<sub>4</sub> concentrations did not change (0.67 ± 0.04 to 0.70 ± 0.05 µg/dl).<sup>54</sup> Significant increases in T<sub>3</sub> and T<sub>4</sub> concentrations were found 1 hour after swimming.<sup>55</sup>

## FEEDING

Feeding a high-energy and high-protein diet to weanlings stimulated TH secretion with a subsequent decrease 3 hours after each meal.<sup>56</sup> Soluble carbohydrates (glucose) rather than protein appear to be responsible for the TH increase in weanlings.<sup>57</sup> The conversion of T<sub>4</sub> to T<sub>3</sub> after a carbohydrate meal was associated with insulin release.<sup>58</sup> This response to carbohydrates is age dependent; by the time horses were 12 to 14 months old, feeding high-carbohydrate and protein diets had minimal effect on TH concentrations.<sup>58</sup> One study in ponies found greater T<sub>3</sub> concentrations when the animals were fed once a day rather than six times a day.<sup>59</sup>

Starvation in different species, including the horse, decreases T<sub>3</sub> and fT<sub>3</sub> concentrations.<sup>47,60,61</sup> Carbohydrate

deprivation inhibits the deiodination of  $T_4$  to  $T_3$  (by the type I deiodinase) to decrease  $T_3$  and increase  $rT_3$  concentrations. Because starvation decreases the basal metabolic rate, the decrease in TH concentrations appears to be an adaptive process to conserve energy. In these animals, TSH concentrations are low or within the normal range despite low TH concentrations. When the effect of food deprivation on baseline TH concentrations was evaluated in euthyroid horses,<sup>61</sup> it was found that serum  $T_3$ ,  $fT_3$ , and  $fT_4$  concentrations decreased, whereas  $rT_3$  concentrations increased after 1 day of food withdrawal. Serum  $T_3$  concentrations were lowest after 2 days of deprivation, whereas  $T_4$ ,  $fT_3$ , and  $fT_4$  reached their lowest concentrations on day 4 of deprivation. Three days after the horses were placed on their normal ration, serum  $T_4$  and  $fT_4$  concentrations increased significantly, and  $rT_3$  concentrations decreased.<sup>61</sup> Prolonged food restriction to Shetland ponies also decreased serum  $T_3$  and  $fT_3$  concentrations.<sup>62</sup> These studies provided valuable information in the interpretation of TH concentrations in anorectic and sick horses. If a decrease (>50%) in serum  $T_3$  and  $T_4$  concentrations can be present in 1 to 2 days of food deprivation, then the validity of measuring TH in diseased horses is questionable.

The mechanisms that regulate thyroid gland function during starvation remain unclear. The adipocyte-derived hormone leptin, which is the main regulator of hunger, is the critical neuroendocrine signal that regulates the HPT axis during fasting and disease.<sup>63</sup> Leptin concentrations decrease during starvation to increase appetite and conserve energy. Feed restriction decreases and excessive caloric intake increases leptin concentrations in horses,<sup>64-66</sup> with THs following similar patterns.<sup>47,60,61</sup> Even though information on leptin has been published in horses and foals,<sup>64,67,68</sup> its direct role on thyroid gland function is unknown.

## EXOGENOUS COMPOUNDS

Goitrogenic substances such as thiocyanate and perchlorate compete with iodide uptake. Iodide oxidation and coupling of iodotyrosines are inhibited by drugs such as sulfonamides, phenylbutazone, phenothiazines, thiouracils, thiopental, and methimazole. A recent study found no effect of trimethoprim-sulfadiazine on equine thyroid function.<sup>69</sup> Soybean meal, linseed meal, and plants of the Brassicaceae family. (i.e., rapeseed) contain goitrogenic substances.<sup>1,15</sup> Phenylbutazone administration decreases TH concentrations in horses,<sup>45,70</sup> and this effect can last up to 10 days after discontinuation of phenylbutazone administration.<sup>70</sup> The TSH stimulation test may be normal or exacerbated in horses receiving phenylbutazone.<sup>45</sup> High levels of nitrates in the water may induce thyroid gland hypertrophy,<sup>71</sup> because nitrates reduce the iodine transport into the thyroid gland.

PTU, in addition to affecting iodine metabolism, inhibits the peripheral conversion of  $T_4$  to  $T_3$ . In human beings, aspirin competes for TH binding sites on transthyretin and TBG, decreasing  $T_4$  and  $T_3$ , and increasing  $fT_4$  and  $fT_3$ . This results in a hypermetabolic state from the increased free fractions of  $T_4$  and  $T_3$ .<sup>38</sup> Anabolic steroids can decrease TBG concentrations<sup>7</sup>; however, short-term administration of anabolic steroids to horses did not affect thyroid function tests.<sup>72</sup> Exogenous compounds containing iodine or iodides are of particular interest. Iodine excess, as well as deficiency, can induce thyroid dysfunction and interfere with thyroid tests. Horses are exposed to iodine or iodide compounds in the form of feedstuffs,

expectorants, leg paints, shampoos, injectable counterirritants, radiographic contrast media, and antiprotozoal drugs (iodochlorhydroxyquin). Animals can respond to excessive amounts of iodine by either suppressing or accelerating hormone production.

Iodine excess reduces iodine uptake and organification, decreases TH concentrations and the response to the TSH stimulation test, and inhibits the cleavage of  $T_4$  and  $T_3$ ; this phenomenon is known as the *Wolff-Chaikoff effect*. The end result of iodine excess may be hypothyroidism. The second way an animal can respond to large amounts of iodide is by elevating TH production. This is referred to as *Jod-Basedow phenomenon*, and in general it is seen in individuals with iodine deficiency.<sup>7</sup>

Newborn foals of mares grazing *Neotyphodium coenophialum*-infected fescue had lower  $T_3$  concentrations than controls,<sup>73</sup> with no differences in  $T_4$  and  $rT_3$  concentrations. Endophyte alkaloids are dopaminergic  $D_2$ -receptor agonists, and DA is an inhibitor of TSH secretion. It is not clear whether the low TH concentrations in these foals is the direct effect of endophyte alkaloids on the fetal HPT axis or on placental and fetal development. Endophyte alkaloids do not appear to affect thyroid function in adult horses.<sup>74</sup>

## ☞ DIAGNOSTIC TESTS

Unlike human practice in which a combination of functional and direct measurements of THs are often used, in equine medicine clinicians are far from assessing thyroid gland function in an organized manner. The traditional approach is to determine TH concentrations (compared with reference values) and make a diagnosis and specific recommendations, in many cases ignoring the underlying cause of abnormal TH concentrations. Normal TH concentrations have a wide range of values and vary among laboratories and measurement techniques (Tables 20-1 and 20-2). For consistent results the practitioner should use the same laboratory. Ratios of circulating hormones may be indicative of dysfunction.

Tests to assess thyroid gland function can be classified as *functional*, *causative*, and *anatomic*. Thyroid tests can be *direct* when serum TH concentrations or thyroid-regulating hormone concentrations are measured; they can be *indirect* when TH concentrations are calculated or when metabolites related to thyroid function are determined.

The  $T_4$  secretion rate (TSR) is a functional test that calculates  $T_4$  secretion after<sup>83</sup> iodide injection. This method is not clinically practical.<sup>19</sup>

Immunoassays are currently used to measure total  $T_4$  and  $fT_4$  concentrations. Equilibrium dialysis is the most accurate method to measure the free fractions of THs; however, it is being replaced by immunoassays. Several radioimmunoassays (RIAs) are validated for equine TH concentrations.<sup>35,84</sup> Quantification of  $T_4$  and  $T_3$  with RIA is not affected by hemolysis.<sup>85</sup> Enzyme-linked immunosorbent assays (ELISA) and immunoluminescence methods are also available. The unbound or free fractions of THs must be measured to determine available hormone to target tissues.<sup>86</sup>

Serum is the preferred sample to measure  $T_4$  and  $T_3$  concentrations, although heparin or EDTA plasma can be used.  $T_4$  is stable in serum at 4° C for several weeks. The clinician should avoid using hemolyzed and lipemic samples, as well as samples from horses receiving "thyroid supplements" (a common practice).

Free THs circulate in blood in equilibrium with protein-bound THs, and changes in TBP (TBG, TBPA, albumin) can affect the total TH concentration. Immunoassays to determine human TBG concentrations are available but are not validated in horses.

In various species the ratio of circulating total T<sub>4</sub> to T<sub>3</sub> is 20:1. In horses, the T<sub>4</sub>/T<sub>3</sub> ratio is 23:1 and the fT<sub>4</sub>/fT<sub>3</sub> ratio is 1.83:1.<sup>31</sup> The concentrations of rT<sub>3</sub> are often increased in hyperthyroidism and NTIS.<sup>7</sup>

Commercial assays to determine TSH concentrations in human beings and dogs are available. The validity of human

TSH assays to measure equine TSH is unknown; however, it is expected to be acceptable based on a 90% homology between human and equine TSH. Increased TSH concentrations are expected in hypothyroidism, and the opposite is expected in hyperthyroidism.<sup>14,79</sup> Equine TSH concentrations have been determined using customized assays.<sup>48,68,69,76,79</sup> Breuhaus<sup>76</sup> validated an equine-specific double-antibody TSH RIA in an equine model of hypothyroidism. In that study, hypothyroidism was induced in healthy horses by administering PTU for 6 weeks. Serum T<sub>3</sub> and fT<sub>3</sub> fell rapidly, whereas fT<sub>4</sub> and T<sub>4</sub> did not decrease until weeks 4 and 5, respectively.

TSH concentrations remained steady until week 5, increasing thereafter. The TSH response to TRH stimulation (1 and 5 mg) was exaggerated. Similar studies of PTU-induced primary hypothyroidism found a decrease in serum of  $T_3$ ,  $T_4$ , and  $rT_3$ , as well as an increase in TSH concentrations.<sup>14,79</sup>

Increased cholesterol concentrations, hypothermia, bradycardia, and anemia are considered indirect indicators of hypothyroidism; however, they are not considered reliable.

Hormonal response tests are useful to differentiate primary from secondary thyroid dysfunction, and they remove the variability of endogenous and exogenous factors that could influence the results.

### THYROID-STIMULATING HORMONE STIMULATION TEST

The TSH stimulation test consists of injecting 2.5 to 5.0 IU of TSH, IV and comparing pre- and postinjection TH concentrations.<sup>87,88</sup> In normal horses,  $T_4$  peaks 3 to 4 hours after injection at a concentration 2.4 times the preinjection value.  $T_3$  doubles within 30 minutes and peaks at 2 hours at a concentration five times baseline.<sup>89</sup> Normal responses are characterized by a rise in  $T_3$  that antedates the  $T_4$ . When 5 IU of TSH were given intramuscularly to horses,  $T_4$  peaked at two times baseline value 3 to 12 hours after injection, and  $T_3$  peaked in 1 to 3 hours.<sup>45</sup> No differences in  $T_4$  concentrations were found between 2.5 and 5 IU of TSH.<sup>87</sup> The suggested protocol for the IV TSH response test is to measure TH concentrations at baseline and 3 to 4 hours after injection.<sup>89</sup> For the intramuscular protocol, hormone concentrations are measured at baseline and 3 and 6 hours after injection.<sup>45</sup> The protocol for 1-day-old foals is to measure  $T_3$  concentrations at baseline and 1 and 3 hours after the IV injection of 5 IU of TSH. A normal response is a 50% increase by 3 hours.  $T_4$  values after TSH stimulation are variable in foals.<sup>81</sup> An insufficient hormonal increase indicates primary hypothyroidism. The ability to perform a TSH stimulation test may be limited by the cost or availability of TSH.

Phenylbutazone decreases TH concentrations in horses, but it does not affect the response of the TSH stimulation test.<sup>45</sup> Dexamethasone blunts the TH response to the TSH stimulation test.<sup>39</sup> This information should be taken into account in the interpretation of the TSH stimulation test.<sup>45,89</sup> Treatment with DA agonists does not appear to affect serum  $T_3$ ,  $T_4$ ,  $rT_3$ , or TSH concentrations in horses.<sup>79</sup>

### THYROTROPIN-RELEASING HORMONE STIMULATION TEST

The TRH stimulation has become a widely used method to assess thyroid gland function and pituitary gland dysfunction in horses.<sup>87,90-95</sup> TRH is administered IV, 1 mg to horses and 0.5 mg to ponies and foals, with hormone measurements at baseline and 4 to 5 hours later. In a normal response both hormones should increase two- to threefold. An inadequate hormone response to TRH would occur in primary or secondary hypothyroidism. In normal animals,  $T_4$  peaks at 4 hours<sup>87,92</sup> and  $T_3$  at 2 hours after TRH administration.<sup>92</sup> Side effects of TRH administration include salivation, urination, defecation, vomiting, pupillary constriction, tachycardia, and tachypnea.<sup>91</sup> A low response to TRH administration suggests dysfunction at either the pituitary or the thyroid gland level. Additional tests (TSH concentrations, TSH stimulation test) may be necessary to differentiate thyroid from pituitary disease. Low TH

and high TSH concentrations, and a low response to the TSH stimulation test suggest thyroid gland dysfunction. Low TH concentrations with low or normal TSH concentrations suggests hypothalamic or pituitary gland dysfunction. Low TH and TSH concentrations with a normal TSH and TH response to TRH stimulation indicates hypothalamic dysfunction. Levothyroxine administration blunts the response to the TRH stimulation test.<sup>41</sup>

### THYROID SUPPRESSION TEST

TSH-independent secretion of THs can be demonstrated by the thyroid-suppression test. Exogenous administration of TH to suppress TSH secretion should also decrease TH secretion. The lack of TH suppression indicates primary hyperthyroidism. After  $T_3$  administration, healthy horses are expected to have a decrease in  $T_4$  concentrations, whereas no changes in  $T_4$  concentrations are anticipated in hyperthyroid animals. This test was used to diagnose hyperthyroidism in a horse with a thyroid adenoma<sup>96</sup>; 2.5 mg of  $T_3$  were administered intramuscularly, and serial sampling revealed no decrease in  $T_4$  concentrations.

### IMAGING

Nuclear scintigraphy (technetium-99m) is useful in assessing equine thyroid gland function.<sup>97</sup> Abnormal uptake patterns have been seen with thyroid carcinoma in horses.<sup>98-100</sup> Ultrasonographic evaluation of the glands can differentiate solid structures from cystic ones.<sup>7</sup> Ultrasonography is the most commonly used imaging modality to assess equine thyroid gland morphology.<sup>96,101</sup>

### BIOPSY

Aspirate or biopsy sampling can help differentiate cysts, neoplasia, hyperplastic goiter, colloid goiter, and inflammation.

## ☪ HYPOTHYROIDISM

Hypothyroidism is defined as TH deficiency, a deficient thyroid activity, or disruption of the HPT axis. Hypothyroidism occurs from diseases that affect thyroid gland function, exogenous compounds that interfere with TH synthesis, and less frequent by disorders of the hypothalamus or pituitary gland. The liver, muscle, skeleton, kidney, heart, salivary glands, pancreas, and CNS during development are target organs for THs.<sup>7</sup> Hypothyroidism manifests in many ways, and the diagnosis can be a challenge because many nonthyroidal factors can lead to misinterpretation of the results. Hypothyroidism can be classified as *primary*, *secondary*, or *tertiary*. Primary hypothyroidism can be caused by iodine deficiency (endemic goiter) or excess (Wolff-Chaikoff effect), thyroiditis, neoplasia, biochemical defects, thyroid agenesis, or ingestion of goitrogenic compounds that block hormone synthesis. Of these, iodine excess, iodine deficiency, and neoplasia have been reported as causes of equine hypothyroidism. Histological lesions consistent with Hashimoto thyroiditis were recently described in horses.<sup>102</sup>

Horses with primary hypothyroidism have decreased  $T_4$  and  $T_3$  concentrations and increased TSH concentrations.<sup>76</sup> Secondary (central) hypothyroidism occurs from pituitary or hypothalamic dysfunction. Reports exist of low

TH concentrations in horses with pituitary adenoma.<sup>90,103,104</sup> *Tertiary hypothyroidism* denotes a defect in TH use, but it has not been reported in horses.

## HYPOTHYROIDISM IN FOALS

The consequences of inadequate circulating TH can be devastating for the developing fetus and newborn foal. Chances for recovery are unlikely once critical developmental stages are passed. Tests to evaluate thyroid gland function may be within normal limits at the time of examination, making it difficult to confirm a previous transient or in utero TH deficiency.<sup>24</sup> The equine placenta is permeable to iodine, but impermeable to T<sub>3</sub> and T<sub>4</sub>, and excessive ingestion of iodine may result in hyperplastic goiter (Figure 20-1, A and B).

### SIGNS

Because decreased iodine intake is considered the main cause of neonatal hypothyroidism and goiter, pituitary gland function in these foals may be normal or increased. The lack of pituitary inhibition from low TH concentrations leads to excessive TSH secretion, thyroid follicular cell hyperplasia, and thyroid enlargement (goiter). The clinical signs reported in hypothyroid foals relate to the crucial role of THs in development and maturation of the nervous, respiratory, and musculoskeletal systems during the pre- and postnatal periods. Hypothyroid foals are often affected at birth. Clinical signs reported in hypothyroid foals include stillbirths, prematurity, weakness, and long hair coat<sup>4,105</sup>; weak suckle reflex<sup>106</sup>; respiratory insufficiency and distress<sup>107,108</sup>; incoordination<sup>20</sup>; lethargy, depression, and rough coat<sup>109</sup>; cold intolerance and hypothermia<sup>24</sup>; physeal dysgenesis<sup>110</sup>; defective ossification

with tarsal bone collapse<sup>110,111</sup>; hypoplastic carpal bones, common digital extensor tendon rupture, forelimb contracture, and mandibular prognathism<sup>112,113</sup>; delayed incisor eruption, growth retardation, and death.<sup>114</sup> Foals can be born apparently normal but may develop skeletal lesions weeks later.<sup>109</sup>

### CAUSE

The major cause of hypothyroidism in foals is nutritional. Congenital thyroid enlargement (congenital goiter) with decreased thyroid function is associated with both inadequate and excessive iodine intake by the mare. Several reports exist of goiter and hypothyroidism in foals associated with ingestion of excessive amounts of iodine in kelp-supplemented rations.<sup>4,105,115-117</sup> The dams of these foals may or may not be affected. Feeding 40 mg or more of iodine daily can produce this syndrome.<sup>106</sup>

### DIAGNOSIS

Foals that exhibit any of the signs mentioned previously, with or without enlarged glands, are suspects. The mare and her nutrition should be examined. Because thyroid gland enlargement does not automatically imply hypo- or hyperthyroidism, functional tests (TSH and TRH stimulation tests) to confirm a diagnosis should be considered. When assessing TH concentrations in sick foals it is critical to compare results to age-matched healthy foals. Also crucial is to remember that high TH concentrations are normal in healthy foals (see Table 20-2). Premature and septic foals may have lower TH concentrations than controls, which does not necessarily mean hypothyroidism. Serum rT<sub>3</sub> concentrations in premature and septic foals may be lower than in term foals.<sup>48,82</sup> A foal with

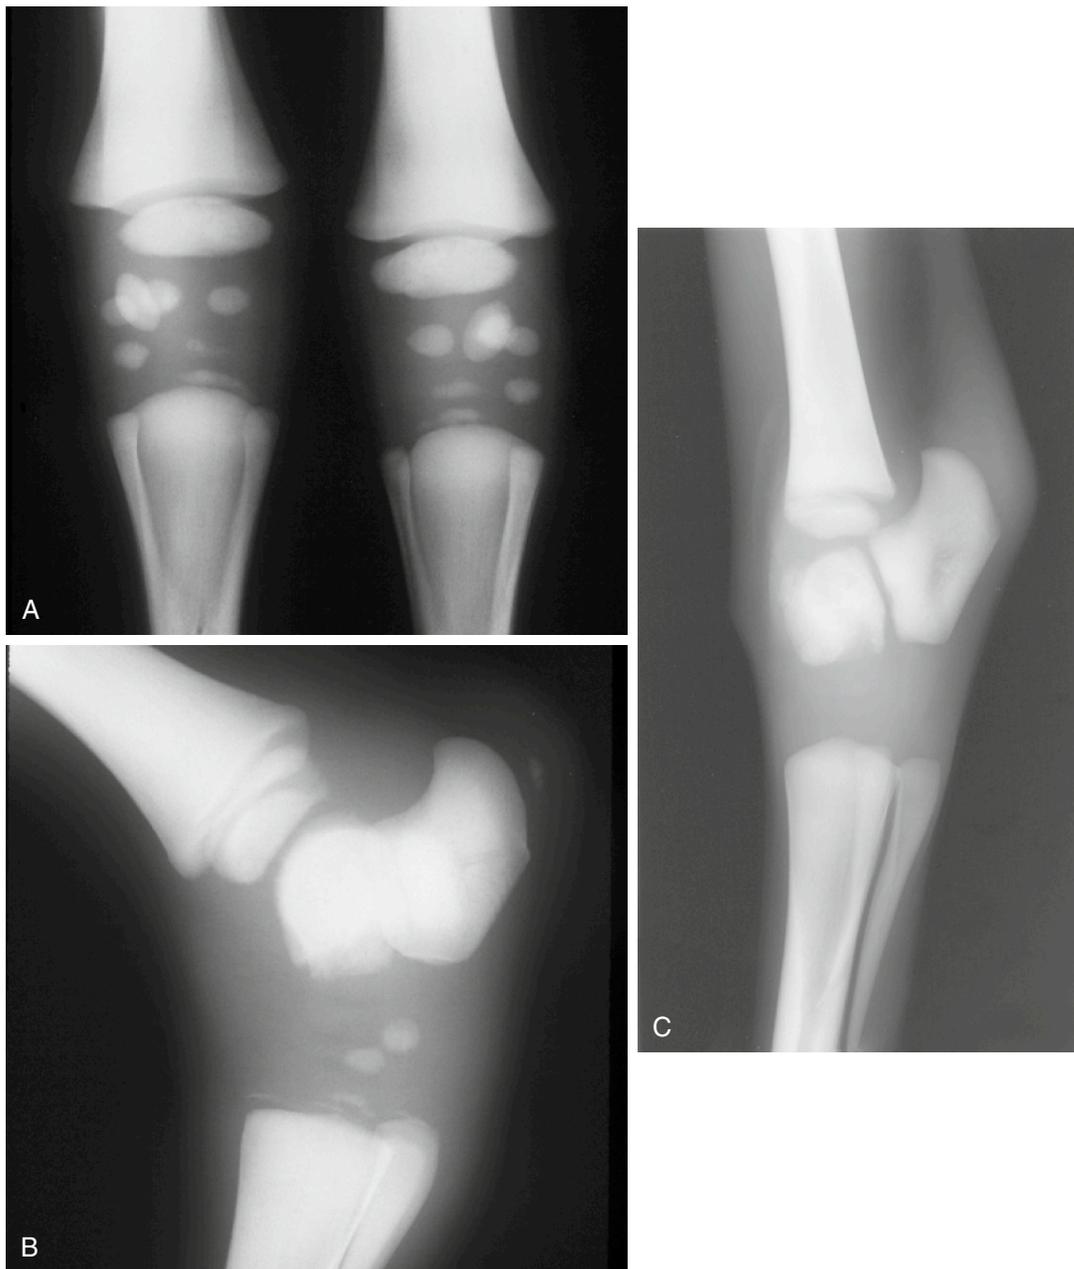

**FIGURE 20-1** A, Newborn foal with respiratory distress and thyroid gland enlargement (congenital goiter). B, Thyroid hormone concentrations were normal but biopsy of the thyroid gland revealed follicular hyperplasia. (Courtesy The Ohio State University)

clinical evidence of hypothyroidism could have normal TH concentrations, suggesting that TH deficiency occurred during development. Hypothyroidism in foals carries a poor prognosis, even after thyroid supplement therapy.

### CONGENITAL HYPOTHYROIDISM AND DYSMATURITY SYNDROME IN FOALS

A syndrome characterized by thyroid gland hyperplasia and multiple congenital musculoskeletal deformities has been described in neonatal foals in Western Canada and North-western region of the United States.<sup>29,108,112,118-121</sup> In some outbreaks, this disorder is reported to affect 30% to 100% of the

newborn foals,<sup>121</sup> with no sex or breed predilection.<sup>119</sup> Abnormal musculoskeletal findings include prognathia, osteochondrosis and inappropriate ossification of carpal and tarsal bones, angular limb deformities, and rupture of the common digital extensor tendons (Figure 20-2, A to C).<sup>121</sup> These foals have signs of dysmaturity including a silky and short hair coat, floppy ears, tendon laxity, and incomplete closure of the abdominal wall.<sup>121</sup> Thyroid gland hyperplasia is associated with hypothyroidism.<sup>120</sup> This syndrome is referred to as *congenital hypothyroidism and dysmaturity* (CHD). The cause of this condition remains unknown. A case-control study found that foals with CHD had a longer gestation time and that mares grazing irrigated pastures, fed greenfeed, not receiving

**FIGURE 20-2** Radiographs from newborn foals with evidence of congenital hypothyroidism. Notice the, **A**, incomplete ossification of the cuboidal bones in the carpus and, **B**, **C**, tarsus. (Courtesy Dr. M.T. Hines [A,B] and the Ohio State University[C].)

mineral supplements, or that left their home farm were more likely to produce affected foals.<sup>121</sup> High nitrate intake has been proposed as the possible cause. Nitrates can cross the and impair thyroid gland function.<sup>71</sup> Greenfeed can concentrate high levels of nitrate and nitrite. Alfalfa, ryegrass, timothy, and cereal crops such as wheat, oats, rye, and barley also accumulate nitrate. In addition, these plants have low levels of iodine. Nitrates can also be in high concentrations in the water, in particular in areas with high use of fertilizers, feedlots, and dairies.<sup>121</sup>

Studies in the Northwestern United States have found an association between ingestion of pasture or hay contaminated with certain winter annuals of the mustard family (e.g., blue mustard, Jim Hill mustard, shepherdspurse, flaxweed) and CHD. It has been postulated that glucosinolates in these plants may be broken down into compounds that are goitrogenic or act adversely on the thyroid gland of the developing fetus.

## HYPOTHYROIDISM IN ADULT HORSES

Hypothyroidism in adults is a rare condition, and unlike foals, is not life threatening. Low-grade anemia, decreased body temperature, heart rate, respiratory rate, and cardiac output have been reported in thyroidectomized horses.<sup>104,122,123</sup> Lethargy, rear limb edema, coarse hair coat, and decreased appetite were seen in thyroidectomized mares.<sup>124</sup> Reproductive problems in hypothyroid mares are irregular and absent estrus cycles.<sup>4,122</sup> Thyroidectomized mares could conceive and carry a foal to term.<sup>124</sup> Stallions exhibit decreased libido.<sup>122,125</sup> Thyroidectomized stallions had decreased total sperm count but normal semen characteristics and could sire foals.<sup>114,124</sup> Bradycardia, obesity, and lethargy were seen in mares with thyroid function that was suppressed from excessive iodine ingestion.<sup>4</sup> Alopecia attributed to iodine and low circulating TH values were documented in a horse treated with an expectorant containing iodide and topical povidone iodine.<sup>126</sup> One report described low T<sub>4</sub> concentrations in agalactic mares.<sup>12</sup> Poor performance in racehorses in warm seasons could be related to low TH concentrations.<sup>76</sup> Hypothyroidism has been implicated as a cause of anhidrosis. Low or no differences in T<sub>3</sub> and T<sub>4</sub> concentrations have been found in anhidrotic horses.<sup>127,128</sup> Low TH concentrations may be present in horses with Cushing's disease and laminitis, but it remains to be documented that hypothyroidism is the cause of the laminitis in these animals.<sup>129</sup> TH concentrations are low, whereas TRH and TSH concentrations are elevated in hypothyroid horses.<sup>130</sup>

## TREATMENT OF HYPOTHYROIDISM

When hypothyroidism is suspected, it is important to determine if the animals are receiving appropriate amounts of iodine. Differentiating hypothyroidism from NTIS is critical because animals with NTIS may not require TH supplementation. Furthermore, TH therapy to euthyroid horses may be harmful, inhibiting the HPT axis and suppressing endogenous TH synthesis and secretion. The National Research Council recommends daily intakes of iodine of 1 to 5 mg per horse depending on age, physiologic status, and body weight.<sup>4</sup> The soil in some geographic areas (e.g., Great Lakes Region) has low or marginally low iodine content. Iodinated casein and thyroprotein (5 g/PO/day) have been used to reverse the effects of hypothyroidism.<sup>114,131</sup>

Hormone supplementation with T<sub>4</sub> should be effective unless a deiodination defect is noted. A starting oral dose of levothyroxine sodium of 20 µg/kg/day is recommended.<sup>33</sup> The animal should be monitored for clinical response to therapy, which can take at least 2 weeks. Periodical measurements of TH concentrations are recommended to adjust dosages. The use of thyroid supplements remains controversial; however, a clear indication for levothyroxine sodium is to induce weight loss in horses with obesity-associated laminitis and IR.

## ☪ HYPERTHYROIDISM

Hyperthyroidism is a hypermetabolic disorder that is the result of high concentrations of fT<sub>4</sub> and fT<sub>3</sub>. High TH concentrations can be found in physiologic states such as pregnancy, fetuses in late pregnancy, and in the first weeks of life.<sup>18-22,24,27-29,37</sup> Few documented cases of equine hyperthyroidism exist.<sup>96,101</sup> Tremors, excitability, tachycardia, sweating, and weight loss have been described in racehorses suspected of hyperthyroidism.<sup>52,132</sup> Horses with hyperthyroidism may improve with antithyroid therapy of potassium iodide (1 g/day, PO).<sup>42,52</sup> The use of thyroidectomy as a means of behavior modification for unmanageable horses had variable success.<sup>114</sup> No reports exist of hyperthyroidism associated with an autoimmune condition in the horse. Hyperthyroidism from a thyroid adenocarcinoma was documented in a horse.<sup>101</sup> After the T<sub>3</sub>-suppression test, T<sub>4</sub> concentrations did not decrease in the affected horse compared with controls.

Horses are at risk for accelerated TH production when exposed to increased quantities of iodine-containing compounds such as expectorants, counterirritants, contrast media, drugs, leg paints, and povidone-based shampoos (Jod-Basedow phenomenon).<sup>7</sup> If severe distress from thyrotoxicosis is present, then administration of glucocorticoids should alleviate the signs.<sup>7</sup>

## ☪ THYROID TUMORS

Tumors of the thyroid gland tend to occur more frequently in lightweight breeds than in draft-breed horses and more often in aged than in young horses.<sup>83</sup> Three cell types are noted in the equine thyroid gland: (1) undifferentiated cells, (2) parafollicular cells (secrete CT), and (3) follicular epithelial cells. A survey of aged horses found thyroid tumors in 30% of the animals,<sup>133</sup> with no tumors in horses younger than 18 years old. The majority of the tumors were microfollicular adenomas.

## ADENOMA

Adenoma is the most common neoplasia of the equine thyroid.<sup>116,133-139</sup> It is an age-related phenomenon, occurring mainly in horses older than 16 years. It is benign, usually unilateral, and is not associated with thyroid dysfunction. Occasionally its size may warrant surgical excision. Prognosis is good. A thyroid adenoma associated with hyperthyroidism was diagnosed in a 23-year-old gelding.<sup>96</sup> In this case the diagnosis was aided by percutaneous biopsy and the use of a T<sub>3</sub>-suppression test, in which T<sub>4</sub> concentration was not suppressed after the administration of 2.5 mg of T<sub>3</sub>, IM. Hemithyroidectomy of the affected gland restored TH concentrations.

## ADENOCARCINOMA

Malignant neoplasia of the thyroid occurs less frequently. In four reported cases of thyroid adenocarcinomas, one horse was euthyroid, two were hypothyroid, and one was hyperthyroid.<sup>98-101</sup> One case of thyroid carcinoma with systemic metastasis and concurrent pituitary adenoma was reported.<sup>140</sup>

## MEDULLARY CARCINOMA

Medullary carcinoma (C cell or parafollicular cell tumors) have been reported in horses.<sup>2,141,142</sup> In these cases, the youngest animal was 8 years old and the tumors were unilateral. In two horses, the complaint was constant gulping that was alleviated by surgical removal of the enlarged glands.<sup>2</sup> A C cell adenoma was reported in a 13-year-old horse with no clinical evidence of endocrine dysfunction.<sup>143</sup> In one horse a C cell adenoma associated with MEN was documented at necropsy.<sup>141</sup> C cell hyperplasia has been described in horses as young as 3 years old.<sup>135</sup> Immunohistochemistry or electron microscopy may be necessary to distinguish C cell tumors from other thyroid neoplasias.

## MULTIPLE ENDOCRINE NEOPLASIA

MEN is a human syndrome characterized by multiple neoplasia of glands with a neuroendocrine origin. One case of a 22-year-old Thoroughbred mare with a C cell adenoma, a pheochromocytoma, and multicentric bilateral nodular hyperplasia of the adrenal medulla was reported.<sup>141</sup> A retrospective evaluation of endocrine tumors in horses that underwent necropsy suggested that hyperplasia and neoplasia of the thyroid and adrenal glands, as occurs in human beings with MEN, occurs in the horse.<sup>140,141</sup>

## TREATMENT

In circumstances that warrant surgical excision, the prognosis is best when the condition is unilateral. Potential surgical complications include infection, hemorrhage, and laryngeal hemiplegia. As the equine parathyroid glands in general are not connected to the thyroid gland, hypocalcemia is not a complication.

## ENDOCRINE PANCREAS

Ramiro E. Toribio

The islet of Langerhans is the endocrine functional unit of the pancreas. Important pancreatic hormones include insulin, glucagon, and SST. The pancreatic  $\beta$  cells secrete insulin in response to glucose and glucagon, whereas SST inhibits insulin secretion. Blood glucose and amino acid concentrations are important regulators of glucagon and insulin secretion. Pancreatic endocrine function is also regulated by sympathetic and parasympathetic fibers that release norepinephrine, epinephrine, and acetylcholine. The sympathetic system inhibits insulin and stimulates glucagon secretion, whereas the parasympathetic system stimulates insulin secretion during food intake.<sup>1,2</sup>

Insulin is the primary hormone controlling the metabolism and storage of body fuels. Its actions involve three major fuels (carbohydrates, proteins, and fats) and three major tissues (liver, skeletal muscle, and adipose tissue). In the liver,

insulin promotes glycogenesis, decreases glycogenolysis, gluconeogenesis and ketogenesis, and stimulates fatty acid synthesis. In adipose tissue, insulin increases glucose uptake, decreases lipolysis and stimulates fatty acid uptake, synthesis and esterification. Insulin increases endothelial lipoprotein lipase activity to enhance chylomicron and triglyceride removal from peripheral circulation and inhibits the hormone sensitive lipase in adipocytes to reduce lipolysis. In skeletal muscle, insulin decreases proteolysis and amino acid output, and increases glucose and amino acid uptake, protein synthesis, and glycogen synthesis.<sup>3</sup> This information is relevant to understand the pathogenesis of equine diseases such as hyperlipemia, pituitary pars intermedia dysfunction (PPID), metabolic syndrome, and polysaccharide storage myopathy.

The equine endocrine pancreas is mature before birth. Pancreatic  $\beta$  cell maturation in the equine fetus occurs in late gestation.<sup>4</sup> Before day 230, glucose has no effect on fetal insulin release; however, after day 290, glucose administration evokes a rapid insulin release.<sup>4</sup> Pancreatic maturation in foals is related to the increase in fetal cortisol concentrations; premature foals with low cortisol concentrations have a poor insulin response to glucose stimulation.<sup>4,5</sup> Immediately after birth the equine  $\beta$  cells are responsive to glucose administration; however, foals develop a physiologic IR in the first day of life that is related to the high cortisol concentrations around delivery.<sup>6</sup>

Glucagon has opposing effects of insulin on glucose metabolism. Catecholamines inhibit glucose-stimulated insulin secretion and increase glucose concentrations. Growth hormone (GH) counteracts insulin actions on lipid and glucose metabolism and is important in setting the basal glucose concentrations (glucostat).<sup>3,7</sup>

## INSULIN RESISTANCE

IR is defined as a decreased response to endogenous insulin (hyperinsulinemia associated with normo- or hyperglycemia) or exogenous insulin administration. IR results from changes in insulin receptors, postreceptor effects, or both. Because a number of insulin receptors must be occupied to achieve a biologic action, when most receptors are nonfunctional, higher insulin concentrations are required to achieve a biologic effect, leading to *insulin insensitivity* or *resistance*. Clinically, this results in hyperinsulinemia with normoglycemia (compensated IR) or with hyperglycemia (noncompensated IR).

IR is reported in horses and ponies with pars intermedia dysfunction, equine metabolic syndrome (EMS), obesity, hyperlipemia, diabetes mellitus (DM), laminitis, endotoxemia, granulosa cell tumors, and osteochondrosis dissecans.<sup>8-13</sup> Carbohydrate-rich diets and glucocorticoids decrease insulin sensitivity in horses.<sup>14,15</sup> Increased insulin sensitivity has been documented in horses with polysaccharide storage myopathy and with equine motor neuron disease.<sup>8,16</sup>

Healthy ponies and Miniature Horses are less responsive than horses to endogenous and exogenous insulin, and obese ponies often develop IR.<sup>10,17,18</sup> Studies on insulin receptor or postreceptor signaling are lacking in equids. In human beings, decreased glucose transport 4 (GLUT4) activity is central to the development of IR; however, few studies assess GLUT4 and IR in the horse.<sup>19,20</sup> Physical activity increases muscular GLUT4 function and is the rationale for recommending exercise in human beings with IR.<sup>21,22</sup> Moderate exercise training in horses increased muscle GLUT4 content.<sup>19</sup> Exercise also increases insulin sensitivity in ponies.<sup>23</sup>

*Glucocorticoids* stimulate proteolysis, increase glycogen formation, stimulate gluconeogenesis, and decrease insulin sensitivity. Glucocorticoids also increase glycemia by decreasing the skeletal muscle and adipocytes response to insulin-stimulated glucose uptake. The anti-insulin effects of glucocorticoids are accompanied by hyperglycemia and hyperinsulinemia.<sup>3</sup> Increased glucocorticoid concentrations are associated with IR, and dexamethasone administration to healthy horses decreases insulin sensitivity.<sup>15</sup> One study found that GH induces IR in horses.<sup>24</sup>

## ☉ DIABETES MELLITUS

DM is defined as persistent hyperglycemia and glucosuria from either hypoinsulinemia or IR. DM is a rare condition in horses<sup>9,25</sup> and is associated with disturbances in the secretion and sensitivity to hormones such as insulin, glucagon, catecholamines, GH, and glucocorticoids.<sup>3</sup> Most cases of IR in horses are associated with PPID, metabolic syndrome, and hyperlipemia.

*Primary DM* is a term used to describe pancreatic  $\beta$  cell dysfunction resulting in low insulin concentrations (insulin-dependent DM, type 1 DM) and hyperglycemia. This distinction is important to differentiate hyperglycemia associated with increased insulin concentrations (IR, type 2 DM). Horses suspected of having DM often have a history of depression, polyuria, polydipsia, polyphagia, progressive weight loss, and a rough hair coat. Similar clinical signs are observed in horses with PPID.

Hypoinsulinemia (primary DM) is an uncommon condition of horses that has been reported with pancreatitis from parasite migration, chronic pancreatitis, ovarian tumors, and pregnancy.<sup>11,26-31</sup> Few pancreatic  $\beta$  cells were present in a mustang diagnosed with DM.<sup>9</sup> Weight loss, depression, polyuria, polydipsia, polyphagia, hyperglycemia, glucosuria, and ketonuria were reported in a 7-year-old pony with chronic pancreatitis and primary DM.<sup>27</sup> Ketonemia, ketonuria, and ketone odor have been reported in diabetic ponies and horses.<sup>26,27,30-32</sup>

Because persistent hyperglycemia and glucosuria defines DM, factors that induce temporary hyperglycemia such as carbohydrate diets, stress, exercise, glucocorticoid treatment, and sedation with xylazine and detomidine must be avoided before testing.<sup>33,34</sup> Hyperglycemia may be present in horses with pheochromocytomas.<sup>35</sup>

Once a clinical diagnosis of DM has been made, diseases frequently associated with IR such as PPID and metabolic syndrome must be ruled out; many test protocols are available for the diagnosis of these conditions. Tests used for the diagnosis of IR in horses include the glucose tolerance test, the insulin tolerance test, the insulin suppression test, the combined glucose-insulin test (CGIT), the euglycemic-hyperinsulinemic clamp (EHC), and the minimal model analysis of a frequently sampled intravenous glucose tolerance test (FSIGT).<sup>11,25,33,36</sup> The EHC and the FSIGT are the most accurate methods to assess insulin sensitivity; however, they are tedious and rarely performed in the clinical setting.

Measurement of serum insulin and glucose concentrations should be the first step in the diagnosis of DM and IR. Insulin concentrations in healthy horses are less than 20  $\mu\text{U}/\text{ml}$ , and concentrations higher than 30  $\mu\text{U}/\text{ml}$  suggest IR. Hyperglycemia with hyperinsulinemia suggests IR, whereas hyperglycemia with hypoinsulinemia is consistent with insulin-dependent DM.

The *glucose tolerance test* is the most frequently used test because it is easy to perform and provides sufficient

information for the diagnosis of IR. The test can be oral or IV. The IV test has fewer confounding factors (gastric emptying, glucose absorption, fasting, gastrointestinal motility) than the oral test.<sup>37</sup> In this test, the clinician places the IV catheter the day before testing to reduce stress. Glucose (0.2 to 0.5 g/kg/IV) is administered and serum concentrations of glucose and insulin determined every 30 minutes for 3 hours. In healthy horses, insulin is released immediately after glucose administration and serum glucose concentrations should return to baseline by 3 hours. In the case of insulin-dependent DM, insulin concentrations do not increase and glucose concentrations remain elevated (>3 hours). In horses with IR, insulin concentrations increase but the return of glucose concentration to baseline values is delayed (>3 hours). Handheld glucose meters can be used to determine glucose concentrations.

In the *insulin tolerance test*, soluble (regular) insulin (1 to 8 IU/kg/IV) is administered and glucose concentrations determined every 15 to 30 minutes for 3 hours.<sup>11,26,27,29,31</sup> Alternatively, crystalline insulin is administered (0.05 to 0.1 IU/kg/IV) and blood samples taken every 15 to 30 minutes for 3 hours. In healthy horses the clinician should expect a 30% to 50% decrease in glucose concentrations at 15 minutes, 60% at 30 minutes, and normal glucose concentrations at 2 hours. Failure of insulin to lower glucose concentrations by more than 30% baseline suggests insulin-resistant DM. When performing the insulin tolerance test it is important to have an injectable solution of dextrose available because insulin may induce hypoglycemic shock.<sup>27,38</sup> This test is being replaced by the CGIT.

In the CGIT, a dextrose solution (150 mg/kg/IV) is rapidly administered and immediately followed by an injection of regular insulin (0.1 IU/kg/IV). In this test the clinician places the IV catheter the day before testing to reduce stress. Blood samples are collected at times 0, 1, 5, 15, 25, 35, 45, 60, 75, 90, 105, 120, 135, and 150 minutes. For practical reasons this test can be limited to 90 minutes. The dextrose dose of 150 mg/kg is recommended because it increases blood glucose concentrations to approximately 200 mg/dl within 5 minutes of injection, which is close to the renal glucose threshold.<sup>33</sup> In healthy horses, glucose returns to baseline by 30 minutes, decreases by 50% baseline at 60 to 75 minutes, and is back to normal by 150 minutes after injection.<sup>33</sup> In horses with IR, glucose concentrations do not decrease below baseline for over 90 minutes. Horses with glucose concentrations above baseline for over 45 minutes are considered insulin resistant.<sup>33</sup> Xylazine interferes with the CGIT in healthy horses, with glucose remaining elevated for more than 75 minutes.<sup>33</sup> This is relevant to the clinician because  $\alpha_2$ -adrenergic receptor agonists (xylazine, detomidine) can lead to the misdiagnosis of IR. Stressful conditions and the use of glucocorticoids should be avoided. In addition, grain and grass should be withheld for 24 hours, but water and grass hay do not appear to affect the results.<sup>33</sup> For additional information on testing, the reader is referred to the section on Equine Metabolic Syndrome.

The FSIGT (minimal model) is primarily used in research, in particular to assess IR in horses with metabolic syndrome. A baseline sample is collected and dextrose (0.5 g/kg/IV in a 50% solution) is administered. Blood samples are collected at 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 12, 14, 16, 18, 20, 30, 40, 50, 60, 70, 80, 90, 100, 120, 150, and 180 minutes after dextrose administration. Glucose concentrations are measured at all time points and insulin concentrations at 0, 2, 4, 6, 8, 10, 14, 18, 20, 30, 60, 90, 120, 150, and 180 minutes.<sup>36</sup> Data is analyzed

by the minimal model method that provides information on the dynamics of glucose clearance, insulin release, and insulin effectiveness. The FSIGT is considered the only method that differentiates insulin-dependent and insulin-independent glucose clearance<sup>13</sup>; however, it is time-consuming, expensive, and can be impractical in clinical cases.

The treatment of DM depends on the primary cause. For obese ponies with IR, decreased caloric intake and increased physical activity are recommended. Treatment of IR associated with PPID and metabolic syndrome is discussed elsewhere. If a diagnosis of primary DM is reached, then treatment with insulin is indicated. During treatment it is important to monitor blood glucose concentrations to adjust insulin dosing. Treatment of DM with insulin has been attempted with variable results.<sup>25</sup> Improvement (in addition to deterioration including hyperglycemia, polyuria, and polydipsia; swelling at the injection sites; and development of antibodies against insulin) has been reported.<sup>25,27</sup> Recommended doses for insulin are 0.05 to 0.1 IU/kg/IV/b.i.d. to t.i.d. for regular insulin and 0.5 to 4.0 IU/kg/IM/b.i.d. for protamine zinc insulin (PZI). It is important to start with a low dose and adjust based on glycemia. Insulin administration can result in hypoglycemic shock, so having a dextrose solution available is suggested. The Somogyi effect is a paradoxical insulin-induced hyperglycemia that appears to be mediated by catecholamines, cortisol, and GH release after acute hypoglycemia.

Antihyperglycemic compounds such as biguanides (metformin) and sulfonylureas (glyburide) that are indicated to treat hyperglycemia and IR have been used in horses with promising results.<sup>9,39</sup> The thiazolidinediones is another group of drugs frequently used to treat type 2 DM; however, they have not been evaluated in the horse.

Evidence indicates that exercise increases insulin sensitivity and skeletal muscle glucose transport in horses and other species, thus physical activity is highly recommended.<sup>19</sup> Attention should be paid to laminitic horses in which physical activity can be detrimental.

## ☞ HYPERINSULINEMIA AND HYPOGLYCEMIA

Hyperinsulinemia may result in hypoglycemic shock. Hyperinsulinemia with hypoglycemia may result from therapeutic<sup>27</sup> or fraudulent<sup>38,40</sup> injections of insulin, as well as from insulin-secreting pancreatic tumors.<sup>41</sup> Endogenous (pancreatic neoplasia) and exogenous (injected) insulin can be differentiated using high-pressure liquid chromatography.<sup>40</sup>

Depending on the degree of hypoglycemia, affected horses may show trembling, ataxia, hyperexcitability, tachycardia, tachypnea, mydriasis, nystagmus, profuse sweating, violent seizures, coma, and death. Hyperinsulinism secondary to a pancreatic adenoma (insulinoma) was documented in a 12-year-old Shetland pony broodmare.<sup>41</sup> The clinical signs, in particular seizures, were episodic and associated with feeding. During seizure episodes the pony was hypoglycemic.

The *glucagon tolerance* test has been used in dogs in the diagnosis of hyperinsulinemia. Glucagon administration increases glucose and insulin concentrations. The glucagon tolerance test was performed in a pony suspected of having hyperinsulinemia from a pancreatic adenoma.<sup>41</sup> Glucagon (1500 µg, IV) administration to the affected pony and a control pony resulted in a rapid increase in glucose and

insulin concentrations in both animals; however, the affected pony had an exaggerated and sustained insulin response.<sup>41</sup> Major adverse effects of glucagon administration are cardiovascular.

During the second half of pregnancy, mares may develop hyperinsulinemia and can have an exaggerated  $\beta$  cell response to glucose infusion.<sup>42</sup>

## ☞ NEOPLASIA

Exocrine pancreatic tumors (adenocarcinomas) are more frequently diagnosed than endocrine (islet cells) tumors. Pancreatic adenocarcinomas reported in the literature resulted in anemia, hyperammonemia, protein losing enteropathy, biliary obstruction, tachypnea, and pleural effusion.<sup>43-46</sup>

### PITUITARY PARS INTERMEDIA DYSFUNCTION (EQUINE CUSHING'S DISEASE)

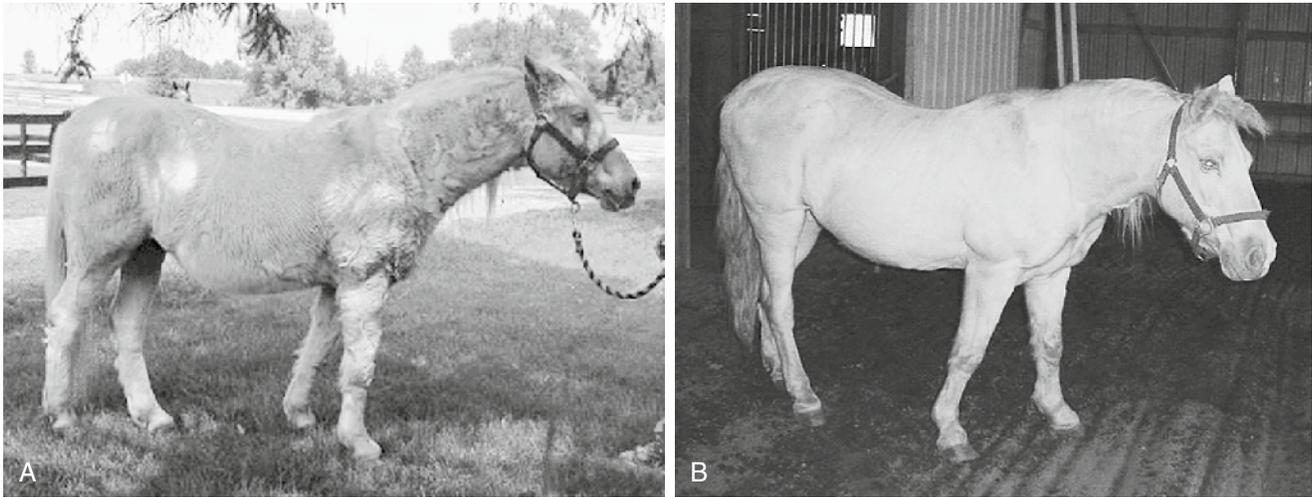

*Dianne McFarlane and Ramiro E. Toribio*

A clinical syndrome associated with hirsutism, laminitis, polyuria and polydipsia, and weight loss has been described in aged horses and ponies.<sup>1-6</sup> The syndrome was originally referred to as *equine Cushing's disease* because of similarities to Cushing's disease in human beings and dogs, in which excessive and autonomous secretion of proopiomelanocortin (POMC)-derived peptides occurs, including ACTH (corticotropin), resulting in secondary hyperadrenocorticism. However, in horses, pituitary adenomas arise from the pars intermedia (intermediate lobe) of the pituitary gland, unlike in human beings and dogs in which pituitary adenomas commonly arise from the anterior lobe (pars distalis, adenohypophysis). As a result, in the horse, hormones from the pars intermedia are excessively secreted as described following. PPID therefore seems to be more appropriate to describe the syndrome because, unlike human beings, adrenocortical hyperplasia and hypercortisolemia are not consistent findings in affected horses. Equine PPID has been described as equine Cushing's disease, equine Cushing's syndrome, pituitary adenoma, hypophyseal adenoma, chromophobe adenoma, pars intermedia adenoma, diffuse adenomatous hyperplasia of the pituitary, PDH, and pars intermedia hyperplasia.<sup>1,3,6-23</sup> However, PPID is used in this section.

## ☞ CLINICAL SIGNS

PPID is a clinical syndrome of aged horses associated with hirsutism, poor hair coat, laminitis, polyuria and polydipsia, muscle wasting, weight loss, docility, lethargy, hyperhidrosis, narcolepsy, blindness, decreased responsiveness to painful stimuli, increased appetite, and recurrent infections.\* Although many clinical signs are associated with PPID, only a subset of the signs typically manifest in the individual affected horse, perhaps because of differences in the secretion profile of

\*References 1, 2, 16, 19, 21, 23.

**FIGURE 20-3** **A**, Horse diagnosed with pars intermedia dysfunction. **B**, The horse was treated with a combination of pergolide and cyproheptadine, and clinical signs improved by 8 weeks of treatment. (Courtesy The Ohio State University.)

POMC-derived peptides or the degree of compression of adjacent neuroendocrine tissues.

Hirsutism (55% to 80%) is considered the most frequent clinical sign in PPID horses, although these estimates may be biased because of the increased tendency to test aged horses with hair coat abnormalities for PPID\* (Figure 20-3). Hirsute horses have a long, thick, often curly hair coat. Other hair coat abnormalities may include a failure to shed in a complete or timely manner. Some horses shed in late spring and grow a winter coat early in the fall; many develop a patchy coat with areas of alopecia. Retention of long hair in the jugular groove, on the legs, or along the ventral abdomen is also a frequent finding. The mechanisms underlying the abnormal hair coat and shedding process are not understood. The pathogenesis of hirsutism is unknown. Holscher et al.<sup>8</sup> suggested that hirsutism in horses with PPID may be the result of increased adrenal gland secretion of androgens, as occurs in women with Cushing's disease. It also has been suggested that hirsutism and hyperhidrosis may result from dysregulation of the thermoregulatory center of the hypothalamus, a consequence of pituitary compression.<sup>7</sup> Horses with adrenal exhaustion or insufficiency may also have an abnormal hair coat.<sup>25</sup>

Chronic laminitis is a frequent finding in horses with PPID.<sup>24</sup> The presentation of endocrinopathic laminitis is more insidious than laminitis as the result of other causes. It has been speculated that laminitis results from increased concentrations of glucocorticoids; however, more recent data suggests IR or hyperinsulinemia may have a role in inciting laminitis in horses with PPID. Laminitis-prone ponies were observed to have increased serum insulin concentrations compared with control ponies.<sup>26</sup> Maintenance of prolonged hyperinsulinemia in clinically normal ponies resulted in induction of laminitis within 72 hours of onset of hyperinsulinemia in all five ponies, suggesting increased serum insulin concentration in the absence of hyperglycemia or underlying IR can induce laminitis.<sup>27</sup> Regardless of the underlying cause of laminitis, PPID should be included in the differential diagnoses in any

older horse with chronic laminitis, even if other clinical signs of PPID are not present.

Polyuria and polydipsia have been reported in up to 76% of horses diagnosed with PPID.<sup>2</sup> However, the pathogenesis behind the development of polyuria and polydipsia is unclear. It has been speculated that compression of the pars nervosa by a pars intermedia adenoma may result in decreased secretion of vasopressin (AVP; antidiuretic hormone [ADH]).<sup>1,7</sup> Hyperglycemia, which is a frequent laboratory finding in these horses, may result in osmotic diuresis. Glucocorticoids can increase GFR and may contribute to diuresis. It is important to rule out other differentials for polyuria and polydipsia, including neurogenic diabetes insipidus, nephrogenic diabetes insipidus, psychogenic polydipsia, and hyperglycemia of various origins (pancreatic disease, pheochromocytoma). Horses that are stalled are the ones most likely to have obvious polyuria and polydipsia.

Weight loss is reported in the majority of horses with PPID (up to 88%) and is often an early clinical sign.<sup>2</sup> However, some horses may be obese or in good body condition.<sup>23</sup> Affected horses often have a weak and pendulous abdomen, a sway back, and lose muscle mass along the dorsum of the back. The pot-bellied appearance is probably the result of lack of tone in the abdominal musculature. The muscle wasting along the dorsal midline and elsewhere results in prominence of the croup, tuber coxae, and tuber sacrale regions. It is unclear what the effect of different POMC-derived peptides is on equine energy metabolism or muscle atrophy. Weight loss in some horses may be the result of other conditions associated with aging (dental problems, disease because of immunosuppression and parasites) rather than the direct effect of an abnormally regulated HPA axis on body condition. Glucocorticoids, in addition to being immunosuppressive, have catabolic effects on skeletal muscle; however, the role of increased concentration of cortisol on weight loss in PPID is unclear. Muscle tissue from horses with PPID shows selective atrophy of type 2 muscle fibers,<sup>28</sup> consistent with what is observed in muscle atrophy associated with excessive cortisol in other species; however, the role of other POMC hormones on muscle atrophy has not been investigated. In horses with normal or

\*References 1, 2, 5, 21, 23, 24.

low cortisol concentrations, other causes may be responsible for the weight loss.

Increased docility in affected horses is often reported by owners and clinicians. Horses with PPID have increased plasma and CSF concentrations of  $\beta$ -endorphin ( $\beta$ -END),<sup>13</sup> which may explain the docility and lethargy in some of these animals. Increased  $\beta$ -END concentrations may also explain the decreased responsiveness to painful stimuli.

Neurologic impairment, although uncommon, has been reported in horses with PPID and includes blindness, seizures, and narcolepsy. Blindness may be caused by compression of the overlying optic chiasm by the enlarged pituitary gland; however, blindness can occur in horses with PPID in the absence of postmortem evidence of optic nerve damage.<sup>29</sup> An increased occurrence of narcolepsy or sleep disorders has been suggested to occur in horses with PPID. The reason that some of these horses develop narcolepsy is unknown. One can speculate that the lack of dopaminergic control may be altering the sleep-wake cycle as occurs in human beings. Narcolepsy can result from decreased orexin activity in the hypothalamus. Orexins (hypocretins) are peptide neurotransmitters expressed in the lateral hypothalamus (orexinergic neurons) that are important in the sleep-wake cycle, and the absence of orexin effects results in narcolepsy.<sup>30</sup> Horses with PPID had decreased CSF concentrations of hypocretin (orexin).<sup>31</sup>

Excessive sweating (hyperhidrosis), and less commonly, lack of sweating (anhidrosis) are reported in horses with PPID, although the mechanisms underlying abnormal sweating have not been determined.

The bulging supraorbital fat pads often observed in horses with PPID are the result of fat redistribution.<sup>2</sup> These may be observed in horses that do not exhibit generalized obesity. Likewise, some horses in good body condition may have a "cresty neck" and fat accumulation around their tail.

Skin infections (dermatophilosis), sinusitis, pneumonia, dental disease, and abscess formation are common sequelae of PPID. The precise mechanism resulting in immune impairment is unknown, but the increased concentration of immunosuppressive hormones, including cortisol,  $\alpha$ -melanocyte-stimulating hormone ( $\alpha$ -MSH) or  $\beta$ -END is likely a contributing factor.

Abnormal estrus cycles and infertility have been reported in horses with PPID.<sup>3</sup> This may be a direct or indirect effect of PPID, or it may be an unrelated effect of advanced age. Compression of the pars distalis or hypothalamus could have a profound effect on reproductive hormones. In addition, a generalized decrease in DA output could directly affect release of reproductive hormones because many are under dopaminergic regulation, including gonadotropin-releasing hormone (GnRH) and prolactin. No controlled studies document the relationship between treated and untreated horses with PPID and fertility.

## EPIDEMIOLOGY

Compared with other equine endocrine disorders, PPID is a common clinical syndrome. In two large-scale surveys, owners reported hair coat abnormalities consistent with PPID in 20% to 30% of aged horses.<sup>32,33</sup> In a study of more than 300 horses 15 years or older, horses were tested using plasma ACTH and  $\alpha$ -MSH concentration, and 15% of horses were positive for PPID.<sup>32</sup> An incidence of 15% to 30% is markedly greater than

originally reported in the 1970s (0.075%-0.15% of 4000 horses of all ages seen in an ambulatory practice).<sup>6</sup> At this time it is unclear whether this change reflects a true increase in prevalence of disease, a change in equine demographics with a larger aged population, or an increased awareness and recognition of disease because of changes in diagnostic testing methods or frequency.

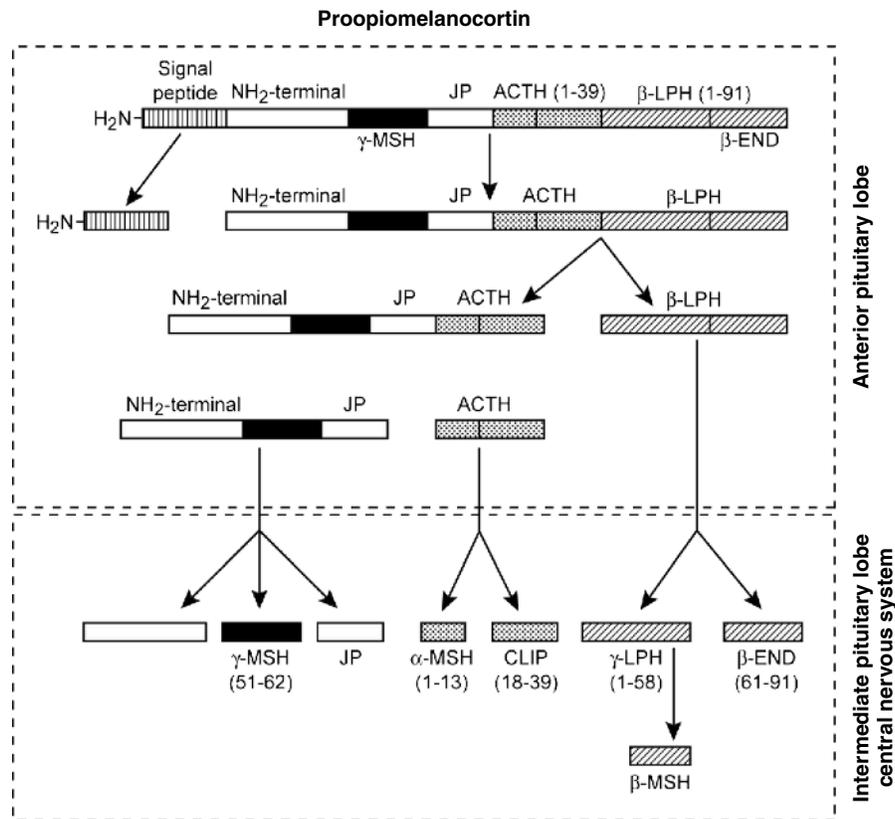

PPID has been diagnosed in horses older than 7 years (range 7-40; average 19 to 21).<sup>1,2,5,22,23</sup> Although all breeds are susceptible, ponies and Morgan horses appear to be predisposed.<sup>2,5,21,23,34</sup> Despite earlier studies suggesting PPID to be more prevalent in female<sup>1,11,13</sup> or male<sup>2</sup> horses, there appears to be no sex preference.<sup>2,5,23,32,34</sup>

Pars intermedia adenomas and microadenomas are often identified at postmortem examination in older horses with no previous history or reported clinical signs of this condition.<sup>35,36</sup> The significance of these clinically silent histological findings is unknown.

## PATHOGENESIS

Pars intermedia hyperplasia and hypertrophy are consistent findings in PPID,<sup>15,21,35</sup> and data suggest it is a lack of inhibitory control on pars intermedia cell function that triggers the excessive cell proliferation and the development of adenomas. The pars intermedia in horses and other species is inhibited by DA of hypothalamic origin.<sup>37</sup> Three neuroendocrine dopaminergic tracts exist: (1) the tuberoinfundibular, (2) the tuberohypophyseal, and (3) the periventricular dopaminergic neurons.<sup>38</sup> It is the periventricular neurons that appear most critical in regulating cell proliferation and hormone production and release in the pars intermedia.<sup>39</sup> The periventricular neurons originate in the periventricular nucleus, adjacent to the third ventricle, and project through the infundibular stalk, terminating in the pars intermedia. In the pars intermedia the periventricular neurons directly innervate melanotropes where they release DA that interacts with dopaminergic D<sub>2</sub>-type receptors on melanotropes. In the presence of DA, the D<sub>2</sub>-receptors act to inhibit POMC mRNA expression and POMC-derived intermediate-lobe hormone release. In rodents, surgical disruption of the periventricular neurons results in increased  $\alpha$ -MSH release, confirming a melanotropic inhibitory role for the periventricular neurons.<sup>39</sup> In contrast, prolactin release is regulated primarily by the tuberoinfundibular dopaminergic neurons. These originate in the arcuate nucleus and release DA at the median eminence. From there DA is transported to the anterior lobe through the hypophyseal portal system.<sup>38</sup>

In their study of the loss of dopaminergic inhibition in horses with PPID, Orth, Holscher, and Wilson et al.<sup>9</sup> found that D<sub>2</sub>-receptor dopaminergic agonists (bromocriptine, pergolide) decreased POMC-derived peptide concentrations in horses with PPID. Millington et al.<sup>13</sup> found low concentrations of DA and DA metabolites in the pars intermedia of horses with PPID. This data suggested that although DA was lacking in the pars intermedia of horses with PPID, response to DA was intact.<sup>9</sup> This understanding has made it possible to recommend DA agonists (e.g., pergolide) in the palliative treatment of PPID. Several studies<sup>25,27,40</sup> have documented the efficacy of DA agonists in treatment of the PPID as described following. More recent studies<sup>41</sup> have suggested that the loss of dopaminergic input to the pars intermedia is a consequence of neurodegeneration of the periventricular neurons. A loss of

**FIGURE 20-4** Processing of proopiomelanocortin (POMC) in the anterior pituitary lobe, the intermediate pituitary lobe, and the central nervous system (CNS). In the anterior lobe, adrenocorticotropic hormone (ACTH) and  $\beta$ -lipotropin ( $\beta$ -LPH) are the major products of POMC. In the intermediate lobe and in the CNS, ACTH is cleaved to produce  $\alpha$ -melanocyte-stimulating hormone ( $\alpha$ -MSH) and corticotropin-like intermediate lobe peptide (CLIP), and  $\beta$ -LPH is cleaved to produce  $\beta$ -endorphin ( $\beta$ -END). (Adapted from Castro MG, Morrison E: Post-translational processing of proopiomelanocortin in the pituitary and in the brain, *Crit Rev Neurobiol* 11:35–57, 1997.)

dopaminergic cell bodies in the periventricular nucleus of the hypothalamus and the nerve terminals in the pars intermedia was demonstrated in horses with PPID using immunohistochemistry.<sup>41</sup> In addition, in horses with PPID, dopaminergic nerve terminals showed evidence of oxidative stress damage, suggesting free radical damage may be a cause of periventricular neuronal damage and cell loss. Oxidative stress has been implicated as a contributing factor in the pathogenesis of many other neurodegenerative diseases.

Evidence from other species suggests additional hypothalamic factors, such as TRH, serotonin, and  $\gamma$ -aminobutyric acid (GABA) are important in regulating melanotrope function in the pars intermedia.<sup>13,37,42</sup> In horses a direct positive effect of TRH on melanotropes has been shown.<sup>43</sup> When equine melanotropes were maintained in culture, treatment with TRH resulted in a release of  $\alpha$ -MSH. In addition, horses administered TRH have a rapid and substantial increase in plasma  $\alpha$ -MSH concentration.<sup>43</sup> In other species, serotonin is also a positive releasing factor for pars intermedia cells.<sup>37</sup> However, the role of serotonin on equine pars intermedia function is unclear, and Millington et al.<sup>13</sup> found no difference in serotonin concentrations in the pars intermedia of affected versus control horses. GABA has a tonic inhibitory effect on POMC synthesis in the pars intermedia of other species<sup>42</sup>; however, the role of GABA in the pathogenesis of equine PPID is unknown.

Both the anterior lobe (corticotropes) and the intermediate lobe (melanotropes) synthesize the identical hormone precursor molecule, POMC<sup>9</sup>; however, in the intermediate lobe the post-translational cleavage and processing of POMC is different from that in the anterior lobe.<sup>13,44</sup> In the anterior lobe, the major products of POMC are ACTH and  $\beta$ -lipotropin ( $\beta$ -LPH) (Figure 20-4). In the intermediate lobe, ACTH is further cleaved to produce  $\alpha$ -MSH and corticotropin-like intermediate lobe peptide (CLIP), and  $\beta$ -LPH is processed to  $\beta$ -END.<sup>44,45</sup> Therefore in the pars intermedia, ACTH is a minor (2%) post-translational product of POMC.<sup>10</sup> It also appears that the POMC production and cleavage in the pars intermedia of the horse with PPID remains intact; however, postcleavage modification of the peptides is altered.<sup>10,13</sup> Millington et al.<sup>13</sup> found that the post-translational processing of  $\beta$ -END in normal tissues was different from that in equine pituitary adenomas, with significantly more of the active (agonist) form of  $\beta$ -END present in the pituitary of horses with PPID.

Although progress has been made in the understanding of the pathogenesis of PPID in horses, many questions remain unanswered. For example, why do a number of horses with PPID have low cortisol concentrations in spite of high ACTH concentrations? Cortisol concentrations are variable in affected horses,<sup>14,16,46,47</sup> and adrenocortical hyperplasia is not a consistent finding<sup>1,14</sup>; therefore it is difficult to explain

hyperglycemia, neutrophilia, and lymphopenia, as well as other clinical signs such as laminitis and predisposition to infections such as those resulting from glucocorticoid excess. Cortisol may be responsible for some of the clinical signs associated with PPID; however, many studies have found that cortisol concentrations in horses with PPID may be within or below the normal range, suggesting that unidentified factors may be as or more important than hypercortisolemia in the pathogenesis of this condition. Furthermore, these findings are consistent with the low frequency (20%) of adrenocortical hyperplasia in horses diagnosed with Cushing's disease.<sup>1,14</sup> One explanation for the low cortisol concentration in some affected horses may be that glucocorticoid synthesis and secretion from the adrenal gland is downregulated from excessive and prolonged exposure to ACTH. Alternatively, ACTH secreted in horses with PPID may be immunologically active but biologically inert.

## ☞ PATHOLOGIC FINDINGS

Horses with PPID have a grossly enlarged pituitary because of hypertrophy, hyperplasia, and adenoma formation in the pars intermedia. Adenomas of the pars intermedia are white to yellow, nodular or multinodular masses that can infiltrate or compress the pars distalis and pars nervosa.<sup>1,14,35</sup> In some horses, pituitary microadenomas (<1 cm) may be evident. Microscopically, these adenomas are comprised of a cellular pattern with large columnar, spindle-shaped, or polyhedral cells that form palisades and pseudoacini.<sup>1,35</sup> The tumor cells are slightly acidophilic with hematoxylin and eosin staining, and they are chromophobic with trichrome stain.<sup>1</sup> Pars intermedia adenomas may compress the overlying hypothalamus or optic chiasm, resulting in necrosis of nuclei that are important in endocrine and metabolic functions.

Adrenal cortical hyperplasia is not a consistent finding; 1 of 5 horses in one study<sup>14</sup> and 4 of 19 horses in another study<sup>1</sup> had adrenal cortical hyperplasia. The lack of cortical hyperplasia in most horses with PPID may indicate that the clinical signs in these horses are not the result of hyperadrenocorticism. The variability in response among affected horses to the ACTH stimulation test may be the result of variable adrenal hyperplasia.

Skin biopsies reveal normal hair follicles in anagen phase, normal epidermis and dermal collagen, and a lack of the characteristic lesions present in dogs with Cushing's disease from cortisol excess (C.C. Capen, personal communication, 2006). Although laminitis is a common finding in horses with PPID, the pathologic features in the lamina of these horses are non-specific.

## ☞ LABORATORY TESTING

The diagnosis of PPID in many cases can be suggested by history, clinical signs, and preliminary laboratory results. Initial testing should include a complete blood count (CBC), a serum chemistry profile, and urinalysis. Horses with PPID may have a normal CBC and serum chemistry profile. Clinicopathologic abnormalities reported in horses with PPID include anemia, neutrophilia, lymphopenia, eosinopenia, hyperglycemia, hyperlipemia, increased liver enzymes, and glucosuria.\*

Persistent hyperglycemia is frequent in affected horses; more than 45% (94% in one study) of horses with PPID had hyperglycemia.<sup>2,5,14,21,49</sup> Many horses with PPID and hyperglycemia have IR (hyperglycemia and hyperinsulinemia).<sup>11</sup> Although insulin-resistant hyperglycemia can be present, it is also possible that hyperglycemia in some horses may result from stressing conditions. Glucosuria is a frequent finding (up to 77% in one study) in horses with PPID and hyperglycemia.<sup>2</sup> Hyperlipemia may be present in horses, but it is more frequent in ponies.<sup>20,50</sup>

Additional testing to help confirm the diagnosis might include determination of resting plasma cortisol and ACTH concentrations. Significant variability is noted in plasma cortisol concentration among horses with PPID,<sup>14</sup> and cortisol concentrations are affected by stress, exercise, and serum glucose concentrations. Therefore measurement of resting plasma cortisol concentrations is not diagnostic for PPID. Resting ACTH concentrations are considered to be more reliable in the diagnosis of PPID than resting cortisol concentrations.

## ☞ DIAGNOSIS

Diagnostic testing for horses suspected of having PPID is based on history, clinical signs, and laboratory findings. Many tests for the diagnosis of PPID have been evaluated; however, based on the limited number of horses studied, as well as the variable results from some of these studies, it is difficult to recommend them without additional validation. One limitation in the diagnosis of PPID is establishing a gold standard; currently perhaps the only well-accepted gold standard is postmortem examination interpreted in conjunction with clinical signs. Another important consideration is the season during which the testing is performed. The equine pars intermedia is known to be more active in the fall; as a result, false-positive diagnostic tests may occur when testing is performed between August and October.

### BASELINE CORTISOL CONCENTRATIONS

Measurement of baseline plasma concentrations of cortisol has been proposed in the diagnosis of PPID. In horses with PPID, resting plasma concentrations of cortisol may be within the normal range,<sup>14</sup> mildly increased,<sup>16</sup> or decreased.<sup>46,47</sup> Therefore measuring baseline plasma cortisol concentrations to diagnose PPID is not recommended. Healthy horses have diurnal variations in plasma cortisol concentrations, with higher concentrations in the morning than in the late evening, although significant individual variation occurs.<sup>16,51-53</sup> No diurnal variations in cortisol concentrations are reported in horses with PPID.<sup>16</sup> Circadian cortisol variation may also be blunted in horses with other diseases or stress-related conditions,<sup>54</sup> thus limiting its usefulness as a diagnostic test.

In addition to plasma, cortisol concentrations have been determined in saliva and urine of healthy horses and horses with PPID.<sup>16,49,51</sup> van der Kolk et al.<sup>52</sup> measured salivary cortisol concentrations in healthy horses and found that there was a trend for higher salivary cortisol concentrations in the morning than in the evening; however, the differences were not statistically significant. They also found that plasma and salivary cortisol concentrations were correlated and that administration of dexamethasone decreased, and administration of ACTH increased, plasma and salivary cortisol concentrations.

\*References 2, 5, 12, 14, 23, 38, 48.

## URINARY CORTICOID:CREATININE RATIO

The urinary corticoid/creatinine (c:c) ratio has been determined in ponies and horses suffering of PPID.<sup>17,50</sup> van der Kolk et al.<sup>17</sup> found that horses with PPID had higher urinary concentrations of corticoids and a higher c:c ratio than healthy horses; however, in their study there was overlap in the c:c ratio between healthy and diseased horses, resulting in a number of false-positive and false-negative results, thus limiting the value of this test alone for the diagnosis of PPID. In addition, horses were included in that study on the basis of the ACTH stimulation test, which itself has significant variability among horses with PPID and between healthy ponies and horses.<sup>21</sup> No ponies were included in the control group, and most of the affected animals were ponies. Additional studies comparing the c:c ratio to well-accepted and validated diagnostic procedures are necessary to recommend this test over other tests.

## DEXAMETHASONE SUPPRESSION TEST

The dexamethasone suppression test (DST) has been a well-accepted and recommended test for the diagnosis of PPID in horses.<sup>16,55,56</sup> This test is based on the lack of suppression of plasma cortisol concentrations in horses with PPID at 19 to 24 hours after dexamethasone administration.<sup>16</sup> It has been suggested that plasma cortisol concentrations are not suppressed by dexamethasone administration in horses with PPID because of production of ACTH from melanotropes of the pars intermedia that, as described previously, are not responsive to cortisol feedback.<sup>16</sup> The most commonly used protocol for dexamethasone suppression is the overnight DST. A baseline blood sample is collected for serum cortisol measurement between 4 to 6 PM, after which dexamethasone is administered (40 µg/kg, IM). Blood samples are collected at 15 and 19 hours (8 AM and noon) after dexamethasone administration. Many clinicians will omit the 15-hour sample and collect only a single suppression cortisol sample at 19 hours postdexamethasone administration. Plasma cortisol concentrations should be less than 1 µg/dl in horses with an intact HPA axis. This test provides simplicity, is inexpensive, and is well accepted by clinicians. Although the test is useful in distinguishing horses with PPID from horses with an apparently functional HPA axis, both false positives and false negatives may occur. False positives are common when horses are tested during the fall. Donaldson et al.<sup>57</sup> reported a false-positive rate of 20% to 40% in healthy ponies and horses, respectively. False-negative test results most commonly are observed in the early course of the disease. Horses with clinical indicators of PPID and normal dexamethasone suppression should be monitored and retested after 4 to 6 months. Although many clinicians are concerned with steroid-induced laminitis results of the DST test, no adverse effects of this test were reported when a large number of horses with PPID were evaluated.<sup>16,49</sup>

## RESTING ADRENOCORTICOTROPIC HORMONE CONCENTRATIONS

Increased plasma concentrations of ACTH and POMC-derived peptides have been reported in horses with PPID.\* Couetil, Paradis, and Knoll<sup>21</sup> found that horses and ponies with PPID

had significantly higher resting plasma concentrations of ACTH when compared with healthy horses and ponies. In this study, plasma ACTH concentrations for the diagnosis of PPID had a sensitivity of 90.9% in horses, 81.8% in ponies, and a specificity of 100% using dexamethasone suppression as the gold standard.<sup>21</sup> Other studies have reported false-positive and false-negative results.<sup>34</sup> Determination of resting ACTH concentrations is a good alternative when the results of the DST are nondiagnostic or when the DST is contraindicated. When determining baseline ACTH concentrations it is important to consider that stressful conditions may increase ACTH plasma concentrations. In addition, plasma ACTH concentrations are higher in the fall. In one study, greater than 90% of healthy animals with normal ACTH concentrations in May had concentrations above the laboratory normal reference range when tested in September and would be falsely considered positive for PPID.<sup>57</sup> Blood samples to determine ACTH concentrations should be collected in cold EDTA tubes, kept at 4° C, centrifuged within 8 hours, and plasma stored frozen until analysis.<sup>21,40</sup>

## ADRENOCORTICOTROPIC HORMONE STIMULATION TEST

The administration of ACTH (1 IU/kg of natural ACTH gel, IM; 25 IU ACTH<sub>1-24</sub>, IV; or 100 IU of synthetic ACTH [Cosyntropin], IV) has been used in different studies with different results.\* A horse with PPID is expected to have an exaggerated (at least fourfold) cortisol response to ACTH stimulation, and when an increased response is present in a horse with elevated resting ACTH concentrations, a more accurate diagnosis of PPID can be made.<sup>58</sup> Dybdal et al.<sup>16</sup> failed to detect a statistical difference in cortisol concentrations between control horses and horses with PPID after administration of 1 IU/kg of natural ACTH gel, IM, between 8 and 10 AM, samples being collected in heparinized tubes before, and 2, 4, 8, and 12 hours post-ACTH administration. van der Kolk et al.<sup>19</sup> found a significantly greater increase in cortisol concentrations in horses with PPID after administration of 25 IU of synthetic ACTH<sub>1-24</sub>, IV, at 9 AM, samples being collected in EDTA tubes just before and 2 hours post-ACTH administration. Although the ACTH stimulation test is useful in assessing adrenal gland function or exhaustion, it does not seem to be the test of choice to assess HPA axis function in horses suspected of having PPID. Combining the ACTH stimulation test with the DST failed to improve the tests' performance in distinguishing horses with PPID from control horses.<sup>16</sup>

## THYROTROPIN-RELEASING HORMONE STIMULATION TEST

Beech and Garcia<sup>46</sup> evaluated the effect of TRH administration on plasma cortisol concentrations in healthy horses and in horses with PPID. They found that TRH administration (1 mg, IV) to horses with PPID, in addition to increasing T<sub>3</sub> and T<sub>4</sub> concentrations, also resulted in a significant increase in plasma concentrations of cortisol within 15 minutes post-TRH administration and that cortisol concentrations remained elevated for 90 minutes. No significant increases in plasma cortisol concentrations were present in healthy horses. Eiler et al.<sup>47</sup>

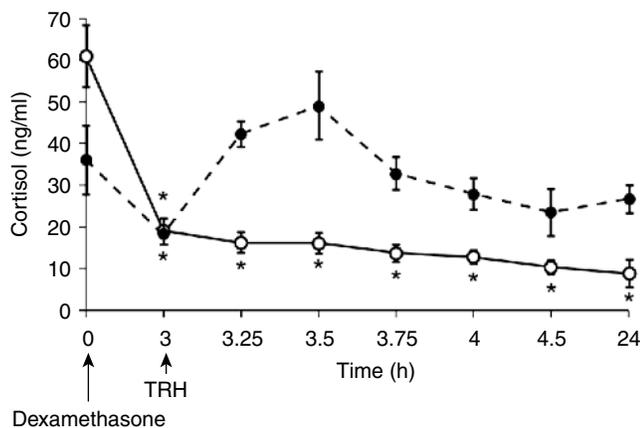

\*References 9, 10, 13, 19, 21, 40, 58.

\*References 5, 16, 17, 19, 58, 59.

evaluated the TRH stimulation test in two horses suspected of having PPID and three healthy horses; they found that maximal cortisol concentrations overall were not statistically different between groups; however, too few horses were included to make any conclusion. Other studies have found increases in plasma cortisol concentrations after TRH administration to healthy horses.<sup>18,43</sup> TRH has been shown to be a direct releasing factor for equine melanotropes.<sup>43</sup> Therefore the increased cortisol response after TRH administration in horses with PPID is likely a result of greater POMC peptide release secondary to hyperplasia and hypertrophy of the melanotropes of the pars intermedia. Some clinicians have advocated the TRH stimulation test as an alternative method to the DST in horses with laminitis or at greater risk for developing steroid-induced laminitis.

### COMBINED DEXAMETHASONE SUPPRESSION TEST AND THYROTROPIN-RELEASING HORMONE TEST

The combination of a DST with the TRH stimulation test was evaluated as a diagnostic method for PPID in 42 horses.<sup>36</sup> After baseline sampling in EDTA-containing tubes, dexamethasone (40 µg/kg, IV) was administered (8 to 10 AM). A second sample was collected 3 hours later, and then TRH (1.1 mg, IV) was administered. Blood samples were collected at 3.5 (30 minutes after TRH administration) and 24 hours after dexamethasone administration. The test was considered positive if cortisol concentration was greater than 1 µg/dl at 24 hours or the 3 hour cortisol concentration increased by greater than or equal to 66% 30 minutes after TRH administration (Figure 20-5).

**FIGURE 20-5** Combined dexamethasone suppression/thyrotropin-releasing hormone (TRH) stimulation test in healthy horses ( $n = 7$ ; open circles) and in horses with pituitary pars intermedia dysfunction (PPID) ( $n = 5$ ; closed circles). Plasma cortisol concentrations decreased 3 hours after dexamethasone administration in both groups; however, TRH administration resulted in a significant increase in cortisol concentrations in horses with PPID but not in healthy horses, and 21 hours after TRH administration cortisol concentrations were still less than baseline in healthy horses but were higher in horses with PPID. \*Significant difference from baseline value at time 0. (Adapted from Eiler H, Oliver JW, Andrews FM, et al: *J Am Vet Med Assoc* 211:79–81, 1997.)

Performance of the test was evaluated using postmortem diagnosis as the gold standard. The TRH component alone had a sensitivity of 41% and a specificity of 92%; the DST alone had a sensitivity of 65% and a specificity of 76%. When considered as a combined test, the sensitivity (88%) and specificity (76%) improved (see Figure 20-5). Based on the results of this study, it seems that the combined DST/TRH test is a promising method for the diagnosis of PPID. Disadvantages include expense and the need for multiple sample collections.

### RESTING INSULIN CONCENTRATIONS

In horses with hyperglycemia, measurement of fasting blood insulin concentrations together with glucose concentrations may be useful. Increased insulin concentration in the presence of persistent hyperglycemia is highly suggestive of IR (reported to occur in approximately 70% of horses with PPID<sup>49</sup>). Other conditions such as EMS and stress are also associated with IR; therefore the presence of IR alone is not diagnostic. Resting glucose and insulin concentrations are reported to have a sensitivity of 58% and 92% for the diagnosis of PPID, respectively.<sup>19</sup> Although IR alone is not diagnostic for PPID, IR does have prognostic value, because horses or ponies with IR are more likely to develop laminitis.<sup>29,60</sup> Therefore measurement of fasting insulin and glucose is recommended in horses suspected of having PPID. If resting insulin and glucose is not diagnostic but IR is suspected, then further tests may be useful to confirm IR, such as the CGIT, the glucose tolerance test, or the insulin tolerance test. Details on the CGIT can be found in the section on Equine Metabolic Syndrome.

### DETERMINATION OF PROOPIOMELANOCORTIN PEPTIDES

Based on the current knowledge of equine pars intermedia dysfunction, it would be reasonable to determine plasma concentrations of POMC-derived peptides (ACTH,  $\alpha$ -MSH,  $\beta$ -END, CLIP) in horses suspected of having PPID. These peptides are increased in horses with PPID.\* Determination of POMC-derived peptides in the clinical scenario has been limited to ACTH plasma concentrations, and the use of human immunoassays to determine equine ACTH concentrations has been validated.<sup>21</sup>

Plasma and CSF  $\beta$ -END concentrations are increased severalfold in horses with PPID.<sup>13</sup> Furthermore, pars intermedia POMC peptides ( $\alpha$ -MSH,  $\beta$ -END, CLIP) are disproportionately higher when compared with ACTH plasma concentrations in affected horses.<sup>9,10</sup>

### DOMPERIDONE RESPONSE TEST

A new test being evaluated for diagnosis of PPID is the domperidone response test.<sup>63</sup> Domperidone is a DA receptor antagonist. In horses with PPID, administration of domperidone is suggested to exacerbate the loss of dopaminergic inhibition and result in release of ACTH from the pars intermedia. In a study of 33 horses, plasma ACTH concentration 8 hours after domperidone administration was positively correlated to histologic PPID severity score and morphometric analysis of pars intermedia size, although not all animals considered

\*References 4, 9, 10, 13, 19, 21, 61, 62.

“positive” by histology and domperidone test exhibited clinical signs of disease. In the absence of any clinical signs it is difficult to determine if the relatively mild histologic changes (diffuse pars intermedia hyperplasia) were indicative of early disease or associated with an increased function of the intermediate lobe for other reasons. A greater number of animals will need to be assessed over time to determine the effect of season, disease, and other physiologic events on pituitary histology and pars intermedia domperidone response. Despite this, early indications suggest the domperidone response test warrants further study.

## RADIOGRAPHIC METHODS

Computed tomography has been used to diagnose PPID in horses, although measurements of the pituitary by this method have poor accuracy.<sup>64-65</sup> Levy, Blevins, and Janovitz<sup>66</sup> used ventral radiography and contrast venography to diagnose PPID in horses and ponies. Magnetic resonance imaging (MRI) is the preferred diagnostic imaging modality in human pituitary disease; however, no studies document the usefulness of MRI in diagnosis of PPID. A number of horses with PPID and neurologic signs had pituitary enlargement on MRI.<sup>67</sup> Although available to equine clinicians, these methods are far from being practical in the diagnosis of PPID; they require anesthesia and expensive equipment and are not cost-effective when compared with other diagnostic methods.

## TREATMENT

Optimal treatment of PPID includes a combination of management and pharmaceutical interventions. PPID is observed primarily in older horses; therefore it is important to treat the dysfunctional HPA axis, as well as many of the pathologic conditions associated with aging. Special attention should be given to providing optimal management, including high-quality feed, dental care, deworming, and farrier care. It is also important to pay particular attention to the skin and hair coat. Many horses cannot properly shed their winter coats and as a result may develop hyperthermia. In addition, horses with PPID are prone to skin infections. The most difficult complication to manage is laminitis, which may be complicated by over-feeding of high-energy hay, grass, or grain. Therefore reducing the amount of soluble carbohydrates is advisable. In addition, in mildly affected horses exercise is recommended. Because of the insidious nature of the laminitis observed in horses with endocrinopathies, close monitoring of hoof growth and freedom of movement is desirable in all aged horses. Periodic radiographic assessment of the feet in horses at risk of PPID may be prudent.

As discussed earlier in this section, the regulation of POMC peptide synthesis and secretion is under the influence of the hypothalamic periventricular dopaminergic systems. Regulation of POMC synthesis and secretion by the pars intermedia of horses with PPID is under similar control as the pars intermedia from unaffected horses and other species.<sup>9</sup> Based on this information, the medical treatment of PPID involves the use of DA agonists or serotonin antagonists.

Bromocriptine and pergolide are the two most commonly used DA D<sub>2</sub>-receptor agonists.<sup>15,25,27,40,68-71</sup> Bromocriptine can be given either orally or by subcutaneous injection (0.03-0.09 mg/kg/b.i.d.),<sup>9,68,72</sup> but its use in treatment of PPID is limited. Oral pergolide is widely used and has been shown to be

beneficial in the treatment of horses and ponies with PPID, with lifelong treatment recommended.<sup>25,27,40,49</sup> Doses of pergolide from 0.2 mg up to 5 mg/horse per day, once a day, or divided twice daily have been used in ponies and horses, with treatment durations of greater than 5 years. Treatment typically should start with a total daily dose of 1.0 mg/day; if no clinical evidence of improvement is noted by 4 to 6 weeks, the dose should be increased gradually every 3 to 4 weeks by 0.5 mg.<sup>23</sup> Success of treatment should be assessed by both documenting improvement of clinical signs and normalization of either DST or plasma ACTH concentration. Most horses show improvement within 6 to 8 weeks of treatment with doses of 1.0 to 2.0 mg of pergolide per day. Failure to respond to pergolide treatment may occur in very advanced disease, if a poor-quality drug is obtained from a compounding pharmacy, or if the drug is not consumed completely by the patient; this may also indicate an incorrect diagnosis. Periodic reassessments of DST or ACTH are recommended as the dose required to control disease may change over time.<sup>25</sup> Some horses treated with pergolide may develop anorexia, which typically resolves by reducing the dose.<sup>23</sup> Although long-term pergolide therapy has been associated with fibrotic cardiac valvular lesions in human beings,<sup>73</sup> similar lesions have not been reported in horses.

A second drug suggested to be useful in treatment of PPID is cyproheptadine, although horses treated with pergolide show a better response than horses treated with cyproheptadine.<sup>23,25,27</sup> Cyproheptadine is a nonselective 5-hydroxytryptamine receptor blocking agent (serotonin antagonist) that reduces ACTH and  $\beta$ -END secretion from ACTH-producing tumors in human beings.<sup>74</sup> Limited information exists on serotonin functions in the hypothalamus and pituitary gland of the horse, and no difference in serotonin concentration was found between the pars intermedia of horses with PPID and control horses.<sup>13</sup> Serotonin is also a histamine receptor (H<sub>1</sub>) antagonist with weak anticholinergic activity. Serotonin inhibits the release of prolactin from anterior pituitary cells in a nonserotonin receptor-dependent fashion by blocking calcium influx at the cell membrane.<sup>75</sup> Cyproheptadine has been used for many years to treat horses with PPID with variable results. It is estimated that one third of horses with PPID show improvement when treated with cyproheptadine.<sup>23,27</sup> This drug is recommended at 0.25 mg/kg, orally, once a day for 4 to 8 weeks.<sup>23</sup> If no clinical evidence exists of improvement and no reduction in plasma ACTH concentrations, then the dosage frequency should be increased to twice a day for 1 month, at which time ACTH concentrations should be determined or the DST repeated. In horses that fail to respond to high doses of cyproheptadine, switching to pergolide is recommended. A combination of cyproheptadine and pergolide has been suggested for horses that do not respond well to either drug alone.

Alternative therapeutic compounds have been suggested to treat horses with PPID. Aqueous extracts of *Vitex agnus-castus* (chasteberry, chaste tree, Evitex formally known as *Hormonise*) have been used to treat horses with PPID. *Vitex agnus-castus* extracts contain compounds (diterpenoids) that stimulate DA D<sub>2</sub>-receptor activity and inhibit different opioid receptors.<sup>76</sup> Because of its dopaminergic effects, *Vitex agnus-castus* has been recommended as an alternative phytotherapeutic agent in the treatment of hyperprolactinemia and premenstrual syndrome in women.<sup>77</sup> In a blinded study there was no clinical improvement or improvement in diagnostic test results in

14 PPID-affected horses treated with *Vitex agnus-castus* extract.<sup>78</sup> Therefore although physiologic and pharmacologic rationale support the possible use of these extracts to increase dopaminergic activity in the equine pituitary, currently no evidence exists to recommend *Vitex agnus-castus* to treat horses with PPID.

Trilostane is an enzymatic inhibitor of 3 $\beta$ -hydroxysteroid dehydrogenase, an important enzyme in steroid synthesis. However, little information exists regarding the effects of trilostane in the equine steroid metabolism.<sup>79</sup> Trilostane has been proposed for the treatment of PPID, as well as in the treatment of EMS.<sup>60,80</sup> In a study of 20 horses or ponies treated over 1 to 2 years, improvement in clinical signs other than hirsutism was recorded; however, DST remained unimproved, suggesting an insufficient response to the drug.<sup>80</sup> Until the mid-1980s trilostane was recommended to treat Cushing's disease in human beings; however, because of its lack of potency in blocking cortisol synthesis, trilostane is no longer recommended to treat this condition.<sup>81</sup> In horses with PPID only a minority have evidence of adrenal hyperplasia; therefore treatments directed at restoring pars intermedia function and limiting expansion of the pituitary mass may be more appropriate than those that target cortisol synthesis inhibition.

## ☞ PITUITARY INDEPENDENT CUSHING'S SYNDROME

Primary adrenocortical tumors are rare in horses,<sup>5,72,82,83</sup> and the few cases reported in the literature were nonfunctional tumors. Only one case of a functional adrenocortical tumor associated with clinical signs consistent with Cushing's disease has been reported.<sup>72</sup> A 12-year-old Dutch Warmblood gelding had a history of polyphagia, polydipsia, reduced muscle mass, hyperhidrosis, lethargy, and delayed shedding of the hair coat. The horse had persistent hyperglycemic and normal adrenocortical response to ACTH stimulation. After unsuccessful treatment with bromocriptine, the horse was euthanized and a unilateral adrenocortical adenoma was found.

## ☞ ECTOPIC CUSHING'S SYNDROME

In human beings and small animals, Cushing's disease results from excessive secretion of ACTH from the pituitary gland, ectopic secretion of ACTH by nonpituitary tumors, ectopic secretion of CRH, or excessive and autonomous secretion of cortisol from adrenocortical tumors. The secretion of ACTH or CRH from nonpituitary tumors results in a condition known as *ectopic Cushing's syndrome* or *ectopic ACTH syndrome*. Ectopic production of ACTH or CRH has not been demonstrated in the horse.

## INSULIN RESISTANCE AND EQUINE METABOLIC SYNDROME

Nicholas Frank

The two most common endocrine disorders affecting horses are PPID (also called *equine Cushing's disease*) and EMS. In general, PPID affects older horses, whereas EMS first develops in young and middle-aged animals. Many horses with EMS exhibit a

predisposition toward obesity that first becomes evident when they reach maturity, and this problem is often exacerbated by environmental conditions that promote weight gain. IR is a key feature of EMS—and the reason for describing the condition as an *endocrine disorder*. However, IR also occurs in a subset of patients with PPID, so this can lead to confusion. For the following discussion, the author will consider EMS to be defined by the presence of IR that cannot be attributed to PPID (resulting instead from the metabolic condition of the animal). Laminitis is the most important clinical feature of EMS, and early recognition of this syndrome can lead to prevention of this painful disease.

## ☞ DEFINITIONS

*IR* refers to the failure of tissues to respond normally to insulin. Skeletal muscle and adipose tissues are affected because they are two important sites for insulin-mediated glucose disposal. The liver also responds to insulin. Gluconeogenesis is inhibited and glycogen synthesis promoted as blood insulin levels rise after feeding. Up to 50% of the insulin secreted by the pancreas is cleared by the liver as blood circulates through this organ before entering the systemic circulation.<sup>1</sup> Hyperinsulinemia may therefore reflect increased production or reduced clearance of insulin.

*Compensated IR* is a term used when hyperinsulinemia is detected in an animal with reduced insulin sensitivity.<sup>2</sup> Insulin secretion from the pancreas increases to compensate for reduced tissue sensitivity and euglycemia is maintained. However, recent results from the author's laboratory show that resting hyperinsulinemia cannot be attributed to increased insulin secretion in all cases, which suggests that insulin clearance may be affected in some animals.

*Uncompensated IR* refers to reduced insulin sensitivity with hyperglycemia. Insulin concentrations may be elevated or within reference range, and it is assumed that uncompensated IR develops as a result of pancreatic insufficiency. Compensated IR is the most common form of IR in horses and ponies, but uncompensated IR should be considered when elevated blood glucose concentrations are detected. It is appropriate to use the term *type 2 DM* when hyperglycemia and glucosuria are present, and clinicians have recognized this condition in a few cases.

*EMS* is a term used to define a clinical syndrome recognized in horses. This is a controversial term because metabolic syndrome in human beings is a collection of risk factors used to predict the likelihood of coronary heart disease.<sup>3</sup> Critics therefore argue that the use of this term in equine medicine is inappropriate, because atherosclerosis and cardiac disease are not detected in affected horses. However, proponents of the term point out that herbivores are unlikely to develop atherosclerosis and laminitis is the manifestation of vascular disease seen in horses. This controversy can be resolved by accepting that EMS differs from the syndrome described in human beings.

EMS is characterized by (1) obesity or regional adiposity, (2) IR, and (3) subclinical or clinical laminitis.<sup>4</sup> Hypertriglyceridemia has also been associated with EMS, and blood leptin concentrations are often elevated in affected animals.<sup>5,6</sup> Leptin is a hormone released by adipose tissues that signals the hypothalamus to suppress appetite after feed consumption. Plasma leptin concentrations generally correlate with body condition score (BCS). However, elevated levels are sometimes detected

in leaner horses, and this suggests a state of energy metabolism dysregulation.<sup>5,7</sup> Studies have been performed to compare horses with low- or high-plasma leptin concentrations, and a cutoff value of 7 ng/ml has been used to define groups.<sup>8</sup> Hypertension has also been associated with laminitis and IR in ponies kept on pasture.<sup>9</sup> Mean arterial blood pressure (ABP) was higher in laminitis-prone ponies when measured in the summer but did not differ from control ponies in the winter.

*Obesity* is defined as an increase in body weight as a result of excessive fat accumulation within the body. When the BCS system developed by Henneke et al.<sup>10</sup> is applied, obesity is defined by a BCS greater than or equal to 7 on a 1 (poor) to 9 (extremely fat) scale. Obesity and IR are associated in horses and ponies.<sup>5,11</sup> It must be recognized, however, that body condition scoring systems are sometimes inadequate for assessing horses with endocrine disorders. Some horses with EMS and many with PPID are thin across the ribs, yet have pronounced adipose tissue deposits in the neck and tailhead regions. This accumulation of adipose tissue at specific locations is referred to as *regional adiposity*.

Laminitis is the most important component of EMS because of its negative effect on the welfare of the patient. It is the development of laminitis that often prompts the owner to seek veterinary attention for the horse, and this condition presents the greatest challenge with respect to management. Subclinical laminitis takes the form of divergent growth rings (also called *founder lines*) on the hooves or radiographic evidence of third phalanx rotation or sinking. This is sometimes referred to as *endocrinopathic laminitis* because of its association with EMS and PPID. The term *prelaminitic metabolic syndrome* has also been used to describe ponies that are at higher risk for developing pasture-associated laminitis because of IR.<sup>6</sup>

## ☞ ROLE OF GENETICS

Genetic predisposition plays an important role in the development of obesity and IR in horses. Ponies tend to be more insulin resistant than horses,<sup>11</sup> and certain breeds and genetic lines of horses appear to more predisposed to obesity and IR.<sup>4,5</sup> Obesity can develop in horses of all breeds, but this problem is most common in Morgan horses, Paso Finos, Arabians, Saddlebreds, Quarter Horses, and Tennessee Walking Horses. Horses that are predisposed to obesity are sometimes referred to as *easy keepers* because they require fewer calories to maintain body weight.

Most horses or ponies with EMS are obese, and this syndrome begins with a genetic predisposition that affects metabolic efficiency. Affected animals seem to require fewer calories to maintain body weight and have an enhanced appetite. Owners often report that the horse spends more time grazing when turned out on pasture. The easy keeper concept is relevant to the issue of genetic susceptibility. Certain breeds or genetic lines may have undergone evolutionary adaptations to survive harsher environments, and these horses or ponies may be more efficient at converting poorer-quality forages into energy. Lack of exercise is also likely to play a role in the development of EMS because exercise increases insulin sensitivity.<sup>12,13</sup>

Genetics and environment interact when affected horses are given free access to pasture, particularly when a small number of animals are grazing on a large area. Carbohydrate intake on pasture is influenced by grazing time, the area grazed, geographic location, climate, soil quality, and season.<sup>14</sup> In many

regions of the country, pasture grass is abundant and rich in nutrients. This is accentuated when certain types of grass are sown to improve pastures for cattle or when fertilizers are used. A second point of interaction occurs when susceptible horses are fed grain. This is unnecessary for metabolically efficient animals and promotes obesity and IR. Unfortunately, many horse owners feed grain to bring their horses in from pasture or because they perceive that their horses are unhappy if they are kept on a hay-only diet. It is a common mistake to feed grain to horses that are able to maintain their body condition on pasture or hay alone. Horses can also be overfed if they are fed as a group or if grain is used as a reward. Some horse owners deliberately feed their horses too much because they prefer a higher BCS, and these biases are sometimes reflected in the judging at horse shows. Other horse owners simply fail to recognize that obesity has developed in the animal.

Finally, human beings interfere with an important interaction between genetics and environment by feeding horses more grain in the winter to prevent weight loss. Seasonal weight loss is a natural occurrence in wild horses and is likely to correct problems with obesity that have developed during other times of the year.

## ☞ CLINICAL SIGNS AND DIFFERENTIAL DIAGNOSES

Obesity is detected on physical examination of the horse and application of a BCS system. A horse suffering from EMS is shown in [Figure 20-6](#). Regional adiposity is commonly detected in IR horses, and mean neck circumference has been negatively correlated with insulin sensitivity in obese horses with IR.<sup>5</sup> Neck circumference can be measured with a tape measure. One can make these measurements by dividing the distance along a line from the poll to the cranial aspect of the withers ( $x$ ) by four and measuring the circumference of the neck at three equidistant points ( $0.25x$ ,  $0.50x$ , and  $0.75x$ ). Expansion of adipose tissues within the neck is commonly referred to as a *cresty neck* and, with the exception of stallions, this finding is suggestive of IR in horses.<sup>5</sup>

Enlarged fat deposits may also be found close to the tailhead or appear as randomly distributed subcutaneous swellings. Geldings are sometimes presented for evaluation of preputial swelling, and mares may show enlargement of the

**FIGURE 20-6** Photograph of a 7-year-old Morgan horse mixed breed mare that suffers from equine metabolic syndrome (EMS).

mammary glands. Both of these problems are related to adipose tissue accumulation, which can interfere with lymphatic return in these regions. Affected horses develop edema in these areas when they are left standing in a stall for too long; this problem improves with exercise. Supraorbital fat accumulation is also a frequent finding. EMS is sometimes recognized when horses develop other medical problems, including colic, hyperlipemia, and reproductive issues. The author has observed that horses with EMS develop pedunculated lipomas at a younger age, presumably because of additional fat surrounding the abdominal viscera. Obesity has also been associated with abnormal reproductive cycling in mares.<sup>15</sup>

Regional adiposity is a feature of EMS, but it must be recognized that fat redistribution is also seen in older horses with PPID. It is therefore necessary to examine the patient for clinical signs of PPID, including delayed hair coat shedding, hirsutism, loss of skeletal muscle mass, polyuria, polydipsia, or increased caloric demand.<sup>16</sup> Testing for PPID is recommended in middle-aged horses with EMS because these conditions overlap in some patients. Affected horses can enter a *transition state* when PPID develops in an animal with EMS. Delayed hair coat shedding is often the first sign of this transition, and owners should be advised to watch for this change. It is also hypothesized that horses with EMS are at greater risk for developing PPID at an earlier age, so treatment for pituitary dysfunction should be considered in middle-aged (10 to 20 years old) horses if clinical signs are recognized.

Horses with EMS commonly suffer from laminitis, which is recognized when lameness is detected or hoof testers are applied to the feet. Some horses are not lame on physical examination but have radiographic evidence of third phalanx rotation or sinking. Laminitis often first develops after the horse has been grazing on pasture grass that is rich in sugars and starches. This happens at times of the year when grass is abundant and growing rapidly or when responding to cooler temperatures in the fall. Owners of horses with recurrent laminitis also report that laminitis episodes occur after changes in season or with the onset of cold weather.

## ☞ PATHOLOGY

Complete blood count and serum biochemical analysis results are usually unremarkable, with the exception of plasma glucose concentrations, which are discussed following. Hyperglycemia is more commonly associated with PPID and may be accompanied by mature neutrophilia and lymphopenia. Elevated serum triglyceride concentrations are sometimes detected in ponies<sup>6</sup> or horses<sup>5</sup> with obesity and IR, but this finding is inconsistent in horses with EMS. Mildly elevated GGT activity has been recognized in a small number of horses with chronic EMS; this may be a result of hepatic lipidosis.

Low resting total triiodothyronine (tT<sub>3</sub>) and total thyroxine (tT<sub>4</sub>) concentrations are sometimes detected in horses with EMS, but the significance of this finding has been overstated in the past. It is a common misconception that obese horses suffer from hypothyroidism because obesity is associated with hypothyroidism in dogs and human beings. However, serum TH concentrations rise appropriately when IV TRH is administered,<sup>17</sup> indicating that the HPT axis is functioning normally in these patients. It is therefore likely that low serum thyroid concentrations simply reflect responses to extrathyroidal changes in metabolism. Breuhaus et al.<sup>18</sup> detected markedly lower serum tT<sub>4</sub> and free thyroxine concentrations in horses

with systemic illness. Phenylbutazone also significantly lowers serum tT<sub>4</sub> concentrations in horses,<sup>19</sup> and this drug is commonly used to treat laminitis in horses with EMS.

## ☞ DIAGNOSTIC TESTING

The ease of testing procedures must be considered when diagnostic tests for IR are selected. Two tests for IR can be used in clinical practice: (1) resting blood measures and (2) the CGIT. The first procedure is straightforward because it is based on a single blood sample, whereas the CGIT is more involved and is therefore reserved for more challenging cases.

### RESTING BLOOD MEASURES

Currently clinicians use a measurement of blood insulin and glucose concentrations to diagnose IR in horses (Table 20-3), but it is hoped that a panel of tests for EMS will be developed in the future. Components of this panel might include connecting peptide (C-peptide), leptin, and adiponectin, as well as metabolites such as triglycerides and nonesterified fatty acids. Plasma triglyceride concentrations are currently available and can be requested as part of a plasma biochemistry analysis. Practitioners are also advised to measure plasma ACTH concentrations at the same time because EMS and PPID sometimes overlap in middle-aged animals.

### RESTING INSULIN CONCENTRATIONS

Two important limitations must be considered when using this test for IR in horses. First, environmental conditions significantly affect results, so care must be taken to collect blood samples under standardized conditions. Second, insulin assays vary between laboratories, so different laboratories yield different results. This does not mean that laboratories are using inaccurate assays; it relates instead to the method used. It is therefore very important to interpret results according to the reference range provided by the laboratory. Clinicians are advised to send samples to a single laboratory and to select one that routinely handles equine serum or plasma. An insulin concentration above the reference range (for horses) provided by the laboratory defines hyperinsulinemia and therefore IR. In the author's laboratory, a resting insulin concentration greater than 20 μU/ml defines IR if the horse has been deprived of feed for approximately 6 hours before sample collection. If hay has been fed, then a cutoff value of 30 μU/ml can be used to define IR, but it is advisable to recheck the patient after feed deprivation. Note that some laboratories report insulin concentrations in pmol/L, and an approximate conversion factor of 7 is used to convert units from μU/ml to pmol/L (i.e., 30 μU/ml is approximately equal to 210 pmol/L).

Environmental conditions affect insulin concentrations. Stress raises insulin concentrations in horses because cortisol and epinephrine are released and these hormones induce IR. Glucose and insulin concentrations are therefore higher in a stressed animal, which increases the likelihood of hyperinsulinemia being detected. One of the most common confounding factors affecting results is laminitis because horses that are painful at the time of testing have higher insulin concentrations. It is therefore strongly recommended that testing be delayed until after the pain of laminitis has subsided. Housing and feeding conditions also affect insulin concentrations. Some recent results from the author's laboratory indicate that insulin sensitivity decreases when horses that have

TABLE 20-3

**Guidelines for Interpreting Resting Glucose and Insulin Concentrations  
in Blood Samples Collected After Feed Deprivation**

Glucose (mg/dl)	Insulin ( $\mu$ U/ml) (Hay: <30)	Interpretation*
<100	< 20 (Hay: <30)	No evidence of insulin resistance (IR) at this time Retest at another time of the year or perform the combined glucose-insulin test (CGIT) if equine metabolic syndrome (EMS) phenotype is recognized Address any problems with obesity
<100	>20	Normoglycemia with hyperinsulinemia Horse suffers from compensated IR; an increased risk of laminitis exists Recommend weight management plan, diet changes, and exercise
<100	>100	Normoglycemia with marked hyperinsulinemia Severe compensated IR; high risk of laminitis Strictly control diet and consider pharmacological intervention
>100	>20	Horse losing its ability to regulate glucose because pancreatic insufficiency is developing Transitioning from compensated to uncompensated IR; high risk of laminitis Test for pituitary pars intermedia dysfunction (PPID)
>120	<20	Glucose levels unregulated and pancreatic insufficiency has developed Horse suffers from uncompensated IR; high risk of laminitis Check urine glucose for evidence of diabetes mellitus and test for PPID

\*Patient is not in pain or stressed; all feed withheld for 6 hours before sampling.

been housed on pasture in a herd are moved into the hospital. Horses are stressed by this change of environment, and insulin concentrations are higher in animals experiencing this transition. A patient that develops laminitis when grazing on pasture may experience this transition when it is moved into a stall to limit exercise.

Feeding conditions also affect insulin concentrations, and several issues must be considered before determining the sampling conditions for each patient. The author and colleagues have previously recommended that horses be fed hay the night before testing. This protocol was adopted after it was observed that horses with EMS became agitated when deprived of feed, resulting in stress-induced IR. However, results of a recent study revealed that horses with hyperinsulinemia had lower insulin concentrations when deprived of feed overnight. This suggests that hay, as well as pasture and grain, raises insulin concentrations in insulin-resistant horses. It is therefore the current recommendation to withhold all feed for approximately 6 hours before sample collection. One strategy is to leave a single flake of hay with the horse late at night and then delay the morning feeding until after the blood sample has been drawn. Unfortunately, some horses still become agitated when deprived of hay, and risks must be balanced in these cases. Owners can be asked to acclimatize their horses to feed deprivation by withholding hay on several occasions beforehand, or hay can be fed to these particular animals.

### RESTING GLUCOSE CONCENTRATIONS

Most insulin-resistant horses maintain blood glucose concentrations within the reference ranges provided by laboratories because they are in a state of compensated IR. However, glucose concentrations tend to be toward the high end of reference range, and affected horses are likely to have exaggerated blood glucose responses to high-sugar feeds. It is therefore important to deprive horses of feed (preferred approach) for

6 hours or to feed only hay the night before blood collection. The reference range for glucose provided by the University of Tennessee Clinical Pathology Laboratory is 75 to 117 mg/dl, but feeding conditions were not controlled when this range was established. Therefore one should expect blood glucose concentrations to be below 100 mg/dl (5.5 mmol/L) in healthy horses if samples have been collected after feed deprivation, unless the animal is stressed at the time of blood collection. A blood glucose concentration above 120 mg/dl (6.5 mmol/L) indicates marked hyperglycemia. Glucose concentrations reported in mmol/L must be multiplied by 18 to convert to mg/dl.

It is important to measure blood glucose concentrations. A problem with only examining resting insulin concentrations is that horses with uncompensated IR or DM will escape detection. Insulin concentrations can return to reference range in these patients as insulin secretion decreases because of pancreatic insufficiency. However, blood glucose concentrations increase as a consequence of IR and reduced insulin output, so patients can be identified by the presence of hyperglycemia and sometimes glucosuria.

### GLUCOSE/INSULIN RATIO

The glucose/insulin (G:I) ratio is calculated by dividing the glucose concentration in mg/dl by the insulin concentration in  $\mu$ U/ml (or mU/L). The correct units must be used, so insulin concentrations reported in pmol/L must be divided by 7 to provide values in  $\mu$ U/ml. Proponents of this test consider a ratio below 10 to be indicative of IR and refer to horses with ratios less than 4.5 as severely insulin resistant or decompensated. If one assumes a glucose concentration of 90 mg/dl, then these cutoff values are equivalent to serum insulin concentrations of 9 and 20  $\mu$ U/ml, respectively.

The G:I ratio is not recommended because the values listed previously fall within the reference range for insulin in

horses. Ratios below 10 are commonly detected in the author's clinic's herd of healthy Quarter Horse and Tennessee Walking Horse mares, and some fall below 4.5. Use of the G:I ratio therefore leads to the overdiagnosis of IR in horses. One other important limitation of the G:I ratio is that insulin results differ between laboratories, depending on the testing procedure used. However, most laboratories use the same colorimetric assay to measure glucose, so these results are more consistent. When resting insulin concentrations are interpreted independently, the reference range for the laboratory can be used to account for differences in methodology. However, this flexibility does not exist for the G:I ratio because set cutoff values have been established. It is therefore conceivable that insulin results from one laboratory will cause the ratio to be low, whereas results from another laboratory will give a ratio that falls within acceptable range.

It should also be noted that glucose concentrations decrease in blood samples if any delay exists between collection and centrifugation. Finally, a horse with uncompensated IR or DM will have a high glucose concentration with a low insulin concentration; this may result in a G:I ratio that exceeds 10 and will therefore be considered normal.

### PROXY MEASUREMENTS

These values can be calculated from blood glucose and insulin concentrations to predict the risk of IR. The two proxies used are (1) the *reciprocal of the square root of insulin (RISQI)* and (2) the *modified insulin/glucose ratio (MIRG)*.<sup>2</sup> The RISQI represents the degree of insulin sensitivity (a low number indicates IR) and the MIRG represents the ability of the pancreas to secrete insulin (most horses with IR have higher values). The RISQI value is more important and can be easily calculated. To do this, 1 is divided by the square root of the insulin concentration to obtain the RISQI value. A RISQI less than 0.29 indicates IR, which is equivalent to a serum insulin concentration of 12  $\mu$ U/ml. However, this method of diagnosing IR is not recommended because values were established for a specific group of animals with the insulin assay used by the research laboratory. In the experience of the author and colleagues, a cutoff value of 12  $\mu$ U/ml is too low and leads to the overdiagnosis of IR.

### COMBINED GLUCOSE-INSULIN TEST

This is a useful test that is likely more sensitive than resting glucose and insulin measurements.<sup>5</sup> Clinicians are therefore advised to consider this test when treating a horse or pony that exhibits the EMS phenotype but has resting glucose and insulin concentrations that fall within reference ranges. These patients may suffer from mild IR that gets worse at certain times of the year in response to changes in season, diet, or both. For instance, resting measures may be normal in a horse that is consuming hay in February, yet the same animal might develop pronounced IR in the summer when grazing on pasture. Two approaches can be taken in these situations. Resting insulin and glucose concentrations can be rechecked at another time of the year, or the CGIT can be performed on the same day to diagnose IR.

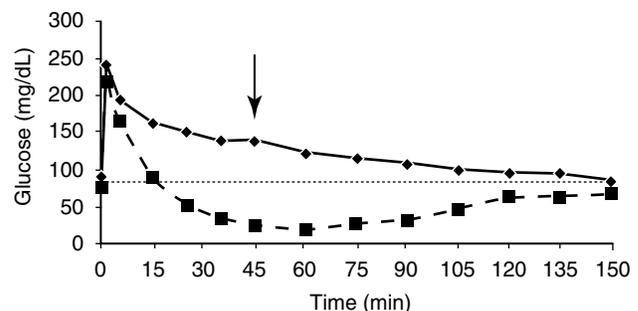

Stress induces false-positive results when the CGIT is used, so testing must be delayed until after laminitis has improved.<sup>20</sup> If testing is performed in a referral hospital, then it is advisable to give the patient several days to acclimate to the surroundings and place an IV catheter the night before testing.

However, testing can also be performed on the farm, with the catheter inserted the same day if the horse remains calm throughout the procedure. Horses should be kept off pasture, and hay should be withheld for approximately 6 hours before the procedure. Sedatives such as xylazine can induce IR, so they should not be given within 12 hours of testing.<sup>21</sup>

A preinfusion blood sample is collected for baseline glucose and insulin measurements, and then 150 mg/kg of body weight 50% dextrose solution is infused IV, immediately followed by 0.10 U/kg of body weight of regular insulin (Humulin R; Eli Lilly, Indianapolis, Ind.) via the same route.<sup>20</sup> These dosages are equivalent to 150 ml of 500 mg/ml (50%) dextrose and 0.50 ml of 100 U/ml regular insulin for a horse weighing 500 kg. Insulin should be drawn into a tuberculin syringe and then transferred to a larger syringe containing 1.5-ml sterile saline (0.9% NaCl) before infusion. Blood glucose concentrations are measured using a handheld glucometer at 1, 5, 15, 25, 35, 45, 60, 75, 90, 105, 120, 135, and 150 minutes postinfusion. A blood sample is collected at 45 minutes and submitted for the second insulin measurement. The test can be shortened to 60 minutes when used in the field, but it is advisable to collect all of the measurements if IR is detected so that the response time can be recorded for future comparisons. Two 60-ml syringes containing 50% dextrose solution should be prepared in case clinical signs of hypoglycemia (sweating, weakness) are seen or if the glucose concentration drops below 40 mg/dl (2.2 mmol/L).

A handheld glucometer is used for this procedure and can be purchased at a drug store. The author's research group uses a Medisense Precision QID glucometer (Abbott Laboratories, Inc) that costs approximately \$65. However, the AlphaTRAK (Abbott Laboratories, Inc., Princeton, N.J.) glucometer is now available for veterinary use. The start-up kit for this glucometer costs approximately \$180. (NOTE: Products and manufacturers are accurate as of 2009.)

IR is diagnosed when either the glucose or insulin response is abnormal during the CGIT. For the glucose response, IR is defined by blood glucose concentrations remaining above the baseline (preinjection) value for 45 minutes or longer (Figure 20-7). The insulin response is evaluated by measuring insulin concentrations at 0 (preinjection) and 45 minutes. Resting

**FIGURE 20-7** Blood glucose concentrations during the combined glucose-insulin test (CGIT) in a healthy nonobese mixed breed horse (*dashed line*) and an obese insulin resistant Morgan horse mare (*solid line*). The horizontal line represents the approximate baseline plasma glucose concentration, and the arrow indicates the time point (45 minutes postinjection) selected to define insulin resistance (IR) when the CGIT is used. Blood concentrations remain above the baseline value for 45 minutes or longer if the horse is insulin resistant.

hyperinsulinemia ( $>30 \mu\text{U/ml}$ ) or detection of a serum or plasma insulin concentration above  $100 \mu\text{U/ml}$  at 45 minutes indicates IR.

## ☞ PATHOPHYSIOLOGY

### OBESSE HORSES WITH EQUINE METABOLIC SYNDROME

Relationships between obesity and IR are complex. It should be remembered that *not all obese horses are insulin resistant and IR is not always accompanied by obesity*.<sup>6,15</sup> However, these conditions are associated, and evidence indicates that IR predisposes ponies to laminitis.<sup>6</sup>

Adipose tissues expand as obesity develops through an increase in adipocyte size (hypertrophy), number (hyperplasia), or both. This is manifested as generalized obesity or regional adiposity, and either can be accompanied by IR. In horses, regional adiposity increases the size of adipose tissues within the nuchal crest, and neck circumference has been negatively correlated with insulin sensitivity in obese insulin-resistant horses.<sup>5</sup> Fat thickness over the rump has also been used as a measure of body fat mass in horses,<sup>22</sup> and some horses develop enlarged fat pads in this area.

Horses that are evolutionarily adapted to sparse forages and harsher conditions may be predisposed to obesity because lipid accumulates more readily when excessive calories are provided in the diet. This state of overnutrition is often induced when genetically predisposed horses are turned out on pasture. The natural equine diet contains little fat, but excess glucose can be converted into fat via *de novo* lipogenesis. Fats are used for energy or stored as triglyceride within cells. When the storage capacity of adipose tissues is exceeded, fats are directed toward nonadipose tissues (repartitioning). Skeletal muscle, liver, and pancreatic tissues attempt to use fats by increasing beta oxidation, but lipid can accumulate within these tissues and alter normal cellular functions. This pathophysiologic mechanism is sometimes referred to as *lipotoxicity*.<sup>23</sup>

Reactive oxygen species are also generated as oxidative pathways are upregulated. Oxidant damage contributes to lipotoxicity and lipid-induced programmed cell death (lipopoptosis). Inflammation accompanies these events, resulting in the release of tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) and interleukin-6 (IL-6) from adipose tissues. Adipocytes release these proinflammatory cytokines that act locally or enter the blood.<sup>24</sup> Hormones and cytokines released from adipose tissues are referred to as *adipokines*. Leptin is an adipokine that is involved in the satiety response within the brain. Obese and insulin-resistant horses often have higher plasma leptin concentrations. In contrast, the release of another adipokine (called *adiponectin*) decreases with obesity and IR, and this may serve as a marker for EMS in the future.<sup>25</sup> IR develops when insulin-sensitive adipose, liver, and skeletal muscle tissues fail to respond normally. Insulin receptors, downstream signaling pathways, and glucose transporters such as GLUT4 are potential sites of dysregulation. More insulin is released from pancreatic  $\beta$  cells to compensate for reduced tissue insulin sensitivity, which results in hyperinsulinemia. Pancreatic insufficiency develops as a result of chronic IR or the effects of lipid accumulation within pancreatic tissues. Uncompensated IR occurs when the pancreas fails to sustain the higher rate of insulin secretion necessary to compensate for reduced

tissue insulin sensitivity, and hyperglycemia develops as a consequence.

All of the pieces of the puzzle must be assembled before one can fully understand the relationship between IR and laminitis in horses and ponies. At present, clinicians are limited to the knowledge that IR predisposes ponies to pasture-associated laminitis and that the disease can be experimentally induced by infusing IV insulin over several days.<sup>6,26</sup> Three broad mechanisms exist by which IR and obesity could predispose horses to laminitis: (1) altered blood flow or endothelial cell dysfunction within blood vessels of the foot, (2) impaired nutrient delivery to hoof tissues, or (3) a proinflammatory or pro-oxidative state induced by chronic obesity and IR. These processes are likely to contribute to the lower threshold for laminitis recognized in horses with EMS. Affected horses cannot withstand the laminitis-triggering events that are tolerated by healthy animals.

### LEAN HORSES WITH EQUINE METABOLIC SYNDROME

The current understanding of chronic IR in the lean horse is very limited, but several explanations have been proposed. One explanation is that the liver responds differently to nutrients in affected animals. In one study, ponies with IR showed exaggerated insulin responses to a meal containing fructose, which suggests that the liver responds differently to certain nutrients in horses with EMS, and this may represent *hepatic IR*.<sup>27</sup> Another proposed cause of IR in leaner animals is the increased production of cortisol locally within adipose tissues surrounding the abdominal organs. This is thought to result from increased  $11\beta$ -hydroxysteroid dehydrogenase 1 ( $11\beta$ -HSD1) activity within visceral adipose tissues, which increases local cortisol production and leads to the development of IR.<sup>4</sup> Johnson<sup>4</sup> referred to this condition as *peripheral Cushing's disease*, but this term is not recommended because it is easily confused with equine Cushing's disease, which results from PPID. Further studies are required to determine the activity of  $11\beta$ -HSD1 in horses with EMS.

Finally, horses may suffer from pancreatic diseases, including neoplasia, pancreatic insufficiency, or pancreatitis. Horses and ponies with exceptionally high blood insulin level are occasionally encountered, and the presence of an insulinoma or GH-secreting tumor should be considered in these cases (although neither condition has been reported to date in the horse). Type 2 DM has been detected in a small number of horses with hyperglycemia and glucosuria, and pancreatic insufficiency is likely in these cases.<sup>28,29</sup> PPID should be considered when uncompensated IR is detected. Pancreatitis has also been reported in horses and may occur more frequently than previously thought.<sup>30,31</sup>

## ☞ POSTMORTEM FINDINGS

On necropsy, horses are obese or exhibit regional adiposity and display evidence of laminitis. Hepatic lipidosis has been noted on some pathology reports, but it is unclear whether this simply reflects increased lipid storage or provides evidence of a pathologic process.

## ☞ MANAGEMENT

Management of IR involves three approaches: (1) reducing the sugar and starch content of the feeds provided to the horse, (2) limiting or eliminating access to pasture until IR improves,

and (3) increasing exercise. The first approach involves selection of hay with a lower sugar and starch content, which can be determined by submitting a sample for analysis. Equi-analytical Laboratories (or its partner company Dairy One Forage Laboratory) analyzes hay and provides starch, ethanol-soluble carbohydrate (ESC), and water-soluble carbohydrate (WSC) content. ESCs include simple sugars such as monosaccharides and disaccharides, whereas WSCs include fructans as well. The laboratory can be contacted at 1-877-819-4110 (or [www.equi-analytical.com](http://www.equi-analytical.com)), and testing costs approximately \$35 per sample. (Note: Products and manufacturers are accurate as of 2009.)

The nonstructural carbohydrate (NSC) content of the hay should be calculated from the values provided by the laboratory. Unfortunately, researchers disagree about the appropriate method of calculating NSC content. Some think that the WSC must be included, so NSC is calculated by adding WSC and starch values together. However, others argue that only ESC is relevant because fructans are primarily digested in the large intestine and do not therefore contribute to the rise in blood glucose concentrations after a meal. At present, it is recommended that NSC be calculated by adding starch and ESC together, and this level should ideally fall below 10% as fed in the hay. It is important to recognize that the relative importance of NSC intake varies with the severity of IR. Horses with severe IR (resting insulin concentration  $>100 \mu\text{U/ml}$ ) must be maintained on a stringent diet with a NSC content less than 10%, whereas mildly affected animals can be fed hay with higher levels. If hay has already been purchased and the NSC level is between 10% and 12%, then soaking the hay in cold water for 60 minutes before feeding should lower the sugar content.

Leaner horses with EMS are challenging to manage from a dietary standpoint because more calories must be provided without exacerbating IR. This can be accomplished by feeding one of the commercial low-sugar/low-starch (low-NSC) pelleted feeds that are now available to horse owners. These feeds vary in their NSC content, so the severity of IR must be taken into account before one is selected. It is also better to divide the daily ration into multiple small meals and to feed hay beforehand to slow gastric emptying. These strategies are used to lower the glycemic response to the meal, which is the degree to which blood glucose concentrations rise in response to the feed. Individual horses may respond differently to the same feed, so it is advisable to recheck glucose and insulin concentrations 7 to 14 days after a new diet has been initiated. Severely insulin-resistant horses are particularly difficult to manage and may require individual diet formulation, with the help of a nutritionist. Rinsed and then soaked molasses-free beet pulp can be fed as lower-cost alternative to commercial feeds. This feed has a low glycemic response, yet provides calories through hindgut fermentation and volatile fatty acid production.

Weight loss should be induced in obese horses by restricting the total number of calories consumed. In horses that are being overfed, removal of all concentrates from the diet is often sufficient to achieve the ideal body weight. Total caloric intake should initially be met by feeding hay in amounts equivalent to 1.5% to 2.0% of current body weight (e.g., 18 to 24 lb of hay per day for a 1200-lb horse). If the horse does not lose weight, then the amount fed should be lowered over several weeks to 1.5% of ideal body weight (e.g., 15 lb of hay for an ideal weight of 1000 lb). These strategies are effective

for horses kept in stalls or dirt paddocks, but weight loss is more difficult to achieve when horses are grazing on pasture. Strategies for limiting grass consumption on pasture include short ( $<1$  hour) turnout periods; confinement in a small paddock, round pen, or area enclosed with electric fence; or use of a grazing muzzle. Appropriate vitamin and mineral supplements should be provided to horses confined to dirt paddocks or stalls. Pasture access must remain restricted or eliminated until insulin sensitivity has improved because carbohydrates consumed on pasture can trigger gastrointestinal events that lead to laminitis in susceptible horses. Grass is an unregulated source of starch and sugar, so these carbohydrates will continue to exacerbate IR, even when other aspects of the diet have been controlled.

Laminitis must be considered when managing horses with EMS, and horses with recurrent laminitis must be kept off pasture permanently. These patients should be housed in dirt paddocks so that they are able to exercise once hoof structures have stabilized. Mildly affected horses can be returned to pasture if IR can be controlled, but care should be taken to restrict pasture access when the grass is going through dynamic phases, such as rapid growth in the spring or preparation for cold weather in the fall. Measurement of pasture grass NSC content at different times of the day has revealed that grazing in the early morning is likely to be safer for horses with IR, except after a hard frost when grasses accumulate sugars.<sup>32</sup>

## ☯ TREATMENT

Most horses or ponies with EMS can be effectively managed by lowering the sugar and starch content of the diet, reducing body fat mass if the animal is obese, instituting an exercise program, and limiting or eliminating access to pasture. However, it takes time for these management changes to take effect, so pharmacologic interventions can be considered to accelerate the improvement if the patient suffers from recurrent laminitis. Two options are currently available to clinicians, and each has its advantages and disadvantages. Levothyroxine sodium can be administered to accelerate weight loss and improve insulin sensitivity in obese horses, but its use should be avoided in leaner horses because of the reduction in body weight it produces.<sup>33</sup> Metformin is the other treatment option. This drug improves insulin sensitivity in insulin-resistant horses and ponies without affecting body weight.<sup>34</sup> However, the long-term effects of metformin on insulin sensitivity have not been determined, and the safety of this drug must be evaluated in horses.

### LEVOTHYROXINE SODIUM

Weight loss can be accelerated and insulin sensitivity improved in obese insulin-resistant horses when levothyroxine sodium is administered orally at a dosage of 48 mg (total per 500-kg horse)/day for 3 to 6 months.<sup>33</sup> Smaller ponies and Miniature Horses can be given 24 mg levothyroxine sodium per day for the same time period. Thyro L (Lloyd Inc; Shenandoah, Iowa) is recommended for this purpose, and 1 teaspoon (tsp) of powder provides 12 mg of levothyroxine sodium, so 4 tsp should be administered in the feed or by mouth once daily. When levothyroxine treatment is discontinued, horses should be weaned off the drug by lowering the dose to 24 mg (2 tsp)/day for 2 weeks and then 1 tsp (12 mg)/day for 2 weeks. The benefits of treating horses with levothyroxine at lower doses for longer periods have not been evaluated.

Measured serum  $tT_4$  concentrations are elevated when levothyroxine is administered at a dosage of 48 mg (4 tsp)/day, but levels vary considerably within and between horses. Serum  $tT_4$  concentrations often range between 40 and 100 ng/ml in treated horses, indicating that levothyroxine sodium is being given at a supraphysiologic dose.<sup>35</sup> However, clinical signs of hyperthyroidism such as sweating or tachycardia have not been observed in treated horses.<sup>36-38</sup> It is important for horses to be placed on a controlled diet when levothyroxine sodium is administered because clinicians have subjectively observed that feed intake increases in response to treatment. Weight loss is unlikely to occur if the horse is given free access to pasture, and the owner will perceive this as a treatment failure.

## METFORMIN

Metformin is a biguanide drug that enhances the action of insulin within tissues at the postreceptor level and inhibits gluconeogenesis within the liver.<sup>34</sup> This drug has been evaluated as a treatment for IR in horses and it is available as Glucophage (Merck Santé S.A.S.; Darmstadt, Germany), which is distributed in the United States by the Bristol-Myers Squibb Company.<sup>15,34,39</sup> When the effects of metformin on insulin sensitivity were assessed in horses and ponies with IR, a positive response was detected initially without hypoglycemia developing, but long-term results were variable.<sup>34</sup> Metformin was administered at a dosage of 15 mg/kg orally twice daily in the aforementioned study, but the pharmacokinetics of this drug have recently been examined and results suggest that the drug should be given every 8 hours.<sup>40</sup> Further studies are required to assess the safety and efficacy of this treatment for IR.

Numerous other treatments have been proposed for the management of IR in horses, including magnesium supplementation, chromium,<sup>41</sup> clenbuterol,<sup>42</sup> and cinnamon. Each of these therapies may be of some benefit, but further studies are required to establish their efficacy.

## DISORDERS OF CALCIUM AND PHOSPHORUS

Ramiro E. Toribio

### ☉ CALCIUM

Calcium is essential for physiologic processes such as muscle contraction, neuromuscular excitability, blood coagulation, enzyme activation, hormone secretion, cell division, and cell membrane stability.<sup>1</sup> Calcium also regulates processes that result in cell injury and cell death, including free radical production, cytokine release, protease activation, vasoconstriction, and apoptosis. Because of the importance of calcium in normal intracellular and extracellular processes, maintenance of a steady concentration of calcium is extremely important.<sup>2</sup>

### DISTRIBUTION AND PHYSICAL PROPERTIES OF CALCIUM

Calcium has structural and nonstructural functions, and it is found in three main compartments: (1) the skeleton, (2) the soft tissues, and (3) the extracellular fluid. The skeleton contains approximately 99% of the total body calcium as hydroxyapatite

crystals. Calcium is a major component of the skeleton, providing support against gravity, protection of vital internal organs (brain, spinal cord, thoracic organs), and a niche for blood-forming elements. The skeleton also acts as a reservoir for calcium. The nonstructural functions are related to calcium as a regulatory ion. The remaining calcium is present in the cell membrane, mitochondria, endoplasmic reticulum (ER) (0.9%), and in the extracellular fluid (0.1%).<sup>1</sup> In blood, virtually all calcium is in plasma. In plasma, calcium exists as a free or ionized form (50% to 55%); bound to proteins (40% to 45%); and complexed to anions such as citrate, bicarbonate, phosphate, and lactate (5% to 10%; Figure 20-8).<sup>1,3</sup> In horses, serum ionized calcium represents 50% to 58% of the total serum calcium concentration.<sup>4,6</sup> Free or ionized calcium ( $Ca^{2+}$ ) is the biologically active form of calcium. Of the protein-bound calcium, approximately 80% is associated with albumin and 20% with globulins.

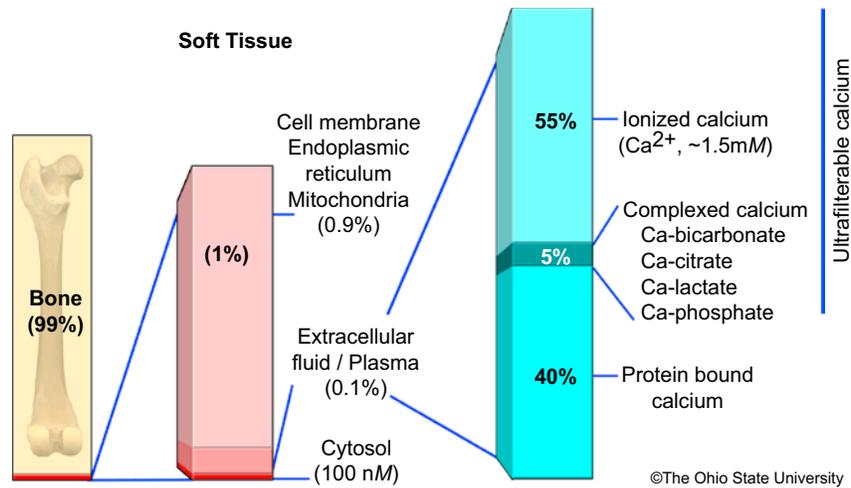

Plasma  $Ca^{2+}$  binds to anionic proteins (albumin), and its affinity for anionic sites is pH dependent. During acidosis a decreased albumin  $Ca^{2+}$  binding occurs from increased  $H^+$  concentrations, increasing  $Ca^{2+}$  concentrations, whereas in alkalosis  $Ca^{2+}$  concentrations are lower. Total calcium concentrations remain unchanged. Hypoalbuminemia results in total hypocalcemia (pseudohypocalcemia), with  $Ca^{2+}$  concentrations remaining within the normal range unless the primary cause of hypoalbuminemia is also altering calcium homeostasis (sepsis, gastrointestinal disease). Plasma and serum calcium concentrations are lower in foals than in adult horses.<sup>7</sup>

### INTRACELLULAR CALCIUM

Cytosolic  $Ca^{2+}$  ( $Ca^{2+}_i$ ) concentrations are very low ( $10^{-6}$  to  $10^{-7}$  M) when compared with extracellular  $Ca^{2+}$  concentrations ( $10^{-3}$  M; Box 20-2). This 10,000-fold  $Ca^{2+}$  gradient between the extracellular and intracellular fluid makes calcium an important cation in signal transduction. Approximately 95% of  $Ca^{2+}_i$  is in the ER and mitochondria (see Figure 20-8). Mechanisms that control changes in  $Ca^{2+}_i$  concentrations include  $Ca^{2+}$  channels in the plasma membrane (PM), the ER, and the sarcoplasmic reticulum (SR). Some of the mechanisms that remove  $Ca^{2+}_i$  from the cytosol include  $Ca^{2+}$ -ATPases and  $Na^+/Ca^{2+}$  in the PM, ER, and SR. The mitochondria are also important in regulating  $Ca^{2+}_i$  by providing energy for active calcium transport and by providing calcium storage.

The release of calcium from intracellular stores depends on messenger-activated channels present in the ER, SR, and mitochondria. For example, by interacting with specific cell membrane receptors, hormones may activate phospholipase C to hydrolyze phosphatidylinositol 4,5-bisphosphate to inositol 1,4,5-triphosphate ( $IP_3$ ) and diacylglycerol.  $IP_3$  is highly diffusible and interacts with  $IP_3$  receptors on the ER and SR, opening calcium channels, and increasing  $Ca^{2+}_i$  concentrations. The ryanodine receptors are intracellular calcium channels present in excitable cells (muscle, neurons), and their activation mediates calcium-induced calcium release (CICR) from the SR.

$Ca^{2+}$  channels (slow channels) are slightly permeable to  $Na^+$  and are abundant in cardiac and smooth muscle. Because  $Ca^{2+}$  channels are slow, depolarization in smooth muscle cells is slow and  $Ca^{2+}$ -dependent. In contrast,  $Na^+$  channels (fast channels) are abundant in skeletal muscle and neurons. During hypocalcemia, fast  $Na^+$  channels open with small changes in the membrane potential; nerve and muscle fibers become very excitable, causing hyperexcitability, muscle fasciculations, and tetany.  $Ca^{2+}$  binds to the exterior of the  $Na^+$  channels to increase the depolarization threshold, thus stabilizing

**FIGURE 20-8** Calcium distribution in the body. The skeleton contains approximately 99% of the total body calcium. The remaining calcium is present in the cell membrane, endoplasmic reticulum (ER), and in the extracellular fluid. In blood, calcium exists as a free or ionized form ( $\text{Ca}^{2+}$ ), bound to proteins, and complexed to anions such as citrate, bicarbonate, phosphate, and lactate. In horses, serum ionized calcium represent 50% to 58% of the total serum calcium concentration.<sup>4,6</sup> (Courtesy The Ohio State University.)

#### BOX 20-2

#### COMMON ABBREVIATIONS ASSOCIATED WITH DISORDERS OF CALCIUM AND PHOSPHORUS

$\text{Ca}^{2+}_i$	Cytosolic $\text{Ca}^{2+}$
PM	Plasma membrane
ER	Endoplasmic reticulum
SR	Sarcoplasmic reticulum
$\text{IP}_3$	Inositol 1,4,5-triphosphate
DOD	Developmental orthopedic disease
PTH	Parathyroid hormone
CT	Calcitonin
PTHrP	Parathyroid hormone-related protein
M-CSF	Macrophage colony-stimulating factor
RANK	Receptor activator of $\text{NF-}\kappa\beta$
RANKL	RANK ligand
OPG	Osteoprotegerin
C cells	Parafollicular cells
HHM	Humoral hypercalcemia of malignancy
PHPT	Primary hyperparathyroidism
NSHPT	Nutritional secondary hyperparathyroidism

the cell membrane. This is the mechanism by which  $\text{Ca}^{2+}$  antagonizes the effects of hyperkalemia.

In skeletal muscle almost all calcium ions required for excitation and contraction come from the SR. In contrast, in the smooth muscle cell the SR is rudimentary, and most of the  $\text{Ca}^{2+}$  required for contraction comes from the extracellular fluid. This has clinical implications because hypocalcemia may result in ileus.

## COAGULATION

$\text{Ca}^{2+}$  (factor IV) is necessary for the coagulation process to occur.  $\text{Ca}^{2+}$  is a co-factor for factors II, VII, IX, X, XI, XII, and XIII, and without  $\text{Ca}^{2+}$  blood clotting does not occur. However, the  $\text{Ca}^{2+}$  concentration required for coagulation is minimal, and low  $\text{Ca}^{2+}$  concentrations do not seem to interfere with the clotting process.

## ☞ CALCIUM AND PHOSPHORUS IN THE HORSE

### REQUIREMENTS

Calcium and phosphorus requirements in horses and ponies depend on the age, physiologic status, and amount of work or exercise performed (Table 20-4). Horses do not have a nutritional drive to meet their calcium needs and are highly dependent on dietary calcium. However, there appears to be a nutritional drive for phosphorus because animals with phosphorus deficiency will eat or lick foreign materials (dirt, rocks, bones) in a condition known as *pica*. Because extracellular  $\text{Ca}^{2+}$  is under the homeostatic control of several factors, serum  $\text{Ca}^{2+}$  concentration is not a reliable indicator of dietary calcium intake. An acceptable diet for horses must have 0.15% to 1.5% of calcium in feed dry matter and 0.15% to 0.6% of phosphorus in feed dry matter (Table 20-5). Calcium/phosphorus ratio less than 1:1 may have negative effects on calcium absorption and skeletal development; however, calcium/phosphorus ratio as high as 6:1 for growing horses may not be detrimental if phosphorus intake is adequate.<sup>8</sup> Adult horses should receive approximately 40 mg of calcium/kg/day. These requirements depend on the physiologic status of the animal; pregnant mares require around 50 to 60 g of calcium/day, whereas lactating mares and growing horses may require 50 to 75 g of calcium/day.

The daily calcium requirements in the lactating mare at the onset of lactation are twice maintenance. Mare's milk calcium

concentration ranges between 1.3 g/kg of fluid milk during the first 2 weeks of lactation to 0.8 g/kg of milk on weeks 15 to 17.<sup>9,10</sup> For a 500-kg mare producing 15 kg of milk/day, with a calcium concentration of 1.2 g/kg of milk, this represents a demand of 36 g of calcium (15 kg of milk × 1.2 g of calcium × 50% absorption) a day, in addition to maintenance.

It has been estimated that average horses must absorb 20 to 25 mg of calcium and 10 to 12 mg of phosphorus/kg/day to balance losses.<sup>11-13</sup> According to the National Research Council,<sup>14</sup> the maximum tolerable content of dietary phosphorus in horses fed adequate amounts of calcium is 1%. Calcium and phosphate content in some mineral supplements and equine feeds are presented in Tables 20-6 and 20-7.

## ABSORPTION

Horses absorb a large proportion of dietary calcium as compared with other species.<sup>15</sup> Horses absorb calcium and phosphorus with high efficiency and with little effect of age.<sup>13,15</sup>

Horses fed diets with adequate amounts of calcium absorb 50% to 75% of the calcium and less than half the phosphorus present.<sup>13,16</sup> Calcium in most forages for horses is over 50% to 60% digestible (Table 20-8). The efficiency of calcium absorption is inversely related to the calcium content of the diet. The proximal half of the small intestine is the main site for calcium absorption in the horse, followed by the distal small intestine and the dorsal colon.<sup>13,17</sup> The amount of calcium

**FIGURE 20-9** Net absorption of calcium from the intestine of the horse. The intestine was divided in six regions: proximal (small intestine I) and distal (small intestine II) halves of the small intestine, cecum, proximal (colon I) and distal (colon II) large colon, and transverse colon and rectum (rectum). (Adapted from Schryver HF, Craig PH, Hintz HF et al: The site of calcium absorption in the horse, *J Nutr* 100:1127–1131, 1970.)

absorbed in the dorsal colon is minimal, and the cecum and ventral colon are mainly secretory sites for calcium (Figure 20-9). High dietary phosphate (or phytate) content inhibits calcium absorption,<sup>18</sup> whereas a high calcium content has minimal effect on phosphorus absorption.<sup>19</sup> Oxalate reduces calcium absorption; a 1% oxalate content in an equine diet reduced calcium absorption by 66%.<sup>20</sup> Oxalate content in the diet higher than 0.5% or a calcium/oxalate ratio below 0.5 can

TABLE 20-9

Plants Containing Harmful Amounts of Oxalate	
Common Name	Scientific Name
Buffelgrass	<i>Cenchrus ciliaris</i>
Pangola	<i>Digitaria decumbens</i>
Setaria	<i>Setaria sphacelata</i>
Purple pigeon grass	<i>Setaria incrassate</i>
Foxtail grass	<i>Setaria</i> spp.
Kikuyu	<i>Pennisetum clandestinum</i>
Napier, mission grass	<i>Pennisetum</i> spp.
Rhubarb	<i>Rheum rhaponticum</i>
Halogeton	<i>Halogeton glomeratus</i>
Greasewood	<i>Sarcobatus vermiculatus</i>
Sour sob, Shamrock	<i>Oxalis</i> spp.
Panic	<i>Panicum</i> spp.
Dallisgrass	<i>Paspalum</i> spp.
Bermuda grass	<i>Cynodon dactylon</i>
Para grass	<i>Brachiaria</i> spp.
Red-rooted pigweed	<i>Amaranthus</i> spp.
Purslane	<i>Portulaca oleraceae</i>
Sugar beet	<i>Beta vulgaris</i>
Sorrel	<i>Rumex</i> spp.
Lambsquarter	<i>Chenopodium</i> spp.
Russian thistle, tumbleweed	<i>Salsola</i> spp.

These plants have an oxalate content higher than 0.5% diabetes mellitus or have a calcium:oxalate ratio less than 0.5. Their ingestion can result in calcium deficiency and clinical signs consistent with nutritional secondary hyperparathyroidism (NSHPT). Some of these plants may also cause gastrointestinal irritation and diarrhea.

result in a negative calcium balance.<sup>21</sup> Some plants containing harmful amounts of oxalate are listed in Table 20-9.

The dietary cation-anion balance (DCAB) affects  $\text{Ca}^{2+}$  absorption; anionic diets with a low DCAB increase intestinal  $\text{Ca}^{2+}$  absorption serum  $\text{Ca}^{2+}$  concentrations,<sup>22</sup> whereas a high DCAB has the opposite effect.

Glucocorticoids affect calcium metabolism in the horse. Dexamethasone decreases intestinal absorption of calcium, decreases bone resorption, and increases urinary excretion of calcium.<sup>23,24</sup>

Limited information exists on the effect of magnesium on calcium and phosphorus absorption in the horse.<sup>25,26</sup> No changes in serum calcium and phosphorus concentrations were detected in foals fed a magnesium-deficient diet; however, mineralization of the aorta was present.<sup>25</sup>

## ELIMINATION

Calcium is eliminated through the kidneys, milk, sweat, feces, and fetus. Because horses absorb a greater proportion of dietary calcium, fecal calcium content is lower than in ruminants when fed equivalent diets.<sup>13,15</sup> Endogenous losses of calcium in horses are estimated around 20 to 25 mg/kg/body weight/day.<sup>11</sup>

Assuming a 50% calcium digestibility, a 500-kg horse would require 20 g of calcium to replace losses, or 40 mg/kg/day; growing and lactating horses can double these requirements. Calcium elimination depends on physiologic status, amount of calcium ingested, presence of substances that interfere with calcium absorption (phosphates, oxalates, phytates), and diseases. The urinary fractional clearance of calcium and the ratio of urinary to serum calcium and phosphorus have been proposed as methods to estimate calcium intake.<sup>27</sup> However, interpretation of calcium clearance is difficult because of the large amounts of calcium eliminated in the equine urine.<sup>28</sup>

The fractional clearance of calcium or phosphorus can be calculated using the following formula:

$$\frac{\text{Urine Ca}^{2+} \text{ or phosphorus}}{\text{Serum Ca}^{2+} \text{ or phosphorus}} \times \frac{\text{Serum creatinine}}{\text{Urine creatinine}} \times 100$$

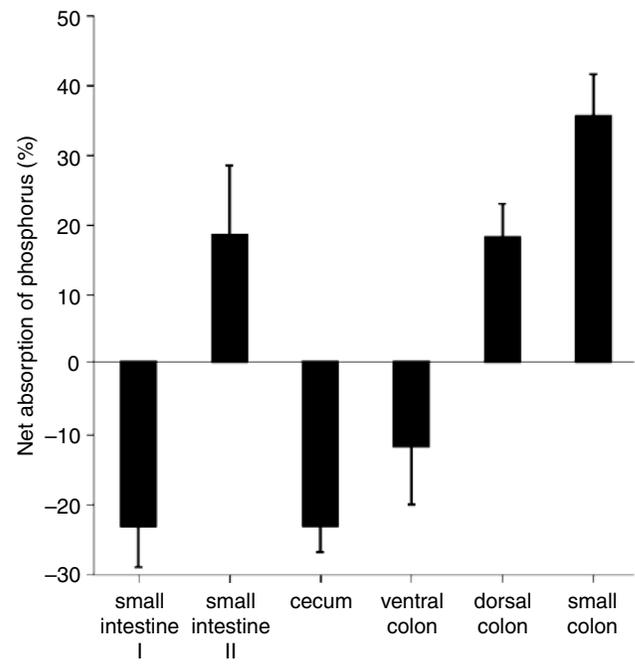

## DEFICIENCY

Calcium deficiency can be acute or chronic. Acute calcium deficiency is manifested with signs of neuromuscular excitability, whereas chronic calcium deficiency presents as abnormal cartilage and bone development, developmental orthopedic disease (DOD), and lameness. When calcium deficiency is suspected, feed analysis is recommended to determine if dietary calcium and phosphorus content are adequate.

## PHOSPHORUS

Similar to calcium, most phosphorus (80%) in the skeleton is bound to calcium as hydroxyapatite crystals. In circulation phosphate is present in two forms: (1) organic phosphate (intracellular) and (2) inorganic (extracellular). Organic phosphate represents most of the phosphorus in circulation that is bound to lipids, proteins, and blood cells; however, only inorganic phosphate ( $\text{PO}_4$ ) is measured. In plasma, phosphorus exists as ionized  $\text{PO}_4$  (40%-50%;  $\text{HPO}_4^{2-}$ ), complexed to cations ( $\text{Na}^+$ ,  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ; 30%-40%), and bound to proteins (1%-15%). At physiologic pH,  $\text{PO}_4$  exists as divalent ( $\text{HPO}_4^{2-}$ ) and monovalent ( $\text{H}_2\text{PO}_4^-$ ) anions in a 4:1 ratio. In acidosis this ratio is 1:1, and it can be as high as 9:1 during alkalosis.<sup>29</sup> Most phosphorus in soft tissues is organic, intracellular, and incorporated into phospholipids, nucleic acids, and energy compounds (ATP and creatine phosphate). Therefore phosphorus is important for nerve function; muscle contraction; electrolyte transport; oxygen transport (2,3-diphosphoglycerate); enzyme activity; gene transcription; metabolism of proteins, carbohydrates, and fats; and cell proliferation.  $\text{PO}_4$  regulation is closely associated to  $\text{Ca}^{2+}$  homeostasis. Serum  $\text{PO}_4$  concentrations and alkaline phosphatase activity are higher in foals than in adult horses because of increased bone osteoblastic activity and bone formation.

Phosphorus requirements depend on age, physiologic status, and amount of work or exercise performed (see Table 20-4). In horses, phosphorus absorption ranges between 30% to 55% and occurs in the small and large intestines (Figure 20-10).<sup>13,30,31</sup> High dietary aluminum and phytate reduce  $\text{PO}_4$  absorption, and phytase activity in the equine large colon can enhance  $\text{PO}_4$  absorption.<sup>32</sup> Most renal  $\text{PO}_4$  reabsorption (>80%) occurs in the proximal tubules by  $\text{Na}^+$ -dependent mechanisms, with minimal reabsorption in the distal nephron, and the urinary fractional excretion of  $\text{PO}_4$  in horses is low (<0.5%). Chronic excess of

**FIGURE 20-10** Net absorption of phosphorus from the intestine of ponies fed an alfalfa diet. (Adapted from Schryver HF, Hintz HF, Craig PH et al: Site of phosphorus absorption from the intestine of the horse, *J Nutr* 102:143-148, 1972.)

phosphorus is associated with clinical signs of calcium deficiency including lameness, abnormal cartilage and bone development, fractures, and osteodystrophia fibrosa (nutritional secondary hyperparathyroidism [NSHPT]). Chronic phosphorus deficiency is manifested as weight loss, weakness, depraved appetite (pica), lameness, and DOD. Serum  $\text{PO}_4$  concentrations are more indicative of dietary phosphorus intake and status than serum calcium concentrations because the homeostatic control for  $\text{PO}_4$  is not as precise as that of  $\text{Ca}^{2+}$ . Normal  $\text{PO}_4$  concentrations are presented in Table 20-10 ( $\text{mg/dl} \times 0.323 = \text{mmol/L}$ ).

Acute renal failure and hypoparathyroidism are associated with hyperphosphatemia.  $\text{PO}_4$  concentrations in horses with chronic renal failure (CRF) are variable.

Conditions that result in cell lysis such as hemolysis, rhabdomyolysis, and tumor necrosis may cause acute hyperphosphatemia. Conditions associated with hypophosphatemia include inadequate intake, decreased intestinal absorption, renal waste, hyperparathyroidism, sepsis, and  $\text{PO}_4$  shift to the intracellular compartment.  $\text{PO}_4$  shift to the intracellular compartment is a frequent cause of hypophosphatemia in critically ill human beings, and occasionally it occurs in horses with starvation, refeeding syndrome, parenteral nutrition (hyperglycemia, hyperinsulinemia), and hyperlipemia (personal communication, Toribio RE, 2008). Acute hypophosphatemia is associated with cell membrane fragility and lysis (hemolysis, rhabdomyolysis).

Treatment of hypophosphatemia should be based on the extracellular deficit; however, this deficit should be overestimated because phosphate is a major intracellular anion and cell depletion is likely to be present in animals with hypophosphatemia. A preferred parenteral treatment is potassium phosphate, although sodium phosphate is a good alternative. Critically ill horses can also be supplemented with oral

potassium phosphate or monosodium phosphate. Hypokalemia and hypomagnesemia are frequent findings in horses with hypophosphatemia. For chronic phosphate deficiency, oral dicalcium phosphate is a good option (see Table 20-6).

Phosphorus homeostasis is discussed following in conjunction with calcium homeostasis.

## ∞ CALCIUM HOMEOSTASIS

Regulation of extracellular ionized calcium (Ca<sup>2+</sup>) concentration is controlled by a complex homeostatic system that includes three major hormones: PTH, CT, and 1,25-dihydroxyvitamin D<sub>3</sub> [1,25(OH)<sub>2</sub>D<sub>3</sub>, or calcitriol].<sup>3,5,33</sup> PTH-related protein (PTHrP) shares considerable homology with PTH, binds and activates the PTH-1 receptor, and is important for calcium homeostasis in the fetus but not in the adult.<sup>34,35</sup> PTH increases during hypocalcemia, whereas CT increases during hypercalcemia.

### PARATHYROID HORMONE

PTH is secreted by the chief cells of the parathyroid gland in response to small changes in extracellular Ca<sup>2+</sup> concentrations. The biologic functions of PTH include stimulation of osteoclastic bone resorption, thereby increasing Ca<sup>2+</sup> release into circulation, stimulation of Ca<sup>2+</sup> reabsorption and inhibition of phosphate reabsorption in the renal tubules, and stimulation of calcitriol synthesis in the kidney. Calcitriol then increases intestinal Ca<sup>2+</sup> and phosphate absorption and inhibits PTH secretion in the parathyroid gland.<sup>1</sup>

The relationship between serum Ca<sup>2+</sup> concentrations and PTH secretion in horses is inverse and sigmoidal, which allows the parathyroid gland to rapidly respond to minimal changes in Ca<sup>2+</sup> concentrations.<sup>2,5,36-39</sup> Changes in extracellular Ca<sup>2+</sup> concentrations are detected by a Ca<sup>2+</sup>-sensing G protein-linked cation receptor (CaR) in the parathyroid cells.<sup>40</sup>

Horses have four parathyroid glands. The parathyroid glands IV (cranial or upper) are usually located in the fat dorsolaterally to the cranial pole of the thyroid gland and along the thyroid artery; however, they can be found in any location around the thyroid gland. In the author's experience, a few horses may also have parathyroid gland tissue embedded within the thyroid tissue. The parathyroid glands III (lower, caudal) can be located at the bifurcation of the bicarotid trunk, at the cranial pole of the thymus, or embedded in the thymus (young horses). Generally they are twice the size of the upper parathyroids. The parathyroid gland consists of chief cells, oxyphil cells, and clear cells, which represents different morphologic and metabolic stages of the same parenchymal cells.

Mature equine intact PTH is a straight chain of 84 amino acids (molecular weight: 9393 daltons in the horse and 9500 daltons in human beings). Other forms of PTH (amino and carboxyterminal peptides) can be found in circulation after cleavage in different organs.<sup>41</sup> Around 50% to 90% of PTH immunoreactivity in blood is from carboxyterminal fragments.<sup>42-44</sup> The plasma half-life of PTH in various species is approximately 2 minutes<sup>44-47</sup>; however, equine PTH half-life has not been determined. The rapid metabolism of PTH, together with the rapid response of the parathyroid chief cells to changes in Ca<sup>2+</sup> concentrations, ensures that PTH concentrations can rapidly adjust to changes in Ca<sup>2+</sup>. Approximately 60% to 70% of PTH is removed in the liver (around 25% by the kidney) and the rest by other organs.<sup>44,45,47</sup>

PTH gene expression and secretion is under the influence of extracellular Ca<sup>2+</sup>, phosphorus, and 1,25(OH)<sub>2</sub>D<sub>3</sub> concentrations. Limited information exists on the role of vitamin-D metabolites on equine parathyroid gland function and calcium regulation; however, it is well accepted that 1,25(OH)<sub>2</sub>D<sub>3</sub> decreases PTH gene expression and secretion.<sup>48</sup> This concept is important in understanding the role of the kidney in vitamin D metabolism and parathyroid gland physiology. In the chief cells, vitamin D binds to the vitamin D receptor (VDR) to decrease PTH gene transcription and secretion. Unlike vitamin D, the effects of Ca<sup>2+</sup> and phosphorus regulating PTH secretion are not only mediated by gene transcription but also by altering PTH mRNA stability and translation.<sup>49</sup> Clinicians have shown that low Ca<sup>2+</sup> concentrations increase PTH mRNA expression in equine parathyroid chief cells.<sup>50</sup>

### PHYSIOLOGIC ACTIONS OF PARATHYROID HORMONE

**Kidney** The kidney is considered the main target organ for PTH, where it regulates Ca<sup>2+</sup> and phosphate reabsorption, as well as 1,25(OH)<sub>2</sub>D<sub>3</sub> synthesis. These effects are mediated by the PTH-1 receptor, which is widely distributed in different segments of the nephron.<sup>43</sup> The PTH-1 receptor is coupled to G proteins to activate adenylate cyclase and increase intracellular cyclic adenosine monophosphate (cAMP). PTH also activates phospholipases (A<sub>2</sub>, C, D), protein kinase A, and protein kinase C.<sup>43,51</sup> The activation of these pathways depends on which segment of the nephron PTH is acting.

**Effect on Ca<sup>2+</sup> and Mg<sup>2+</sup> reabsorption** It has been estimated that 60% of filtered calcium and 20% of filtered magnesium are reabsorbed in the proximal tubules.<sup>52,53</sup> The

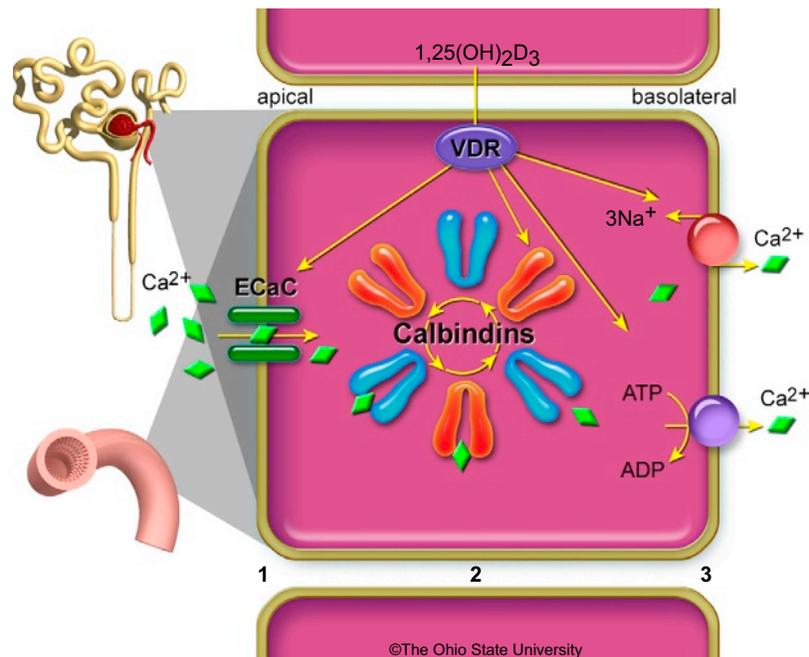

reabsorption process in the proximal convoluted tubules (PCT) is passive and driven by high luminal concentrations of  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$ .<sup>52,53</sup> In the PCT,  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  reabsorption is paracellular, and the difference between  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  reabsorption in this segment of the nephron results from differential permeability. In the cortical thick ascending loop of Henle (CTAL),  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  transport is paracellular, but more permeability exists in  $\text{Mg}^{2+}$  (60% for  $\text{Mg}^{2+}$  versus 20% for  $\text{Ca}^{2+}$ ). The lumen in the CTAL is positively charged, and the driving force for  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  reabsorption is the transepithelial voltage gradient generated by the  $\text{Na}^+/\text{K}^+/\text{2Cl}^-$  co-transporter.<sup>54</sup> PTH increases  $\text{Ca}^{2+}$  reabsorption in the CTAL by increasing the activity of the  $\text{Na}^+/\text{K}^+/\text{2Cl}^-$  co-transporter.<sup>53</sup> Paracellin-1, a recently discovered protein, is essential for paracellular permeability of  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  in the CTAL.<sup>55</sup> PTH has minimal effect in the distal convoluted tubules (DCTs), where  $1,25(\text{OH})_2\text{D}_3$  is the main calcium-regulating hormone. Unlike the PCT and CTAL, where calcium transport is paracellular, calcium transport in the DCT is transcellular, mediated by epithelial calcium channels (ECaCs), calcium-binding proteins (calbindin), basolateral proteins, and regulated by  $1,25(\text{OH})_2\text{D}_3$  (Figure 20-11).<sup>56,57</sup>

**Effects on Phosphorus** PTH is central to renal phosphate regulation. The movement of phosphate in the PCT occurs against electrochemical and concentration gradients, and is mediated by  $\text{Na}^+$ /phosphate co-transporters. PTH lowers  $\text{Na}^+$  and phosphate transport across the brush border by enhancing the degradation of the  $\text{Na}^+$ /phosphate co-transporters.<sup>58,59</sup> The end result is decreased phosphate reabsorption and phosphaturia. Low PTH concentrations result in hyperphosphatemia, whereas the opposite occurs with high PTH.

**Effects on Vitamin D Metabolism** PTH increases the synthesis of  $1,25(\text{OH})_2\text{D}_3$  by increasing gene expression and synthesis of  $1\alpha$ -hydroxylase and by decreasing synthesis of 24-hydroxylase, which inactivates  $1,25(\text{OH})_2\text{D}_3$ . These effects are mediated by cAMP.<sup>43</sup>

**Bone** Bone is a very active organ that is in a continuous process of bone resorption and bone formation. Bone formation is mediated by osteoblasts, whereas bone resorption is mediated by osteoclasts. In adult vertebrates, the process of bone resorption is in equilibrium with bone formation. In growing animals, bone formation exceeds bone resorption, whereas in old animals and human beings the opposite occurs. No PTH receptors exist in the osteoclasts but rather in the osteoblasts. Thus the effect of PTH on osteoclast activation is indirect and mediated by the osteoblast. On PTH stimulation, the osteoblasts secrete a series of factors, including macrophage colony-stimulating factor (M-CSF) and receptor activator of NF- $\kappa$ B ligand (RANKL).<sup>60</sup> These two factors (M-CSF and RANKL) are essential for osteoclast function (Figure 20-12). Osteoclasts express receptor activator of NF- $\kappa$ B (RANK), which is a transmembrane receptor for RANKL. The interaction of RANKL with RANK and the interaction of M-CSF with its receptor result in osteoclast recruitment and activation. To keep a bone formation to resorption balance, the osteoblasts also release osteoprotegerin (OPG), which is a soluble decoy receptor for RANKL, interfering with RANKL action on the osteoclasts.<sup>61</sup> Other factors that stimulate osteoclast differentiation include  $1,25(\text{OH})_2\text{D}$  and IL-11.

Serum markers of bone formation in horses include osteocalcin, N-terminal peptide of type I procollagen, and bone-specific alkaline phosphatase.<sup>62-64</sup> Serum markers of bone

**FIGURE 20-11** Schematic representation of the ECaC and the transcellular transport of calcium in the small intestine and kidney. The transcellular transport of  $\text{Ca}^{2+}$  is considered a three-step process in which calcium (1) enters the cell passively, (2) its diffusion through the cytosol is facilitated by calcium-binding proteins (calbindins), and (3) at the basolateral membrane calcium is extruded by a  $\text{Ca}^{2+}$ -ATPase and a  $\text{Na}^+$ - $\text{Ca}^{2+}$  exchanger.  $1,25(\text{OH})_2\text{D}$  increases all three steps of transepithelial calcium transport.

resorption include the cross-linked carboxyterminal telopeptide of type I collagen and total deoxypyridinoline.<sup>62,64</sup>

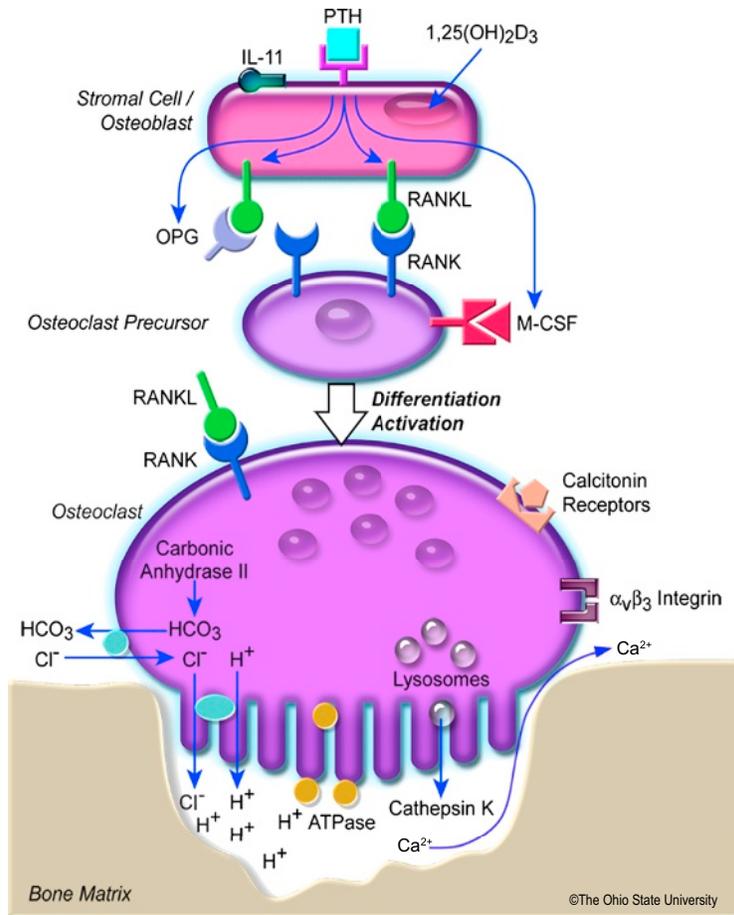

**Intestine** PTH has minimal direct effect on intestinal calcium or phosphorus absorption. Indirect effects are mediated by renal synthesis of  $1,25(\text{OH})_2\text{D}$ .

## VITAMIN D

Vitamin D plays an important role in  $\text{Ca}^{2+}$  and phosphate homeostasis and to lesser extent in magnesium metabolism. Vitamin D derives from dietary sources (vitamin  $\text{D}_2$  comes from yeasts and plants, and vitamin  $\text{D}_3$  from animal-derived diets) and from activation of 7-dehydrocholesterol. In mammals, vitamin  $\text{D}_3$  is produced in the skin by ultraviolet light (290-315 nm) photolytic cleavage of 7-dehydrocholecalciferol, producing previtamin  $\text{D}_3$ ; after thermal isomerization, this forms vitamin  $\text{D}_3$  (cholecalciferol).<sup>65</sup> From the skin, vitamin  $\text{D}_3$  is translocated to the bloodstream by a vitamin D-binding protein (DBP). The next step in the formation of active vitamin  $\text{D}_3$  is the hydroxylation of carbon 25, which occurs primarily in the liver, although other organs may also activate vitamin  $\text{D}_3$  into 25-hydroxyvitamin  $\text{D}_3$

[ $25(\text{OH})\text{D}_3$ ]. This reaction is catalyzed by a microsomal and mitochondrial mixed function  $\text{P}_{450}$  oxidase known as 25- $\alpha$ -hydroxylase. The conversion of vitamin  $\text{D}_3$  into  $25(\text{OH})\text{D}_3$  is a poorly regulated reaction, and therefore plasma concentrations of  $25(\text{OH})\text{D}_3$  are considered an indicator of the vitamin-D status.

25-Hydroxyvitamin  $\text{D}_3$  is transported in blood bound to DBP, and at normal plasma concentrations this metabolite is considered inactive. The active metabolite of vitamin  $\text{D}_3$ , 1,25-dihydroxyvitamin  $\text{D}_3$  [ $1,25(\text{OH})_2\text{D}_3$ ], is produced in the kidney by another cytochrome  $\text{P}_{450}$  mixed-function oxidase, 25(OH)D-1 $\alpha$ -hydroxylase (1 $\alpha$ -hydroxylase). Under physiologic conditions, the kidney is considered the main site for  $1,25(\text{OH})_2\text{D}_3$  synthesis, although other organs (placenta, skin, monocytes) have 1 $\alpha$ -hydroxylase activity. Unlike 25-hydroxylase, 1 $\alpha$ -hydroxylase is a tightly regulated enzyme. Mutations of the 1 $\alpha$ -hydroxylase gene in human beings and laboratory animals results in vitamin D-dependent type I rickets.<sup>66</sup> This chapter will refer to both vitamin-D active metabolites,  $1,25(\text{OH})_2\text{D}_3$  and  $1,25(\text{OH})_2\text{D}_3$ , as 1,25-dihydroxyvitamin D [ $1,25(\text{OH})_2\text{D}$ ]. In blood,  $1,25(\text{OH})_2\text{D}$  concentrations are 1/1000 the concentrations of  $25(\text{OH})\text{D}$ . The half-life of  $25(\text{OH})\text{D}$  can be measured

**FIGURE 20-12** Representation of the cellular interactions responsible for osteoclastic activation and bone resorption. Factors that stimulate osteoclast differentiation include parathyroid hormone (PTH),  $1,25(\text{OH})_2\text{D}$ , and IL-11. Calcitonin (CT) inhibits osteoclastic activity. Osteoblasts secrete macrophage colony-stimulating factor (M-CSF), as well as receptor activator of  $\text{NF-}\kappa\text{B}$  (RANK) and receptor activator of  $\text{NF-}\kappa\text{B}$  ligand (RANKL). Osteoclasts express RANK, which is a transmembrane receptor for RANKL. Osteoblasts also release osteoprotegerin (OPG), which is a soluble decoy receptor for RANKL. (Adapted from Rodan GA, Martin TJ: Therapeutic approaches to bone diseases, *Science* 289:1508–1514, 2000.)

in weeks, whereas the half-life of  $1,25(\text{OH})_2\text{D}$  is measured in few hours. Both  $25(\text{OH})\text{D}$  and  $1,25(\text{OH})_2\text{D}$  are inactivated at target organs by a D24  $\alpha$ -hydroxylase.

PTH and hypophosphatemia induce  $1\alpha$ -hydroxylase activity in the kidney, whereas increased  $\text{Ca}^{2+}$ , phosphate, and  $1,25(\text{OH})_2\text{D}$  inhibit  $1\alpha$ -hydroxylase and stimulate  $24$ -hydroxylase, making this an effective self-regulatory mechanism. The synthesis of  $1,25(\text{OH})_2\text{D}$  is not related to calcium homeostasis.

### REGULATION OF VITAMIN D METABOLISM

Blood concentrations of  $1,25(\text{OH})_2\text{D}$  are regulated by PTH,  $\text{Ca}^{2+}$ , phosphorus, and  $1,25(\text{OH})_2\text{D}$ . The role of CT in vitamin-D metabolism remains unclear. Low extracellular  $\text{Ca}^{2+}$  concentrations stimulate PTH release, which increases renal  $1\alpha$ -hydroxylase activity and  $1,25(\text{OH})_2\text{D}$  synthesis. Hypophosphatemia also increases renal  $1\alpha$ -hydroxylase activity. An autoregulatory mechanism exists by which  $1,25(\text{OH})_2\text{D}$  inhibits  $1\alpha$ -hydroxylase.

### ACTIONS OF VITAMIN D

Most of the biologic actions of vitamin D result from its active metabolite,  $1,25(\text{OH})_2\text{D}$ , which stimulates intestinal  $\text{Ca}^{2+}$  and phosphate absorption, as well as renal  $\text{Ca}^{2+}$  and phosphate reabsorption. These actions are mediated by the VDR that is found in target organs (intestine, bone, kidney, parathyroid gland), as well as in organs not involved in  $\text{Ca}^{2+}$  homeostasis (skin, pancreas, immune system, and reproductive organs).<sup>67</sup>

In the intestine, as in the kidney,  $1,25(\text{OH})_2\text{D}$  regulates transcellular  $\text{Ca}^{2+}$  transport which occurs in three steps: (1) calcium entry by ECaC, (2) calcium diffusion across the cytosol that is facilitated by calcium-binding proteins (calbindins), and (3) calcium extrusion at the basolateral side by  $\text{Ca}^{2+}$ -ATPases and a  $\text{Na}^+$ - $\text{Ca}^{2+}$  exchangers (see Figure 20-11).<sup>68,69</sup> Vitamin D increases the expression of these proteins. In addition to its effects on intestinal calcium transport,  $1,25(\text{OH})_2\text{D}$  increases phosphate transport by stimulating of the sodium phosphate co-transporter.

In the kidney, important effects of  $1,25(\text{OH})_2\text{D}$  include suppression of  $1\alpha$ -hydroxylase, stimulation of  $\text{Ca}^{2+}$  reabsorption in the DCT,<sup>67</sup> and phosphorus reabsorption in the PCT.

In bone,  $1,25(\text{OH})_2\text{D}$  is important for skeletal development and bone mineralization. Vitamin D deficiency in young animals results in rickets and osteomalacia in adults. No cases of rickets or osteomalacia have been documented in horses. Vitamin D ( $1,25(\text{OH})_2\text{D}$ ) induces osteoclast activity and bone resorption, which is important to maintain normocalcemia and normophosphatemia.

In the parathyroid gland, PTH synthesis is negatively regulated by  $1,25(\text{OH})_2\text{D}$ . PTH increases  $1\alpha$ -hydroxylase activity in the kidney, increasing plasma concentrations of  $1,25(\text{OH})_2\text{D}$ , which then inhibits PTH gene expression and synthesis and controls parathyroid gland chief cell growth and differentiation.<sup>70</sup> This is the explanation for the development of parathyroid hyperplasia in human beings and animals with CRF and vitamin D deficiency.

Vitamin D has nonclassical functions. Anemia, predisposition to infections from impaired immune system, skeletal muscle weakness, cardiomegaly, pancreatic glucose-mediated insulin secretion, and infertility are among conditions reported with vitamin D deficiency.<sup>67</sup> Vitamin D is important in skin and hair development, as well as in cell proliferation and differentiation. Because of these properties, several vitamin

D-based compounds with antiproliferative and prodifferentiation properties have been developed to treat various pathologic conditions in human beings and small animals (seborrhea, psoriasis, secondary hyperparathyroidism, breast cancer, prostate cancer, leukemia).<sup>67</sup>

### VITAMIN D METABOLISM IN THE HORSE

The amount of information on vitamin D in the horse is limited when compared with other species. Horses have unique features with regard to calcium metabolism, including high serum total and ionized calcium concentrations, poorly regulated intestinal calcium absorption, high urinary fractional clearance of calcium, a high  $\text{Ca}^{2+}$  set-point, and low serum concentrations of vitamin-D metabolites ( $25(\text{OH})_2\text{D}$  and  $1,25(\text{OH})_2\text{D}$ ).<sup>5,13,50,71-78</sup> As previously mentioned,  $25(\text{OH})\text{D}$  concentrations are considered an indicator of vitamin-D status. Plasma concentrations of  $25(\text{OH})\text{D}$  in the horse are approximately one tenth the plasma concentrations of  $25(\text{OH})\text{D}$  in other species.<sup>75-77</sup> In human beings and in most domestic animals, plasma concentrations of  $25(\text{OH})\text{D}$  range between 50 to 100 nmol/L,<sup>72</sup> with minimal differences between young animals and adults<sup>73</sup>; a plasma  $25(\text{OH})\text{D}$  concentration below 40 nmol/L is indicative of vitamin-D deficiency. In contrast, in the horse, plasma concentrations of  $25(\text{OH})\text{D}_3$  of 5 to 10 nmol/L or below are normal.<sup>75-77</sup> Despite the low vitamin-D concentrations, rickets or osteomalacia have not been documented in horses.<sup>79</sup> Horses with limited access to sunlight and fed a vitamin D-deficient diet had decreased growth, lameness, and lower bone density.<sup>79</sup> In northern latitudes, the synthesis of  $25(\text{OH})\text{D}_3$  and  $1,25(\text{OH})_2\text{D}_3$  in horses during winter months is low<sup>74,75</sup> (see Table 20-10). One study found that plasma  $25(\text{OH})\text{D}$  and  $1,25(\text{OH})_2\text{D}_3$  concentrations were very low or undetectable in healthy horses and ponies when compared with vitamin D metabolite concentrations from other species.<sup>71</sup> In the same study, renal  $1\alpha$ -hydroxylase activity could not be detected. Likewise, preliminary studies in the author and colleagues' laboratory did not detect  $1\alpha$ -hydroxylase mRNA expression in equine kidneys, indicating that equine  $1\alpha$ -hydroxylase activity is minimal.

### CALCITONIN

Calcitonin (thyrocalcitonin) is a 32-amino acid peptide that inhibits osteoclast function during hypercalcemia. The parafollicular cells (C cells) of the thyroid gland secrete CT. Equine CT has 90% homology to human CT.<sup>80</sup> Secretion of CT is controlled by several factors,  $\text{Ca}^{2+}$  being the most important. The C cells of the thyroid gland sense changes in extracellular  $\text{Ca}^{2+}$  concentrations by the same calcium-sensing receptor present in parathyroid chief cells and renal tubular cells.<sup>81</sup> CT decreases plasma  $\text{Ca}^{2+}$  and phosphorus concentrations by inhibiting osteoclastic bone resorption—and to lesser extent by increasing urinary excretion of  $\text{Ca}^{2+}$  and phosphorus. Despite these effects on  $\text{Ca}^{2+}$  and phosphorus metabolism, the importance of CT on mammalian  $\text{Ca}^{2+}$  homeostasis remains unknown. Some authors have concluded that CT may be important in extreme hypercalcemia, but in the day-to-day  $\text{Ca}^{2+}$  variations, CT may not play a relevant role.<sup>3,82</sup> Based on recent research, the most important CT function in mammals is to prevent excessive bone resorption during lactation.<sup>83</sup> Postprandial increases in serum CT concentrations are mediated by gastrin.

Unlike terrestrial vertebrates, CT plays a very important role in regulating  $\text{Ca}^{2+}$  concentrations in saltwater fish, where the ambient calcium concentrations are extremely high (10 mM; 40 mg/dl). Few studies have evaluated CT in the

horse.<sup>84-87</sup> Equine osteoclasts are responsive to CT stimulation.<sup>85</sup> Serum concentrations of CT in horses have been measured using human CT RIAs.<sup>88</sup> However, defining the normal range of CT is a downside of these studies. The author and colleagues have evaluated serum CT concentrations in horses using different human CT immunoassays and have found a wide range of values among healthy horses.<sup>89</sup>

### PARATHYROID HORMONE-RELATED PROTEIN

PTHrP, first discovered as the factor responsible for humoral hypercalcemia of malignancy (HHM),<sup>34</sup> has important physiologic functions in skeletal development. PTH and PTHrP share homology in their first 13 amino acids and act through the same receptor (PTH-1 receptor). Although PTH is exclusively produced by the parathyroid glands, PTHrP is produced by almost every tissue in the body and has a broad range of functions.<sup>33,35</sup> Under physiologic conditions PTHrP functions are considered to be paracrine, autocrine, and intracrine (inside the cell), whereas the endocrine functions of PTHrP are considered pathologic (HHM). PTHrP is critical in fetal calcium regulation; however, in the adult, PTHrP has little effect on calcium homeostasis. Through different regions, PTHrP has different functions: the amino-terminus interacts with the PTH-1 receptor, initiating PTH-like actions (bone resorption, renal Ca<sup>2+</sup> reabsorption); the midregion PTHrP is important for transplacental Ca<sup>2+</sup> transport; and the carboxyterminal (osteostatin) inhibits osteoclastic bone resorption.<sup>35</sup> High concentrations of PTHrP (10,000-fold higher than plasma) are found in milk of lactating human beings and animals, including mares.<sup>90</sup> Although the functions of PTHrP in milk are unclear, PTHrP is important for Ca<sup>2+</sup> transport into the milk, and perhaps for intestinal Ca<sup>2+</sup> absorption in the newborn.

HHM, a paraneoplastic syndrome resulting from excessive secretion of PTHrP by some tumors, has been reported in

horses with lymphoma, gastric and preputial squamous cell carcinoma, ameloblastoma, and multiple myeloma.<sup>91-95</sup>

## ☪ CALCIUM DISORDERS IN THE HORSE

Calcium dysregulation in horses is associated with hypocalcemic or hypercalcemic disorders. Equine conditions associated with abnormal calcium homeostasis include hypocalcemia of foals,<sup>96</sup> hypoparathyroidism,<sup>97,98</sup> primary hyperparathyroidism (PHPT),<sup>99</sup> NSHPT,<sup>100</sup> hypercalcemia of malignancy,<sup>93-95</sup> vitamin-D toxicity,<sup>101</sup> renal failure,<sup>102</sup> exercise-induced hypocalcemia,<sup>36,103</sup> and sepsis.<sup>5,104,105</sup> Normal calcium concentrations of horses are presented in Table 20-10.

### HYPOCALCEMIA

Different pathologic concentrations are associated with hypocalcemia in the horse (Box 20-3). Clinical signs of hypocalcemia result from increased neuromuscular excitability and decreased smooth muscle cell contractility (Box 20-4). Extracellular Ca<sup>2+</sup> concentrations affect the voltage at which the Na<sup>+</sup> channels in nerve and muscle fibers are activated; Ca<sup>2+</sup> decreases Na<sup>+</sup> permeability and increases the depolarization threshold. Thus Ca<sup>2+</sup> is a Na<sup>+</sup> channel antagonist. When Ca<sup>2+</sup> concentrations are low Na<sup>+</sup> channels are easily activated, resulting in nerve and muscle fiber hyperexcitability, muscle fasciculations, tremors, and tetany. Tachycardia and cardiac arrhythmias may be present during hypocalcemia, although bradycardia may develop during severe hypocalcemia, probably from decreased cardiac muscle contractility.

### SYNCHRONOUS DIAPHRAGMATIC FLUTTER

Synchronous diaphragmatic flutter (SDF) or *thumps* refers to a rhythmic movement on the flank as a result of diaphragmatic contractions that are synchronous with the heartbeat.

#### BOX 20-3

##### CLINICAL CONDITIONS IN THE HORSE IN WHICH HYPOCALCEMIA HAS BEEN REPORTED

Colic	Pancreatitis
Enterocolitis	Furosemide administration
Sepsis	Excessive administration of NaHCO <sub>3</sub>
Endotoxemia	Oxalate ingestion
After endurance exercise	Primary hypoparathyroidism
Late pregnancy	Hypomagnesemia
During lactation (lactation tetany)	Cantharidin toxicosis
During transport (transit tetany)	Liver disease
Acute renal failure	Dystocia
Chronic renal failure (CRF)	Malignant hyperthermia
Rhabdomyolysis	Magnesium toxicosis
Pleuropneumonia	Retained placenta
Heat stroke	Postoperative myopathy

#### BOX 20-4

##### CLINICAL SIGNS REPORTED IN HORSES WITH HYPOCALCEMIA

Anxiety	Hypersalivation
Asphyxia	Hyperthermia
Ataxia	Ileus
Bruxism	Laryngeal spasm
Cardiac arrhythmias	Muscle fasciculation
Colic	Seizures
Convulsions	Stiff gait
Death	Synchronous diaphragmatic flutter (SDF)
Depression	Tachycardia
Dysphagia	Tachypnea
Dyspnea	Tetany
Excitation	Tremors
Hyperhidrosis	Trismus

SDF results from ionized hypocalcemia, hypomagnesemia, or both, and it has been reported in horses with gastrointestinal disease,<sup>5,106</sup> lactation tetany (eclampsia),<sup>107</sup> thoracic hematoma,<sup>108</sup> blister beetle toxicosis,<sup>109</sup> urethral obstruction,<sup>110</sup> endurance exercise,<sup>111</sup> hypoparathyroidism,<sup>98,112</sup> idiopathic hypocalcemia,<sup>96</sup> and sepsis.<sup>5</sup> Depolarization of the right atrium stimulates action potentials in the hyperexcitable phrenic nerve as it crosses over the heart.

This condition is frequent in horses after prolonged exercise, in which significant amounts of electrolytes ( $\text{Ca}^{2+}$ ,  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Mg}^{2+}$ ,  $\text{Cl}^-$ ) are lost from excessive sweating.<sup>113,114</sup> During alkalosis, increased binding of  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  to plasma anions is noted, in particular albumin, resulting in ionized hypocalcemia and hypomagnesemia. Exercising horses often develop alkalosis from hyperventilation (respiratory alkalosis) and sweat loss of chloride (metabolic hypochloremic alkalosis).<sup>108</sup> Serum ionized magnesium ( $\text{Mg}^{2+}$ ) concentrations are often low in horses with SDF, and as in hypocalcemia, hypomagnesemia also increases neuromuscular excitability. Hypomagnesemia should always be included in the differential diagnosis of hypocalcemia and SDF.

### HYPOCALCEMIC TETANY

Low  $\text{Ca}^{2+}$  concentrations increase cell membrane excitability, and some horses may develop excessive and sustained skeletal muscular contractions or tetany. Lactation tetany occurs in mares from 2 weeks before foaling up to few days after weaning. The predisposing cause of lactation tetany is calcium loss in milk. Mares producing large amounts of milk, eating a low-calcium diet, and performing physical work (draft mares) are more at risk. Some horses transported for long distances may develop hypocalcemia and transit tetany.<sup>107</sup> Clinical signs may include anxiety, depression, ataxia, stiff gait, muscle fasciculations and tremors, tachypnea with flared nostrils, dyspnea, dysphagia, hypersalivation, hyperhidrosis, and seizures (see [Box 20-3](#)).

### HYPOCALCEMIC SEIZURES

As occurs with peripheral nerves, decreased  $\text{Ca}^{2+}$  concentrations in the CNS increases neuroexcitability. Hypocalcemic seizures have been reported in foals and horses with hypocalcemia, sepsis, and hypoparathyroidism.<sup>96</sup> Clinical signs usually improve with calcium treatment, although some animals may require repeated treatments with calcium salts. Horses with hypocalcemic seizures have a poor prognosis for recovery.

### ILEUS

Smooth muscle cells have more voltage-gated  $\text{Ca}^{2+}$  channels and fewer voltage-gated  $\text{Na}^+$  channels than skeletal muscle fibers; therefore  $\text{Na}^+$  is less important for the action potential and muscle contraction. This results in slower and prolonged contractions ( $\text{Ca}^{2+}$  channels are slow channels). Although in skeletal muscle almost all  $\text{Ca}^{2+}$  required for contraction comes from the SR, in smooth muscle cells the SR is a rudimentary organelle and cells depend on extracellular  $\text{Ca}^{2+}$  for contraction. Therefore any pathologic condition that reduces  $\text{Ca}^{2+}$  affects smooth muscle contractility. This is evident in horses that develop ileus and colic secondary to hypocalcemia (after exercise, transport, sepsis). Treatment with calcium gluconate may restore gastrointestinal motility.

### RETAINED PLACENTA

Retained placenta in mares has been reported to occur in up to 10% of foalings.<sup>115</sup> Low serum total and ionized calcium concentrations are frequently seen in mares with retained

placenta and acute endometritis. As for gastrointestinal motility, it is likely that decreased uterine tone and contractility results from a similar mechanism as ileus. One study found that Friesian mares with retained placenta had statistically lower serum total calcium concentrations than mares without retained placenta.<sup>116</sup> Furthermore, 64% of mares treated with a combination of oxytocin in a calcium-magnesium borogluconate solution responded to treatment compared with 44% of the mares treated with oxytocin in saline solution. No differences in serum magnesium concentrations were found in this study.

### TREATMENT OF HYPOCALCEMIA

As for other electrolytes, when treating hypocalcemia, the clinician should consider calcium deficit, maintenance, losses, and sequestration. If parathyroid gland function is normal, then the amount of calcium required is minimal. Calcium therapy is more critical in horses that develop rapid hypocalcemia and in horses with impaired parathyroid gland function that cannot restore normocalcemia. The decision to treat horses with hypocalcemia should be based on the presence of hypocalcemia and not on the presence of clinical signs of hypocalcemia. In most cases, horses with ionized hypocalcemia do not show signs of hypocalcemia, or the signs are very subtle, and the lack of therapy may result in additional complications (ileus). Horses with mild hypocalcemia in general restore their normocalcemia without calcium administration; however, calcium administration should be considered. Horses with functional kidneys can rapidly eliminate large amounts of calcium, and hypercalcemia from excessive calcium administration is rare, in particular if the horse is receiving fluid therapy.

The use of standard formulas to calculate electrolyte deficits based on extracellular fluid and body weight do not apply to calcium. Calcium can rapidly be eliminated or sequestered in different compartments, and larger doses of calcium are often times required.

The following formula is used to calculate  $\text{Ca}^{2+}$  deficit:

$$\frac{(6.5\text{mg/dl} - \text{Ca}^{2+}) \times (0.3) \times (\text{body weight}) \times (10)}{\text{Ca}^{2+} \text{ ratio}} = \text{Ca}^{2+} \text{ deficit}$$

in which the difference between the measured  $\text{Ca}^{2+}$  and normal  $\text{Ca}^{2+}$  (6.5 mg/dl) is multiplied by the extracellular fluid volume, the body weight (kg), and a factor of 10 ( $\text{Ca}^{2+}$  is expressed in dl, but body weight is in kg = L), and then divided by the  $\text{Ca}^{2+}$  ratio ( $\text{Ca}^{2+}$ /total calcium). For a 450-kg horse with a serum  $\text{Ca}^{2+}$  concentration of 4.5 mg/dl and a total calcium of 10 mg/dl, the estimated  $\text{Ca}^{2+}$  deficit will be 6000 mg:

$$\frac{(6.5 - 4.5) \times (0.3) \times (450\text{kg}) \times (10)}{0.45} = 6000\text{mg}$$

This is a deficit of elemental calcium, and calcium gluconate or borogluconate are the salts of choice for parenteral treatment. Calcium gluconate contains 9.3% of elemental calcium; in other words, every 100 ml of calcium gluconate 23% solution contains 2.14 g of elemental calcium or 21.4 mg/ml. The horse in this example would require approximately 300 ml of calcium gluconate 23% solution over 24 hours to replace the  $\text{Ca}^{2+}$  deficit ( $\text{Ca}^{2+}$  conversion factors: mg/dl = mmol/L  $\times$  4; mmol/L = mg/dl  $\times$  0.25).

Total calcium concentration can be used to estimate calcium deficit; however, total calcium concentration has more variability than  $\text{Ca}^{2+}$  concentration. A horse may have total hypocalcemia, but serum  $\text{Ca}^{2+}$  concentrations may be within the normal range and calcium administration may not be necessary. Unfortunately, measurement of  $\text{Ca}^{2+}$  concentrations is not readily available for many practitioners. Replacing total calcium and normal total calcium (11.5 mg/dl) in the same formula, and dividing by a 0.5  $\text{Ca}^{2+}$  ratio, gives a close approximation of calcium deficit.

Frequent monitoring of  $\text{Ca}^{2+}$  concentration is important to adjust dosage. Some horses with severe gastrointestinal disease and sepsis remain hypocalcemic despite aggressive calcium supplementation. Rapid administration of calcium may result in cardiovascular complications, in particular in septic horses, which may be more vulnerable to the cytotoxic effects of calcium. Horses can handle large calcium dosages.<sup>117,118</sup> Based on our experience treating critically ill horses, calcium doses of 2 mg/kg/hr are safe in horses. This represents approximately 50 ml of calcium gluconate 23% solution for a 500-kg horse in 1 hour, while receiving fluid therapy. A number of studies have found that calcium administration to septic patients may be detrimental.

Calcium chloride may be a good option to treat equine hypocalcemia; however, it is not available in large volumes and may cause irritation at the administration site. The clinician should not add calcium salts to fluid solutions containing bicarbonate because calcium carbonate complexes may form and precipitate.

Oral treatment with calcium salts is feasible in horses with nonlife-threatening hypocalcemia. Dicalcium phosphate and calcium carbonate (limestone) can be used safely (see Table 20-6).

## HYPOCALCEMIC DISORDERS

### HYPOPARATHYROIDISM

Hypoparathyroidism is a condition characterized by hypocalcemia, hyperphosphatemia, and decreased serum PTH concentrations. Hypomagnesemia may be present. Primary hypoparathyroidism results from decreased synthesis and secretion of PTH, whereas secondary hypoparathyroidism most commonly results from hypomagnesemia or sepsis.  $\text{Mg}^{2+}$  has a permissive effect on PTH secretion, and low  $\text{Mg}^{2+}$  concentrations impair PTH release.

#### PRIMARY HYPOPARATHYROIDISM

This condition has been reported in horses.<sup>98,112</sup> Horses with clinical signs of hypocalcemia, including ataxia, seizures, hyperexcitability, SDF, tachycardia, tachypnea, muscle fasciculations, stiff gait, recumbency, ileus, and colic. The diagnosis is based on the determination of serum concentrations of  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ , phosphorus, and PTH. Hypocalcemia, hyperphosphatemia, hypomagnesemia, and low serum PTH concentrations are the features of primary hypoparathyroidism.<sup>98,112</sup> The low PTH leads to hypocalcemia, as well as decreased renal excretion of phosphorus, and it contributes to hypomagnesemia because PTH also stimulates  $\text{Mg}^{2+}$  reabsorption in the distal nephron. Horses with primary hypoparathyroidism may benefit from magnesium sulfate or chloride administration.

#### SECONDARY HYPOPARATHYROIDISM

Secondary hypoparathyroidism as a pathologic entity has not been described in horses; however, septic horses with hypocalcemia and impaired parathyroid gland function are

most likely suffering a secondary hypoparathyroidism from hypomagnesemia and increased concentrations of inflammatory mediators. The author and colleagues have documented hypocalcemia, hypomagnesemia, and inappropriately low PTH concentrations in septic horses.<sup>5</sup> Moreover, studies have shown that inflammatory mediators that are increased in critically ill horses (IL-1, IL-6, TNF- $\alpha$ ) impair PTH secretion.<sup>5,119,120</sup> Like others,<sup>96</sup> the author and colleagues have observed a number of critically ill foals with clinical evidence of hypocalcemia in which serum intact PTH concentrations are not increased, suggesting hypoparathyroidism. Secondary hypoparathyroidism with hypercalcemia was reported in an 11-year-old Andalusian gelding with CRF and polycystic kidney disease.<sup>97</sup>

### SEPSIS

For reasons not yet understood, hypocalcemia is a frequent finding in human beings and animals with sepsis.<sup>5,104,105,121-123</sup> Sepsis is the most common cause of hypocalcemia in equine patients,<sup>5,124</sup> in particular those with severe gastrointestinal disease.<sup>5,104,105,124</sup> Hypocalcemia has been associated with equine mortality.<sup>124</sup>

In horses with enterocolitis admitted to Ohio State University Veterinary Hospital, 75% had total hypocalcemia, 80% had ionized hypocalcemia, and 70% had ionized hypomagnesemia.<sup>5</sup> Of interest, some horses with evidence of sepsis and hypocalcemia had inappropriately low serum PTH concentrations for the degree of hypocalcemia, indicating parathyroid gland dysfunction. Hypocalcemia is also frequent in septic foals. Increased endotoxin concentrations may be the trigger that leads to parathyroid gland dysfunction and hypocalcemia.<sup>120</sup> Horses with gastrointestinal disease may have detectable concentrations of endotoxin in plasma,<sup>125-127</sup> and parenteral administration of endotoxin to healthy horses results in hypocalcemia.<sup>120,128</sup>

The mechanisms responsible for the development of hypocalcemia during sepsis are poorly understood. Possible causes of hypocalcemia include renal loss of calcium,<sup>129</sup> calcium sequestration in the gastrointestinal lumen,<sup>130</sup> intracellular calcium accumulation,<sup>131</sup> impairment in calcium mobilization,<sup>132-134</sup> tissue sequestration,<sup>121,129</sup> impairment of calcium release by target tissues in response to PTH,<sup>129</sup> failure to synthesize 1,25(OH) $_2$ D,<sup>122</sup> and parathyroid gland dysfunction.<sup>5</sup> Renal loss of calcium as a cause of hypocalcemia in septic horses seems unlikely because horses were found with endotoxemia, enterocolitis, and hypocalcemia that had low fractional urinary clearance calcium.<sup>5,120</sup>

### EXERCISE-INDUCED HYPOCALCEMIA

Horses under intense exercise develop electrolyte and acid-base abnormalities. Unlike human beings, who develop either ionized hypo- or hypercalcemia, ionized hypocalcemia seems to be a more consistent finding in exercising horses.<sup>135</sup> Common clinical signs in horses with exercise-induced hypocalcemia include SDF, muscle weakness, muscle fasciculation, ileus, colic, excitation, and cardiac arrhythmias. Hypocalcemia in exercising horses results from sweat losses of calcium,<sup>113,136</sup> calcium movement to the intracellular compartment,<sup>137</sup> and increased calcium binding to albumin because of alkalosis.<sup>137</sup> Exercising horses develop respiratory alkalosis from hyperventilation, metabolic alkalosis from sweat chloride losses (hypochloremic), or a combined alkalosis.

Information on exercise-associated hypocalcemia is lacking. A recent study in exercising horses found that serum  $\text{Ca}^{2+}$

decreased while serum PTH increased, indicating parathyroid gland function as the cause of hypocalcemia was unlikely.<sup>36</sup> However, the PTH increase was not sufficient to restore normocalcemia. Another study in endurance horses<sup>103</sup> found that serum PTH concentrations did not increase in all horses that developed hypocalcemia, indicating parathyroid gland dysfunction. Renal loss of calcium as a cause of hypocalcemia during exercise is unlikely because urinary losses of calcium decrease in exercising horses.<sup>114</sup>

### CANTHARIDIASIS

Equine cantharidiasis (blister beetle toxicosis) is a condition reported in the Southern and Midwestern United States and is produced by the ingestion of alfalfa contaminated with blister beetles (*Epicauta* spp.), which produce cantharidin (cantharidic acid) (see Chapter 22 for further discussion).<sup>109,138</sup> Horses are very susceptible to the irritant effects of this toxin over mucosal surfaces (gastrointestinal and urinary tracts). Cantharidin causes acute hypocalcemia and hypomagnesemia, SDF, muscle fasciculations, ataxia, dyspnea, laryngeal spasm, and cardiac arrhythmias.<sup>138</sup> Some horses with cantharidiasis develop myocardial necrosis.

### ACUTE RENAL FAILURE

Hypocalcemia and hypomagnesemia are common findings in horses with acute renal failure (see Chapter 19 for further discussion). Reabsorption of  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  in the kidney is highly dependent on functional epithelial cells, and these cells are very susceptible to various insults (hypoxia, toxins). The loss of the epithelial cells and their absorptive capacity leads to increased urinary loss of  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$ .

### EXERTIONAL RHABDOMYOLYSIS

The pathogenesis of hypocalcemia in exertional rhabdomyolysis is unknown (see Musculoskeletal chapter for further discussion). Speculations are that muscle fiber damage during intense exercise results in  $\text{Ca}^{2+}$  influx and sequestration into the sarcoplasm and SR. A severalfold increase in sarcoplasmic  $\text{Ca}^{2+}$  concentrations have been reported in horses with exertional rhabdomyolysis,<sup>139</sup> indicating that elevations in  $\text{Ca}^{2+}$  concentrations may be important in the pathogenesis of ER.

Other causes of hypocalcemia include oxalate toxicity, tetracycline and furosemide administration, and bicarbonate overdose. Hypovitaminosis D remains to be documented as a cause of hypocalcemia in horses.

## HYPERCALCEMIC DISORDERS

Hypercalcemic disorders can be divided in two categories: (1) hypercalcemia associated with parathyroid gland dysfunction (parathyroid-dependent hypercalcemia), and (2) hypercalcemia independent of the parathyroid gland function (hypercalcemia develops despite parathyroid gland suppression). Parathyroid-dependent hypercalcemia in the horse is limited to PHPT, whereas parathyroid-independent hypercalcemia results from various conditions (secondary hyperparathyroidism, renal failure, cancer, vitamin-D intoxication).

### PRIMARY HYPERPARATHYROIDISM

In PHPT the parathyroid gland chief cells secrete excessive and autonomous amounts of PTH and do not respond to the negative feedback of  $\text{Ca}^{2+}$ . In horses, PHPT results from parathyroid adenomas or parathyroid hyperplasia. Parathyroid carcinoma

has not been reported in the horse. Elevated PTH concentrations lead to increased renal  $\text{Ca}^{2+}$  reabsorption (hypocalciuria), decreased phosphorus reabsorption (hyperphosphaturia), increased bone resorption, and increased  $1,25(\text{OH})_2\text{D}_3$  synthesis. Thus hypercalcemia, hypophosphatemia, hyperphosphaturia, and increased intact PTH concentrations are the laboratory findings of PHPT. The end result of PHPT is loss of cortical bone, and a condition known as *osteodystrophia fibrosa*. PHPT associated with osteodystrophia fibrosa has been reported in ponies and horses.<sup>99,140-143</sup> These horses may have enlargement of the facial bones, lameness, and a poor body condition. Radiographic findings include osseous proliferation of the maxilla and mandible, as well as loss of the lamina dura surrounding the molars.<sup>99</sup> Endoscopic examination may reveal narrowing of the nasal passages. Tests to rule out other conditions associated with hypercalcemia include assessment of renal function and measurement of PTHrP and vitamin-D metabolite concentrations.

Postmortem findings in horses affected with PHPT include enlargement of the maxilla and mandible, stenosis of the nasal passages, and loosening of premolars and molars. Histologic examination of the parathyroid gland is important to confirm the diagnosis of PHPT (hyperplasia); however, finding the parathyroid glands in horses may be a difficult task because of their small size and variable location.

### SECONDARY HYPERPARATHYROIDISM

In secondary hyperparathyroidism, excessive PTH secretion is the response of the parathyroid gland to hypocalcemia, hyperphosphatemia, or both (as well as hypovitaminosis D) from renal disease or from nutritional imbalances.

### RENAL SECONDARY HYPERPARATHYROIDISM

In the case of renal secondary hyperparathyroidism in small animals and human beings, phosphorus retention from renal disease and decreased  $1,25(\text{OH})_2\text{D}$  synthesis stimulate PTH secretion.<sup>144</sup> In addition, phosphorus lowers serum  $\text{Ca}^{2+}$  concentrations and inhibits  $1\alpha$ -hydroxylase, an enzyme required for  $1,25(\text{OH})_2\text{D}$  synthesis. Decreased concentrations of  $1,25(\text{OH})_2\text{D}$  also impair intestinal absorption of  $\text{Ca}^{2+}$ , contributing to hypocalcemia and PTH release. In contrast, horses with CRF have hypercalcemia, with variable phosphorus concentrations. Because equine intestinal calcium absorption is poorly regulated, the kidneys are important in eliminating the excess of calcium. The author and colleagues believe that calcium retention from abnormal renal function rather than increased PTH concentrations is the reason for the development of hypercalcemia in horses with CRF. Serum PTH concentrations in horses with CRF and hypercalcemia are often in the normal range.<sup>97,145</sup>

### NUTRITIONAL SECONDARY HYPERPARATHYROIDISM

Horses fed a diet low in calcium, high in phosphorus, or both, may develop NSHPT. This condition, also known as *bran disease*, *Miller's disease*, *big head*, *osteodystrophia fibrosa*, *osteitis fibrosa*, and *equine osteoporosis*, can affect one or many animals in a herd. Diets containing a phosphorus/calcium ratio of 3:1 or higher may result in NSHPT.<sup>100,146</sup> NSHPT is relatively uncommon in developed countries; however, occasionally a young horse may display clinical signs consistent with NSHPT, including enlargement of facial bones, upper respiratory noise, and lameness. In older horses, facial bone enlargement may not be evident. In the past NSHPT was associated with

grain-rich diets; however, with improvements in animal nutrition, NSHPT is rarely associated with excessive grain feeding. Rather it is associated with pastures containing large amounts of oxalates (see Table 20-9), which bind dietary calcium to form insoluble calcium oxalate  $[\text{Ca}(\text{COO})_2]$ .<sup>147</sup>

Excessive dietary phosphorus increases phosphorus and decreases calcium absorption, leading to hypocalcemia, hyperphosphatemia, and hyperparathyroidism in horses.<sup>141</sup> Hyperphosphatemia stimulates PTH secretion and inhibits renal  $1,25(\text{OH})_2\text{D}$  synthesis. Because  $1,25(\text{OH})_2\text{D}$  inhibits parathyroid cell function, low  $1,25(\text{OH})_2\text{D}$  concentrations contribute to parathyroid cell hyperplasia and PTH secretion. PTH increases osteoclastic activity, excessive bone resorption, and bone loss.<sup>148</sup> Facial bone loss and excessive accumulation of unmineralized bone matrix (osteodystrophia fibrosa) results in facial enlargement (big head) (Figure 20-13).

Because this is a condition of slow progression, the homeostatic mechanisms that regulate extracellular  $\text{Ca}^{2+}$  concentrations (PTH, vitamin D, CT) may be effective to maintain  $\text{Ca}^{2+}$  close to or within the normal range.

Clinical signs may include intermittent, shifting lameness, and a stiff gait.<sup>149,150</sup> In most cases swelling of the facial bones is noted. Younger animals may develop physeal enlargement and limb deformities.<sup>146</sup> The facial changes and the bone resorption around the *lamina dura* of the molars and premolars may result in masticatory problems. These horses are physically weak and may be in poor body condition. In severe cases, teeth may become loosened and spontaneous fractures may occur. Upper airway obstruction and dyspnea may be present.<sup>151,152</sup>

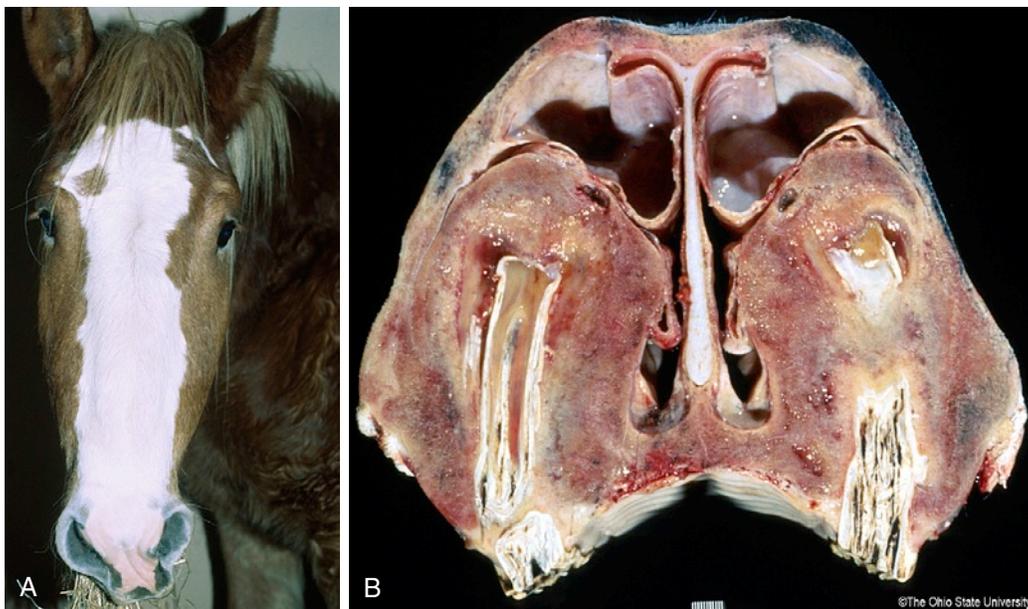

Clinical laboratory findings include mild hypocalcemia and hyperphosphatemia; however, these values may be within the reference ranges. Serum intact PTH concentrations are increased.<sup>149</sup> Urinary excretion of calcium is low and excretion of phosphorus is high. Serum alkaline phosphatase activity

may be increased. Radiologic findings include decreased bone density,<sup>149,153</sup> however, bone density must be decreased 30% before radiographic evidence exists.<sup>154</sup> Resorption of the dental alveolar sockets may be present before any other radiographic changes.

Supplementation with calcium carbonate (limestone;  $\text{CaCO}_3$ ) and dicalcium phosphate in the diet has resulted in clinical improvement.<sup>100</sup> The addition of alfalfa hay and decreasing the amount of grain may be helpful. An affected animal may require a total of 100 to 300 g/day, and the diet should have a calcium/phosphorus ratio of 3 or 4:1. Limestone may decrease feed palatability and adding molasses may be recommended. Confinement of severely affected horses is advised. The use of nonsteroidal anti-inflammatory drugs (NSAIDs) may be indicated in horses with severe pain. Supplementation with vitamin D has been proposed. Young horses may require up to 12 months for complete recovery. For horses consuming feeds with high oxalate content, an additional 20 mg of calcium/kg and 10 mg of phosphorus/kg of body weight per day may be necessary.<sup>21</sup>

### HYPERVITAMINOSIS D

The ingestion or administration of ergocalciferol (vitamin  $\text{D}_2$ ) or cholecalciferol (vitamin  $\text{D}_3$ ) results in disturbances of the calcium and phosphorus metabolism in domestic animals.<sup>101,155-162</sup> Intoxication with both forms of vitamin D has been reported in horses.<sup>101,156,162</sup> Ingestion of plants containing  $1,25(\text{OH})_2\text{D}$ -like compounds results in typical clinical signs of vitamin intoxication.<sup>157,159-161</sup> The ingestion of *Solanum glaucophyllum* (*S. malacoxylon*) results in a condition known as *enteque seco* in Argentina and *espichamento* in Brazil.<sup>155,161</sup> In Hawaii, the ingestion of *S. sodomaeum* results in hypercalcemia. The ingestion of day jessamine (*Cestrum diurnum*), a shrub widely distributed in the Southern United States (from Florida to California) may cause hypervitaminosis D.<sup>157</sup> In Europe,

**FIGURE 20-13** A, Belgium yearling presented to the Ohio State University Veterinary Teaching Hospital with clinical signs consistent with nutritional secondary hyperparathyroidism (NSHPT), including enlargement of facial bones and upper respiratory noise. The horse was fed excessive amounts of grain. B, Narrowing of the nasal passages, loss of bone mass, and excessive accumulation unmineralized bone matrix (osteodystrophia fibrosa) was evident. (Courtesy The Ohio State University.)

the ingestion of *Trisetum flavescens* by horses results in a condition known as *enzootic calcinosis*. Hyperphosphatemia is the most consistent and early laboratory finding in horses with vitamin-D intoxication.<sup>156</sup> Serum calcium concentrations may be within the normal range or increased.<sup>101,156,160,162</sup> Because vitamin D is an important negative regulator of parathyroid cell proliferation, hypervitaminosis D causes parathyroid cell atrophy.<sup>158</sup>

Clinical signs include weight loss, poor appetite, lameness, painful stiffness, and reluctance to move.<sup>156,162</sup> Acute death from severe cardiovascular mineralization has been reported.<sup>101</sup> Renal mineral deposition may precede mineralization elsewhere, leading to renal failure, uremia, hyposthenuria, polyuria, and polydipsia.<sup>101</sup> Lameness is probably the result of calcification of ligaments and tendons.

Radiographically, these horses have increased bone density, decreased size of the medullary cavity, and increased calcification of soft tissues.

The prognosis for horses with hypervitaminosis D is poor. Treatment may include reducing dietary calcium intake. The use of calcium-binding agents such as sodium phytate, which is high in many cereals, has been proposed.<sup>162</sup> Glucocorticoids are used in human beings with hypervitaminosis D, with the rationale that they may inhibit the vitamin D-mediated calcium absorption in the intestine. Dexamethasone administration to pony foals results in decreased intestinal absorption of calcium, decreased bone resorption, and increased urinary excretion of calcium.<sup>23,24</sup> Dexamethasone has been administered to horses with hypervitaminosis D with inconclusive results.<sup>162</sup>

Postmortem examination may reveal mineralization of soft tissues. Extensive cardiovascular mineralization of the endothelium of the aorta and pulmonary vessels, as well as of the endocardium of the atrium and ventricles, is frequent. Mineralized plaques may be present in the endothelium and endocardium. Mineralization may be found in the kidney, liver, lymph nodes, lungs, ligaments, and tendons. Osteopetrosis of the epiphyses and metaphyses may be present. Atrophy of the parathyroid chief cells may be severe.<sup>158</sup>

### PSEUDOHYPERPARATHYROIDISM

This term has been used to describe a paraneoplastic condition known as *HHM*. Tumors in human beings and animals may secrete PTHrP, resulting in hypercalcemia. HHM has been described in horses with gastric, vulvar, and preputial squamous cell carcinoma, adrenocortical carcinoma, lymphosarcoma, and ameloblastoma.<sup>92-95,163,164</sup>

### NEONATAL HYPERCALCEMIA AND ASPHYXIA

Clinical observations indicate that a number of critically ill newborn foals develop hypercalcemia that is not associated with renal failure or excessive PTH secretion (personal communication, Toribio RE, 2008). Many of these foals have severe hypotension, somnolence, and often die of asphyxia. Factors to consider in the pathogenesis of this condition include PTHrP and 1,25(OH) cholecalciferol.

### TREATMENT OF HYPERCALCEMIA

Hypercalcemia as an equine emergency is rarely presented; however, the differential diagnosis of hypercalcemia is important in the treatment of hypercalcemia. Mild to moderate hypercalcemia in general is not life threatening, and treatment should be directed to the primary cause (PHPT, CRF).

Hypervitaminosis D can be fatal when mineralization of vital organs occurs. Surgical removal of epithelial tumors may be a successful treatment in some patients. In cases of severe hypercalcemia that require treatment, initial therapy should include the administration of 0.9% saline solution and loop diuretics. Furosemide is the diuretic of choice because it inhibits the Na<sup>+</sup>/K<sup>+</sup>/2Cl<sup>-</sup> co-transporter in the distal nephron, increasing urinary excretion of calcium. Thiazide diuretics are contraindicated because they stimulate calcium reabsorption. Glucocorticoid administration should be considered.

## MAGNESIUM AND DISEASE

Ramiro E. Toribio\*

### ☞ MAGNESIUM

Magnesium is an essential macroelement that participates in physiologic processes such as enzymatic activation, intermediary metabolism of carbohydrates, fats, and proteins, nucleic acid metabolism, regulation of membrane function, nerve function, muscle contraction, and cell proliferation.<sup>1,2</sup> Despite all these vital functions, magnesium is not under the tight control of a hormonal homeostatic system, and its extracellular concentrations depend on gastrointestinal absorption, renal excretion, and bone exchange.<sup>1,2</sup> However, various hormonal and nonhormonal factors influence extracellular magnesium concentrations.<sup>1</sup> Similar to total calcium and ionized calcium (Ca<sup>2+</sup>), total magnesium (tMg) in biologic fluids exists bound to proteins, chelated to organic anions, and ionized or free (Mg<sup>2+</sup>).

Mg concentrations are higher in the intracellular compartment, where it binds to negatively charged molecules (ATP, DNA, RNA), enzymes, and other proteins. Approximately 90% of intracellular magnesium is bound to ribosomes, polynucleotides, and to the phosphate backbone of nucleic acids to stabilize base pairing.<sup>3</sup> By interacting with various proteins, magnesium affects the cell cycle and stabilizes cell membranes.<sup>3</sup> Mg<sup>2+</sup> interacts with Ca<sup>2+</sup> in the intra- and extracellular compartments. Depending on the physiologic system or binding molecule, Mg<sup>2+</sup> and Ca<sup>2+</sup> interact in the following ways: (1) Mg<sup>2+</sup> and Ca<sup>2+</sup> can have similar biologic effects, (2) Mg<sup>2+</sup> and Ca<sup>2+</sup> can bind to molecules with different affinities resulting in synergy or antagonism, (3) they can be direct antagonists to each other, or (4) their effects can be dependent. The pathophysiology of magnesium-related disorders is often complicated by the Ca<sup>2+</sup> status of the animal. Likewise, Ca<sup>2+</sup>-related disorders can be complicated by the Mg<sup>2+</sup> status. Hypomagnesemia exaggerates the effects of Ca<sup>2+</sup>, whereas hypermagnesemia may antagonize the effects of Ca<sup>2+</sup>.

Magnesium concentrations in body fluids are reported as mg/dl, mEq/L, or mmol/L. As the atomic weight of magnesium is 24.3 and its valence is 2<sup>+</sup>; 1 mEq of magnesium equals 12.15 mg (0.5 mmol) of magnesium. Conversion factors are as follows: mmol/L = mg/dl × 0.41; mg/dl = mmol/L × 2.43; mg/dl = mEq/L × 1.21; mmol/L = mEq/L × 0.5. Dietary magnesium is reported as g/kg or parts per million (ppm; mg/kg).

The editors acknowledge and appreciate the contributions of Allison J. Stewart, a former author of this chapter. Her original work has been incorporated into this edition.

## MAGNESIUM REQUIREMENTS IN THE HORSE

Based on urinary and fecal losses of magnesium, it has been estimated that adult horses must absorb 5 mg/kg/body weight of magnesium to replace daily obligatory losses.<sup>4</sup> With an average absorption of 40%, dietary magnesium requirements for adult horses are around 12.5 mg/kg/body weight/day (7.5-12.0 g/horse/day).<sup>4</sup> A daily supply of 13 to 15 mg/kg/body weight/day should cover the requirements for most adult horses,<sup>5</sup> but these needs can be higher depending on the physiologic status. Growing, lactating, and exercising animals have higher demands; mares in early lactation and horses under intense exercise may require 15 to 30 mg/kg of magnesium (10-15 g/horse/day).<sup>4</sup> A daily magnesium intake of 5 to 6 mg/kg has been associated with hypomagnesemia.<sup>6</sup>

## DISTRIBUTION OF MAGNESIUM WITHIN THE BODY

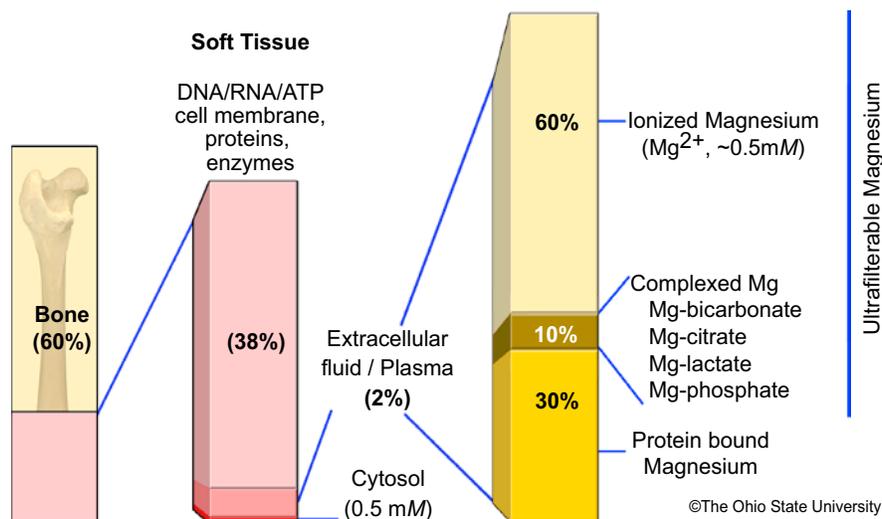

Magnesium (molecular weight: 24.3) is the fourth most abundant cation in the body, being surpassed by  $\text{Ca}^{2+}$ ,  $\text{Na}^+$ , and  $\text{K}^+$ , but is the second most abundant intracellular cation after  $\text{K}^+$ .<sup>7</sup> Magnesium distribution resembles that of  $\text{K}^+$ . The body of domestic animals contains 0.05% magnesium by weight, of which 60% is in the skeleton (0.5% to 1% bone ash), 38% in the soft tissue, and 1% to 2% in the extracellular fluid. Approximately 30% of bone  $\text{Mg}^{2+}$  is surface limited and readily available (thus serving as a reservoir to maintain extracellular  $\text{Mg}^{2+}$  concentrations), whereas the remaining 70% has structural functions as part of the hydroxyapatite lattice and its release depends on bone resorption. Cells with higher metabolic activity have higher magnesium content. Although most magnesium is in the intracellular compartment, intracellular and extracellular  $\text{Mg}^{2+}$  concentrations are similar, and the transmembrane gradient is small when compared with that of  $\text{Ca}^{2+}$ . Red blood cell (RBC) magnesium concentrations are around three times the serum magnesium concentrations.

In circulation, tMg is bound to proteins, chelated to organic anions (carbonate, sulfate, lactate, citrate), and ionized ( $\text{Mg}^{2+}$ ). It is the ionized form of magnesium that is important for most biologic processes, in particular those related to neuromuscular excitability. When possible it is better to measure  $\text{Mg}^{2+}$  than tMg concentrations. In the horse, 60% of the serum magnesium is ionized, 30% is protein bound, and 10% is complexed to weak acids<sup>8-13</sup> (Figure 20-14). Serum tMg concentrations depend on protein concentrations (albumin), whereas  $\text{Mg}^{2+}$  concentrations depend on the acid-base status. Acidosis increases  $\text{Mg}^{2+}$ , and alkalosis does the opposite. This is clinically relevant as conditions associated with alkalosis (nasogastric reflux, duodenitis and jejunitis, exercise-associated alkalosis from hyperventilation and chloride loss) can lead to low  $\text{Mg}^{2+}$  concentrations, resulting in clinical signs of hypomagnesemia with normal tMg concentrations. Feeding an acidic diet with a low DCAB will increase the percentage of  $\text{Mg}^{2+}$ .<sup>8</sup>

Reported normal serum concentrations in horses are as follows: tMg = 1.4 to 2.2 mg/dl (0.6-0.9 mmol/L)<sup>8,9,12-14</sup>, and  $\text{Mg}^{2+}$  = 0.45 to 0.6 mmol/L.<sup>8-14</sup> One study found higher tMg concentrations in donkeys.<sup>11</sup> Serum tMg and  $\text{Mg}^{2+}$  concentrations tend to be higher in foals.<sup>13</sup>

## MAGNESIUM ABSORPTION

Mg is absorbed as a freely diffusing ion ( $\text{Mg}^{2+}$ ) by paracellular (passive, nonsaturable, concentration dependent) and transcellular (saturable, active transport) mechanisms.<sup>2,15</sup> Magnesium absorption occurs in the distal small intestine and colon of monogastric animals.<sup>2,16-18</sup> In horses, most  $\text{Mg}^{2+}$  absorption occurs in the small intestine, with approximately 25% being absorbed in the proximal small intestine, 30% to 35% in the distal small intestine, and 5% to 10% in the large colon.<sup>18</sup> Intestinal magnesium absorption is proportional to its amount in the diet, but its absorptive efficiency decreases as dietary magnesium content increases.<sup>2,16</sup> Increased dietary

**FIGURE 20-14** Magnesium (Mg) distribution in the body. Approximately 60% of the total body magnesium is in the skeleton, 38% is in soft tissue, and 2% in the extracellular fluid. Although most Mg is in the intracellular compartment bound to proteins and nucleotides, free cytosolic  $\text{Mg}^{2+}$  concentrations are similar to extracellular  $\text{Mg}^{2+}$  concentrations. In equine blood, 60% of magnesium exists as a free or ionized form ( $\text{Mg}^{2+}$ ), 30% is bound to proteins, and 10% is complexed to anions such as citrate, bicarbonate, phosphate, and lactate.<sup>8-13</sup> (Courtesy The Ohio State University.)

magnesium leads to increased serum, erythrocyte, and tissue magnesium concentrations, especially in bone.<sup>2,19</sup> Dietary calcium content has minimal effect on magnesium absorption.<sup>2</sup> The digestibility of magnesium ranges between 30% to 50%, depending on diet, activity, and age. These values are higher in horses than other herbivores.<sup>18</sup> Alfalfa and alfalfa hay have the highest magnesium digestibility (50%) compared with pelleted feed and grain (20% ~ 30%).<sup>20</sup> Digestibility for oral supplements such as magnesium oxide (MgO), magnesium sulfate (MgSO<sub>4</sub>), and magnesium carbonate (MgCO<sub>3</sub>) is similar, ranging between 50% to 70%. Magnesium digestibility is higher in foals.<sup>21</sup> Excessive amounts of fatty acids, oxalates, phytates, phosphates, and fiber decrease intestinal Mg<sup>2+</sup> absorption. High dietary phosphate content decreases magnesium absorption in horses; however, phytates, calcium, and aluminum content have a minimal effect.<sup>18,22</sup> Malabsorption syndromes and enteropathies decrease absorption.

## MAGNESIUM EXCRETION
