### Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of their patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products instructions, or ideas contained in the material herein.

## PREFACE

This is the third edition of *Equine Internal Medicine*. Like its two predecessors, it has been written and edited with the aim of promoting a clearer comprehension of the principles of medical disease and/or problem development by focusing on the basic pathophysiologic mechanisms that underlie the development of various equine diseases. As with previous editions, basic information is presented and then related to the clinical characteristics of each disease and its therapy and management.

All the chapters that appeared in the first two editions have been updated, and a number of them have been extensively revised or rewritten. Although the bulk of the chapters address specific diseases along systems-based lines, we realize that the practitioner is initially confronted with a specific problem that may have its origin in one or more of the body's systems. The first section of the book is therefore devoted to an in-depth discussion of the basic mechanisms by which problems might develop and the principles underlying the treatment of many of them. The reader can build on this foundation by reading about specific disorders in the second section of the book, which is divided into chapters dealing with problems of a particular body system or of a specific nature.

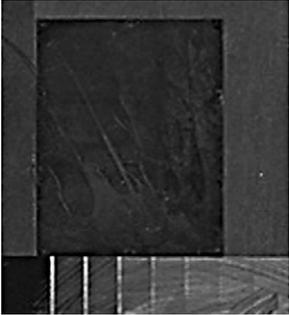

Many true experts have contributed to this text. Their depth of knowledge about all aspects of equine internal medicine is encyclopedic and daunting. We are grateful for their efforts and diligence in helping us to produce what we hope will come to be regarded as the definitive text on medical diseases of horses. We are indebted to them for their efforts. We trust that they derive a sense of pride from the part they have played in producing what we hope represents the gold standard in equine medical textbooks.

In these days of progressive globalization of the world's societies and associated growth in the international movement of horses for breeding, recreational, and competitive purposes, there has also a worldwide increase in expectations relating to the standard of veterinary care and evaluation of sick horses. The sophistication of specialist training programs and the increased number of equine internists also taking advantage of postgraduate doctoral opportunities have resulted in a wealth of new information and the maturing of an increasingly complex and challenging discipline—equine internal medicine. The delivery of superior health care and increased client expectations that have been associated with the growth of this discipline have led to the appearance of extremely well-informed and astute equine general practitioners everywhere and specialist equine internists on most continents. More than ever before, equine internal medicine now stands as an autonomous specialty in the veterinary profession. We trust that the third edition of *Equine Internal Medicine* will prove to have as much universal appeal and application as those that preceded it.

Finally, we would be remiss if we did not thank the many people at Elsevier for their persistence and efforts. Penny Rudolph and Lauren Harms in particular deserve our gratitude. They and many others have assisted in manuscript preparation, correspondence, and all the other tasks that must be accomplished to get a book like this into print. Without them and the generosity of our colleagues, this book would not have been published. We think that everyone's efforts have been worthwhile.

*Stephen M. Reed, DVM, Dipl ACVIM*  
*Warwick M. Bayly, BVSc, MS, PhD, Dipl ACVIM*  
*Debra C. Sellon, DVM, PhD, Dipl ACVIM*

# CONTENTS

## ☞ PART I: Mechanisms of Disease and Principles of Treatment

- 1 The Equine Immune System, 1
- 2 Mechanisms of Infectious Disease, 57
- 3 Clinical Approach to Commonly Encountered Problems, 91
- 4 Pharmacologic Principles, 148
- 5 Aspects of Clinical Nutrition, 205
- 6 Recognizing and Treating Pain in Horses, 233
- 7 Critical Care, 246
- 8 Epidemiology, 280

## ☞ PART II: Disorders of Specific Body Systems

- 9 Disorders of the Respiratory System, 290
- 10 Cardiovascular Diseases, 372
- 11 Disorders of the Musculoskeletal System, 488
- 12 Disorders of the Neurologic System, 545
- 13 Disorders of the Skin, 682
- 14 Disorders of the Hematopoietic System, 730
- 15 Disorders of the Gastrointestinal System, 777
- 16 Disorders of the Liver, 939
- 17 Equine Ophthalmology, 976
- 18 Disorders of the Reproductive Tract, 1004
- 19 Disorders of the Urinary System, 1140
- 20 Disorders of the Endocrine System, 1248
- 21 Disorders of Foals, 1311
- 22 Toxicologic Problems, 1364

**MECHANISMS  
OF DISEASE  
AND PRINCIPLES  
OF TREATMENT**

# THE EQUINE IMMUNE SYSTEM

## CHAPTER 1

*Paul Lunn, David Horohov*

### EQUINE IMMUNOLOGY

Although much of modern immunology has focused on humans and murine models of human diseases, the horse has played a significant role in our understanding of immunologic processes. These contributions include the earliest work on serotherapy and passive transfer; immunoglobulin structure and function; immunity to infectious agents; immunodeficiencies; and, more recently, reproductive immunology. Work in the horse continues in many of these areas to the benefit of equine medicine and comparative immunology. The overall organization and function of the equine immune system are similar to those of other mammalian species, although there are differences. The reader is referred to any one of a number of texts<sup>1-3</sup> for a more in-depth review of basic immunology. Here we shall focus on those aspects of the immune system that may be of most interest to equine researchers and clinicians. When possible, pertinent references to equine work will be provided.

### ∞ INNATE IMMUNITY AND THE ACUTE INFLAMMATORY RESPONSE

Immune defenses include both *innate responses* and *adaptive responses*, each of which is mediated by cellular and soluble components. Although we often regard the innate and adaptive responses as separate, they are in fact intimately related, sharing many of the same processes and components. The major difference lies in the specificity and recall capability that characterizes the adaptive response. It is both the specificity of adaptive responses, mediated by antibodies or by effector cells such as cytotoxic T-lymphocytes (CTLs), and the phenomena of immunological memory that are responsible for the capacity to completely protect an animal against a particular pathogen. Nevertheless, the role innate responses play in both prompting the adaptive response as well as providing valuable time for specific adaptive responses to develop cannot be overstated.

The horse, like every other species, is under constant assault from a variety of microbes that share its living space.

Although most of these organisms are thought to be harmless, their disease-causing potential is evident when they cause opportunistic infections in individuals with compromised immune systems.<sup>4</sup> Mammals, in general, have evolved a variety of defensive measures to prevent infections. The first line of defense includes the physical barriers provided by the skin and the mucosal surfaces of the digestive, respiratory, and urogenital tracts. In addition to providing a barrier to penetration, the surface of the skin contains various enzymes, fatty acids, and oils that inhibit the growth of bacteria, fungi, and viruses. Mucous membranes and mucosal secretions contain bacteriolytic enzymes, bacteriocidal basic polypeptides, mucopolysaccharides, and antibodies that prevent colonization and penetration of these surfaces. Mucus also provides a physical barrier that entraps invading organisms and leads to their eventual disposal.<sup>5</sup> Particles trapped in the mucous secretions of the respiratory tract, for example, are transported upwards through the action of ciliary cells to the trachea, where they are swallowed.<sup>6</sup> Once they are swallowed, the acidic secretions and digestive enzymes of the stomach destroy most organisms. Normal epithelial and tissue architecture is essential for successful exclusion of bacteria, and the disruption of this mechanism makes the host susceptible to infection by bacteria that normally colonize the upper airway.<sup>7,8</sup>

### ACUTE PHASE PROTEINS, PRO-INFLAMMATORY CYTOKINES, AND COMPLEMENT

Once breached, the host presents a variety of internal defenses to contain and eliminate the invaders. Invading organisms can initiate an inflammatory response either via the activation of plasma protease systems directly, such as by bacterial cell wall components, or by the secretion of toxins or other proteins that can directly activate the inflammatory response.<sup>9</sup> The cell walls and membranes of bacteria contain various proteins and polysaccharides with characteristic, often repeating, molecular structures. These pathogen-associated molecular patterns (PAMPs) include such molecules as lipopolysaccharides (LPSs), peptidoglycans, lipoteichoic acid, and flagellins.<sup>10</sup> Other PAMPs include single- and double-stranded ribonucleic acid (RNA) found on viruses and unmethylated

deoxyribonucleic acid (DNA) characteristic of bacteria. These PAMPs are recognized by a class of receptors known as *toll-like receptors* (TLRs), initially identified in *Drosophila melanogaster* (the fruitfly).<sup>10</sup> This ancient family of receptors recognizing different PAMPs is widely distributed on the various cells of the body. Not surprisingly, a number of different TLRs are found on the cells of the immune system, particularly those cells involved in the initial encounter with invading microbes. The binding of a PAMP to its specific TLR leads to an intracellular signaling event, culminating in the expression of various accessory proteins that provide the co-stimulatory signals for the developing adaptive immune response. Injured cells also release products that initiate plasma protease cascades or produce pro-inflammatory cytokines that augment the inflammatory process. Resident macrophages that encounter the invader add to the genesis of the inflammatory response through the production of pro-inflammatory cytokines such as interleukin (IL)-1, IL-6, and tumor necrosis factor alpha (TNF- $\alpha$ ).<sup>9</sup> Cytokines are hormonelike proteins that mediate a variety of cellular responses. A vast number of cytokines are involved in the regulation of innate and adaptive immune responses. IL-1, for example, is a pleiotropic mediator of the host response to infections and injurious insults (Box 1-1). Many of the effects of IL-1 are mediated through its capacity to increase the production of other cytokines, such as granulocyte colony-stimulating factor (G-CSF), TNF- $\alpha$ , IL-6, IL-8, platelet-derived growth factor (PDGF), and IL-11 (cytokines, chemokines, and interleukins are discussed later). IL-6 is responsible for the increased production of *acute phase proteins* (Table 1-1) by hepatocytes. Although the function of some of the acute phase proteins remains unclear, many of these proteins and the cytokines that elicited them are responsible for the characteristic physical signs of inflammation, including increased blood flow and vascular permeability, migration of leukocytes from the peripheral blood into the tissues, accumulation of leukocytes at the inflammatory focus, and activation of the leukocytes to destroy any invading organisms.<sup>11</sup>

The acute phase proteins include a number of *complement* proteins. The complement system is an interacting series of proteases and their substrates, resulting in the production of physiologically active intermediaries that can damage membranes, attract neutrophils and other cells, increase blood flow and vascular permeability, and opsonize bacteria and other particles for phagocytosis.<sup>12</sup> The complement cascade can be activated in two ways (Figure 1-1). The *classical pathway* involves the recognition and binding of C1 to antigen-antibody complexes. Bound C1 is proteolytic and cleaves C4. This cleavage of C4 leads to the binding of C2 to C4b. C2 is in turn cleaved by C1 into C2a. The C4bC2a complex is referred to as the *classical pathway* C3 convertase because it is a protease capable of cleaving C3 into C3a and C3b. Another C3 convertase is generated via the alternate pathway. The activation of complement via the *alternate pathway* does not involve antibodies; instead, certain microbial products (zymosan and LPS) stimulate the association of Factor D, a proteolytic enzyme, with the complex of Factor B and C3b leading to the formation of the C3bBb complex, which is the alternate pathway C3 convertase. C3a, produced by the cleavage of C3 by the C3 convertases can bind to mast cells, causing them to degranulate, and is thus referred to as an *anaphylatoxin*, as is C4a. C3b serves as an opsonin for C3b receptor-bearing phagocytic cells. C3b is also required for the formation of the membrane attack complex by the terminal complement components, C5 through C9. In this process C5 is cleaved by either the C4b2a3b (Classic pathway C5 convertase) or C3b, Bb, and properidin (alternate pathway C5 convertase). C5 is cleaved into C5a and C5b. C5a is a chemoattractive factor for neutrophils and monocytes.<sup>13</sup> C5b forms a complex with C6, C7, and C8 on cell surfaces. This leads to the insertion and polymerization of C9 that forms a pore in the membrane, leading to cell lysis.

**BOX 1-1**  
**BIOLOGIC ACTIVITIES OF INTERLEUKIN 1**

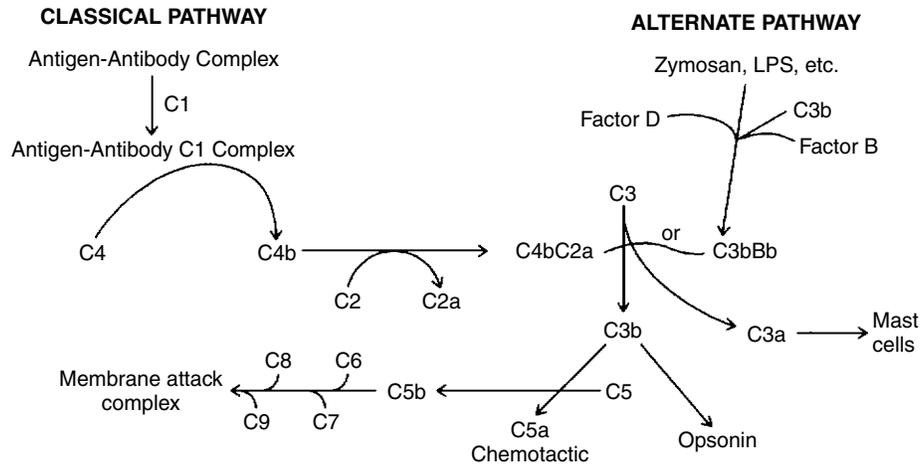

Activates T cells	Induces fever
Activates B cells	Cytotoxic for some tumor cells
Enhances NK cell killing	Cytostatic for other tumor cells
Fibroblast growth factor	Stimulates collagen production
Stimulates PGE synthesis	Stimulates keratinocyte growth
Stimulates bone resorption	Stimulates mesangial cell growth
Chemotactic for neutrophils	Activates neutrophils
Activates osteoclasts	Induces IL-6 production

NK, Natural killer; IL, interleukin.

**TABLE 1-1**

**Acute Phase Proteins**

Name	Function
C3, C4, and Factor B	Opsonins
C-reactive protein	Opsonin and complement activator
Fibrinogen	Fibrin precursor, clotting factor
Kininogen	Kinin precursor
Alpha <sub>1</sub> -acid glycoprotein	Function unknown, immunomodulatory
Ceruloplasmin, Ferritin	Iron restriction
Haptoglobin	Binds free hemoglobin
Hemopexin	Binding free heme
Serum amyloid A (SAA)	Lipid transporter, inhibitor of neutrophil function
Serum amyloid P (SAP)	Lipid transporter, inhibitor of neutrophil function
$\alpha_1$ -antichymotrypsin	Protease inhibitor
$\alpha_2$ -macroglobulin	Protease inhibitor
Cysteine protease inhibitor	Protease inhibitor

## LIPID MEDIATORS

Prostanoids are lipid mediators that regulate the inflammatory response.<sup>14,15</sup> The prostanoids group includes the prostaglandins (PGs), leukotrienes (LTs), and prostacyclin (PGI<sub>2</sub>), and they are the product of cyclooxygenase cleavage of arachidonic acid followed by endoperoxidation (Figure 1-2). The major sources of prostanoids in acute inflammation are the phagocytes, endothelial cells, and platelets. Prostanoids, in general, mediate the cardinal effects of pain, fever, and edema characteristic of the acute inflammatory response, but their particular roles are somewhat confounding and can be either pro- or anti-inflammatory (Table 1-2).<sup>16</sup> Prostanoid production depends on the activity of the two isoforms of the cyclooxygenase enzymes within cells: COX-1, which is present in most cells and its expression is generally constitutive, and COX-2, whose expression is low or undetectable in most cells, but its expression increases dramatically upon stimulation, particularly in cells of the immune system. Increased COX-2 expression by inflammatory stimuli likely accounts for the high levels of prostanoids found in chronic inflammatory lesions and is the basis for the development of COX-2-specific inhibitors for treating chronic inflammatory diseases.<sup>17</sup> However, studies using mice have indicated that the earliest prostanoid response to deleterious environmental stimuli depends on COX-1, and only as the inflammatory process progresses does COX-2 become the major source of prostanoids.<sup>18</sup> Further, evidence for increased cardiovascular risk associated with COX-2 inhibitors has called into question the use of COX-2 inhibitors as treatments for inflammatory diseases.<sup>19,20</sup>

Both COX isoforms produce PGH<sub>2</sub>, which is the common substrate for a series of specific synthase enzymes that produce PGD<sub>2</sub>, PGE<sub>2</sub>, PGF<sub>2</sub>, PGI<sub>2</sub>, and TXA<sub>2</sub> (see Figure 1-2). It is the differential expression of these enzymes within cells present at sites of inflammation that will determine the profile of prostanoid production. For example, mast cells predominantly generate PGD<sub>2</sub>, whereas resting macrophages produce TXA<sub>2</sub> in excess of PGE<sub>2</sub>, although this ratio changes to favor PGE<sub>2</sub> production after activation. Likewise, the biological effect of a prostanoid depends on its binding to G protein-coupled cell surface receptors. The receptors for PGF<sub>2</sub>, PGI<sub>2</sub>, and TXA<sub>2</sub>

are called FP, IP, and TP, respectively. In contrast, PGD<sub>2</sub> acts through two receptors, the DP receptor and the recently identified CRTh2 receptor, and there are four subtypes of receptors for PGE<sub>2</sub>, termed EP1–EP4. The prostanoid receptors themselves are coupled to various G protein-coupled intracellular signaling pathways. The DP, EP2, EP4, IP, and one isoform of the EP3 receptor can couple to G<sub>s</sub> and thus increase intracellular cAMP concentration, which in T cells and other inflammatory cells is generally associated with inhibition of effector cell functions. By contrast, the EP1, FP, IP, and TP receptors, as well as other EP3 isoforms, couple to G<sub>q</sub>, and activation of these receptors leads to increased intracellular calcium levels and immune cell activation. Finally, TP, CRTh2, and yet another EP3 receptor isoform can each couple to G<sub>i</sub>, causing cAMP levels to decline while also mobilizing intracellular calcium. Many cells of the immune system express multiple receptors that couple to these apparently opposing pathways. The impact of prostanoids present during an inflammatory response is thus determined by the array of receptors the cells express and the intracellular pathways to which they are coupled. Activation of these receptors, even when coupled to similar pathways, might evoke different responses because of differences in the levels of expression (both constitutive and induced) or in the patterns of desensitization. The role of prostanoids in a given inflammatory response depends not only on the presence of the lipid mediators in the lesion but also on the receptor profile on immune cells and the biochemical signaling pathways of these receptors.<sup>18</sup> Thus PGE<sub>2</sub> is considered proinflammatory because it promotes vasodilation by activating cAMP-coupled EP2 receptors on vascular smooth muscle and increases vascular permeability indirectly by enhancing the release of histamine and other mediators from tissue leukocytes such as mast cells. PGE<sub>2</sub> is also the prostanoid responsible for fever production. However, as inflammation progresses, PGE<sub>2</sub> synthesis by macrophages is enhanced as a result of increased expression of COX-2 and PGE-synthase, and the resulting increased levels of PGE<sub>2</sub> inhibit leukocyte activation, mast cell degranulation, and relax smooth muscle contractions. In the lung PGE<sub>2</sub> promotes bronchodilation through activation of G<sub>s</sub>-coupled EP2 and EP4 receptors. Thus in these situations PGE<sub>2</sub> may be considered anti-inflammatory.

## CHEMOTAXIS AND LEUKOCYTE TRAFFICKING

One of the initial and most crucial aspects of the acute inflammatory response is the recruitment of leukocytes (primarily neutrophils) to the site of injury. Neutrophils constitute the first line of the cellular defense and are the initial cells involved in an inflammatory response. These phagocytic cells are derived from multipotent stem cells located chiefly in the bone marrow. Under the influence of a variety of signals provided from both within and outside of the bone marrow, these stem cells become committed to developing into cells of the granulocyte lineage. The critical signal is provided by a family of growth factors known as *colony-stimulating factors* (CSFs) that provide both proliferative and differentiative signals leading to the development of granulocytes and other leukocytes. Once released into the circulation, these cells must find their way to the site of the inflammatory response. The production of various chemotactic factors by host cells, bacteria, and other invaders causes various leukocytes to enter the circulation and be carried to the site of the injury.<sup>21</sup> Chemokines are soluble proteins produced by host cells that induce the directional migration and activation of leukocytes, as well as other somatic cell types, and thus play a major role in the inflammatory response.<sup>22</sup> Interleukin 8 (IL-8) plays a central role in this process. Other chemokines promote humoral and cell-mediated immune reactions; regulate cell adhesion, angiogenesis, leukocyte trafficking, and homing; and contribute to lymphopoiesis and hematopoiesis.<sup>23</sup>

The specific trafficking of leukocytes from the blood to inflammatory sites depends on both the production of chemotactic factors and the interaction of specific receptors on the leukocytes with corresponding adhesion molecules on the endothelial surface of the blood vessels. Neutrophil adherence

is a two-step process first involving endothelial cell surface molecules known as *selectins*.<sup>9</sup> Small venular endothelium overlying a site of inflammation and exposed to thrombin, platelet activating factor (PAF), IL1, histamine, or other mediators released by clotting, platelet activation, or mast-cell activation express P-selectin.<sup>24</sup> P-selectin mediates the process in which neutrophils initially interact with the endothelial surface in a process known as “rolling,” in which the circulating neutrophil interacts with the endothelial cell before the actual adherence.<sup>25</sup> Selectins function by binding to carbohydrate ligands present on the cell surface. In the case of neutrophils, the ligand is sialylated Lewis-X antigen for the endothelial E-selectin. The second part of the adherence process is the tight binding of *integrins* on the neutrophil surface with intracellular adhesion molecules (ICAMs) on the endothelial cell surface. Leukocyte integrins are heterodimeric proteins with distinct  $\alpha$  and shared  $\beta$  polypeptide chains. The  $\alpha$  and  $\beta$  chains can combine in different heterodimers to form multiple shared and unique specificities. Neutrophil expression of  $\alpha$ M $\beta$ 2 and  $\alpha$ X $\beta$ 2 is activation dependent. Neutrophils can be activated by a number of soluble proteins, including formylmethionyl-leucylphenylalanine (fMLP), *N*-formulated peptides present in bacterial but not eukaryotic proteins. Host factors present at the site of inflammation can also activate neutrophils, notably the complement proteins (C5a, C3a) and cytokines such as IL-8 and tumor necrosis factor (TNF), and immune complexes.<sup>26</sup> Expression of integrins by activated neutrophils allows them to become tethered to the endothelial surface. The migration of neutrophils through the vascular wall is less well understood than these initial events leading to firm adhesion. The  $\beta$ 2 integrins, as well as  $\alpha$ v $\beta$ 3, PECAM-1 and integrin-associated protein (IAP), appear to play a role in this process. Endothelial

cell-produced IL-8 also is believed to have a critical role in this process. Once through the endothelium, the phagocytes will follow chemotactic signals and migrate toward the point of injury. They may adhere to other cells during migration to the site of inflammation, and these interactions also depend on  $\alpha$ M $\beta$ 2 and  $\alpha$ X $\beta$ 2 integrins. Migration through the extracellular matrix is mediated by  $\beta$ 1,  $\beta$ 3, and  $\beta$ 5 integrins recognizing specific protein ligands.

Neutrophils recruited and activated in this manner will actively phagocytose microscopic invaders and attempt to destroy them using reactive oxygen products generated via an NADPH-oxidase-dependent "respiratory burst."<sup>25,27</sup> In the process the neutrophils release additional pro-inflammatory mediators, thus amplifying this response. Among those cells attracted to the area are *natural killer (NK)* cells capable of lysing virus-infected and other abnormal cells. The production of interferon- $\alpha/\beta$  by macrophages and other cells enhances the cytolytic activity of the NK cells. The NK cells themselves can be the source of interferon- $\gamma$ , another pro-inflammatory cytokine. Depending on the magnitude of the initial insult and the susceptibility of the invader to neutrophil-mediated destruction, the inflammatory response may be either acute or chronic.

Acute inflammation is thus a rapid response to an injury that is characterized by accumulations of fluid, plasma proteins, and neutrophils that rapidly resolves once the initial

inflammatory stimulus is removed. Deactivation signals include PGE<sub>2</sub>, cortisol, IL-10, and transforming growth factor- $\beta$  (TGF- $\beta$ ). Some of those chemotactic agents responsible for initiating the response (IL-8, FMLP, C5a, LTB<sub>4</sub>, and PAF) also serve to downregulate its intensity by inducing the shedding of IL-1 receptors from neutrophils.<sup>28</sup> The shedding of this decoy receptor may have anti-inflammatory effects as it effectively binds and neutralizes this cytokine. Likewise, many of the acute phase proteins are thought to have immunomodulatory activity downregulating neutrophil function.<sup>29</sup> Acute inflammatory responses may often be subclinical and resolve without complications. However, if the invader is resistant to neutrophil-mediated destruction or the degree of injury is large, the response may become more chronic with the added recruitment of macrophages and lymphocytes, and fibroblast growth.

The essential characteristic of the innate immune response is that it does not exhibit specificity for the invading organism. Thus the induction of an innate immune response does not require prior exposure to the invading organism nor is it augmented by repeated exposure to the same organism. Whereas resistance may be genetically controlled, the genes encoding resistance are not found within the gene complex that controls adaptive immune responses. In most instances these mechanisms are adequate for eliminating casual

invaders. However, pathogenic organisms have evolved various methods for avoiding elimination. In response to these organisms, the specialized cells and products of the adaptive immune response are mobilized.

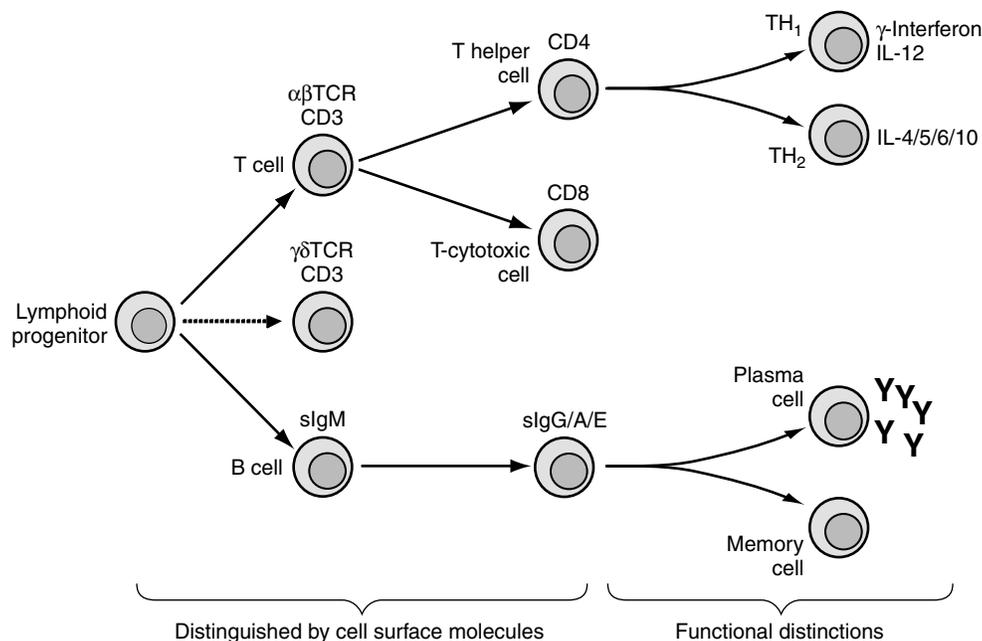

## ADAPTIVE IMMUNITY

The adaptive immune response is initiated in response to an encounter with a foreign agent and depends on antigen-specific immune responses mediated by different divisions of the lymphocyte family (Figure 1-3). In contrast to the non-specific nature of the innate immune response, an important characteristic of the adaptive immune response is the specificity of this interaction. Thus exposure of the host to a particular microbe or parasite results in the induction of immune responses that are directed against specific components of the invading organism that do not affect unrelated organisms. The specificity of the adaptive immune response is the result of the interaction of specific molecular structures or *antigens* of the invader with antigen-specific receptors on lymphocytes. All types of chemical structures can serve as antigens, but not all antigens can induce an immune response. *Immunogens*, those antigens that can stimulate an immune response, are usually high molecular-weight, chemically complex molecules. Proteins, nucleic acids, lipids, and polysaccharides can all serve as immunogens. Large immunogens, such as proteins, contain multiple *antigenic determinants* or epitopes, which interact with lymphocytes via their antigen-specific receptors. Haptens consist of single antigenic determinants and can effectively combine with the binding site of antibody molecules. However, because they consist only of a single antigenic determinant, they cannot cross link B-cell receptors (antibody molecules), and they are also unable to stimulate T cell responses. Haptens therefore cannot stimulate an immune response unless multiple haptens are physically attached to a larger molecule, known

as a *carrier*. Although these distinctions between antigens, haptens, and immunogens appear minor, they provide the underlying basis for our understanding of many allergic and autoimmune responses.

Like the innate response, the adaptive immune response to a specific antigen consists of both humoral and cellular effector mechanisms. The humoral component is mediated by immunoglobulins or antibodies found in plasma and tissue fluids. Antibodies are produced by B lymphocytes, small lymphoid cells characterized by the cell surface expression of immunoglobulin molecules. B cells represent fewer than 15% of the circulating peripheral blood mononuclear cells but are present in higher proportions in lymph nodes and the spleen. B cells are derived from the fetal liver and bone marrow of mammals and the bursa of Fabricius of birds. In the bone marrow B cells are the products of a putative lymphoid stem cell derived from the pluripotent stem cell. Under the influence of various cytokines produced by bone marrow *stromal* cells, the B cell precursor undergoes its 3-day development into a mature B cell. Upon stimulation with specific antigen, B cells differentiate into *plasma cells* that produce enormous quantities of specific antibody. The activation, proliferation, and differentiation of B lymphocytes into plasma cells depends on other cells, including T lymphocytes, which represent the cellular component of the adaptive immune response. The T lymphocyte is also derived from the multipotent stem cell and lymphoid precursor in the bone marrow, although its subsequent development into the mature T cell occurs in the *thymus*. Within the thymic environment the prothymocyte undergoes a developmental and selective process while emigrating through the cortex into the medullary region of the thymus. Fewer than 3% of all the immature thymocytes found in the cortex survive to become peripheral T cells.

Although the induction of an antibody response requires the interaction of B and T lymphocytes, these cells recognize

**FIGURE 1-3** Major divisions of the lymphocyte family. To the left of the diagram, different populations of lymphocytes are distinguished by expression of different cell surface molecules. To the right of the diagram, the distinctions are functional.

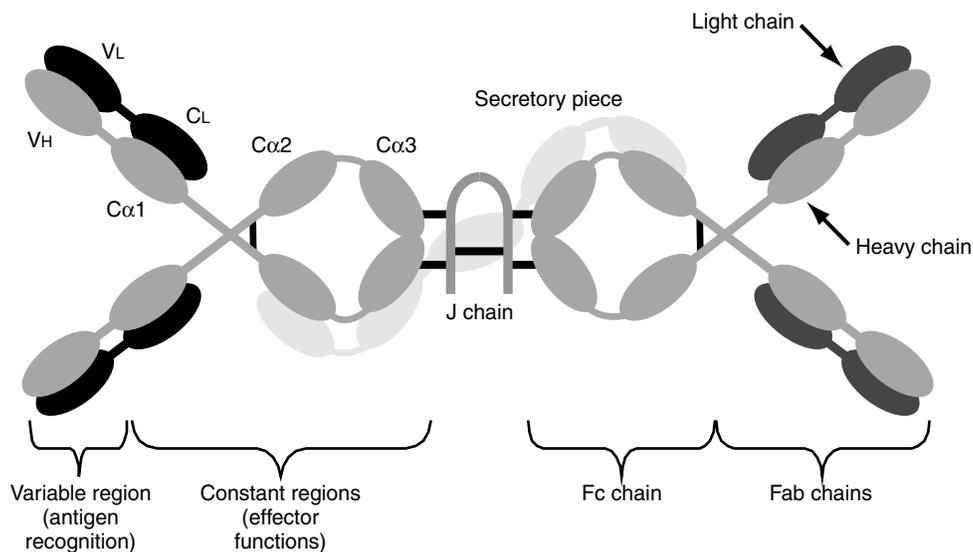

different epitopes on the same antigen. Indeed, antigen recognition by B cells and T cells is fundamentally quite different. B cells, and antibodies, recognize antigens in solution or on cell surfaces in their native conformation, whereas T cells recognize antigen only in association with self molecules known as *major histocompatibility complex* antigens found on most cells' surfaces. The adaptive immune response thus differs from innate immunity in that it is antigen driven and those cells that mediate the adaptive immune responses, T and B lymphocytes, express specific receptors for the antigen. Because the immune system will respond to the antigens of both live and killed pathogens, it is possible to stimulate immunity without causing infection, which is the basis of vaccination. Although this principle appears to be straightforward, vaccination does not always yield the expected result. Why some vaccines work and others fail is a complex issue, a major component of which is the nature of the antigen-specific receptors of lymphocytes.

### IMMUNOGLOBULIN: ANTIGEN-SPECIFIC RECEPTOR OF B LYMPHOCYTES

The antigen-specific receptor of the B cell is cell surface-bound antibody. An antibody molecule is composed of two identical light chains and two identical heavy chains that form a disulfide-linked Y-shaped molecule (Figure 1-4). The light chain can be divided into two domains, a conserved carboxy-terminal domain and a highly variable amino-terminal domain. Analysis of heavy chains reveals a similar domain structure, with the amino-terminal domain being highly variable and the presence of three constant domains. The antigen-binding region of an antibody molecule is formed by the association

of the amino ends of a light and a heavy chain, whereas the carboxyl end of the heavy chain determines the isotype of the molecule. Five different *isotypes*, or classes, of antibody molecules have been identified in most species, including the horse: IgD, IgM, IgG, IgA, and IgE (Table 1-3).<sup>30,31</sup> Additionally, the IgG isotype can be subdivided into subclasses based on physico-chemical properties. Analysis of equine genomic DNA has indicated the existence of one IgM, one IgD, one IgE, one IgA, and seven IgG genes.<sup>31</sup> Before the availability of genetic characterization of the equine immunoglobulin heavy chain gene loci, at least four IgG subclasses were identified by physico-chemical means and defined serologically by monoclonal antibodies as IgGa, IgGb, IgGc, and IgG(T).<sup>32</sup> Each of these "classical" (older) IgG subclasses has been identified as a gene product of one or more of the equine heavy chain gene loci.<sup>30,31</sup> It appears that both IgGb and IgG(T) are encoded by two loci each, raising the possibility that these classical subclasses may each comprise two distinct subclasses. At the time of writing, this remains uncertain, although ongoing studies are starting to resolve the issue.<sup>30</sup> The gene product of at least one IgG heavy chain locus is not defined by the classical IgG subclasses, and it remains to be determined whether it is expressed as a protein and what its role may be.<sup>31</sup> Given the current remaining uncertainties as to the role of equine IgG subclasses as defined by nomenclature based on heavy chain gene locus, this edition of this text will continue to use the classical nomenclature.

Membrane-bound IgM and IgD serve as the antigen-specific receptors for B lymphocytes. Each contains a membrane-spanning region near its carboxy end that is inserted into the mRNA during differential splicing of the heavy chain exons. Although rarely detectable in the circulation, IgD is

**FIGURE 1-4** Molecular structure of secretory immunoglobulin (Ig) A. This schematic illustrates the major features of immunoglobulin molecules. The illustrated IgA molecule is dimeric, with the two immunoglobulin units joined by a "J-chain" and a series of disulphide bonds, and IgG molecules are monomeric. Each immunoglobulin unit consists of two heavy chains and two light chains. The heavy chains have four subunits and the light chains two. One end of the immunoglobulin unit has a highly variable protein structure and is involved in antigen recognition, whereas the remainder of the immunoglobulin unit has a constant structure in each immunoglobulin class and subclass and determines the functional characteristics of the molecule, such as binding complement, or recognition by macrophages or neutrophil Fc receptors. This specialized dimeric IgA molecule also has a secretory piece that increases its stability in the harsh mucosal environment.

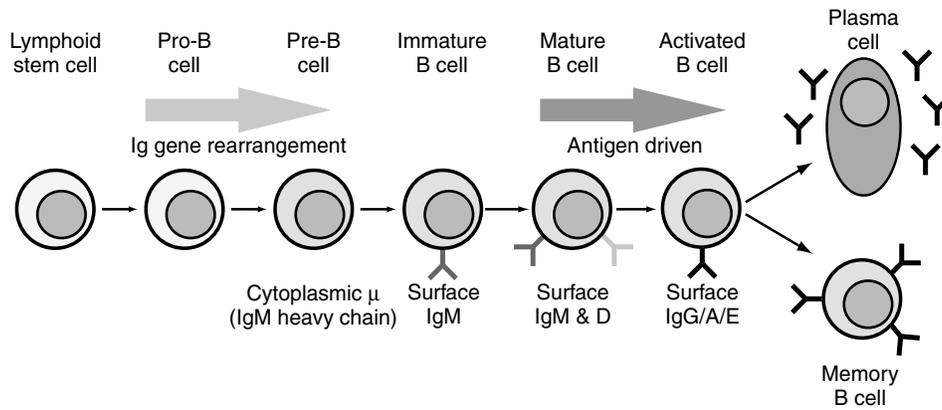

TABLE 1-3

Immunoglobulin Isotypes	
Isotype	Immunologic Function
IgD	Antigen receptor of naïve B lymphocytes. An IgD heavy chain gene has been identified in the horse, and it is probably expressed.
IgM	Surface IgM is found on naïve, activated, and memory B cells. Secreted IgM is a pentamer and represents the major antibody produced during a primary response. IgM efficiently mediates agglutination, neutralization, opsonization, and complement activation.
IgG	The principle immunoglobulin found in plasma representing up to 80% of the total immunoglobulin concentration. Various subclasses of IgG have been identified (see text). The classical view is that there are four IgG subclasses in the horse (IgGa, IgGb, IgGc, and IgG(T)) defined by physicochemical properties and monoclonal antibodies, although seven IgG heavy chain genes have been identified and there is evidence that all are expressed. The major functions of IgG include opsonization and neutralization reactions. IgGa and IgGb are effective in fixing complement and participates in antibody-dependent cellular cytotoxicity (ADCC) while IgGc and IgG(T) are not, although they appear to play an important role in exotoxin neutralization and immunity to parasites. As our understanding of IgG heavy chain gene expression and function increases, a new nomenclature (i.e., IgG1–7) will replace the classical nomenclature (i.e., IgGa).
IgA	IgA, the most abundant antibody in secretions (e.g., tears, mucus, saliva, colostrum) is a dimer composed of two IgA molecules joined by a J chain. IgA in the plasma is predominantly monomeric. IgA antibodies can be neutralizing but only activate complement via the alternative pathway.
IgE	Most IgE is found associated with the surface of mast cells and basophils and only very small amounts are present in the plasma. The cross-linking of two IgE molecules with specific antigen results in the degranulation of the mast cells and basophils. Thus IgE is the primary antibody responsible for Type I hypersensitivity reactions and appears to play a central role in immunity to parasites.

The different effector function capabilities of the seven equine IgG subclasses have implications for vaccine strategies. *Mol Immunol* 2008;45:818-827; and Wagner B, Miller DC, Lear TL, Antczak DF. The complete map of the Ig heavy chain constant gene region reveals evidence for seven IgG isotypes and for IgD in the horse. *Journal of Immunology* 2004;173:3230-3242. Ig, immunoglobulin.

present in large quantities on the surface of naïve B lymphocytes. Following activation, the surface expression of IgD is lost, although the cell may continue to express the membrane form of IgM. Early in an immune response, the B cell secretes large amounts of the pentameric form of IgM. As the immune response proceeds, the B cell will switch the isotype of its heavy chain. Isotype switching involves the substitution of one heavy chain–constant region in place of another. The genes encoding the five different constant regions of the heavy chain are sequentially arranged on the chromosome ( $C_{\delta}$ ,  $C_{\mu}$ ,  $C_{\gamma}$ ,  $C_{\epsilon}$ , and  $C_{\alpha}$ ). Initially, the first two constant region genes encoding the  $\delta$  and  $\mu$  constant regions are used to form the heavy chain. The 5' region of each constant region gene segment contains repetitive regions of DNA known as *switch sequences*.<sup>33</sup> The switch sequences appear to play a role in this rearrangement and may serve as the target for specific recombinases. When switching occurs, a new constant region segment is selected and the intervening genes are removed either by splicing or looping out. Isotype switching affects only the heavy chain–constant domains and has no effect on the antigen specificity of the immunoglobulin molecule. The signal for B cells to undergo isotype switching is provided by T lymphocytes in the form of various cytokines.<sup>34</sup> For example, IL-4 induces isotype switching to the IgE isotype, whereas interferon- $\gamma$  blocks this induction and augments IgG production.<sup>35,36</sup> IgA is produced in response to the combination of the cytokines IL-4, IL-5, and transforming growth factor- $\beta$  (TGF- $\beta$ ).<sup>37</sup>

The antigen specificity of a particular antibody molecule (and the B cell that produces it) is determined by the combination of the variable domains of the light and heavy chains. The association of these two domains results in the formation of an antigen-binding groove or pocket that contains regions of hypervariability that define the specificity of a particular antibody molecule. It has been estimated that more than  $10^8$  different antibody specificities are possible. The generation of this tremendous amount of diversity in antibody specificity occurs during B cell ontogeny in the bone marrow.<sup>38</sup> Within a given B cell, the genes encoding the heavy and light chains of an antibody molecule are organized into specific gene segments. Thus the light chain is formed from variable ( $V_L$ ), joining ( $J_L$ ), and constant ( $C_L$ ) gene segments that together form the variable and constant domains of the light chain. In the germ line of an undifferentiated cell, several hundred different  $V_L$  and several dozen  $J_L$  gene segments can be found. Likewise, the heavy chain of a B lymphocyte is composed of  $V_H$ , diversity (D), and  $J_H$  segments that form the variable domain, and these join to the constant region genes to form the complete heavy chain molecule. Similarly, in the germ line a large number of  $V_H$  gene segments and a smaller number of D and  $J_H$  segments are found. During the differentiation of a B cell (Figure 1-5), there is the sequential selection and rearrangement of a  $V_L$  segment with a  $J_L$  segment and the accompanying deletion of intervening  $V_L$  and  $J_L$  segments (Figure 1-6). The rearranged VJC sequence is then transcribed into mRNA and translated into the light chain. A somewhat similar sequence follows for

**FIGURE 1-5** B cell differentiation. Different stages of B lymphocyte development can be recognized by expression of immunoglobulin molecules. This maturation requires a series of gene rearrangements in order to select the genes that will encode the antigen binding part of the immunoglobulin molecule (variable region) and subsequently to select the genes that determine the class or subclass of the antibody molecule. Initially immature B cells express IgM (the majority of peripheral blood B cells), but after antigen exposure the B cell becomes activated and may express any of the immunoglobulin classes or subclasses. This decision depends in large part on cytokine signals from T-helper cells. Finally activated B cells either mature into short-lived antibody secreting plasma cells or become long-lived memory B cells.

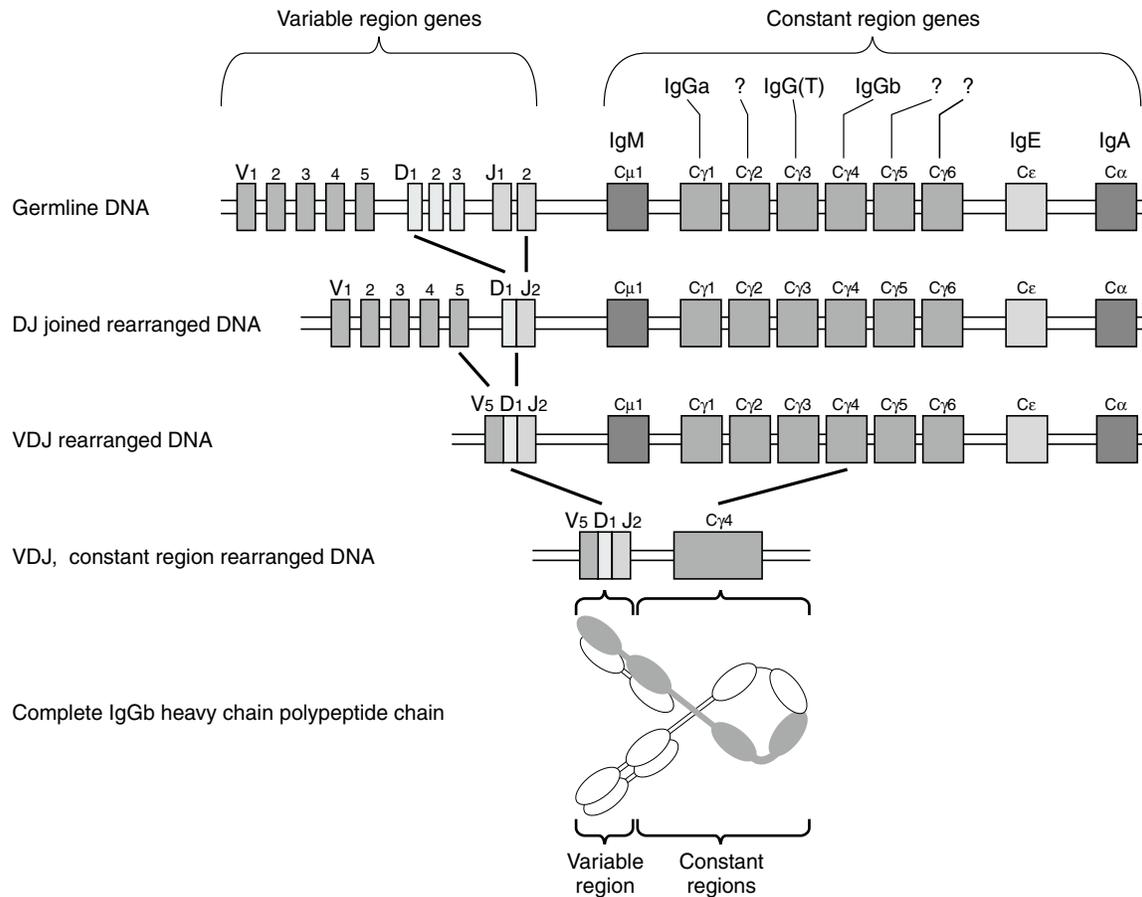

heavy chains except that two rearrangements are necessary, a D to  $J_H$  rearrangement followed by a  $V_H$  to  $DJ_H$  rearrangement. Once completed, the VDJ segment is brought into the proximity of the appropriate  $C_H$  segment and transcribed. Not all of the gene segment rearrangements produce functional genes. Because a B cell has two sets of heavy chain genes, one on each chromosome, and most species, including the horse, have two different sets of light chain genes,<sup>39,40</sup> there are several chances to form appropriate heavy and light chains. Once the heavy and light chain gene segments are successfully recombined, the genes on the sister chromosome neither recombine nor are they expressed. This process of allelic exclusion ensures that the B cell produces antibodies of a single specificity. Although this random assortment of gene segments accounts for much of the diversity in antibody specificity, additional mechanisms are also involved, including junctional diversity, which results from the imprecise joining of gene segments and somatic mutations. Somatic mutations are point mutations in the hypervariable region of either the heavy or light chain that occur during the proliferation of antigen-activated B lymphocytes. Such mutations appear to play a role in increasing antibody affinity for its antigen. Thus fewer than 1000 genes can give rise to more than  $10^8$  molecules of the various specificities needed to recognize the vast number of antigens the host may encounter.

### TcR AND CD3 COMPLEX: ANTIGEN-SPECIFIC RECEPTOR OF T CELLS

T lymphocytes can be differentiated from B lymphocytes in that they do not express surface immunoglobulins but instead express the T cell receptor (TcR). T cells also express another antigen called CD3. (The designation CD stands for *cluster designate* and is the result of an international workshop to standardize the terminology used to describe leukocyte surface antigens recognized by monoclonal antibodies.) The TcR and CD3 form a multimeric complex on the T cell surface, and

this complex is involved in antigen-specific recognition.<sup>41</sup> The TcR structure was first identified using antibodies that recognized a surface antigen expressed on a cloned T lymphoma cell line. This antibody recognized a disulfide-linked heterodimer composed of an acidic ( $\alpha$ ) and a basic ( $\beta$ ) protein of 40 to 45,000 molecular weight. Similar heterodimers were found on a variety of antigen-specific T cell lines but not on B cells. Peptide mapping studies of the  $\alpha$  and  $\beta$  chains from many different T cell lines demonstrated that they contained variable and constant domains reminiscent of immunoglobulin structure. Further analysis indicated that, like immunoglobulin genes, the TcR genes underwent gene rearrangements during T cell development. Subsequently, two additional TcR genes were identified, the  $\gamma$  chain and  $\delta$  genes corresponding to a second heterodimer. Thus two TcR exist, an  $\alpha/\beta$  heterodimer that constitutes the TcR on almost 90% of all T cells and a  $\gamma/\delta$  heterodimer present on approximately 10% of the peripheral T cells. The significance of these two different TcR heterodimers has not yet been determined. It should be noted that  $\gamma/\delta$  T cells have not yet been identified in the horse. It is clear that  $\gamma/\delta$  T cells represent a functionally distinct population of T cells typically associated with mucosal surfaces.<sup>42</sup> As such they are thought to play an important role in immunologic surveillance.

Analysis of the predicted amino acid sequences for the TcR proteins confirmed a structural similarity with antibody molecules. One peculiarity in the structure of the TcR was observed from the amino acid sequence analysis. Whereas both the  $\alpha$  and  $\beta$  chains of the TcR contained a transmembrane region, both proteins had very short cytoplasmic tails. It therefore seemed unlikely that TcR itself could transmit any cytoplasmic signal in response to antigen binding. This led to the search for other proteins associated with the TcR. Solubilization of the T cell membranes revealed that five other proteins could be immunoprecipitated with the TcR. Similar results were obtained when anti-CD3 antibodies were used. Thus the TcR heterodimer is noncovalently associated with

**FIGURE 1-6** Immunoglobulin gene rearrangement–somatic recombination process for production of an immunoglobulin heavy chain. The figure shows a hypothetical series of V, D, and J variable heavy chain genes, positioned 5' to the known equine heavy chain constant region gene loci. In the first step in somatic recombination a D and a J gene segment are joined, and in the second step a V gene segment is joined to complete the VDJ recombination and form a gene capable of encoding the variable region. Subsequently one of the seven equine  $\gamma$  heavy chain constant regions, labeled with their corresponding IgG subclass when known, was selected to complete the gene rearrangement. Because the C $\gamma$ 4 heavy chain constant region gene was selected, this leads to production of an IgGb heavy chain.

the CD3 complex of proteins. The five proteins of the CD3 complex ( $\gamma$ ,  $\delta$ ,  $\epsilon$ ,  $\zeta$ , and  $\xi$ ) are involved in signal transduction following TcR binding to antigen.<sup>43</sup> Unlike the TcR  $\alpha$  and  $\beta$  proteins, the CD3 proteins have large intracellular domains, some of which are phosphorylated in response to stimulation of the TcR. In addition to providing a signaling mechanism for the TcR, the CD3 complex is also required for the expression of the TcR heterodimer on the cell surface.<sup>41</sup>

The generation of diversity in the TcR during T cell ontogeny employs a mechanism quite similar to that used to generate immunoglobulin diversity. The TcR  $\alpha$  and  $\gamma$  chains resemble immunoglobulin light chains in that they are composed of V, J, and C gene segments. The particular V, J, and C segments used are selected from a germ line configuration containing a few (C region) to several hundred (V region) gene segments. The selection and rearrangement of the gene segments are similar to those employed by the immunoglobulin light chain and appear to involve the same recombinase. Likewise, the  $\beta$  and  $\delta$  chains resemble heavy chains, each being composed of V, D, J, and C gene segments, and their selection and rearrangement from germ line genes also parallel immunoglobulin heavy chain rearrangement. Thus

the generation of diversity is the result of the combination of multiple gene segments and junctional diversity. However, unlike immunoglobulins, the TcR genes do not undergo somatic mutations.

## T LYMPHOCYTE SUBSETS

Mature thymocytes and T lymphocytes can be further divided into two distinct populations on the basis of their expression of either the CD4 or CD8 antigen.<sup>44</sup> The expression of these antigens is directly correlated with the specificity of the T cell. The expression of either CD4 or CD8 also correlates to some extent with the T cell's function. Thus those cells that express the CD8 antigen are typically CTLs, whereas those that express the CD4 antigen are typically helper cells that produce those cytokines that enhance antibody and cell-mediated immune responses. Whereas the T lymphocytes in the periphery express either CD4 or CD8 antigens, cortical thymocytes express both antigens. During the process of thymic selection, these cells convert to either CD4<sup>+</sup> or CD8<sup>+</sup> cells or they are eliminated (Figure 1-7). It is at this stage of their development that T cells are said to "learn" to recognize antigen. It is also at this stage

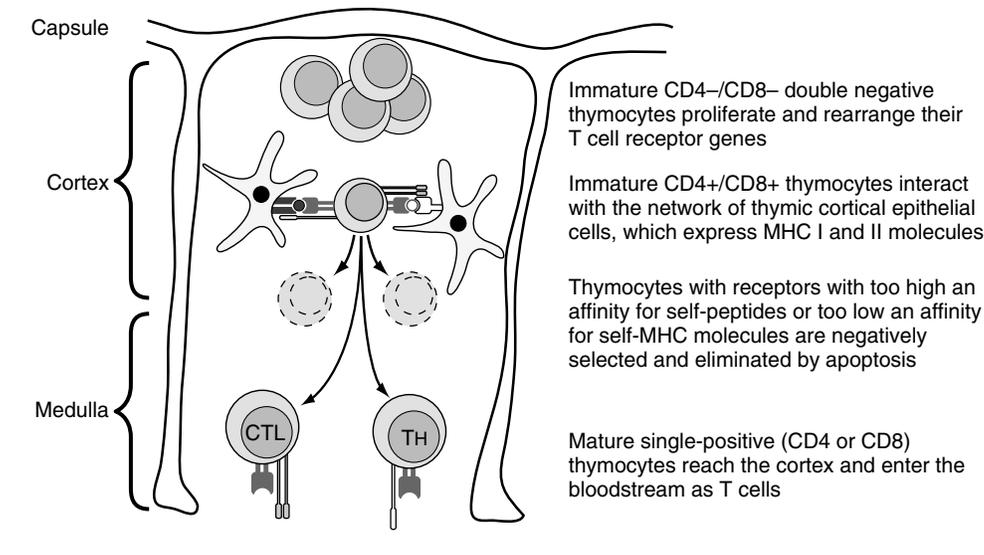

FIGURE 1-7 Thymic development.

that autoreactive T cells are eliminated. Although experimental studies have shown that both positive and negative selection of the T cells is occurring, the exact mechanism of these selective processes remains unknown. Interestingly, although T cells expressing the  $\alpha/\beta$  heterodimer of the TcR can be either CD4<sup>+</sup> or CD8<sup>+</sup>,  $\gamma/\delta$  cells are either CD8<sup>+</sup> or CD4<sup>-</sup> CD8<sup>-</sup>. These results suggest that the  $\gamma/\delta$  cells undergo a different developmental process than do the  $\alpha/\beta$  cells. Like the CD3 complex, both the CD4 and the CD8 antigen are involved in the intracellular signaling event following TcR engagement with its specific antigen. Unlike B cells, and antibodies, that recognize antigens in solution or on cell surfaces in their native conformation, T cells recognize only *processed* antigen in association with self molecules known as *major histocompatibility complex* (MHC) antigens.

### MAJOR HISTOCOMPATIBILITY ANTIGENS AND ANTIGEN PRESENTATION

The MHC was originally defined in terms of its role in allograft rejection. Following the rejection of a primary allograft, antibodies that reacted with the allograft could be found in the recipient's sera. These antibodies could be used to identify or type tissues to determine the suitability of a donor for transplantation. It was also determined that multiparous females had similar antibodies in their sera as a result of the exposure to paternal MHC antigens on the fetus.<sup>45</sup> Through the use of these sera, it was possible to identify a large number of serologically defined transplantation antigens. Subsequent genetic analysis of the MHC region demonstrated that there were a number of closely linked genes encoding several different, though related, antigens that were involved in allograft rejection. These closely related genes are collectively referred to as *MHC I genes* and their products as *MHC I antigens*. In addition to the serologically defined MHC I antigens, another group of antigens was identified within the MHC; these antigens were involved in the stimulation of mixed lymphocyte responses and the control of immune responsiveness. These MHC II antigens are structurally and functionally distinct from the MHC I antigens, except that both are involved in T cell recognition of antigen.

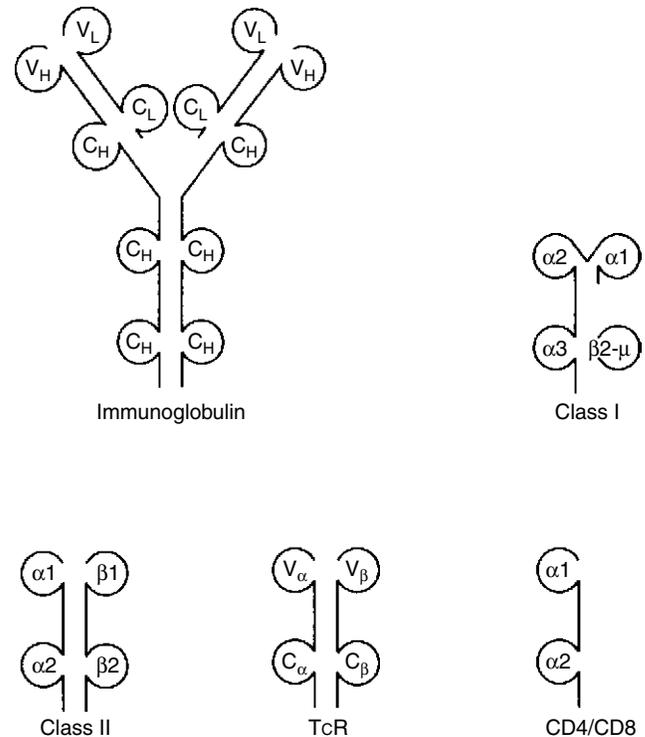

MHC I antigens are cell surface glycoproteins consisting of two noncovalently associated proteins, an MHC-encoded transmembrane protein of approximately 44 kd ( $\alpha$  chain) and  $\beta_2$ -microglobulin, a 12 kd protein encoded outside of the MHC.<sup>3</sup> MHC I antigens are expressed on the surface of most nucleated cells. The highest level of expression is on lymphoid cells with lower expression on fibroblasts, muscle cells, and neural cells. MHC I antigens are not detectable on early embryonal cells, placental cells, and some carcinomas. The level of expression of MHC I antigen can be modified by treatment with cytokines or infection with viruses. Interferons and TNF- $\alpha$  augment MHC I antigen expression. This augmented expression is the result of increased production of MHC I mRNA, and the regulatory region of the MHC I antigen genes has been shown to contain interferon and TNF- $\alpha$  responsive elements that control the transcriptional activity of these genes.

The MHC I region of most animal species, including the horse, contains a number of MHC I  $\alpha$  chain genes, some of which are pseudogenes and are not expressed.<sup>46</sup> The known total of different equine MHC class I genes (loci) expressed as mRNA is seven.<sup>47</sup> In the horse these genes are located on chromosome 20, and those genes that are expressed exhibit a great deal of polymorphism.<sup>48,49</sup> Much of this polymorphism is localized in the  $\alpha_1$  and  $\alpha_2$  domains, the  $\alpha_3$  domain being more conserved. The polymorphism of these two domains is related to their role in presenting antigen to T cells. The physiologic role of MHC I antigens was defined when it was discovered that cytotoxic T cell (CTL) lysis of virus-infected cells was restricted to target cells expressing the same MHC I antigen as the CTL.<sup>50</sup> This observation led to the realization that T cells recognized the combination of self-MHC and foreign antigen. Furthermore, those T cells that recognized MHC I antigens invariably expressed the CD8 co-receptor. The nature of the association between MHC I and the foreign antigen remained unclear until X-ray crystallographic studies of human MHC I antigen were performed.<sup>51,52</sup> In addition to revealing the structural organization of the domains of the MHC I antigen, the image also revealed a cleft that lay between the  $\alpha_1$  and  $\alpha_2$  domains. It was proposed that this cleft binds the processed peptide epitopes for presentation to the T cell receptor. Indeed, the cleft of the crystallized protein used for the X-ray diffraction

studies was found to contain a contaminating peptide.<sup>51</sup> Other experiments showed that the incubation of cells with purified viral peptides resulted in the lysis of the cells by virus-specific, MHC I-restricted CTL.<sup>52</sup> Together these results support the notion that the *endogenous processing* of viral antigens leads to the association of viral peptides with MHC I antigens on the surface of the infected cell, and this is recognized by the TcR-CD3 complex in association with CD8.<sup>52</sup> How these viral antigens get to the cell surface is the result of a peptide transport system whose function is to transport processed peptides from the cytosol to the ER.<sup>53</sup> Once in this compartment, peptides are handed off to newly formed MHC class I molecules and stabilize a trimolecular complex with  $\beta 2$  microglobulin. This complex is then transported to the cell surface, where antigen presentation occurs. Because this is a normal cellular process for eliminating degraded proteins from the cell, it is not surprising that MHC I antigens are normally loaded with these self-peptides. Indeed, it is this encounter with MHC I loaded with self-peptides in the thymus that is responsible for the deletion of autoreactive clones during T cell ontogeny. This unique peptide-binding characteristic of MHC-I molecules has led to their use as immunologic reagents (tetramers) for the identification and enumeration of antigen-specific CD8<sup>+</sup> T cells.<sup>54</sup> In the horse tetramers based on the equine MHC class I molecule 7-6, associated with the ELA-A1 haplotype, have been used to identify and enumerate equine infectious anemia virus (EIAV)-specific cytotoxic T cells.<sup>55</sup> In the future similar approaches may be used to analyze CTL responses to a variety of viruses and provide important information on the role these cells play in protection from these infections.

MHC II antigens are heterodimeric, transmembrane glycoproteins composed of an acidic  $\alpha$  chain (25 to 35 kd) and a basic  $\beta$  chain (25 to 30 kd).<sup>56</sup> A third chain, the invariant chain, is associated with the MHC II antigen during assembly in the endoplasmic reticulum but is not expressed on the cell surface. Both the  $\alpha$  and  $\beta$  polypeptides are encoded within the MHC region. Both polypeptides possess two extracellular domains. The  $\alpha$  chain has a single disulfide bond located in its membrane proximal ( $\alpha_2$ ) domain, and the  $\beta$  chain has a disulfide bond in both of its extracellular domains. Structurally, the MHC II antigens resemble MHC I antigens and are also members of the immunoglobulin superfamily, a group of proteins that have structural similarities to immunoglobulin molecules (Figure 1-8).<sup>57</sup>

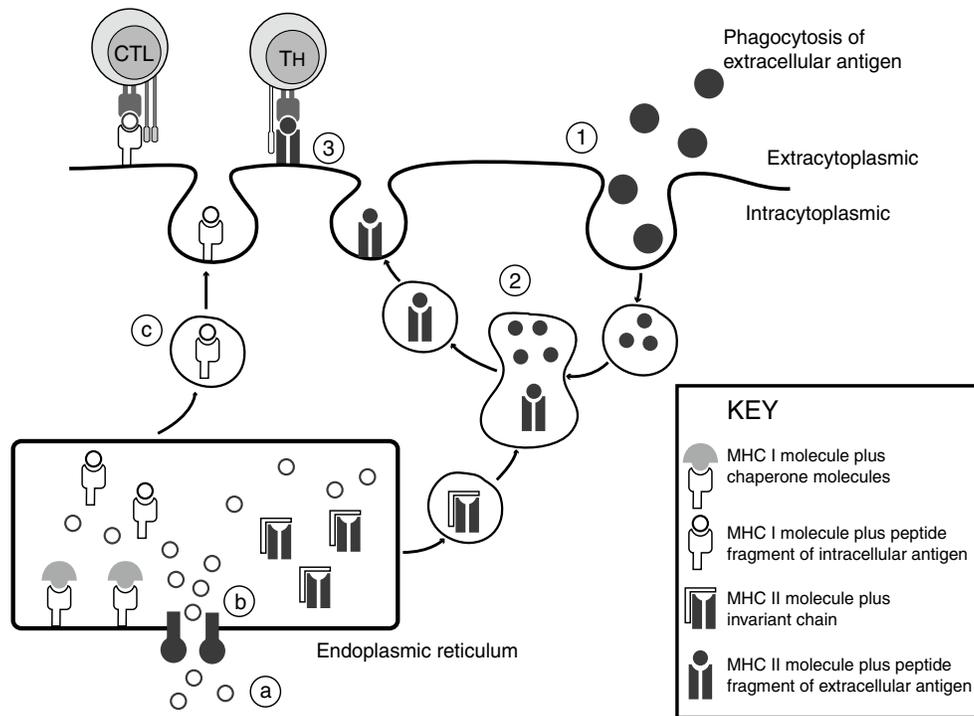

The MHC II genes are functionally and structurally distinct from the MHC I genes. Unlike MHC I antigens, the MHC II antigens are restricted in their expression to certain cells of the immune system: B lymphocytes, dendritic cells, macrophages, and activated T lymphocytes of some species. Other cells may also express MHC II antigens after treatment with various cytokines.<sup>58-60</sup> Interferon- $\gamma$ , TNF- $\alpha$ , 1,25-dihydroxyvitamin-D3, and granulocyte-macrophage colony stimulating factor can induce MHC II antigen expression on monocytes and macrophages and other cells. IL-4 enhances MHC II antigen expression on B cells. A number of agents downregulate MHC II antigen expression, including glucocorticoids, prostaglandins, and  $\alpha$ -fetoprotein. Although MHC II antigen expression is also regulated at the transcriptional level, no interferon or TNF- $\alpha$  response elements have been identified in the regulatory regions of MHC II genes. In fact, the regulatory region of MHC I and MHC II genes are quite different, and this fact is probably responsible for the differences in tissue distribution for these two MHC antigens.<sup>46</sup>

**FIGURE 1-8** The immunoglobulin superfamily. Immunoglobulin serves as the prototype model for the superfamily. Both the heavy and light chains of an immunoglobulin molecule can be divided into variable ( $V_H$  and  $V_L$ ) and constant domains ( $C_H$  and  $C_L$ ). Analogous regions have been identified on a variety of other molecules involved in immune recognition including class I and class II antigens, the T cell antigen receptor (TcR), and the CD4 and CD8 antigens found on T cells (see text). Disulfide bonds forming the domains are not shown.

Like the MHC I genes, the MHC II region contains genes for multiple MHC II antigens, some of which appear to be pseudogenes and are not expressed. Those  $\alpha$  and  $\beta$  chains that are expressed exhibit a high degree of allelic variability, although typically the  $\beta$  chain exhibits the most polymorphism. Unlike the MHC I genes, the variability in the MHC II genes is the result of point mutations. There is also correspondingly less polymorphism in the MHC II genes when compared with the MHC I genes. The MHC II region of other species, including the horse, have been studied using human DNA probes, and extensive polymorphism involving several genes has been identified.

Whereas antigens processed via the endogenous pathway are associated with MHC I antigens, antigen processed via the *exogenous pathway* is associated with MHC II antigens (Figure 1-9).<sup>52</sup> Here endocytosed antigen, such as that phagocytosed by a macrophage, is partially degraded in a prelysosomal compartment of low pH and limited proteolytic activity. The processed protein associates with a peptide binding site at the junction of the  $\alpha_1$  and  $\beta_1$  domains of the MHC II molecule. This association of the epitope with the MHC II molecule protects it from further degradation. The MHC II molecule is then re-expressed on the cell surface for subsequent presentation to the T cell. The immune system contains a distinct group of antigen-presenting cells called *dendritic cells* (DCs) that are specialized to capture antigens and initiate T cell immunity

**FIGURE 1-9** Antigen processing pathways. This figure depicts major histocompatibility complex (MHC) I antigen presentation to the left of the diagram and MHC II antigen presentation to the right. In MHC I antigen presentation (a) peptides generated by degradation of proteins in the cytoplasm are transported into the endoplasmic reticulum (b). In this location MHC I molecules bound by a membrane protein calnexin bind the peptides, which allows release of the MHC I molecules by the calnexin and transport through the Golgi complex to the cell surface (c). In MHC II antigen presentation antigen is taken up by phagocytosis (1) into the endosome compartment and routed to lysosomes for degradation. Vesicles containing MHC II molecules produced in the endoplasmic reticulum fuse with the endosomes (2) and the MHC II molecules bind with the degraded peptides for transport back to the cell surface (3). The MHC II molecules are prevented from binding the endogenous peptides in the endoplasmic reticulum by the presence of invariant chain, which is only lost in the acidic endosomal environment.

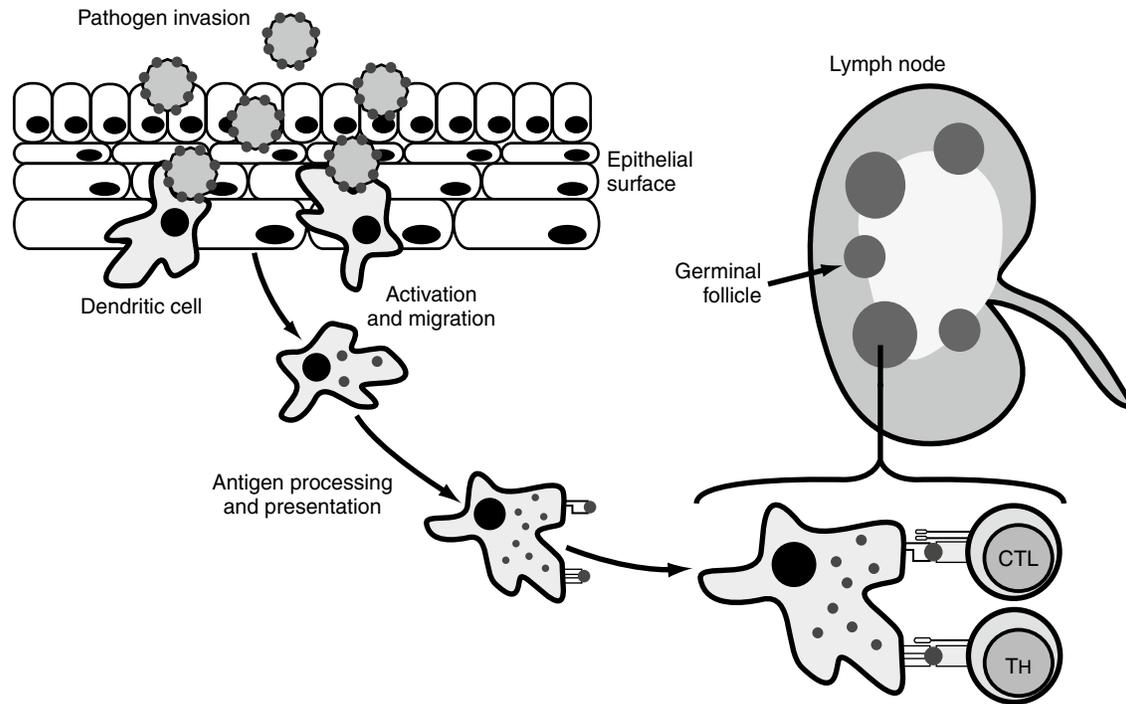

and move freely from epithelial surfaces to adjoining lymph nodes.<sup>3</sup> DCs can be found in a variety of locations in the body and are often named according to their microscopic appearance. Hence interdigitating cells found in lymph nodes, veiled cells in lymphatics, and Langerhan's cells in skin are all DCs. Immature DCs can take up antigens by micropinocytosis using their extensive cellular processes or receptor mediated phagocytosis. This results in activation and migration to a regional lymph node where antigen presentation to T lymphocytes occurs. Mature DCs have high levels of MHC II expression on their surfaces and are no longer phagocytic but are extremely efficient stimulators of both MHC I- and MHC II-restricted T cell responses in the draining lymph node (Figure 1-10).

In a complex immunogen certain antigenic determinants are particularly effective at stimulating an antibody response. These *immunodominant* epitopes are often located at exposed areas of the antigen such as in polypeptide loops. These types of structures are often quite mobile and may allow for easier access to the antibody binding site. T cell epitopes possess a particular structural characteristic of amphipathic helices. However, structure alone does not determine the immunogenicity of a particular antigen, and T cell recognition of foreign antigen requires more than just the expression of the processed antigen on the surface of the antigen presenting cell.

Additional signals provided by the antigen presenting cell are also required for the activation of the T lymphocytes. Among these are signals provided by other accessory molecules found on the antigen presenting cell and various cytokines present in the extracellular environment.

### SIGNALING THROUGH THE ANTIGEN-SPECIFIC RECEPTORS

The encounter of specific antigen either by a T cell or a B cell's antigen-specific receptor results in an intracellular signaling cascade that eventually leads to the production of various proteins and the proliferation of the stimulated cell. T cell recognition of antigen involves the engagement of a TcR-CD3-CD4 or TcR-CD3-CD8 complex with processed peptide in the cleft of a MHC II or MHC I molecule (Figure 1-11).<sup>3</sup> The engagement of the TcR-CD3 complex with the appropriate MHC antigen containing peptide results in the binding of CD4 or CD8, depending on the MHC antigen, with the TcR-CD3 complex. In doing so the Lck protein tyrosine kinase associated with the cytoplasmic tail of CD4/CD8 phosphorylates the cytoplasmic regions of the CD3 proteins in regions known as *immunoreceptor tyrosine-based activation motifs* (ITAMs; Figure 1-12). These ITAMs serve as docking sites for other kinases, including

**FIGURE 1-10** The role of professional antigen-presenting cells (APCs). In this figure pathogen invasion is followed by antigen uptake by a dendritic cell, the most potent of the APC family. The dendritic cells become activated and migrate to a local lymph node, where they are extremely effective at stimulating naïve T cells including both T helper cells and CTLs.

ZAP70 and Fyn. Recruitment of ZAP70 to CD3 results in its subsequent phosphorylation and activation by Lck. Once activated, the ZAP70 can subsequently phosphorylate other signal proteins, including phospholipase C (PLC; Figure 1-13). Activation of PLC leads to the cleavage of phosphatidylinositol biphosphate ( $PIP_2$ ) into inositol 3-phosphate ( $IP_3$ ) and diacylglycerol (DAG). Both  $IP_3$  and DAG are second messengers with  $IP_3$ , causing the release of stored  $Ca^{2+}$  from the endoplasmic reticulum and DAG-activating protein kinase C. The increase in intracellular  $Ca$  levels and the activation of protein kinase C lead to the phosphorylation of various transcriptional factors. These transcriptional factors regulate the expression of the genes for various cytokines and/or their receptors (see Figure 1-13). The process is subsequently downregulated by various phosphatases that are recruited to and subsequently dephosphorylate the CD3 ITAMs. A similar process occurs in a B cell when its surface immunoglobulin receptor is cross-linked upon binding to specific antigen.

### CO-STIMULATORY SIGNALS

In addition to the interaction of TcR-CD3 and CD4/CD8, other cell surface antigens are involved in the signaling pathways.<sup>3</sup> Of greatest importance is the interaction of CD28 on the T cell with B7 on the antigen presenting cell. In the absence of CD28/B7, co-stimulation T cells are rendered functionally inactive or anergic. Upon restimulation, these anergic T cells failed to proliferate or produce cytokines such as IL-2. The induction of anergy can be prevented either by the addition of exogenous IL-2 or, more important, by interaction of the CD28 cell surface antigen with its ligands, B7-1(CD80) and B7-2(CD86). Stimulation of CD28 appears to be necessary for

subsequent intracellular signaling events following TcR stimulation as CD28 cross-linking enhances various biochemical events triggered by TCR-mediated signaling, including the activation of PLC, Lck, and Raf-1 kinase, as well as inducing the influx of  $Ca^{2+}$  and generation of phosphoinositides. Other molecules, including the TNF-receptor family member CD40, regulate either T cell growth or cell death. The engagement of CD40 on the T cell with its ligand, CD40L, on the antigen presenting cell leads to NF- $\kappa$ B activation and thus promotes cell survival and cell cycle progression. The binding of other members of this family, notably TNF- $\alpha$ , to their receptor on activated T cells typically results in the activation of a biochemical cascade of caspases that lead to apoptosis. The cytotoxic activity of these receptors is the result of their intracytoplasmic portion of the receptor containing death effector domains. By contrast, CD40 lacks the intracellular death domains and instead has amino acid motifs that bind TNF-R-associated factors (TRAFs) and promote NF- $\kappa$ B activation. In addition to their role in promoting T cell activation and growth, both the CD28/B7 and TNF-receptor pathways may also play a dominant role in the induction of specific T helper cell subsets.

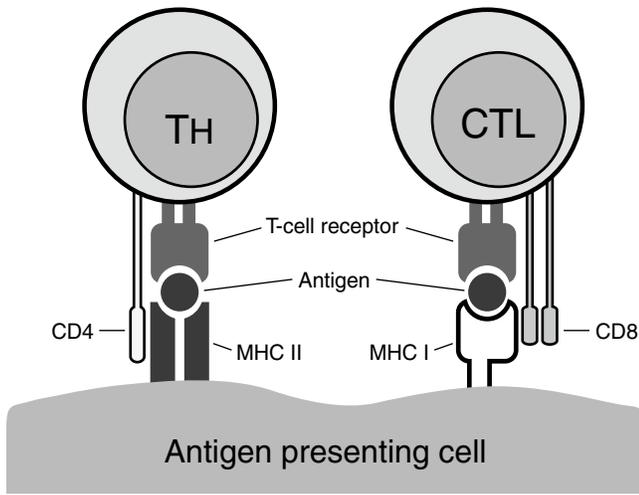

### ☞ CYTOKINES, CYTOKINE RECEPTORS, AND T HELPER CELL SUBSETS

Frequent mention has been made in this chapter of the role of cytokines in regulating immune responses. Indeed, this particular area of immunology has seen impressive growth over the past several years. This rapid acquisition of knowledge is the result of the application of modern molecular biology techniques to the identification and characterization of specific

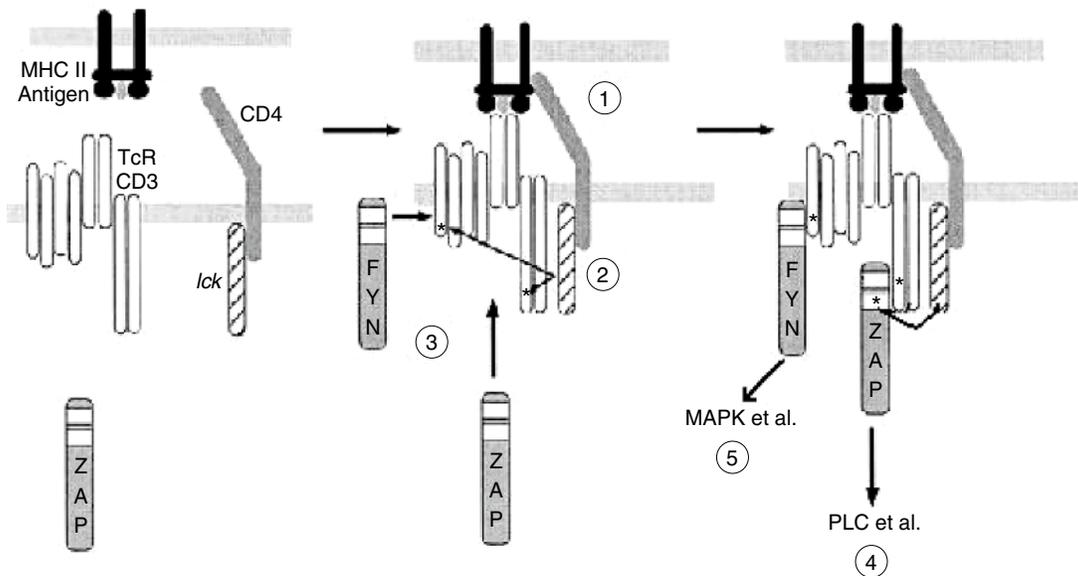

cytokines. Initial studies of the role of soluble factors in the regulation of immune responses were often confounded by the heterogeneous nature of the culture supernatants used as the source of the cytokine activity. Furthermore, the use of biological assays to identify specific cytokines resulted in the practice

of assigning descriptive names to newly discovered cytokines (e.g., lymphocyte activating factor, T cell growth factor).<sup>61</sup> This quickly led to confusion because individual cytokines often exhibited multiple biological activities and the biological assays were not specific for a particular cytokine. Once the genes for the cytokines had been cloned and the resulting proteins identified, it was possible to eliminate much of this confusion. The adoption of the interleukin (IL) terminology for naming cloned immunoregulatory cytokines has further clarified the biological function and role of particular cytokines.<sup>62</sup> Once a new cytokine's gene is identified and the biological activity of the purified protein characterized, it is assigned an interleukin designation. To date, more than 50 different cytokines and chemokines have been cloned, sequenced, and synthesized in bacterial and eukaryotic expression systems. This has led to both a better understanding of cytokine function and to their application in a variety of clinical settings. Table 1-4 contains a list of interleukins and their known biological activity. Not all cytokines have been given interleukin designation. Interferons, certain growth factors (platelet derived growth factor, TGF- $\beta$ ), and TNF- $\alpha$  have retained their original names. It should also be emphasized that other cells besides T cells produce cytokines and interleukins. For example, monocytes and macrophages are the major source of IL-1, IL-6, and TNF- $\alpha$ . Thus the term *lymphokine*, which was originally used to describe immunoregulatory products of lymphocytes, has been replaced with *cytokine*, which denotes the more varied sources of immunoregulatory molecules.

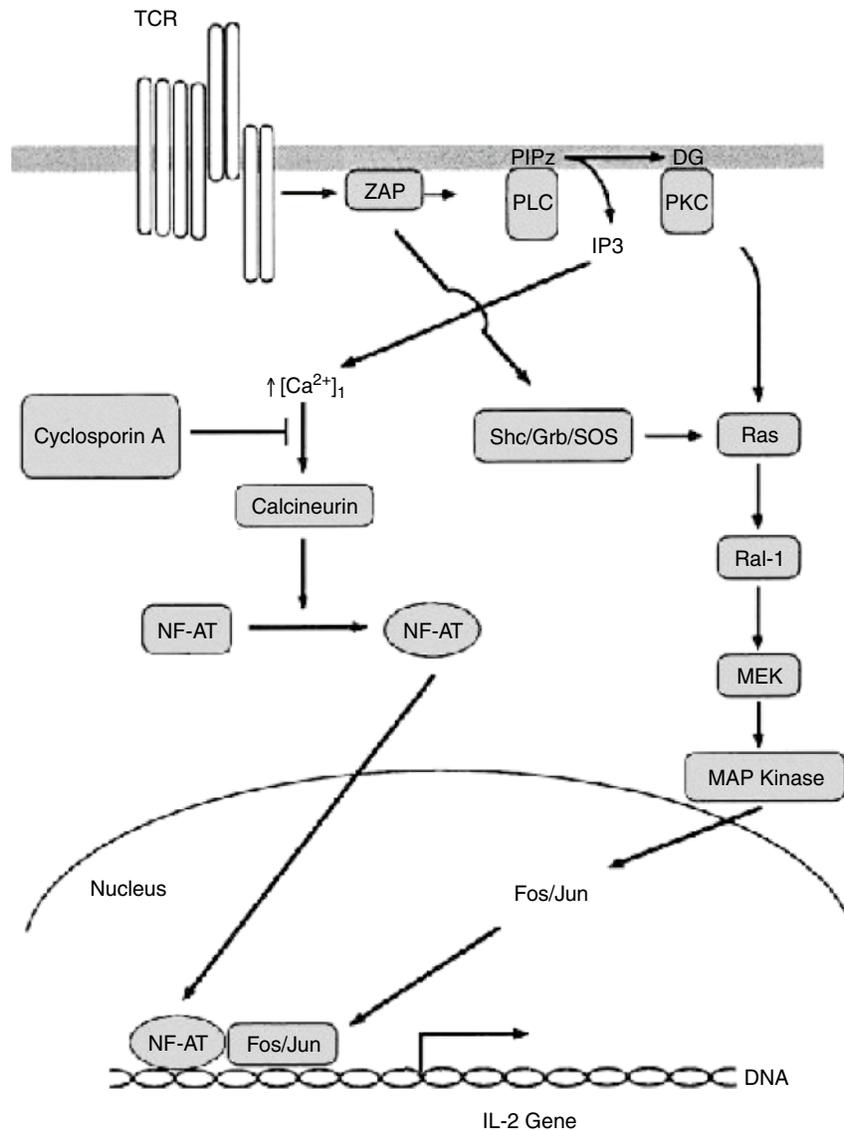

Many cytokines have similar structures and can be grouped into like families. Hence helical cytokines have alpha helices as the predominant structure with IL-2 serving as the prototypical cytokine for this family (Figure 1-14). This family can be further divided into two subclasses according to the length

**FIGURE 1-11** Class I and class II restricted T cell recognition: the role of T cell CD4 and CD8 molecules. T cells use their T-cell receptors to recognize processed antigen presented in combination with either MHC I or MHC II molecules. T cells exclusively express either CD4 (T-helper cells) or CD8 (cytotoxic lymphocytes; CTLs), and the CD4 molecule is required for interaction with MHC II molecules, whereas CD8 is required for MHC I interaction. As a result, T-helper cells recognize antigen presented by MHC II, and CTLs recognize only antigen presented by MHC I molecules.

**FIGURE 1-12** Intracellular signaling by the TcR-CD3 receptor. TcR recognition of its specific peptide in the peptide binding groove of a MHC molecule on an antigen-presenting cell results in the attraction of CD4/CD8 to the complex (1) and the phosphorylation of CD3 proteins by *lck* associated with CD4/CD8 (2). The phosphorylation of these sites (\*) on CD3 leads to the attraction and binding of other kinases (*fyn* and ZAP 70) to CD3, where they are in turn phosphorylated and activated. Activation of ZAP70 leads to the subsequent activation of phospholipase C (4), and activation of *fyn* ultimately leads to the MAP kinases pathway and cell division (5) (see also Figure 1-13).

**FIGURE 1-13** Intracellular signaling pathway. Following activation of ZAP70, and other receptor-associated kinases, there is a subsequent propagation of the signal as subsequent kinases and target proteins are phosphorylated. Increases in intracellular  $Ca^{2+}$  lead to the activation of calcineurin that is necessary for NF-AT activation. This step is the target for cyclosporin A, a potent and specific immunosuppressive agent. Activation of the transcriptional factors NF-AT and *fos/jun* leads to their translocation into the nucleus and the binding to regulatory DNA sequences upstream of the promoter for the IL-2 gene.

of the helices: long helical (many growth factors including IL-3 and IL-7) and short helical (IL-2, IL-4, and IL-13). IL-1 is a  $\beta$ -trefoil cytokine whose overall structure is composed of 12 antiparallel  $\beta$  strands that form a bowl-like structure. Most chemokines and other smaller cytokines contain both  $\alpha$  helices and  $\beta$  sheets, typically a single  $\alpha$  helix and more than two  $\beta$  sheets. TNF- $\alpha$  is the prototype for the  $\beta$ -sandwich family whose structure characteristic consists of five antiparallel strands with an overall jelly roll structure.

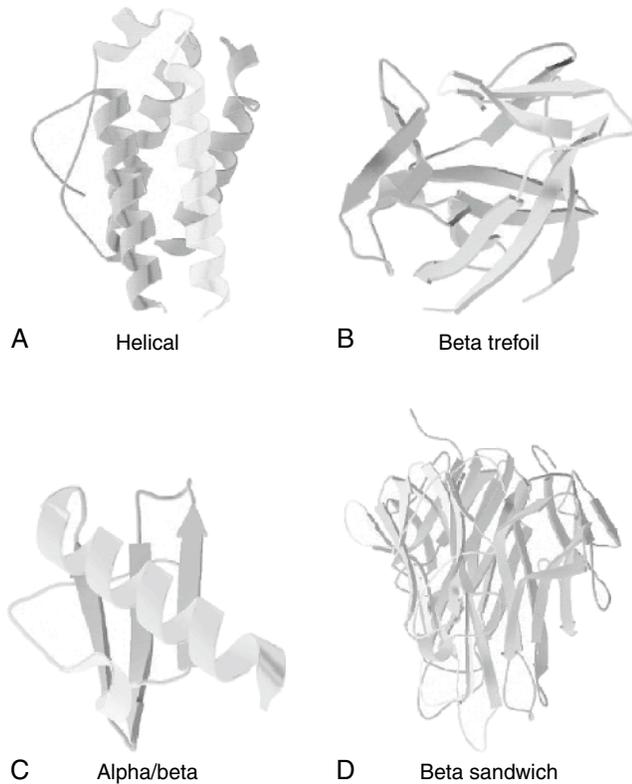

The availability of cloned cytokines has also permitted the subsequent identification and characterization of cytokine-specific receptors. Cytokine receptors can also be grouped into major families: Class I or Class II receptor families, immunoglobulin superfamily receptors, the TNF receptor family, and TLRs (IL-1, IL-18).<sup>63</sup> The best characterized of these is the Class I

receptor for IL-2, which is composed of three subunits:  $\alpha$ ,  $\beta$ , and  $\gamma$ . Whereas the  $\alpha$  and  $\beta$  subunits are involved in specific binding to IL-2, the  $\gamma$  chain is involved in signal transduction once IL-2 is attached to the receptor. Five different immunologically important cytokines share this common cytokine receptor  $\gamma$  chain, though each has its own unique  $\alpha$  and/or  $\alpha\beta$  binding subunits (Figure 1-15). Other common signaling chains of this type of receptor include  $\beta c$  (IL-3, IL-5, and GM-CSF) and gp130 (IL-6 and IL-11). Class II receptors are illustrated by the interferons whose receptors consist of at least two chains. In contrast to the chains being denoted  $\alpha$  and  $\beta$ , analogous to the nomenclature for type I cytokine receptors, the chains are called *IFNAR-1* and *IFNAR-2* for  $\alpha/\beta$  interferons and *IFNGR-1* and *IFNGR-2* for interferon- $\gamma$ . A third receptor, CRF2-4, is a component of the IL-10 receptor.

TABLE 1-4

<b>Interleukins</b>	
<b>IL</b>	<b>Biologic Activities and Source</b>
1	Lymphocyte activating factor; multiple biologic activities affecting a variety of lymphoid and nonlymphoid cells
2	T cell growth factor; provides proliferative signal for T cells; also affects B cells, macrophages, and NK cells; high concentrations of IL-2 stimulate cytolytic activity in NK cells and T cells; produced by activated Th1 and some CD8 <sup>+</sup> cells
3	Multi-CSF; promotes the growth of various hematopoietic cell precursors; produced by T cells and myelomonocytic cell lines
4	B cell stimulatory factor 1; stimulates growth, maturation, and differentiation of B cells; also provides proliferative and differentiation signals for some T cells; produced by Th2 cells
5	T cell-replacing factor; stimulates B cell proliferation and immunoglobulin synthesis; also stimulates T cell proliferation and differentiation as well as eosinophil formation in the bone marrow; produced by Th2 cells
6	B cell differentiation factor; promotes maturation and immunoglobulin production by B cells; stimulates T cell growth and IL-2 synthesis; induces the production of acute phase proteins by hepatocytes; produced by macrophages, T cells, stromal cells, fibroblasts, and a variety of other cell lines
7	Pre-B cell growth factor; stimulates proliferation and maturation of early B and T cells as well as mature T cells; produced by bone marrow-derived stromal cells
8	Neutrophil chemokine produced by monocytes and hepatocytes
9	Also known as <i>P40</i> ; supports the growth of certain T cell clones; produced by CD4 <sup>+</sup> T cells
10	Cytokine synthesis inhibitory factor; inhibits the production of IL-2 and interferon- $\gamma$ by Th1 cells; produced by Th2 cells
11	An IL-6-like factor produced by bone marrow stromal cells
12	NK cell differentiation factor; augments NK cell function and stimulates generation of Th1 cells; produced by macrophages
13	Produced by Th2 cells; downregulates cytokine production by macrophages/monocytes while activating B cells
14	A high-molecular-weight B cell growth factor produced by T cells and some B cell lines
15	A T cell growth factor similar in function to IL-2
16	Chemokine for CD4 <sup>+</sup> T cell subset; produced by T cells, mast cells, and eosinophils
17	A family of related cytokines; enhances expression of the ICAM-1 on fibroblasts; also stimulates epithelial, endothelial, or fibroblastic cells to secrete IL6, IL8, and G-CSF and PGE <sub>2</sub>
18	An inducer of IFN-gamma production by T-cells
19	A homolog of IL-10
20	An autocrine factor for keratinocytes that regulates their participation in inflammation
21	Stimulates proliferation of B-cells stimulated by cross-linking of the CD40 antigen, bone marrow progenitor cells, and naïve T cells
22	A proinflammatory cytokine that increases the production of acute phase proteins
23	Produced by dendritic cells; stimulates the production of IFN- $\gamma$ by T-cells
24	Selectively suppresses the growth of tumor cells by promoting cell death by apoptosis
25	Produced by stromal cells and supports proliferation of cells in the lymphoid lineage
26	Induces the expression of IL6, IL8, and ICAM-1 in primary bronchial epithelial cells
27	Similar to IL-17; expressed in brain
28	Type III interferons; similar to Type I interferons in function and induction
29	Another Type III interferon
30	Similar to IL-27, an early product of antigen presenting cells that stimulates IFN- $\gamma$ production
31	Produced by Th2 cells and is related to the IL-6 family of cytokines; possible role in pruritis, alopecia, and other allergic skin lesions
32	Inducer of inflammatory cytokine production by monocytes; highly expressed in synovial tissue of rheumatoid arthritis
33	Inducer of Th2 cytokines

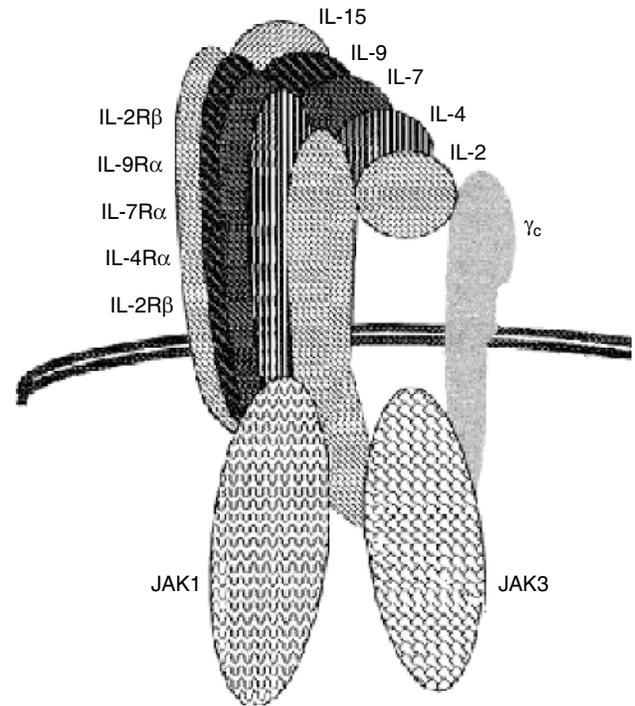

*IL*, Interleukin; *NK*, natural killer; *CSF*, colony-stimulating factor; *ICAM-1*, intracellular adhesion molecule-1.

**FIGURE 1-14** Cytokine structural families. (a) helical cytokine, (b)  $\beta$ -trefoil, (c)  $\alpha/\beta$ , and (d)  $\beta$  sandwich.

The TNF receptor family is composed of two separate receptors, TNF-RI and TNF-RII. Though both can bind TNF, no structural homology is found in their intracellular domains, indicating that they signal by distinct mechanisms. TNF-RI is thought to be the main signaling receptor because many biological actions of TNF, including cytotoxicity, fibroblast proliferation, and the activation of NF- $\kappa$ B, can be elicited in the absence of TNF-RII. The IL-1 receptor is a member of the Toll-like receptor family. As discussed previously, this receptor superfamily represents an ancient signaling system that was initially identified in *Drosophila melanogaster*. The introduction of a pathogen into *Drosophila* spp. leads to the activation of proteases that cleave a precursor and generates an extracellular ligand of a receptor called Toll, the intracellular part of which is homologous to the IL-1 receptor cytoplasmic tail. Other Toll-like receptors are involved in other signaling pathways involved in innate immune and inflammatory responses, indicating that this receptor superfamily represents an ancient signaling system.<sup>64</sup>

A common feature of all these receptor families is that signaling is initiated through the recruitment of protein tyrosine kinases and other cytosolic proteins to the receptor.<sup>65,66</sup> Although most cytokine receptors lack intrinsic kinase activity, they do have a family of Janus protein tyrosine kinases (JAKs) associated with their cytoplasmic tails. Following binding of a ligand to its cognate receptor, receptor-associated JAKs are activated. A family of transcriptional factors known as STAT (signal transducers and activators of transcription) are in turn activated by tyrosine phosphorylation by the activated JAKs, allowing the STAT to dimerize. After dimerization the STATs translocate into the nucleus and bind to the DNA

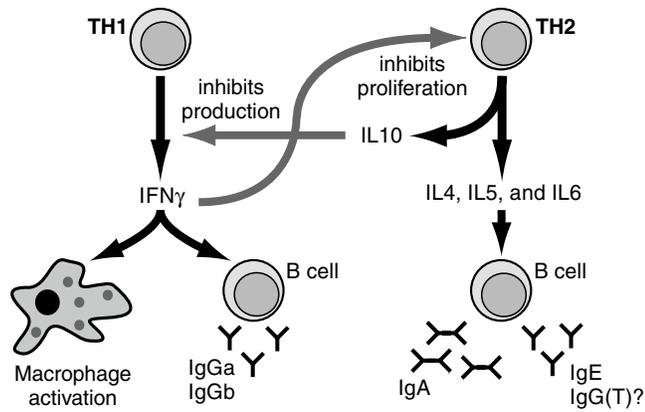

**FIGURE 1-15** Type I cytokine receptors. These receptors are characterized as having a cytokine specific  $\alpha$  and  $\beta$  chain involved in ligand binding and a shared or common  $\gamma$  chain that is used for intracellular signaling. The Janus kinases (JAK) are associated with the cytoplasmic tails of these receptors and are responsible for the signal transmission.

sequence it recognizes via a DNA binding domain on the protein. The binding of the STAT proteins to DNA subsequently modulates gene expression. It is the sharing of receptor subunits, combined with a similar sharing of JAKs and STATs, that accounts for similar biological functions of many cytokines (see Table 1-4).

In addition to the JAKs and STATs, other transcriptional factors can activate multiple genes involved in inflammatory responses and apoptosis. One of these transcriptional factors, NF- $\kappa$ B, regulates many pro-inflammatory cytokines, including TNF- $\alpha$ , IL-1, and IL-8. NF- $\kappa$ B itself is activated by a number of cytokine receptor–signaling cascades, including TNF receptors.<sup>67</sup> In the cytoplasm NF- $\kappa$ B is associated with an inhibitory protein, I $\kappa$ B, which prevents its translocation to the nucleus. Phosphorylation of I $\kappa$ B leads to its degradation and the translocation of NF- $\kappa$ B to the nucleus, where it binds to its corresponding DNA motif, altering gene transcription. NF- $\kappa$ B activation is also associated with resistance to apoptosis, probably as the result of its effect on IL-8 transcription because this chemokine is anti-apoptotic.<sup>68</sup> Increased levels of IL-8 in inflammatory lung lesions and the increase in NF- $\kappa$ B activation likely account for the neutrophil accumulation seen in some forms of human asthma<sup>69</sup> and equine recurrent airway obstruction.<sup>70</sup>

## IMMUNOREGULATION

The generation of an immune response requires the interaction of multiple leukocyte subsets, including macrophages, dendritic cells, B cells, and both CD4<sup>+</sup> and CD8<sup>+</sup> T cells.

**FIGURE 1-16** Th1 and Th2 regulation. The Th1 lymphocyte subsets provide help for macrophage activation, cytolytic activity, and production of a subset of IgG subclasses. The Th2 promotes antibody responses, including IgA, IgE, and the remainder of the IgG subclasses. This is mediated by production of cytokines, which have a regulatory effect on each other.

Whereas the initial interactions of B and T cells involves the recognition of specific epitopes, which in the case of the T cell are presented in the context of MHC antigens, subsequent interactions are mediated by the cytokines produced by the various cells. Although macrophages, B cells, and even nonhematopoietic cells produce a variety of cytokines with immunoregulatory activity, it is the T helper cell that plays a central role in regulating immune responses. Much effort over the past decade has focused on the characterization of helper T cells and the soluble factors they produce. It is now apparent that CD4<sup>+</sup> helper cells may be further divided into distinct helper cell subsets on the basis of the cytokines they produce (Figure 1-16). Thus Th1 cells produce interferon- $\gamma$  and IL-2, two cytokines involved in the induction of cell-mediated immune responses. Th2 cells, on the other hand, produce IL-4, IL-13, and IL-5, cytokines involved in the induction of antibody responses. The best evidence for separate T helper cell populations comes from the study of intracellular parasite infections in mice. Those strains of mice resistant to *Listeria donovani* infection develop a cell-mediated immune response characterized by activated macrophages and Th1 helper cells. By contrast, the susceptible BALB/c strain of mice generates a vigorous antibody response and Th2 helper cells. Th1 cells have also been implicated in various autoimmune diseases characterized by the induction of self-reactive cytotoxic cells. Th2 cells in turn play a central role in the resistance to extracellular parasites, such as intestinal helminthes, and in the induction of allergic diseases. A similar contribution of Th1 and Th2 responses in protective and pathologic responses in the horse has been described.<sup>71,72</sup> Regulatory T cells (Tregs) are specialized subsets of T cells that play a central role in the prevention of hyperimmune responses and autoimmunity and are thought to represent traditional suppressor cells.<sup>73</sup> Although naturally occurring Tregs constitute 5% to 10% of the CD4<sup>+</sup> T cell population, antigen-specific or adaptive Tregs, also known as Th3 cells, are also present. These different Tregs subsets can be identified on the basis of the expression of cell surface markers, production of cytokines, and mechanisms of action. Most Tregs

express the CD25 surface antigen and produce various immunoregulatory cytokines and growth factors, including IL-10 and/or TGF- $\beta$ .<sup>74</sup> Besides CD25, Tregs can express several other activation markers, such as the glucocorticoid-induced TNF-receptor-related protein (GITR), OX40 (CD134), L-selectin (CD62 ligand [CD62L]), and cytotoxic T lymphocyte-associated antigen 4 (CTLA-4 or CD152).<sup>74</sup> However, it should be noted that these markers can also be expressed to various degrees on activated T cell subsets and various antigen-presenting cells.<sup>74</sup> A specific subpopulation of Tregs can be identified on the basis of the expression of the transcriptional factor FoxP3. The FoxP3<sup>+</sup> Tregs are thought to be important regulators of autoimmunity insofar as loss of function or mutation in this factor leads to the development of autoimmune disease.<sup>74</sup> A population of NK cells and natural killer T (NKT) cells with regulatory function has also been described whose immune suppressive function is mediated by secretion of various cytokines (IL-13, IL-4, IL-10) or by direct cell-cell contact.<sup>74</sup> Although the suppressive function of most Tregs is likely mediated by the production of suppressive cytokines, direct contact with Th1 cells, which limits interaction with dendritic cells, is another mechanism.<sup>74,75</sup>

Although it remains unclear as to what determines whether a helper cell will be a Th1 or Th2 cell, it has been proposed that it is the initial encounter with the antigen during the innate immune response that may determine its fate. Multiple factors are probably involved in this process, but the single most important factor is the type and amounts of cytokines present at the time of the initial encounter with the antigen. Among the cytokines that may play a role, IL-12 and interferon- $\gamma$  are the main inducers of Th1 responses, and IL-4 and IL-10 play a similar role for Th2 responses. IL-12, produced by macrophages and dendritic cells, is a potent inducer of interferon- $\gamma$  that inhibits Th2 cell induction. The evidence from a variety of models to date suggests that IL-12 is the single most important factor in regulating the differentiation and magnitude of the Th1 response; however, this should not preclude the possibility that additional factors, such as IL-18, may have an equally important role in regulating Th1 responses in some situations. It is also apparent that IL-4 plays a similar crucial role in the induction of Th2 immune responses. IL-4 production by mast cells and IL-10 production by macrophages favor Th2 development in part by inhibiting Th1 cells. Other signals (e.g., PGE<sub>2</sub>) can induce differentiation of potent antigen presenting cells with dendritic morphology that produce low levels of IL-12 and high levels of IL-10 preferentially inducing Th2 differentiation.

In addition to cytokines, another influence on T helper cell differentiation is the interaction of the B7/CD28 and CD40/CD40L co-stimulatory pathways.<sup>3</sup> In particular, these co-stimulatory pathways may regulate the differentiation of Th1 and Th2 cells by affecting the intensity and the strength of signals through the CD3/TCR complex and those provided through the co-stimulators. High-intensity stimulation favors Th2 development, whereas lower intensity signals favor Th1 cells. The association of stronger co-stimulation with Th2 responses contrasts with the ability of higher concentrations of antigen to mostly induce Th1 responses, whereas lower doses induce Th2 responses suggesting that Th differentiation may be influenced quite differently by the strength of signals through the CD3/TCR complex versus signals delivered through co-stimulators and their associated enzymes.<sup>3</sup>

## TH PARADIGMS

The role of cytokines in regulating immune responses can best be illustrated in two scenarios, the first involving the induction of a Th1 immune response in response to viral infection and the second an allergic response to inhaled mold antigens. In the first scenario, viral antigen present at the site of an ongoing infection in the respiratory tract is processed by a resident macrophage via the exogenous pathway. The processed epitope is presented on the surface of the macrophage or a dendritic cell in the context of a MHC II antigen to a CD4<sup>+</sup> T cell in a regional lymph node. Additionally, these cells produce IL-12 that induces NK cells, attracted to the site of the infection, to produce interferon- $\gamma$  that, along with antigen presentation, activates the T cell and drives it toward a Th1 phenotype. Meanwhile, CD8<sup>+</sup> T cells encounter viral antigen on the surface of virus-infected cells that has been processed via the endogenous pathway and is now associated with the MHC I antigens on the infected cell's surface. Once antigen-activated, these T cells express the high affinity form of the IL-2 receptor. The CD4<sup>+</sup> Th1 cell produces IL-2 and interferon- $\gamma$ . The interaction of IL-2 with its receptor drives the clonal proliferation of the activated CD8<sup>+</sup> T cells. The interferon- $\gamma$  also stimulates the CD8<sup>+</sup> cell to differentiate into CTLs that produce additional interferon- $\gamma$ . These CTLs can lyse the target cells either through the production of TNF- $\alpha$  or via the activation of the *fas* receptor on the target cell via the *fas* ligand (*fasL*) expressed on the activated CTL. Both pathways lead to target cell apoptosis via the activation of cytoplasmic caspases in the target cell. Meanwhile, virus-specific B cells have also encountered antigen and in the presence of interferon- $\gamma$  differentiate into IgG-secreting plasma cells. This combination of IgG antibodies and CTL cells serves to eliminate the virus. PGE<sub>2</sub> and IL-10 production by macrophages exert anti-inflammatory effects on the response, and that, coupled with the production of soluble cytokine receptors, dampens the immune response as the invader is eliminated.

In the second scenario, the introduction of mold antigens into the respiratory tract leads to the processing of the antigen by macrophages and dendritic cells, as before. However, in the absence of IL-12 and interferon- $\gamma$ , and perhaps the presence of IL-3, IL-4, IL-9, IL-10, or PGE<sub>2</sub>, there is the induction of Th2 cells that produce additional IL-4 and IL-13. These cytokines cause those B cells recognizing the allergens to isotype switch to IgE antibodies that bind to mast cells. Subsequent degranulation of these mast cells ensues, as the result of antigen binding to the IgE, leading to the production of other mediators, including IL-4 and PGE<sub>2</sub> that exacerbate this response. In the continued presence of the allergen, a secondary inflammatory response characteristic of recurrent airway obstruction occurs.

## THE ROLE OF CYTOKINES IN THE HORSE

The field of equine immunology continues to expand with the development of better reagents. Recent advances in gene cloning technology have led to the cloning and expression of a number of equine cytokines. Thus the cDNA sequences for a number of equine cytokines are known, and specific protocols are now available to measure their expression (Table 1-5). Through use of these procedures, it has been possible to identify the role of Th1 and Th2 cells in both protective and pathologic responses in the horse

(Table 1-6).<sup>71,76,77</sup> The results from these and other studies confirming the role of inflammatory cytokines in equine sepsis and in joint and airway diseases emphasize the similarities between equine and human immune systems. As such, the potential for manipulating these responses using recombinant cytokines or anticytokine reagents is as applicable to equine medicine as it is to human medicine.

## LYMPHOCYTE TRAFFICKING PATHWAYS

Leukocyte trafficking has been reviewed previously, with a particular emphasis on the innate immune response. Lymphocytes involved in adaptive immune responses differ in their migration from most other cells in that they recirculate instead of making one-way trips. Memory and naïve T lymphocytes, with their different capacities for response to antigens, differ also in their migration pathways through the body. Two general pathways of lymphocyte recirculation have been demonstrated. Naïve T lymphocytes take the most common route, which involves entry into the lymph node by extravasation from the high endothelial venule (HEV) and return to the peripheral circulation via the efferent lymphatic. The endothelial cells of HEVs have a distinctive appearance and specialized receptors and can support a great deal of lymphocyte migration. This allows rapid repeated circulation of naïve lymphocytes through lymph nodes where there is the greatest chance of exposure to their specific antigens. Memory lymphocytes, on the other hand, leave the bloodstream in peripheral vascular beds, particularly in inflamed tissues, and return to lymph nodes via afferent lymphatics. This leads to the exposure of primed memory lymphocytes to the most likely early sites of antigenic encounter and allows for an early response to recall antigens. Thus memory lymphocytes are most common in inflammatory lesions and in the epithelial surfaces of the lung and gut wall. Differing expression of the adhesion and homing molecules may play an important role in mediating these different migration pathways.

For lymphocytes to follow the previously outlined maturation and migration pathway, the first step is for the naïve lymphocyte to get into a lymph node so that it can meet its antigen on a professional antigen-presenting cell. To achieve this, the T-lymphocyte needs to exit in the HEV. The naïve lymphocyte expresses L-selectin, and this can bind to the vascular addressins GlyCAM-1, CD34, and MAdCAM-1, which are expressed on HEVs and promote rolling similar to that mediated by P- and E-selectin when they bind to phagocytes. These molecules are expressed on a variety of tissues, but in HEVs they have specific patterns of glycosylation that makes them bind L-selectin. These differences represent the key to the specificity of the migration of lymphocytes to HEVs. This weak interaction initiates the process of extravasation that is promoted by locally bound chemokines (e.g., IL-8), which increase the affinity of the lymphocyte integrins for their ligands.

Approximately 25% of lymphocytes passing through an HEV leave, and this could mean  $1.4 \times 10^4$  cells in a single lymph node every second, and in the body  $5 \times 10^6$  lymphocytes may extravasate through HEVs every second (human). The "sticking" process (rolling, activation, arrest) takes a few seconds, with transendothelial migration and passage through the HEV basement membrane occurring in about 10 minutes. After leaving the blood, most T cells travel through the lymph node uneventfully and leave via efferent lymphatics; however,

Th2	<i>Strongylus vulgaris</i> Insect bite hypersensitivity

*Th*, T helper cell.

in rare events a naïve T cell recognizes its specific peptide/MHC complex and becomes activated, eventually leading to formation of effector and memory T-cells. That process takes 4 or 5 days, and, once activated, the migration pathway of memory T cells differs considerably from naïve cells. All activated T cells lose the L-selectin molecules that mediated homing to lymph nodes and increase the expression of other adhesion molecules. The homing of individual lymphocytes to specific sites is regulated by expression of specific adhesion molecules. Memory cells are specifically attracted to areas of inflammation as a result of the increased levels of adhesion receptor ligands expressed on vascular endothelium in these regions. This is typically a result of TNF- $\alpha$  production by regional macrophages encountering infections. Sometimes infections do not result in TNF- $\alpha$  production, but memory cells also migrate randomly throughout the body. When they encounter their antigens, they can produce cytokines like TNF- $\alpha$  themselves, which in turn causes local endothelial cells to increase expression of E-selectin and VCAM-1 and ICAM-1. This will subsequently recruit more effector and memory cells to the region.

## MUCOSAL IMMUNITY

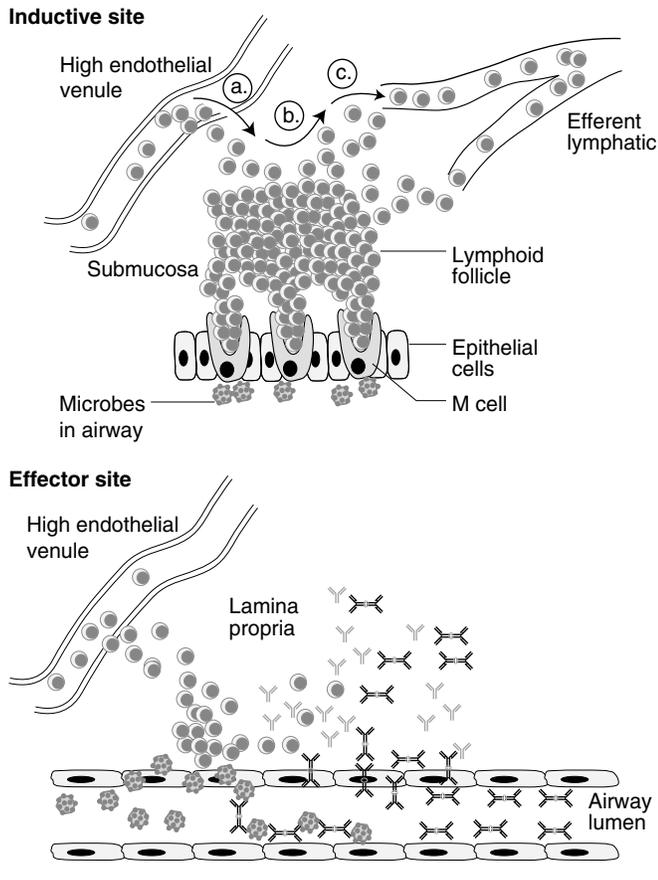

The mucosal immune system comprises a series of distinct compartments within the immune system, which are adapted to immunologic response in unique environments such as the gut or respiratory or urino-genital tract. The mucosal immune system is perhaps the most important component of our adaptive immune system, and the reader is referred elsewhere for an appropriately detailed description of its general features,<sup>1</sup> and of its role in equine immunity in the context of respiratory disease.<sup>78</sup> The mucosal immune system may represent the original vertebrate immune system, and it certainly protects the largest vulnerable area of the mammalian body and composes a large proportion of the total lymphocyte populations and immunoglobulin pool.<sup>79,80</sup>

The mucosal immune system consists of organized and dispersed lymphoid tissues that are closely associated with mucosal epithelial surfaces, and mucosal immune responses generated in one location are transferred throughout the mucosal immune system by lymphocytes programmed to home to regional effector sites. The principal immunoglobulin produced by the mucosal immune system is secretory IgA, which in humans is the most abundant immunoglobulin class in the body. Secretory IgA has unique adaptations that promote transport out onto mucosal surfaces, where it protects the body from bacteria and viruses principally by immune exclusion (i.e., by physically preventing attachment to mucosal surfaces).

The importance of mucosal IgA has already been demonstrated in immunity to numerous equine diseases.<sup>78</sup> Secretory IgA (sIgA) is formed by dimerization of two IgA monomers, which are attached by means of disulphide bonds to a J-chain also produced by the same plasma cell that secretes the IgA. This confers the advantage of increased valency to sIgA, which can bind up to four of its targets, thus increasing its agglutinating ability. Secretory IgA protects the body from bacteria and viruses principally by immune exclusion (i.e., by physically preventing attachment to mucosal surfaces). Immunoglobulin A is relatively noninflammatory (i.e., it does not fix complement as effectively as IgG or IgM), consistent with a role in defense by immune exclusion.<sup>3</sup> Similarly, although myeloid cells possess Fc receptors for IgA, it is not clear that IgA functions as an efficient opsonin or promotes phagocytosis.

Coordination of the mucosal immune response depends on organized mucosal-associated lymphoid tissue (MALT) principal examples of which are the pharyngeal tonsils and the intestinal Peyer's patches. In the gastrointestinal tract MALT is distributed throughout the gut, but in the respiratory tract these tissues are found only in the nasopharynx and oropharynx. MALT consists of lymphoid follicles containing IgA-committed B cells, surrounded by interfollicular T cell areas with APCs and high endothelial venules (HEVs), with an overlying follicle-associated epithelium (FAE). Naïve lymphocytes enter the MALT by extravasation from the HEVs (there are no afferent lymphatics in MALT), and, after antigen encounter in the MALT, they leave through efferent lymphatics. The FAE is specialized for antigen sampling, by having reduced secretion of mucus, and through the presence of specialized antigen uptake cells termed *microfold* or *M cells*. These M cells are typically closely associated with underlying aggregates of lymphocytes, often within large basolateral membrane pockets, and play a critical role in mucosal immune surveillance. Adherent macromolecules or particles bound to the apical M cell membrane undergo endocytosis or phagocytosis and are released at the pocket membrane, where antigen presentation is initiated by dendritic cells resulting in activation of antigen-specific B cell (Figure 1-17). Subsequent trafficking and recirculation of memory IgA-positive B cells to the other components of the mucosal immune system (e.g., respiratory tract, intestinal tract), is responsible for the dissemination of local mucosal IgA responses throughout what is termed the common *mucosal immune system*. After homing of these B cells to effector sites, such as the lamina propria of the gut and respiratory tract, and extravasation into the lamina propria from HEVs, further antigen encounter and second signals from antigen presentation cells and from T helper cells result in further differentiation into IgA producing plasma cells. The short half-life of IgA secreting plasma cells requires a constant generation of precursors in induction sites and flow to effector sites. Antigen sampling and presentation are not restricted to organized MALT because throughout the mucosal surfaces dendritic cells play a key role in antigen uptake and presentation, subsequently migrating to local lymph nodes or MALT to initiate immune responses.

After release of secretory IgA by plasma cells into the interstitium, it is bound by the polymeric Ig receptor on the abluminal surface of epithelial cells. Subsequently, the sIgA is transported across the epithelial cell and released at the luminal surface together with secretory component formed by cleavage of part of the polymeric Ig receptor. Secretory component can also be found in a free form in mucosal secretions. Secretory

**FIGURE 1-17** Initiation of mucosal immune responses. Respiratory mucosal immune responses typically originate after antigenic encounter at inductive sites, which are the tonsils of the nasopharynx and oropharynx in the horse. Naïve lymphocytes enter the inductive sites from high endothelial venules (HEV) via the specialized cuboidal endothelium of those vessels in response to specific molecular signals. Antigens, such as microbes, are taken up by microfold or M cells, which are part of the highly specialized follicle associated epithelium present at these sites. Antigenic material is transported across the M cell, and antigen presentation to B and T lymphocytes is accomplished by dendritic cells in the underlying tissues. The underlying lymphoid follicle is composed primarily of B lymphocytes, surrounded by T lymphocyte areas. Antigen-specific B lymphocytes become committed primarily to IgA production at these sites, although some IgG B lymphocytes are also generated. Subsequently, the primed lymphocyte populations exit the inductive site via efferent lymphatics, eventually reaching the blood circulation through the thoracic duct. Then these cells traffic to HEVs of effector sites throughout the respiratory epithelium and extravasate to make up the intraepithelial lymphocyte and lamina propria lymphocyte population and to give rise to lymphoid aggregates. Subsequent antigen encounter results in terminal differentiation to plasma cells, primarily IgA producing, although some IgG plasma cells are also formed. IgG is largely restricted to tissues, but secretory IgA is transported to the respiratory epithelial surface, where it can aggregate infectious organisms. (From McGorum BC, Dixon PM, Robinson NE, et al. *Equine respiratory medicine and surgery*, Edinburgh, Saunders, 2007).

component confers resistance to proteolytic enzymes found in the respiratory and gastroenteric environment, some of which are secreted by pathogens, and prolongs the longevity of sIgA. During its transit through the epithelial cell sIgA can neutralize intracellular infections encountered in the endosomal

compartments of cells.<sup>81</sup> In addition, sIgA can bind antigens in the submucosa and literally transport or excrete them to the mucosa by this mechanism. The majority of the IgA in the mucosa is dimeric sIgA, whereas the bone marrow-derived IgA in circulation is predominantly monomeric.

In the horse our understanding of the architecture and functions of the mucosal lymphoid system is best developed for respiratory lymphoid tissues.<sup>78</sup> Although lymphoid tissues are distributed throughout the respiratory tract, the greatest masses comprise the nodular lymphoid tissue of the nasopharynx and oropharynx, which can have an overlying lymphoepithelium specialized for antigen uptake and processing, as in the case of tonsillar tissues. Additional nodular lymphoid tissues are typically present at sites where antigen-laden mucus and air currents converge throughout the trachea and bronchi and are called *bronchus-associated lymphoid tissue* (BALT). Tonsils represent the most complex mucosal nodular lymphoid tissues. Horses possess all of the various tonsillar tissues that are recognized in other species, and they are anatomically complex.<sup>78</sup> The nasopharyngeal tonsil is the largest mass of lymphoid tissue in the respiratory tract of horses of all ages, and its epithelium has been extensively characterized.<sup>82</sup> This epithelium has a classical FAE and is heavily folded, forming crypts; it also contains M cells. The nasopharyngeal tonsil exists in the dorsal recess of the nasopharynx, and extends ventrally toward the opercula on either side of the nasopharynx. Therefore it is ideally placed for the sampling of antigens before entry to the airways or alimentary tract and may serve as an important target for intranasal vaccines. This tissue appears to be most abundant in young foals and atrophies with age, though many lymphoid follicles remain throughout the nasopharynx.

The nasopharyngeal epithelium also contains numerous lymphocytes. Immunohistochemical studies indicate that the majority of these lymphocytes are CD8<sup>+</sup> T lymphocytes, although B lymphocytes are also present.<sup>82</sup> The contribution of these lymphocytes to mucosal cellular immune defenses of the upper respiratory tract is poorly studied. However, following intranasal challenge of yearling and 2-year-old horses with EHV-1, virus-specific cytotoxic activity is detectable in several mucosal lymphoid tissues of the upper respiratory tract, as well as the local draining lymph nodes, and is particularly evident in the nasopharyngeal lining.<sup>83</sup> This cellular immune response is presumably mediated by CD8<sup>+</sup> T lymphocytes found in the nasopharyngeal epithelium and underlying lamina propria and may provide an important contribution to the clearance of infectious virus from the upper respiratory tract.

## ONTOGENY OF THE EQUINE IMMUNE SYSTEM

Few studies of the prenatal development of the equine immune system have been conducted. As in other species, the thymus is the first lymphoid organ to develop, and mitogen responsive cells can be identified there from day 80 of the 340 day gestational period of the horse.<sup>84</sup> Subsequently, these cells appear in peripheral blood at 120 days, lymph nodes at 160 days, and the spleen at 200 days. Cells responsive in mixed lymphocyte reactions are detectable in the thymus from 100 days and in the spleen at 200 days. Immunoglobulin production is detectable before 200 days, and newborn foals typically have IgM concentrations in their serum of approximately 165 µg/ml. Overall, it appears that functional T lymphocytes are present by day 100 and B lymphocytes by day 200 of

gestation. Immunologic competence of the equine fetus has been assessed in terms of specific antibody responses. In utero immunization of foals in late gestation with keyhole limpet hemocyanin in an alum adjuvant results in detectable specific antibody production and T cell responsiveness at the time of birth.<sup>85</sup> In addition, the equine fetus can respond to coliphage T2 at 200 days, and Venezuelan equine encephalitis virus at 230 days.<sup>86,87</sup>

Detailed studies of the appearance of lymphocyte subpopulations defined by monoclonal antibodies have not been performed in the equine fetus. However, some information regarding the maturation of thymocytes in young horses is available. During thymic maturation of T cells, stem cells migrate into the thymus and mature into T cells under the influence of the epithelial microenvironment.<sup>88,89</sup> In this process different patterns of cell surface differentiation and antigen expression distinguish successive stages of thymocyte maturation. In humans the earliest thymic precursor cells express low levels of CD4.<sup>90</sup> This CD4 expression is lost as early thymocytes become double negative CD4-CD8-cells and then demonstrate their T cell commitment by TCR $\beta$  gene rearrangement, which is an essential trigger for subsequent events and leads to low levels of expression of a cell surface TCR $\beta$ -CD3 complex.<sup>91</sup> Intermediate thymocytes are CD4<sup>lo</sup>CD8<sup>lo</sup>, but after TCR $\alpha$  gene rearrangement and expression of cell surface TCR $\alpha\beta$ , they rapidly become CD4<sup>hi</sup>CD<sup>hi</sup>TCR-CD3<sup>hi</sup>.<sup>90</sup> Subsequently, thymocytes selected on the basis of productive TCR gene rearrangement and lack of self-reactivity become mature T cells expressing either CD4 or CD8 (single positive) in combination with high levels of TCR-CD3. Using two-color FACS analysis, it is possible to demonstrate similar patterns of EqCD3, EqCD4, and EqCD8 antigen expression in the equine thymus.<sup>92,93</sup>

## IMMUNOCOMPETENCE IN FOALS

Infectious disease in neonatal foals is associated with high morbidity and mortality. Although failure of passive transfer is a major cause of this problem, immaturity of the immune system has also been considered a potential contributing factor. As a result, a number of studies of neonatal immunocompetence have been completed and reviewed.<sup>94</sup>

## INNATE IMMUNE RESPONSES IN FOALS

A number of studies have reported neutrophils to be fully functional from birth,<sup>95-97</sup> but their function is significantly impaired before absorption of colostrum antibodies, which are required for opsonization.<sup>97,98</sup> A recent study of foal neutrophil development over the first 8 months of life demonstrated killing (measured by chemiluminescence) to be reduced in the first 2 weeks of life, as was phagocytic ability when assays were performed using autologous serum.<sup>99</sup> When serum from adult horses was used, neutrophil phagocytic ability in foals was normal. This latter difference may have been due to absence of either adequate immunoglobulin or complement in foal serum. A similar study of foals younger than 7 days of age confirms that phagocytosis and oxidative burst activity of neutrophils is reduced in foals of this age, although the use of adult serum did not improve phagocytosis.<sup>100</sup> Similarly, alveolar macrophages recovered from bronchoalveolar lavages may be low in number in foals up to 2 weeks of age and have impaired chemotactic function.<sup>101</sup>

The importance of complement in foals is illustrated by the finding that the opsonic capacity of foal serum for bacteria is halved by heat inactivation.<sup>12</sup> Interestingly, complement activity in the first week of life is considerably elevated in colostrum-deprived foals, possibly as an alternative defense mechanism.<sup>102</sup> In bovine colostrum-fed foals, serum complement levels reach adult levels by 1 to 3 weeks of age.<sup>103</sup>

## ADAPTIVE CELL-MEDIATED IMMUNITY IN FOALS

Recent studies have measured lymphocyte numbers and subpopulations in foals.<sup>104-106</sup> Foals are born with B and T lymphocytes and with CD4+ and CD8+ T lymphocyte subsets. Lymphocyte counts rise in the first 4 months of life, and the proportion of B lymphocytes increases. A comprehensive study of lymphoproliferative responses in foals from the day of birth through 4 months of age found no difference between foals and adults.<sup>106</sup> Another study reported foal lymphoproliferation as low on the day of birth, possibly as a result of high serum cortisol levels.<sup>107</sup> Foals do exhibit reduced levels of IFN $\gamma$  production throughout the prenatal period, which could account for their susceptibility to *Rhodococcus equi* and other intracellular pathogens.<sup>108</sup> Decreased production of this cytokine could be due to dysregulation of its production or reflect the fact that most T lymphocytes in the foal are naïve. Currently, markers for the development of memory lymphocytes are unavailable in horses, although increased expression of MHC II antigen on T lymphocytes throughout the first year of life may identify a developing population of memory cells.<sup>59</sup> Although there is evidence for the capacity of foals to mount immune responses in utero,<sup>85-87</sup> there have been few studies of antigen specific immune responses in the first days of life, except in the context of the immunosuppressive effect of passive transfer of immunity.<sup>109</sup> When foals are immunized with antigens against which they have no maternally derived specific antibodies, it is clear that they can mount immune responses from at least 3 months of age, and possibly sooner.<sup>110</sup>

## ANTIBODY-MEDIATED IMMUNITY IN FOALS

**Passively Transferred Maternal Antibody** During the first 1 to 2 months of life, foals depend on passively transferred immunity for protection from infectious disease. The diffuse epitheliochorial nature of the equine placenta does not allow for in utero immunoglobulin transfer to foals. Although minor concentrations of some immunoglobulins can be detected at birth, the foal is born essentially agammaglobulinemic and acquires passive immunity by the ingestion and absorption of colostrum from the dam.<sup>111,112</sup> Colostrum is a specialized form of milk containing immunoglobulins, which are produced during the last 2 weeks of gestation under hormonal influences.<sup>113</sup> Colostrum contains primarily IgG<sub>a</sub>, IgG<sub>b</sub> (IgG<sub>a</sub> plus IgG<sub>b</sub> is the equivalent of IgG), and IgG(T), with smaller quantities of IgA and IgM, all of which have been concentrated into mammary secretions from the mare's blood.<sup>114,115</sup> Colostrum is produced only one time each pregnancy and is replaced by milk that contains negligible immunoglobulins within 24 hours of the initiation of lactation.<sup>111,114</sup> This extremely rapid decline in immunoglobulin concentrations in mammary secretions is consistent with equine colostrum production ending at or even before parturition.<sup>115</sup> The absorptive capacity of the

foal's gastrointestinal tract for immunoglobulins is greatest during the first 6 hours after birth, and then steadily declines until immunoglobulins can no longer be absorbed when the foal is 24 hours old. This "closure" of the gut to absorption of large intact molecules is due to replacement of specialized enterocytes by more mature cells.<sup>116</sup>

#### De Novo Antibody Production in Foals

Few studies of *de novo* antibody production have been conducted in foals without the effect of passively transferred maternal antibody. In a study of 10 pony foals fed only bovine colostrum, endogenous equine antibody production measured by radial immunodiffusion (RID) resulted in serum concentrations of IgG of 200 mg/dl by 2 weeks of age, 400 mg/dl by 1 month, and 1000 mg/dl by 3 months of age.<sup>117</sup> In a smaller study of two colostrum-deprived pony foals, comparing them with 18 colostrum-fed foals, and measuring serum  $\gamma$ -globulin levels by immunoelectrophoresis, very similar results were obtained, although it was apparent that the colostrum-deprived foals achieved higher serum  $\gamma$ -globulin levels between 6 weeks and 3 months of age than did colostrum-fed foals.<sup>111</sup> In a third study, antibody concentrations in six colostrum-deprived foals were substantially higher than in five control foals between 3 and 5 months of age.<sup>102</sup> These three studies provide evidence for substantial endogenous production of IgG in the first month of life in foals deprived of equine colostrum and suggest that the onset of production is earlier, and the rate is higher, in foals deprived of colostrum. This observation is consistent either with nonspecific immunosuppression in colostrum-fed foals or to stimulation of immunoglobulin production in colostrum-deprived foals. In another study of foals from mixed breed horses fed only bovine colostrum, endogenous IgG production started later and was first detected at 1 month of age in the majority of foals, reaching similar levels to foals fed equine colostrum by 2 months of age.<sup>118</sup>

In colostrum-fed foals, serum IgG concentration falls to its lowest level at 1 to 2 months of age as a result of catabolism of maternally transferred immunoglobulin, subsequently rising toward adult levels as a result of endogenous immunoglobulin production.<sup>99,105,106,112</sup> A study by Sheoran et al.<sup>114</sup> extended these observations and extensively documented changes in serum IgG subclass concentrations in five Quarter Horse foals in the first 9 weeks of life. This study showed that IgG (the equivalent of IgGa plus IgGb) concentrations were lowest at 1 month of age. However, the subsequent increase in IgG concentration was due to *de novo* IgGa production, not IgGb. At the end of this study at 9 weeks of age, there was still no clear evidence of IgGb production, although IgGa and IgG(T) concentrations had reached or exceeded adult levels. In adult horse serum, IgGb comprises more than 60% of total serum IgG and is by far the dominant subclass in foal serum after passive transfer of immunity.<sup>114</sup> IgGb has also been shown to have a critical role in immunity to a variety of pathogens,<sup>119,120</sup> and it is possible that the naturally late onset of endogenous production may be a factor in the increased susceptibility of foals to infections such as bacterial respiratory disease at this age.<sup>121,122</sup> This possibility was investigated in a study by Grondahl et al.,<sup>12</sup> in which the opsonic capacity of foal serum was measured during the first 42 days of life using the foal pathogens *Escherichia coli* and *Actinobacillus equuli*. No differences were detected over time, and foal serum was as effective

as adult horse serum. Although this study did not provide evidence of decreased opsonization in serum of older foals, the studies were extended only to samples from 42-day-old foals, and in this *in vitro* system immunoglobulin concentrations may not have been rate limiting. Finally, Holznagel et al.<sup>123</sup> studied immunoglobulin concentrations throughout the first year of life in foals and demonstrated that all foal immunoglobulin concentrations measured showed decreasing serum levels at 4 weeks of age, after which point all but IgGb began to rise. This pattern was the result of catabolism of maternal immunoglobulins and the different times and rates of onset of endogenous production of immunoglobulin classes and subclasses; IgA and IgG(T) levels stabilized at 8 to 12 weeks of age. IgGa levels peaked at 8 weeks of age and then slowly declined throughout the duration of the study. IgGb levels reached their nadir at 2 to 5 months of age and did not begin to rise until after 16 weeks of age. This factor could provide a basis for reduced endogenous antibody-mediated immunity in the first year of life. This study also showed that at 1 year of age, serum immunoglobulin concentrations had still not yet reached adult levels.

A factor that significantly affects *de novo* immune responses in foals is the suppressive effect of passively transferred antigen-specific maternal antibodies. The rate of decline of these antibodies varies for both individuals and different infectious agents. The half life for maternal IgG in foals is estimated at 20 to 30 days.<sup>111</sup> Studies of antigen specific antibodies demonstrated similar half lives for anti-influenza virus and antitetanus antibodies of 27 to 29 days for IgGa, 35 to 39 days for IgGb, and 35 days for IgG(T).<sup>124</sup> For many important pathogens the concentration of maternal antibodies in foals falls to nonprotective levels by 2 to 3 months of age.<sup>125,126</sup> However, the remaining antibody can still render the foal unresponsive to vaccination for weeks or even months to come. In the case of equine influenza virus<sup>127,128</sup> and tetanus toxin, maternal antibodies can persist until 6 months of age and prevent immune responses in foals vaccinated before reaching that age.<sup>124</sup> When foals are vaccinated against antigens against which they have no passively transferred antibody, normal antibody responses have been documented from at least 3 months of age.<sup>110</sup>

#### IMPLICATIONS FOR IMMUNOCOMPETENCE IN FOALS

The previously presented evidence suggests that the foal's immune system is competent in many regards, with the innate immune system completely functional at least by the second week of life and with the full complement of lymphocytes present from birth. Antibody is entirely provided by passive transfer at first, although endogenously produced immunoglobulin is detectable within a few weeks of birth and predominates from 1 to 2 months of age. Nevertheless, there are some key features of the foal immune system that can limit its ability to defend against infection. A critical factor is antigen specific and nonspecific immunosuppression resulting from transferred maternal antibody. As the foal ages, the continuing immunomodulatory effect of maternal antibody may limit foal immunoresponsiveness while no longer providing comprehensive protection itself. Of similar importance is the fact that although the lymphocytic immune system is complete from the time of birth, it is naïve. Neonates can mount normal immune responses but require appropriate presentation of antigen and co-stimulatory signals.<sup>129</sup> Antigen presentation in the

absence of co-stimulatory second signals (e.g., T helper cells) can induce immune deviation or a failure to mount the appropriate immune response, and particularly so in neonates.<sup>130-132</sup> The absence of memory responses and a well-developed repertoire of immune responses is a serious handicap that only appropriate antigenic encounters can overcome. Most important, recent studies have documented that maturation of the adaptive immune system of the foals in terms of both the humoral<sup>123</sup> and cellular arms<sup>108,133</sup> is incomplete throughout the first year of life.

## HYPERSENSITIVITY AND AUTOIMMUNITY

*Hypersensitivity* refers to an altered state of immunoreactivity resulting in self-injury. Four different types of hypersensitivity can be defined by the type of immunologic process underlying the tissue injury, as was originally proposed by Gell and Coombs.<sup>1</sup> The general features of this classification system are presented in Table 1-7. The most common and important type of hypersensitivity disease, at least in humans, is Type I hypersensitivity, mediated by IgE. In these diseases some individuals produce IgE antibodies against a normally innocuous antigen, which is called an *allergen*.<sup>2</sup> Exposure to the allergen triggers mast cell degranulation as described later, and a series of responses result that are characteristic of *allergy*. Allergic diseases are so important that more is known about the function of IgE in this hypersensitivity disease than about its normal role in host defense. In this definition, and throughout this

chapter, the term *allergy* refers only to Type I hypersensitivity diseases mediated by IgE,<sup>2</sup> whereas in other definitions *allergy* can refer to the entire spectrum of hypersensitivity diseases.<sup>3</sup> Other forms of hypersensitivity disease depend on IgG antibodies (Types II and III hypersensitivities) or T cells (Type IV hypersensitivity). Each of these disease processes can play a role in the immunopathogenesis of *autoimmune disease*, in which the body mounts an adaptive immune responses to self tissue antigens.

Clinical hypersensitivity diseases, such as recurrent airway obstruction (RAO) or purpura hemorrhagica, can involve more than one type of hypersensitivity reaction simultaneously, which limits the utility of this classification for clinical diagnosis. Alternative strategies for classifying these diseases may have greater clinical utility. For example, antibody mediated hypersensitivity diseases (Types I, II, and III) are *immediate* in onset if preformed antibody exists in circulation or tissues, with some variation in time course dependent on the antibody isotype involved. Cell mediated hypersensitivity (Type IV) is delayed, even in sensitized individuals, for 1 to 3 days, while effector cells are recruited to the site of antigen exposure.<sup>3</sup> The goals of this section are as follows:

- Review the classical hypersensitivity types in order to explain the immunopathogenesis of hypersensitivity diseases.
- Describe immediate and delayed hypersensitivities of horses and their immunologic basis.
- Identify autoimmune conditions of horses with a known immunologic basis.

Detailed descriptions of clinical aspects of hypersensitivity and autoimmune diseases and their diagnosis and management are presented elsewhere in this book. Detailed explanations of many immunologic mechanisms involved in these disease processes are provided previously in this chapter.

TABLE 1-7

Four Types of Hypersensitivity*						
	TYPE I	TYPE II	TYPE III		TYPE IV	
	IgE	IgG	IgG	Th1	Th2	CTL
Antigen	Soluble antigen	Cell or matrix associated antigen	Soluble antigen in excess (immune-complex formation)	Soluble antigen	Soluble antigen	Cell-associated antigen
Effector mechanism	Mast cell degranulation	Fc-receptor positive cells (phagocytes of reticulo-endothelial system)	Fc-receptor positive cells, complement	Macrophage activation	Eosinophil activation	Cytotoxicity
Examples of hypersensitivity reaction	Systemic anaphylaxis, <i>Culicoides</i> hypersensitivity	Penicillin-associated hemolytic anemia	Purpura hemorrhagica	Equine recurrent uveitis	Chronic <i>Culicoides</i> hypersensitivity	Contact dermatitis

*Ig*, Immunoglobulin; *Th*, T helper cell (type 1 or 2); *CTL*, cytotoxic T lymphocyte.  
\*The four types of hypersensitivity can be differentiated by the immune mediator involved, the form of antigen recognized, and the effector mechanism elicited in producing pathology. Equine examples of each condition are given when available.

## CLASSICAL TYPES OF HYPERSENSITIVITY REACTION

### TYPE I HYPERSENSITIVITY

As described previously, Type I hypersensitivity, or allergy, is mediated by IgE antibody specific for allergens, which are extrinsic antigens normally not recognized by the healthy immune system.<sup>2</sup> IgE is predominantly found in tissues, where it is bound to mast cells through the *high-affinity IgE receptor*, which is called *FcεRI* and has been identified in the horse.<sup>4</sup> When antigen binds to IgE on the surface of mast cells, cross-linking two or more IgE molecules and their FcεRI receptors, this triggers the release of chemical mediators from the mast cells, which cause Type I hypersensitivity reactions. Basophils and eosinophils (when activated) also possess FcεRI receptors and therefore can participate in the same process. In addition to FcεRI receptors, there is an unrelated *low-affinity IgE receptor* called *CD23*, which is present on many lymphocytes, monocytes, eosinophils, platelets, and follicular dendritic cells. The role of CD23 appears to be to enhance IgE responses to specific antigens when those antigens are complexed with IgE. Thus CD23 on antigen presenting cells can capture IgE bound antigens. In the horse CD23 has been identified, and its expression is upregulated by equine IL-4.<sup>5</sup>

The selective stimulation of IgE responses depends on characteristics of the antigen (allergen), the individual affected (genetic factors such as MHC antigens), and the mechanism of antigen presentation. The antigen must be capable of eliciting a Th2 immune response in order to stimulate IgE production. Small, soluble proteins, frequently enzymes, containing peptides suitable for MHC II antigen presentation and presented to mucosal surfaces at low doses, are particularly efficient at generating IgE responses. Low doses of antigen specifically favor Th2 over Th1 responses, and exploiting this relationship is the basis of some therapeutic hyposensitization strategies (see under Immunomodulators). These processes are thought to be regulated by regulatory T cells (Tregs). Natural Tregs are CD4/CD25 positive, and in healthy individuals they suppress Th2 cytokine production.<sup>2</sup> When Tregs are deficient, atopy can result. When CD4 T helper cells are exposed to IL-4, as opposed to IL-12, during antigen presentation by dendritic cells, they are driven toward becoming Th2 cells. This process is critical to promoting IgE responses and may be favored at enteric and respiratory mucosal surfaces, or skin, where parasite invasion typically occurs. This makes teleologic sense insofar as IgE responses are very important for antiparasitic immunity.<sup>6</sup> The dendritic cells at such locations are frequently programmed to stimulate Th2 responses.<sup>2</sup> Cross-linking of FcεRI receptors on granulocytes also results in CD40L expression and IL-4 secretion, which further promotes IgE production by B lymphocytes and sustains allergic reactions.

Some individuals maintain IgE responses to a wide variety of allergens, a condition called *atopy*. Affected individuals have high levels of IgE in the blood and increased eosinophil populations. In humans this condition depends partly on genetic factors, including genetic variations in the IL-4 promoter sequence or association with particular MHC II genes. Nevertheless, environmental factors are also important, as atopy is increasingly common in humans in economically developed parts of the world. Four possible explanations for this are decreased exposure to infectious disease during childhood,

environmental pollution, allergen levels, and dietary change. The first explanation is currently favored, and its basis is the proposal that many infectious diseases bias the immune system toward Th1 responses<sup>2</sup> and that their decreased prevalence results in an increased tendency to mount Th2 responses, which may be the natural bias of the neonatal immune system.<sup>7</sup>

### EFFECTOR MECHANISMS IN TYPE I HYPERSENSITIVITY ALLERGIC REACTIONS

When triggered by antigen cross-linking of IgE bound to FcεRI cell surface receptors, activated mast cells release chemical mediators stored in preformed granules and synthesize leukotrienes and cytokines. In Type I hypersensitivity reactions the outcome of this reaction can vary from anaphylactic shock to minor localized inflammation. Mast-cell degranulation causes an *immediate allergic reaction* within seconds, but there is also a sustained *late-phase response* that develops up to 8 to 12 hours later as a result of recruitment of Th2 lymphocytes, eosinophils, and basophils.

*Mast cells* are highly specialized cells of the myeloid lineage that are common in mucosal and epithelial tissues near small blood vessels. The range of inflammatory mediators released by degranulating mast cells is wide and includes enzymes that can remodel connective tissues; toxic mediators such as histamine and heparin; cytokines such as IL-4, -5, -13, and TNF-α; and lipid mediators, including leukotrienes and PAF.<sup>2</sup> Histamine causes an increase in local blood flow and permeability. Enzymes activate matrix metalloproteinases that cause tissue destruction, and TNF-α increases expression of adhesion molecules and attracts inflammatory leukocytes. These reactions are all appropriate when the mast cell is reacting to an invasive pathogen, but in allergy this is the basis of the immediate inflammatory response and also the initiating step in the late-phase response.

The role of *eosinophils* in inflammation is tightly controlled at several levels. Synthesis in the bone marrow depends on IL-5 produced by Th2 cells in the face of infection or other immune stimulation. Transit of the eosinophils to tissues depends on two chemokines, *eotaxin 1* and *eotaxin 2*. Activation of eosinophils by cytokines and chemokines induces them to express FcεRI and complement receptors and primes the eosinophil to degranulate if it encounters antigen that can cross-link IgE on its surface. Mast cell degranulation and Th2 activation recruit and activate large numbers of eosinophils at the site of antigen encounter. Basophils are similarly recruited, and together their presence is characteristic of chronic allergic inflammation. Eosinophils can trigger mast cells and basophil degranulation by release of major basic protein. This late-phase response is an important cause of long-term illnesses such as chronic asthma in humans.

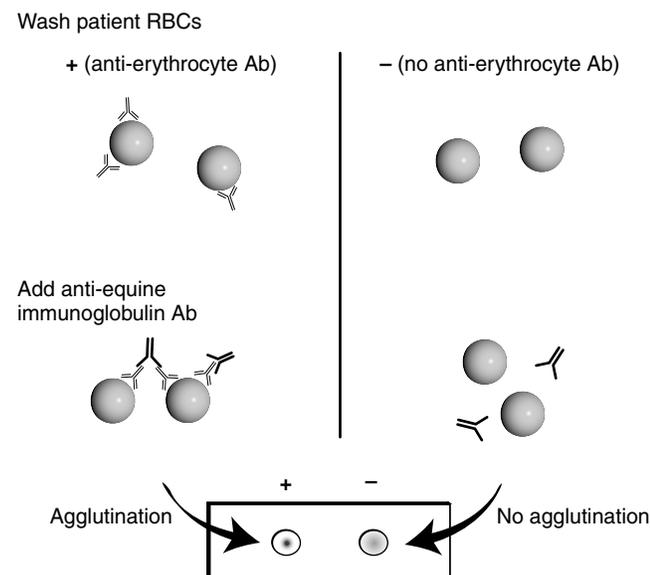

### CLINICAL MANIFESTATIONS OF TYPE I HYPERSENSITIVITY REACTIONS DEPEND ON THEIR SITES

The clinical outcome of Type I hypersensitivity reactions depends on the amount of IgE present, doses of allergen, and the sites of allergen introduction. Direct introduction of allergen into the bloodstream or rapid enteric absorption can lead to widespread activation of connective tissue mast cells associated with blood vessels. This potentially disastrous event is called *systemic anaphylaxis* and can cause catastrophic loss of blood pressure and airway obstruction owing to bronchoconstriction

and laryngeal swelling. This leads to anaphylactic shock and can follow administration of drugs against which an individual has an established IgE response. Treatment with epinephrine can control these potentially fatal events.

*Penicillin* is one example of a drug that can cause Type I hypersensitivity reactions in humans, although it is less certain that it can induce this type of hypersensitivity reaction in the horse. Penicillin can act as a hapten (see the section on equine immunology). Penicillin alone can elicit antibody formation by B cells but cannot elicit T helper cell responses because it is not a protein. However, the  $\beta$ -lactam ring of penicillin can react with amino groups on host proteins to form covalent conjugates, and the modified self-peptides can generate Th2 responses in some individuals. The Th2 cells can in turn release cytokines, which activate penicillin-binding B cells to produce IgE. In this scenario penicillin is a B cell antigen and becomes a T cell antigen by modifying self-peptides. Intravenous penicillin results in protein modification and recognition and cross-linking of mast cell IgE, leading to anaphylaxis.<sup>2</sup>

Allergen inhalation, in contrast, induces local inflammation of the respiratory tract—for example, in the upper airways, as in allergic rhinitis, or in the lower airways, as in human asthma. Similarly, allergen introduction into the skin causes local histamine release initially and a wheal-and-flare reaction, followed by a late-phase response several hours later. When allergens are ingested and reach the skin from the bloodstream, a disseminated form of the wheal-and-flare reaction occurs that is called *urticaria* or *hives*. Prolonged inflammation of the skin results in *eczema* or *atopic dermatitis* in some individuals. Ingestion of allergens causes activation of gastrointestinal mast cells, resulting in fluid loss across the bowel and smooth muscle contraction. The clinical presentation is diarrhea and vomiting. Sometimes ingestion of allergens can lead to systemic anaphylaxis, if they are absorbed rapidly, or urticaria, as is sometimes seen after oral penicillin administration.

**FIGURE 1-18** Direct Coombs' test. *Ab*, Antibody; *RBCs*, red blood cells.

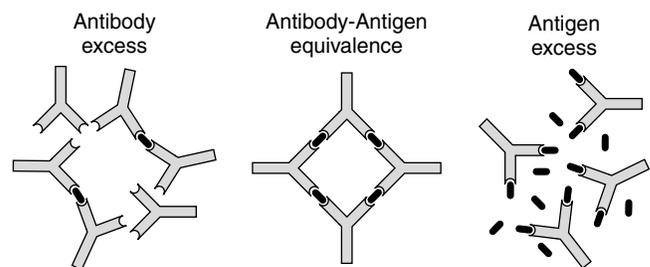

## TYPE II HYPERSENSITIVITY

Type II hypersensitivity disease occurs when the causal antigen is associated with cells or tissue components of the body and there is an IgG antibody response to this antigen. Phagocytes, or other cells expressing Fc $\gamma$  receptors, mediate destruction of the affected tissue or removal from the circulation by the reticulo-endothelial system in the case of antibody-positive erythrocytes or platelets. Antibody-mediated hemolytic anemia and thrombocytopenia are examples of drug-associated Type II hypersensitivities. In the case of the horse, penicillin is an established cause of hemolytic anemia.<sup>8</sup> Diagnosis can be accomplished using a Coombs' test (Figure 1-18). Penicillin binds to the erythrocyte surface and is targeted by antipenicillin antibodies of the IgG isotype. Interestingly, quite large numbers of horses have antipenicillin antibodies of the IgM isotype, but this does not lead to disease.

## TYPE III HYPERSENSITIVITY

In Type III hypersensitivity the antigen is soluble and present in the circulation. Disease results from formation of antibody-antigen aggregates or *immune complexes* under certain specific conditions.<sup>2</sup> Although immune complexes are generated in all antibody responses, they are generally harmless. Large complexes fix complement and are removed from circulation by the reticulo-endothelial system. However, small complexes can form at antigen excess (Figure 1-19), and these can deposit in blood vessel walls and tissues, where they ligate Fc receptors on leukocytes, causing an inflammatory response, increased vascular permeability, and tissue injury. Complement activation also contributes to this process. Local injection of antigen can sometimes lead to a necrotizing skin lesion caused by Type III hypersensitivity, and this is called an *Arthus reaction*.

The classical example of a Type III hypersensitivity reaction is *serum sickness*, which is seen after administration of horse antiserum in humans (e.g., in treating snake bites). After an IgG response to the horse, serum is generated (7-10 days), and signs of fever, urticaria, arthritis, and sometimes glomerulonephritis result. The foreign antigen is cleared as part of this process, which makes this condition ultimately self-limiting. Alternative scenarios for induction of Type III hypersensitivity reactions include persistent infectious diseases in which pathogens are not completely cleared from tissues or

**FIGURE 1-19** Antibody-antigen precipitation. Antibody can precipitate soluble antigen in the form of immune complexes. This is most efficient when concentrations of antibody and antigen reach equivalence, and large immune complexes are formed. However, when antigen is in excess some immune complexes are too small to precipitate and can produce pathologic changes such as are seen in Type III hypersensitivities.

autoimmune diseases in which antigen persists. Inhaled antigens that induce IgG responses can lead to immune complex formation in the alveolar wall, as occurs in *farmer's lung*, compromising lung function.<sup>2</sup> Any such circumstance in which immune complexes are deposited in tissues can lead to this type of pathology.

### TYPE IV HYPERSENSITIVITY

Cell-mediated Type IV hypersensitivities cause delayed hypersensitivity reactions. A variety of cutaneous hypersensitivity reactions are seen, such as the contact hypersensitivity seen after absorption of haptens such as pentadecacatechol in poison ivy or the local Th1 response seen in the diagnostic tuberculin reaction. When Type IV hypersensitivity results in a Th2 response, the principle outcome is eosinophil activation and recruitment such as in chronic asthma.

## IMMEDIATE HYPERSENSITIVITY DISEASES IN THE HORSE

Previously, a major limitation of our ability to study hypersensitivity disease in the horse has been the lack of reagents capable of detecting equine IgE. Although equine IgE has long been known to exist,<sup>9,10</sup> and the genetic sequence has been known since 1995,<sup>11-13</sup> the only reagents for studying it have historically been conventional polyclonal antisera produced by vaccination with physico-chemically purified IgE<sup>14,15</sup> or made in chickens after vaccination with recombinant fragments of the IgE heavy chain.<sup>16</sup> Although many valuable studies have been performed using these reagents,<sup>17-20</sup> the recent availability of well-characterized monoclonal antibodies recognizing equine IgE holds much promise for future studies.<sup>21,22</sup> It has already been demonstrated that the onset of IgE production in horses does not occur before 9 to 11 months of age and does not reach adult levels before 18 months.<sup>23</sup> This may help explain why hypersensitivity disease is uncommon in horses before puberty.

The following section describes a series of equine diseases with characteristics of immediate hypersensitivity disease. This is not an exhaustive list of equine hypersensitivity diseases, and additional examples will be found throughout this book.

### SYSTEMIC ANAPHYLAXIS

The incidence of true systemic anaphylaxis in horses is unknown, although the condition has been reported in association with administration of a wide range of compounds, including serum, vaccines, vitamin E-selenium preparations, thiamine, iron dextrans, and antibiotics such as penicillin.<sup>24,25</sup> Target organs in experimental equine anaphylaxis are the lung and the intestine.<sup>24</sup> Sudden dyspnea; hypotension, as evidenced by poor peripheral pulse character; rapid onset of urticaria; and collapse are cardinal signs of the onset of systemic anaphylaxis.

The therapeutic goals in treating systemic anaphylaxis are to (1) prevent or reverse the complications caused by mediator release, (2) maintain respiratory integrity, and (3) maintain cardiovascular stability. Not all anaphylactic reactions require therapy. However, rapid recognition of those that do is critical to patient survival. Intravenous access via an indwelling intravenous catheter and airway patency should be established immediately because cardiovascular collapse and upper airway

obstruction caused by angioedema can occur rapidly. Because the conscious horse does not tolerate tracheal intubation, emergency tracheotomy may be required. Oxygen should be administered if available because bronchoconstriction and cardiovascular collapse result in hypoxemia. The fluid requirement of horses in anaphylactic shock is not known, but large volumes of balanced polyionic fluid should be administered rapidly.

The principal therapeutic agent is epinephrine, which is a potent sympathetic stimulant. Epinephrine administration may cause excitement in the horse. Epinephrine should be administered intramuscularly (10 to 20 µg/kg, equivalent to 5 to 10 ml of 1:1000 dilution of epinephrine for a 450-kg horse) if dyspnea or hypotension are mild. Epinephrine should not be administered subcutaneously because its potent vasoconstriction can lead to poor absorption and tissue necrosis. If dyspnea or hypotension is severe, epinephrine should be administered intravenously or endotracheally if there is no venous access (3 to 5 µg/kg or 1.5 to 2.25 ml of 1:1000 dilution of epinephrine for a 450-kg horse). Epinephrine doses can be repeated every 15 to 20 minutes until hypotension improves. The side effects of epinephrine therapy are tachyarrhythmias and myocardial ischemia, which can be life threatening. Alternatively, an epinephrine or norepinephrine drip can be instituted for cases of refractory hypotension. Other therapeutic agents, such as antihistamines, β-agonists, or other pressors, may be indicated, although their value is less certain. Though its effects may be delayed, glucocorticoid therapy is indicated to help reverse persistent bronchospasm and angioedema and break the cycle of mediator-induced inflammation triggered during hypersensitivity reactions. Ideally, a rapid acting glucocorticoid should be used, such as prednisolone sodium succinate 0.25 to 10.0 mg/kg, administered intravenously. Glucocorticoid therapy during the acute phase will aid in preventing the late-phase reaction.

### INSECT BITE HYPERSENSITIVITY

Horses commonly suffer from hypersensitivity to salivary antigens of *Culicoides* and *Simulium* species leading to an intensely pruritic skin disease with characteristics of both immediate and delayed-type hypersensitivity.<sup>26</sup> The clinical sign of urticaria, combined with the presence of increased numbers of IgE positive cells in the skin and high levels of *Culicoides*-specific IgE in serum are all evidence of immediate (Type I) hypersensitivity in the immunopathogenesis of this disease.<sup>17,18</sup> This pathogenesis has received further support from studies employing the newly available monoclonal antibodies to equine IgE.<sup>22</sup> Interestingly, one recent study demonstrated that in addition to IgE, the IgG(T) subclass can also bind skin mast cells and elicit clinical signs consistent with hypersensitivity.<sup>27</sup> It remains to be seen if IgG(T) plays a role in the pathogenesis of naturally occurring insect bite hypersensitivity. In some breeds a genetic predisposition based on an MHC-linkage has been demonstrated.<sup>28,29</sup>

### RECURRENT AIRWAY OBSTRUCTION

Recurrent airway obstruction is a severe inflammatory disease of middle-aged and older horses induced by exposure of susceptible horses to inhaled organic dust, generally from hay, although a summer pasture-associated form is also observed in the southern United States.<sup>30</sup> Hay dust contains a mixture of mold spores, forage mites, particulates, and endotoxins, which

can induce and exacerbate airway inflammation. Removal of the hay dust by returning the horse to pasture leads to decreased inflammation within a few days. In RAO-susceptible horses, exposure to hay dust leads to invasion of the lungs and airways by neutrophils within 4 to 6 hours and concurrent airway obstruction resulting from bronchospasm, inflammation, and increased mucus viscosity, which principally affect the bronchioles. RAO-affected horses develop nonspecific airway hyperresponsiveness, which is a bronchospasm in response to a wide variety of stimuli, including inflammatory mediators and neurotransmitters. Horses affected by RAO demonstrate increased histologic lesions and worsening airway function with increasing age. In addition, significant histopathologic changes are present before abnormal airway function can be detected.

The immunologic basis of RAO remains poorly elucidated. Two pieces of evidence suggest a role for Type I hypersensitivity in this disease. First, IgE levels are increased in bronchoalveolar (BAL) fluid of RAO-affected horses,<sup>14</sup> and second, allergen-specific IgE is increased in affected horses.<sup>20,31,32</sup> However, the immediate onset of airway obstruction typical of a Type 1 reaction to exposure to allergens is rarely observed because clinical signs of RAO only develop several hours after antigenic exposure.<sup>30</sup> A study of immunoregulatory cytokines in RAO demonstrated evidence for a Th-2 bias in RAO, with increased levels of IL-4 and IL-5 and decreased IFN- $\gamma$  mRNA in BAL cells.<sup>33</sup> However, other investigators have documented increased IFN- $\gamma$  levels in RAO.<sup>34</sup> It seems likely that a number of immunologic processes, including IgE mediated pathology, increased expression of Toll-like receptor 4,<sup>35</sup> and dysregulation of cytokine responses,<sup>36</sup> may be involved in this disease.

## IgG-MEDIATED DISEASES

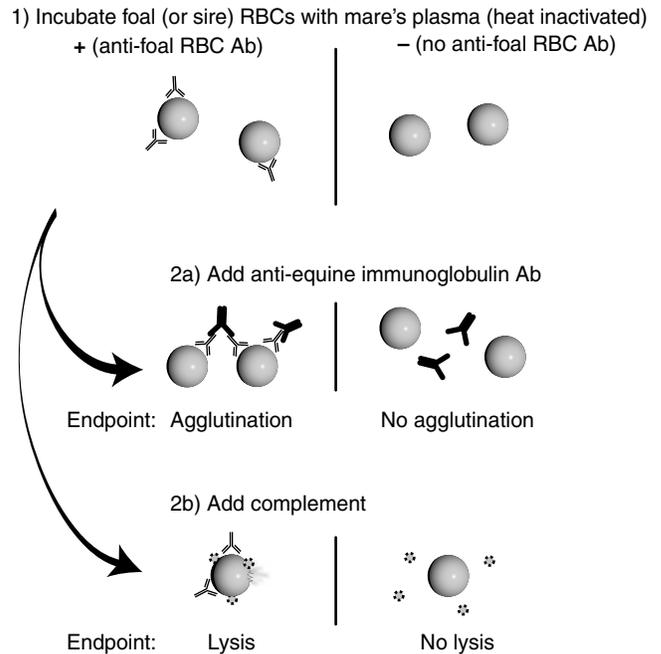

IgG-mediated diseases, which broadly correspond to Type II and III hypersensitivities, have also been termed *immune-complex diseases* in the horse.<sup>3</sup> The examples described here are distinguished from the other immediate hypersensitivities of the horse described previously in that there is no evidence for the involvement of IgE in their pathogenesis.

### NEONATAL ISOERYTHROLYSIS AND ALLOIMMUNE THROMBOCYTOPENIA

Neonatal isoerythrolysis is a common condition of foals and is extensively reviewed elsewhere in this text. The condition results from the passive transfer of maternal antibodies in colostrum that recognize allogenic foal erythrocyte antigens principally of the Aa and Qa haplotype inherited from the sire. A similar condition occurs in mules as a result of the inheritance of a donkey-specific erythrocyte antigen.<sup>37,38</sup> A severe, potentially life-threatening anemia results as the antibody-positive erythrocytes are removed by the reticulo-endothelial system or, less commonly, lysed by complement. A similar condition less commonly affects platelets, causing severe neonatal thrombocytopenia in horses<sup>39</sup> and mules.<sup>40</sup> These conditions are typical of Type II hypersensitivities and are mediated by circulating IgG recognizing cell surface antigens on erythrocytes. Diagnosis can be performed using a variation of the Coombs' test (Figure 1-20).

### PURPURA HEMORRHAGICA

Purpura hemorrhagica is an acute disease of the horse characterized by edema of the head and limbs; leucocytoclastic vasculitis; petechial hemorrhages in mucosae, musculature,

**FIGURE 1-20** Neonatal isoerythrolysis test. Ab, Antibody; RBCs, red blood cells.

and viscera; and sometimes glomerulonephritis.<sup>41</sup> It is usually associated with *Streptococcus equi* subsp. *equi* infection of the upper respiratory tract disease. Serum of affected horses contains immune complexes of *S. equi* subsp. *equi*-specific antigens with equine IgA.<sup>41</sup> The glomerulonephritis sometimes seen in association with purpura has been attributed to deposition of similar immune complexes containing streptococcal antigens and IgG.<sup>42</sup>

## DELAYED HYPERSENSITIVITY DISEASES IN THE HORSE

Documented immunologic characterization of delayed hypersensitivity conditions of the horse are lacking, although contact hypersensitivities have been reported in horses.<sup>3</sup> One very well-characterized example of this type of condition is recurrent uveitis.

### EQUINE RECURRENT UVEITIS

Equine recurrent uveitis (ERU), also known as *moon blindness* or *periodic ophthalmia*, is the most important cause of blindness in horses.<sup>43</sup> The disease results in both acute and chronic ocular inflammatory disease, and chronic sequelae include development of posterior and anterior synechiae, cataracts, lens opacities, secondary glaucoma, and blindness. Eyes of affected horses contain IgG antibodies and autoreactive T cells specific for retinal antigens.<sup>44</sup> A specific cause has not been identified. However, sensitization to a variety of pathogens, and in particular to *Leptospira* spp.,<sup>45,46</sup> is thought to induce the immune mediated pathology that is central to the disease.<sup>47</sup> Treatment with corticosteroids and other anti-inflammatory agents is essential to prevent visual debility or blindness. However, treatment failures are common, and the disease frequently recurs with further ocular damage months after the initial event, commonly leading to euthanasia.<sup>43</sup>

Our understanding of the immunologic basis of ERU has been extended by studies of the immunoregulatory events in the eyes of affected horses. It has been shown that the T lymphocytes that invade the iris-ciliary body during this disease produce a pattern of IFN- $\gamma$  cytokine production typical of a T helper 1 (Th1) response.<sup>48</sup> These studies indicate that ERU is an equine example of a Type IV hypersensitivity disease mediated by Th1 cells.

## ☞ AUTOIMMUNITY

Although a number of equine diseases are considered to be autoimmune in etiology, few have been extensively studied.<sup>49</sup> Much of the explanation given in the previous sections for the immunopathologies involved in hypersensitivity disease can be applied to autoimmune disease. Well-described equine autoimmune diseases include neonatal isoerythrolysis and alloimmune thrombocytopenia, which are described previously and have characteristics of Type II hypersensitivities, as does immune-mediated anemia in adults.<sup>50</sup> Less well-described entities include systemic lupus erythematosus<sup>51</sup> and pemphigus foliaceus,<sup>52</sup> which have characteristics of both Type II and III hypersensitivity diseases. As described previously, equine recurrent uveitis appears to represent a Type IV hypersensitivity, and there is some morphologic and immunologic evidence for similarly classifying cauda equine syndrome (polyneuritis equi).<sup>53-55</sup>

With the exception of a few conditions, such as neonatal isoerythrolysis and penicillin-associated hemolytic anemia, there are few autoimmune conditions in which the cause is well understood. One exception, however, is the anemia that can develop subsequent to administration of human recombinant erythropoietin to horses.<sup>56,57</sup> There is substantial evidence that horses mount an antibody response to the exogenous erythropoietin that cross-react with the endogenous hormone and result in erythroid hypoplasia. The lesson of this example may be that in the modern world, with increasing availability of recombinant drugs that mimic natural biologic compounds, we would do well to remember that the immune system has an exquisite ability to distinguish what is foreign and to reject it vigorously.

## IMMUNODEFICIENCY

Immunodeficiencies occur in both primary and secondary forms and have been extensively reviewed.<sup>1,2</sup> Primary immunodeficiencies have a genetic basis, whereas secondary immunodeficiencies result from failure of passive transfer in foals, immunosuppressive infections or drug treatments, neoplasia, or malnutrition. Immunodeficiencies can affect specific components of the immune system, such as the lymphoid or phagocytic system. Typically, immunodeficiency is suspected in any of the following circumstances:<sup>3</sup>

- Onset of infections in the first 6 weeks of life
- Repeated infections that are poorly responsive to therapy
- Infections caused by commensal organisms or organisms of low pathogenicity
- Disease resulting from the use of attenuated live vaccines

- Failure to respond to vaccination
- Marked neutropenia or lymphopenia that persists for several days

Equine immunodeficiency is most commonly suspected on the basis of the first three reasons—that is, because of increased susceptibility to infection. The most common immunodeficiency recognized in clinical practice is failure of passive transfer in foals.<sup>4-6</sup> Other causes of immunodeficiency vary from well-defined clinical entities, such as severe combined immunodeficiency of Arabian foals,<sup>7</sup> to cases in which immunodeficiency is suspected on clinical grounds, but the specific cause or nature of the problem is difficult or impossible to define.<sup>8</sup> Regardless of their cause, immunodeficiencies result in increased susceptibility to infections, which are in turn poorly responsive to appropriate therapy. Defects in antibody production tend to predispose to pyogenic infection, whereas deficiencies in cell-mediated responses lead to infections with organisms normally nonpathogenic in horses such as *Candida albicans*, *Cryptosporidium* spp., or adenovirus. When any immunodeficiency is suspected, specific diagnostic tests are indicated to define the deficiency. The aim of the next section is to identify tests that clinicians can apply practically in such cases and to explain their merits and limitations.

## ☞ TESTS OF EQUINE IMMUNE FUNCTION

Tests of components of the immune system (e.g., lymphocytes, immunoglobulins) generally can either quantitate that component or measure its functional capacity. In [Table 1-8](#) the components of the immune system that currently can be analyzed in this manner are identified, and corresponding quantitative and functional tests are listed. The table also identifies those tests that are likely to be commercially available, and it should be noted that few of the functional tests are available unless the clinician is able to identify a sympathetic and capable equine immunologic research laboratory. Despite these limitations, the available tests do permit the identification of many of the well-defined causes of immunodeficiency in horses.

### TESTS OF ANTIBODY-MEDIATED IMMUNITY

Some assays of B lymphocyte function and number are described later, but the principal tests of humoral immunity are quantitative assays of immunoglobulin concentration and measurements of specific antibody responses to vaccination. The variety of classes of immunoglobulins in the horse is complex and reviewed earlier in this chapter.<sup>9</sup> For practical purposes our attention is generally focused on IgG (representing the combination of two subclasses: IgGa and IgGb), IgG(T), IgA, and IgM.

The current gold standard for measurement of concentrations of immunoglobulin classes is the RID assay. The disadvantage of this test is its cost and the time required to perform the assay (24 hours or more), which makes it generally unsuitable for screening for failure of passive transfer of immunity in foals. Nevertheless, this form of test remains the single most valuable assay available to the clinician trying to measure total antibody concentrations in the horse. Currently, test kits are available for IgG, IgG(T), IgA, and IgM (VMRD Inc., Pullman, Wash.), although specific IgG subclass RID tests are available

TABLE 1-8

### Components of the Immune System and Tests for Quantitative or Functional Analysis\*

Components of the immune system that can be evaluated in horses and appropriate tests for quantitative or functional analyses of each component. The list of tests is not exhaustive but restricted to tests of likely practical value for which normal data are available. Tests listed in bold are routinely available to clinicians.

Component	Quantitative Tests	Functional Tests
Immunoglobulin	<b>Radial immunodiffusion, membrane-ELISA, electrophoresis, precipitation tests<sup>†</sup></b>	Response to vaccination
Lymphocytes	<b>Complete blood cell count, DNA-PK<sub>cs</sub> genetic evaluation,<sup>‡</sup> FACS analysis of lymphocyte subsets using monoclonal antibodies</b>	Response to vaccination, intradermal PHA test, in vitro lymphoproliferation assays
Neutrophils and macrophages	<b>Complete blood cell count</b>	Chemiluminescence and bactericidal assays, flow cytometric evaluation of phagocytosis and oxidative burst
Eosinophils and basophils	<b>Complete blood cell count</b>	No commonly available tests
Complement	No commonly available tests	No commonly available tests
Acute phase proteins	<b>Electrophoresis</b>	No commonly available tests

ELISA, Enzyme-linked immunosorbent assay; DNA-PK, DNA-protein kinase catalytic subunit; FACS, fluorescence-activated cell sorter; PHA, phytohemagglutinin.

\*Components of the immune system that can be evaluated in horses and appropriate tests for quantitative or functional analyses of each component. The list of tests is not exhaustive but restricted to tests of likely practical value for which normal data are available. Tests listed in bold type are routinely available to clinicians.

<sup>‡</sup>See SCID for description of DNA protein kinase catalytic subunit genetic testing.

for research use only that extend this range to include all the well-characterized IgG subclasses (i.e., IgGa, IgGb, IgGc, and IgG(T); Bethyl Laboratories, Montgomery, Tex.). The RID test is based on the ability of antigen and antibody to precipitate at equivalence when combined in proportion in agar gel plates. The serum being tested is added to punched-out wells in agar, impregnated with antibody to the specific immunoglobulin class being measured, and allowed to diffuse outward and bind with the anticlass-specific antisera. A precipitate forms when equivalence is reached and the area within the precipitate ring is directly proportional to the concentration of the patient's immunoglobulin class. Normal ranges of serum immunoglobulin concentrations are typically provided with commercial kits, and normal serum, milk, and colostrum concentrations of equine immunoglobulins have been described in numerous published studies. These results have been summarized and are available in tabular form in two sources.<sup>3,10</sup> More recent studies of foal and adult horse serum IgG and IgM concentrations using currently available RID assays measured considerably higher normal values in some instances.<sup>11,12</sup> In addition, an extensive study of immunoglobulin concentrations in adult and foal serum and nasal secretions and in colostrum and milk using an experimental monoclonal antibody based-system has been reported.<sup>13</sup>

By far the most common question that a clinician seeks to answer with regard to a horse's immune status is whether a foal has achieved adequate passive transfer of immunity. Whatever test is chosen must be able to distinguish serum concentrations of IgG of <200 mg/dl, 200 to 400 mg/dl, 400 to 800 mg/dl, and >800 mg/dl in order to permit diagnosis

of total or partial failure of passive transfer. The test should be rapid, in order to allow early initiation of therapy, which decreases the utility of the RID test. A wide variety of tests have been used for this purpose: zinc sulfate turbidity, latex bead agglutination tests, ELISA assay, turbidometric analysis, glutaraldehyde coagulation, or infrared spectroscopy.<sup>14-17</sup> Addition of serum to zinc sulfate solution causes precipitation of immunoglobulins, principally IgG. Although the degree of resultant turbidity is usually proportional to the IgG concentration, turbidity may be increased by hemolysis in the sample, poor operating conditions, and poor-quality reagents. In the glutaraldehyde coagulation test, glutaraldehyde forms insoluble complexes with basic proteins in the serum.<sup>18</sup> Gel formation in 10 minutes or less is equated with a serum IgG concentration of 800 mg/dl or greater, whereas a positive reaction in 60 minutes is indicative of at least 400 mg IgG/dl serum. Like the zinc sulfate turbidity test, hemolysis may falsely overestimate the IgG concentration. In the latex agglutination test (Foalcheck, Haver Mobay Corp., Shawnee, Kan.), the patient's serum is mixed with the anti-equine IgG absorbed to latex particles. Macroscopic agglutination is proportional to serum IgG. Currently, for rapid diagnosis, the most convenient test system may be membrane filter-based ELISA systems (e.g., SNAP, Idexx, Westbrook, Me.; Figure 1-21). This test can be performed "foal-side" with whole blood. Tests such as the glutaraldehyde coagulation test are simpler and cheaper, although they have the disadvantage that serum is required. While some data suggest that the glutaraldehyde coagulation test may be more sensitive than membrane-filter ELISAs in detecting

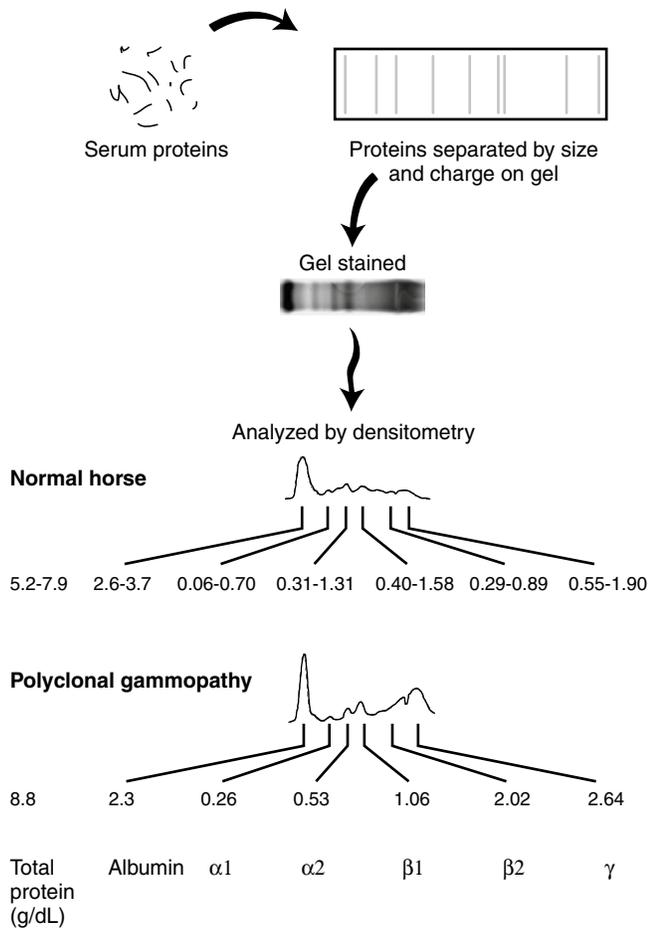

**FIGURE 1-21** Membrane-based ELISA system (SNAP; Idexx, Westbrook, Me.) for measuring serum IgG concentration. The diluted test equine serum sample is applied to a “patient spot” on a membrane impregnated with a capture antibody recognizing equine IgG. Calibration spots corresponding to specific concentrations of equine IgG (400 and 800 mg/dl) are adjacent to the patient spot. An enzyme-conjugated second antibody against equine IgG is applied to the entire membrane, and finally the device is triggered to release an enzyme substrate that produces a colored reaction corresponding to the amount of enzyme-conjugated antibody on the membrane. By comparison with the calibration spots, the test sample IgG concentration can be estimated.

failure of passive transfer,<sup>15,22</sup> particularly in differentiating normal foals (>800 mg/dl IgG) from partial failure of passive transfer (400 to 800 mg/dl), specificity can be relatively poor. The latter problem affects many of the rapid diagnostic tests for failure of passive transfer, and a more extensive discussion of test selection for this condition is presented later in the section covering this disease.

Alternative available tests that give information about serum immunoglobulin content include electrophoresis and immunoelectrophoresis (IEP). IEP analysis can demonstrate the presence of all the currently recognized equine immunoglobulin classes. However, the test has a relatively poor sensitivity and gives no quantitative information, as might be obtained from rocket electrophoresis.<sup>23</sup> Serum electrophoresis gives quantitative information about albumin and  $\alpha$ ,  $\beta$ , and  $\gamma$  globulin concentrations (Figure 1-22), and its utility is demonstrated when detecting the monoclonal gammopathies that accompany plasma cell myelomas.<sup>24</sup> Nevertheless, in the diagnosis of immunodeficiencies electrophoresis should be seen as an adjunct to RID assays, which are superior in terms of specificity and sensitivity.

## TESTS OF CELLULAR IMMUNITY

The simplest test of the cellular arm of the immune response is a total and differential white blood cell count, and this should be the starting point for any evaluation. Identification of an absolute lymphopenia, for example, is a critical finding in a suspected case of severe combined immunodeficiency (SCID) in an Arabian foal, although the result must be repeatable in a series of tests given the variability of blood lymphocyte counts. Such a finding would logically lead to genetic testing to confirm the diagnosis.<sup>7</sup> The evaluation of a lymph node biopsy for normal architecture, including the presence or absence of cells in either the B lymphocyte- or T lymphocyte-dependent areas, is another powerful test of the immune system. However, in profound immunodeficiencies such as SCID, lymphoid organs may be impossible to locate ante mortem. Beyond these readily available conventional techniques, three other more complex types of analysis can be of value: flow cytometric analysis (primarily of lymphocytes, although other cell types can be analyzed), lymphocyte function testing, and functional analysis of phagocytic cells.

**FIGURE 1-22** Serum protein electrophoresis. The complex mixture of serum proteins are separated by migration through<sup>19-21</sup> an agarose gel slab in response to an electric field. Proteins are stained, and the intensity of staining of different bands is measured by densitometric scanning. These measurements are used to identify different types of globulins and albumin corresponding to stained bands.

## FLOW CYTOMETRY

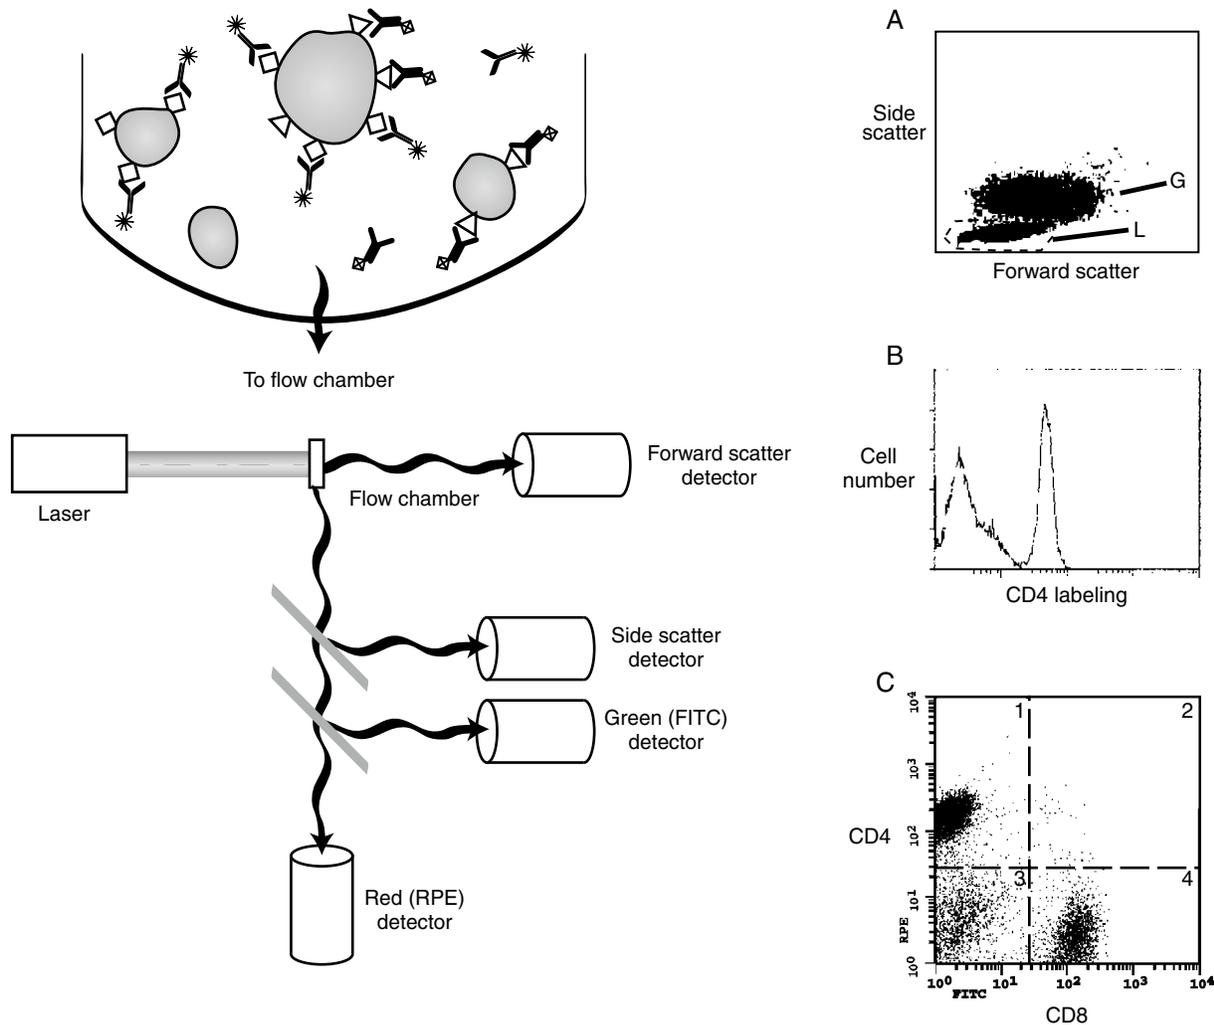

It is currently feasible to take the equine differential white blood cell count a step further, because monoclonal antibodies are now available that can differentiate the morphologically identical equine lymphocyte family into distinct subsets with specific functions (Table 1-5).<sup>25</sup> Flow cytometry allows rapid measurements to be made of individual cells in a fluid stream. Flow cytometers utilize lasers to measure multiple parameters, including light scatter and fluorescence characteristics of cells, and are complex instruments to construct, but the principles of their operation are relatively simple (Figure 1-23). The fluidics system of the flow cytometer delivers cells one by one to a point in space intersected by a laser beam. The laser beam emits light of a defined wavelength to illuminate the cell, which results in both scattered light of the same wavelength and fluorescent light of a different wavelength that is collected by photodetectors and converted into electronic signals.

Light is collected by the forward collection lens on the other side of the flow chamber from the laser source. Here light scattered from 1 to 20 degrees from the laser-beam axis

is collected as “forward scatter,” and its amount depends on the size of the cell being analyzed. At 90 degrees (orthogonal) to the laser beam, path light is collected for the purpose of measuring “side scatter” and fluorescent emission. Optical filtration separates scattered light and fluorescent light to permit their independent measurement. Side scatter light depends on the granularity of cells. Fluorescent light can be detected independently for a number of fluorochromes of different wavelengths, and typical examples would be fluorescein (FITC) or phycoerythrin (PE).

Signals from the different detectors can be processed directly or after logarithmic amplification. The advantage of log amplification for the fluorescent signals is that it amplifies weak signals and compresses large signals, allowing their simultaneous display. By these means signals with a 10,000-fold difference in intensity can be displayed. Signals are typically displayed as either histograms or dual parameter correlated plots (dot plots), and statistical analysis is completed by computer. Histograms are analyzed by setting markers in particular channels and dot plots by drawing rectangular or polygonal boxes around data points. The software also allows the setting of “gates” for determining which events are collected in the first instance or which events are to be included in later analyses. Typically, these gating techniques are employed using forward and side scatter to differentiate cell types, such as lymphocytes, monocytes, and granulocytes. The final key characteristic of flow cytometers is their capacity to analyze large numbers of “events” (cells) in a short time, making it possible to analyze many thousands of cells in a matter of seconds.

An example of such an analysis is shown in Figure 1-23. In this instance the goal was to identify lymphocytes expressing the equine homologs of the CD4 and CD8 molecules using two monoclonal antibodies independently labeled with the FITC (CD4) and PE (CD8) fluorochromes. For this analysis a peripheral blood leukocyte population was prepared by simply lysing the erythrocytes in a blood sample using distilled water. Subsequently, the whole leukocyte population was stained in solution using the monoclonal antibodies. Alternatively, lymphocytes could have been purified from blood using differential centrifugation techniques before staining. However, identical analytical results are obtained in the horse using the more rapid technique of whole leukocyte preparation and exploiting the capacity of the flow cytometer to distinguish lymphocytes from other cells.<sup>26</sup> During the flow cytometric analysis the first step was to identify the lymphocytes using the different forward and side scattering characteristics of different leukocyte populations. Panel A in Figure 1-23 shows a dot-plot of forward scatter versus side scatter, with each dot representing a cell. Granulocytes (G) can be distinguished from lymphocytes (L) by their greater granularity (side scatter) and size (forward scatter). The dotted line is a “gate” drawn around the lymphocyte population. Subsequent analysis of fluorescence is directed toward only those cells that fall within this gate. After establishing the physical characteristics of the cells to be analyzed, their fluorescence can be examined. In Panel B of Figure 1-23, a histogram is shown depicting CD4 (FITC) staining. A vertical marker identifies a gate set based on staining by a negative control antibody. Therefore all cells to the right of this marker are staining positively for CD4. For two-color staining dot plots are again used. In Panel C each dot represents a cell, and its position relative to the two axes illustrates its

**FIGURE 1-23** Flow cytometric analysis (see text for key); *FITC*, Fluorescein isothiocyanate; *RPE*, R-phycoerythrin.

staining characteristics; the dotted lines represent the cut-off points for negative or positive staining. Therefore all cells in quadrants 1 and 2 are positively stained for CD4, and all cells in quadrants 2 and 4 are positively stained for CD8. Effectively, quadrant 1 contains all the helper T lymphocytes (CD4 positive), quadrant 4 contains all the cytotoxic T lymphocytes (CD8 positive), quadrant 3 contains the B lymphocyte population, and quadrant 2 is empty because there are no “double-positive” T lymphocytes in the blood of horses. The sum of the cells in quadrants 1 and 4 represents the T lymphocyte population.

This technique has revolutionized immunobiologic studies in recent years, finding its most obvious clinical application in enumerating human CD4-positive lymphocytes in cases of acquired immune deficiency<sup>27</sup> and in classifying leukemias and lymphomas.<sup>28,29</sup> A large number of antibodies are now available for use in the horse<sup>25</sup> (see Table 1-5), and recent reports describe the use of this approach in charting the response to microbial infection,<sup>11,30,31</sup> and in differentiating equine leukemia.<sup>29,32,33</sup> Several recent studies provide examples of normal values for peripheral blood analysis.<sup>11,12,34,35</sup>

## LYMPHOCYTE FUNCTION TESTING

Unfortunately, tests of lymphocyte function are generally limited in their availability in the field. In vitro tests of lymphocyte function include lymphocyte proliferation responses to mitogens such as pokeweed (B cell dependent), phytohemagglutinin (T cell dependent), or concanavilin A (T and B cell dependent). These assays are generally not commercially available, although they are commonly performed by immunologic researchers. In addition, some caution should be used because it may not always be valid to draw inferences about the intact animal from the results of these in vitro tests,<sup>3</sup> and because of significant variability in results, it is essential to perform parallel studies on suitable age-matched control horses. The end point of these tests is usually read by determining the incorporation of radioactive <sup>3</sup>H-thymidine into the total population of proliferating cells. Nonradioactive alternatives exist, and one strategy uses intracellular labeling of lymphocytes with 5-carboxyfluorescein diacetate-succinimidyl ester (CFSE). Labeled cells fluoresce, and after subsequent divisions in response to mitogens, this fluorescence decreases by half for each cycle of cell division. This allows for measurement

of equine lymphocyte proliferation using flow cytometry, and simultaneous two-color staining allows for measurement of proliferation in specific lymphocyte subsets.<sup>36</sup>

Two tests that can be of value and are readily available in practice are response to vaccination, as measured by rising serum titers, and response to intradermal phytohemagglutinin, which is dependent on a delayed-type hypersensitivity T lymphocyte response and develops in normal animals without prior sensitization.<sup>37</sup> A 50- $\mu$ g dose of phytohemagglutinin (PHA) in 0.5 ml of phosphate-buffered saline is injected intradermally while 0.5 ml of phosphate-buffered saline is administered intradermally at a distant site. At the PHA site an increase in wheal size of 0.6 mm or less indicates a defect in cell-mediated immunity. Response to vaccination has proved to be a potent means of identifying immunodeficiency in such conditions as juvenile llama immunodeficiency syndrome.<sup>38</sup> Similarly, the equine immune response to a polyvalent inactivated bovine vaccine has been used to document the immunosuppressive effects of corticosteroid administration.<sup>39</sup> For practical purposes, response to rabies or tetanus vaccination may be the most suitable available tests provided that no routine vaccination had been administered in the immediate past. Equine rabies or tetanus antibody titer determination is typically commercially available, and the majority of available vaccines are sufficiently potent to provoke a fourfold increase in titer in normal horses.

### PHAGOCYTE FUNCTION TESTING

Testing of equine neutrophil migration, phagocytic function, and bactericidal activity has been reported by several investigators.<sup>40-43</sup> The techniques employed are typically only available in research laboratories and are not well adapted to investigations of individual animals unless adequate age-matched control animals are also examined. More quantitative information can be obtained by adapting assay systems to flow cytometric analysis. Two reports describe flow cytometric analysis of neutrophil phagocytosis of either fluorescent microspheres<sup>44</sup> or yeast cells.<sup>45</sup> Raidal et al. have described testing of alveolar macrophage and blood neutrophil phagocytic function using fluorescent-labeled bacteria and oxidative burst activity using oxidation of dichlorofluorescein.<sup>46-49</sup> These flow cytometric approaches have great promise and have been applied to various studies, including measurements of the effect of age<sup>48-50</sup> and of exercise<sup>51</sup> on neutrophil function.

### TESTS OF INNATE IMMUNITY

Components of the innate immune response that have been measured in the horse include the numbers of granulocytes and monocytes in peripheral blood and their phagocytic function (see previous discussion); natural cytotoxicity in terms of lymphokine-activated killer (LAK) cell activity;<sup>41,52,53</sup> and measurement of soluble factors, including several acute-phase proteins,<sup>54-58</sup> and complement. Equine complement activity can be measured using a hemolytic assay in which antibody sensitized chicken erythrocytes are used as target cells, and the amount of serum required to lyse 50% of these targets is expressed as CH<sub>50</sub> units.<sup>59</sup> More recently, a flow cytometric assay has been described.<sup>60</sup> These tests have been used in some instances to detect relative immunodeficiency in terms of LAK cell activity in exercised horses<sup>53</sup> or complement activity in foals.<sup>61</sup> Currently, these techniques have very limited availability.

## PRIMARY IMMUNODEFICIENCIES

### SEVERE COMBINED IMMUNODEFICIENCY

SCID is a lethal primary immunodeficiency, affecting Arabian foals, humans, mice, and dogs, characterized by failure to produce functional B and T lymphocytes, and resulting in lack of any antigen-specific immune responses.<sup>1,62-64</sup> The vast majority of affected foals are Arabians, in which the condition is inherited as an autosomal recessive trait, and results from a lack of DNA protein kinase activity that prevent V(D)J recombination.<sup>7,65</sup> In studies conducted in the United States and reported in 1977, the incidence of SCID among Arabian foals was at least 2% to 3%,<sup>66</sup> suggesting a carrier prevalence rate between 25% and 26%. However, in more recent studies conducted in the United States using a precise molecular diagnosis of the carrier state, carrier prevalence was consistently 8%.<sup>67,68</sup>

### CLINICAL SIGNS AND LABORATORY FINDINGS

Affected foals are clinically normal at birth but develop signs of infection during the first 1 to 3 months of life. The age of onset of infection depends on the adequacy of passive transfer and degree of environmental challenge. As maternal antibodies are catabolically eliminated, SCID foals are increasingly susceptible to infections with bacterial, viral, fungal, and protozoal agents. Bronchopneumonia is a common disease, often caused by adenovirus, which is the most significant pathogen of SCID foals, affecting two thirds of all animals.<sup>69</sup> Adenoviral infection frequently extends to the gastrointestinal and urogenital system and causes pancreatic disease, leading to loss of endocrine and exocrine tissue and possibly contributing to the impaired growth and weight loss observed in SCID foals.<sup>1</sup> Other common infections in SCID foals include *Pneumocystis carinii* pneumonia; *Rhodococcus equi* infections; enteritis, frequently caused by *Cryptosporidium parvum*<sup>70</sup>; arthritis; and omphalophlebitis.

Clinical signs in SCID foals may include nasal discharge, coughing, dyspnea, diarrhea, fever, and weight loss. Although antibiotics, plasma, and supportive care prolong the course of disease, death invariably occurs before 5 months of age. The only exception to this rule was a single foal experimentally treated with a bone marrow transplant from a histocompatible donor that lived until 5 years of age before dying of an unrelated cause.<sup>71</sup> A consistent hematologic finding is absolute lymphopenia (<1,000  $\mu$ /L), with neutrophilia a variable finding resulting from bacterial infection. Total serum globulins and serum IgG can be normal in the first weeks of life if passive transfer is adequate but decline as maternal immunoglobulins are catabolized. Normal foals synthesize IgM from 180 days of gestation and have detectable IgM at birth in presuckle samples, whereas SCID foals have no IgM.<sup>72</sup> After colostrum ingestion SCID foals also have IgM, although with its relatively short half life it is undetectable by 2 to 4 weeks of age.<sup>1</sup>

### ETIOLOGY AND PATHOGENESIS

Normal maturation of T and B cells requires rearrangement of a series of germ line genes in order to create genetic sequences that can encode the wide diversity of antigen receptors required by these lymphocytes (the T cell receptor or immunoglobulin antigen binding sites, respectively, as described under Equine Immunology). These genes are called the V, D, and J genes, and the overall process is called V(D)J recombination. This process

depends on two groups of enzymes, the recombinase activating gene (RAG) products and DNA-protein kinase (DNA-PK), which is critical for DNA double-stranded break repair. In SCID foals a component of DNA-PK called *DNA-PK catalytic subunit* (*DNA-PK<sub>cs</sub>*) is defective, and consequently V(D)J recombination events do not occur, lymphocytes do not mature, and the immature lymphocytes are eliminated.<sup>7,65</sup> The defect is a five nucleotide deletion in the *DNA-PK<sub>cs</sub>* gene that produces a premature stop codon and prevents formation of the complete enzyme.

### DIAGNOSIS

Antemortem diagnosis of SCID is suggested by appropriate clinical signs in a foal of Arabian breeding with persistent marked lymphopenia (usually <500/ $\mu$ l) and the absence of serum IgM by RID. If presuckle serum is unavailable for testing, serum IgM cannot be used as a diagnostic aid until the foal is older than 3 weeks. Previously, all suspected cases required confirmation by the necropsy finding of hypoplasia of the spleen, thymus, and lymph nodes with the absence of any normal lymphoid architecture. With the identification of the genetic defect causing SCID, the current standard for definitive diagnosis is demonstrating that the foal is homozygous for the defective SCID gene. This test depends on PCR amplification of a specific region of the *DNA-PK<sub>cs</sub>* gene, and evaluation of the amplicon in a Southern blot using probes specific for normal and mutant sequences.<sup>7</sup> This test is commercially available (VetGen, Ann Arbor, Mich.); requires whole blood or cheek swabs; and can identify homozygous affected, heterozygous carriers, and normal animals.

### TREATMENT

Supportive care may prolong the course of disease, but affected foals die by 5 months. Immunologic reconstitution is currently impractical and an ethically questionable procedure.

### CLIENT EDUCATION

Arabian mares and stallions intended for breeding should be tested for SCID carrier status. When two heterozygous carriers are bred, the progeny will include 25% SCID foals, 50% carriers, and 25% homozygous normal foals. Therefore prevention of SCID requires identification of carriers and either removing them from the breeding population or breeding them exclusively with homozygous normal animals and subsequent testing of progeny before their own breeding future is planned.

## ANEMIA, IMMUNODEFICIENCY, AND PERIPHERAL GANGLIONOPATHY—FELL PONY IMMUNODEFICIENCY SYNDROME

In the late 1990s a new syndrome of anemia, immunodeficiency, and peripheral ganglionopathy was described in Fell pony foals.<sup>73,74</sup> Affected foals become ill within 2 to 3 weeks of birth and die by 3 months of age. Affected animals have been described in the United Kingdom, elsewhere in Europe,<sup>75</sup> and in the United States.<sup>76</sup>

### CLINICAL SIGNS AND LABORATORY FINDINGS

Clinical signs include ill thrift, anemia, respiratory infection, glossal hyperkeratosis, and diarrhea. Anemia can be severe and is normochromic and normocytic to macrocytic, with small numbers of late erythroid precursors in bone marrow.<sup>74,77</sup>

Some foals are affected by cryptosporidial enteritis and adenoviral bronchopneumonia and pancreatitis. Plasma proteins and blood lymphocyte counts can be normal or low. T cell subsets measured by flow cytometry are normal, although MHC II expression is low.<sup>78</sup> In vitro lymphoproliferative responses are normal.<sup>78</sup> On necropsy lymphoid organs can be small, and secondary lymphoid follicles and plasma cells are absent.<sup>74</sup> Neuronal changes are characterized by neuronal chromatolysis in the cranial mesenteric, dorsal root, and trigeminal ganglia.

### ETIOLOGY AND PATHOGENESIS

There is preliminary evidence that this is a genetic disease inherited as an autosomal recessive trait, although the underlying defect is unknown.<sup>79</sup>

### DIAGNOSIS

Previously, diagnosis depended on the antemortem presence of clinical signs in Fell pony foals and histologic confirmation of erythroid hypoplasia in the bone marrow, neuronal chromatolysis in peripheral nerve ganglia, absence of secondary lymphoid follicles, and low numbers of plasma cells in spleen and mesenteric lymph nodes. More recently, it has been shown that IgM levels measured after 4 weeks of age can assist in diagnosis, as can flow cytometric measurement of B lymphocytes.<sup>80,81</sup>

### TREATMENT

Treatment of specific infections is of limited efficacy in affected foals, particularly those affected by severe anemia and diarrhea, and all die by 3 months of age.

### CLIENT EDUCATION

While the underlying basis of this disease is unknown, it is difficult to give specific advice. If the condition is shown to be an autosomal recessive trait, then both the dam and sire of affected foals will be confirmed as carriers and breeding is discouraged.

## SELECTIVE IGM DEFICIENCY

Selective IgM deficiency is characterized by substantially reduced or absent serum IgM with normal or increased concentrations of other immunoglobulins and no other evidence of immunodeficiency.<sup>1,82</sup> Serum IgM concentrations are more than two standard deviations below the mean of age-matched control animals. All other immunologic parameters are normal, although in one case a lack of response to the B cell mitogen lipopolysaccharide was reported.<sup>83</sup> The syndrome has been most frequently described in Arabians and Quarter Horses, although the diagnosis has been made in other breeds.

### CLINICAL SIGNS AND LABORATORY FINDINGS

Two clinical syndromes have been described. The first condition affects foals between 2 and 8 months of age, which develop severe pneumonia, arthritis, and enteritis with or without septicemia; many die before 10 months of age. Gram-negative bacterial infections are common (especially with *Klebsiella* species), and age at onset of signs is generally older than in foals with combined immunodeficiency. Some affected foals survive but have a history of repeated bacterial infections that respond temporarily to therapy but recur once antimicrobials are discontinued. These foals grow poorly and generally die

within 2 years. Rarely, foals can recover from IgM deficiency, suggesting that such cases may actually be secondary rather than primary immunodeficiencies.<sup>84</sup>

The second presentation involves horses between 2 and 5 years of age, many of which have or ultimately develop lymphosarcoma. These individuals may have external or internal lymphadenopathy or both. Chronic weight loss, depression, and other nonspecific signs usually accompany lymphosarcoma. In cases associated with lymphosarcoma, the IgM deficiency is presumed to be a secondary rather than a primary immunodeficiency.

Routine laboratory findings are not diagnostically specific. Hematologic abnormalities consistent with chronic inflammatory disease, such as anemia, neutrophilia, and hyperfibrinogenemia, are commonly present. The total plasma protein and serum globulins are usually normal.

### ETIOLOGY AND PATHOGENESIS

Although a genetic basis is suspected, the pathogenesis of selective IgM deficiency is unknown.<sup>1</sup> It seems likely that there are primary and secondary forms of this syndrome.

### DIAGNOSIS

Definitive diagnosis of selective IgM deficiency is made by measuring the major serum immunoglobulins by RID and determining the absolute lymphocyte count. Horses with selective IgM deficiency have serum IgM concentrations persistently less than 2 standard deviations below that of age-matched controls (<15 mg/dl at 4 to 8 months old; <25 mg/dl at >8 months old) coupled with normal concentrations of IgG ( $\geq$ 400 mg/dl) and a normal lymphocyte count. Normal values for equine IgM concentrations have recently been reported.<sup>85</sup> Because seriously ill foals may have transiently depressed serum IgM concentration, suspected cases should be tested at least twice to document that IgM concentrations remain low. All other immunoglobulin concentrations are normal.

### TREATMENT

Other than supportive care and antimicrobial therapy, there is no effective treatment for selective IgM deficiency. Because transfused plasma concentrations of IgM are low and the half life is quite short, any benefit would be only temporary.

### CLIENT EDUCATION

The prognosis must be guarded; however, recovery has been reported.<sup>84</sup> If primary immunodeficiency is diagnosed or suspected, it is probably inadvisable to rebreed the sire and dam.

### OTHER PRIMARY IMMUNODEFICIENCIES

Transient hypogammaglobulinemia and agammaglobulinemia are reported as established primary immunodeficiency syndromes in horses. However, these conditions have been infrequently reported and consequently remain poorly defined. Available information is presented later in this chapter. A further form of immunodeficiency affecting humoral immunity was described by Boy et al.<sup>86</sup> in a 10-month-old Arabian colt. The animal exhibited an absence of serum IgM, IgA, and IgG(T) and a normal concentration of IgG. In vitro testing of peripheral blood mononuclear cells (PBMCs) with T cell mitogens elicited normal responses, and responses to B cell mitogens were weak. On postmortem examination there was generalized lymphocyte depletion of lymphoid organs.

To increase our understanding of these and other currently unidentified immunodeficiency syndromes of horses, it is critical that every effort be made to identify such cases and thoroughly investigate them. Newly available immunologic resources may make it possible to define these diseases further and increase our diagnostic and prognostic resources, provided the case material can be identified.

### COMMON VARIABLE IMMUNODEFICIENCY

*Common variable immunodeficiency* is the most common primary immunodeficiency in humans,<sup>87</sup> and sporadic cases have been reported in recent years in horses.<sup>88-90</sup> The disease is characterized by a deficiency of all immunoglobulin classes, accompanied by various defects in cellular function, but most consistently by a failure of B lymphocyte maturation. A pattern of recurrent infections and decreased serum immunoglobulin levels is seen. Medical management of these cases has been reported, with survival times of more than 1 year in some instances, even without the use of immunoglobulin replacement therapy.<sup>88</sup>

### TRANSIENT HYPOGAMMAGLOBULINEMIA

Transient hypogammaglobulinemia has been reported in only two foals, an Arabian and a Thoroughbred, and is characterized by delayed onset of immunoglobulin synthesis.<sup>84,91</sup> Affected foals manifested signs consistent with bacterial and viral infections when passively acquired immunoglobulins are catabolized to nonprotective concentrations. For unknown reasons, the onset of autologous immunoglobulin production, which generally occurs at birth, is delayed until these foals are approximately 3 months of age. Hematologic studies may be suggestive of chronic infection, although total plasma protein is normal or reduced slightly. Diagnosis is based on the presence of low serum IgG (<200 mg/dl) and IgG(T) (<20 mg/dl) at 2 to 4 months of age, with low-normal serum IgM (>15 mg/dl) and IgA (>20 mg/dl). Lymphocyte counts are normal. Antimicrobial therapy and plasma transfusions are necessary to minimize infections. Affected foals usually survive if they have not concomitantly suffered failure of passive transfer and they receive appropriate support between 2 and 4 months of age. The fact that foals spontaneously recover from this condition raises the question of whether it may be a secondary immunodeficiency.

### AGAMMAGLOBULINEMIA

Agammaglobulinemia is characterized by absence of B lymphocytes and failure to produce immunoglobulins in the presence of normal cell-mediated immunity.<sup>1</sup> The disease has been described in five colts of Thoroughbred, Standardbred, and Quarter Horse breeds.<sup>84,92,93</sup> Clinical signs commence between 2 and 6 months of age and result from bacterial infections such as pneumonia, enteritis, and arthritis. Multisystemic infections that respond poorly to therapy are common, and laboratory changes reflect chronic inflammatory disease. The fact that this syndrome has only been described in colts suggests an X-linked mode of inheritance, as occurs in a similar disease of humans. A maturation defect from stem cells to B cells has been suggested.<sup>1</sup> Affected foals have persistently subnormal serum concentrations of all immunoglobulin classes and normal lymphocyte counts. Serum IgM and IgA are generally absent at the time of evaluation and maternally derived IgG and IgG(T) decline with time. At 2 months of age, IgG is less than 300 mg/dl, which declines to less than 100 mg/dl.

by 6 months. There is no serologic response to immunization, and B lymphocytes, as determined by immunofluorescence, are absent. Tests of cell-mediated immune function such as intradermal PHA and *in vitro* blastogenesis are normal. Plasma and antimicrobial therapy result only in transient improvement. Affected horses die from disseminated infection between 1 and 2 years of age.

## ☞ SECONDARY IMMUNODEFICIENCIES

### FAILURE OF PASSIVE TRANSFER

Failure of passive transfer is the most common immunodeficiency disorder of horses and has recently been extensively reviewed.<sup>2,94</sup> It occurs in all breeds secondary to inadequate absorption of colostrum antibodies. Failure of passive transfer is significantly correlated with increased susceptibility to infectious disease and death in neonatal foals.<sup>95,96</sup> The newborn foal is capable of mounting a normal immune response, as described earlier in this chapter. However, neonatal foals are immunologically naïve and thus have not yet developed memory responses or produced antigen-specific antibody and other forms of adaptive immunity. During the first 1 to 2 months of life, foals are dependent on passively transferred immunity for protection from infectious disease. The diffuse epitheliochorial nature of the equine placenta does not allow for *in utero* immunoglobulin transfer to foals. Although minor concentrations of some immunoglobulins can be detected at birth, the foal is born essentially agammaglobulinemic and acquires passive immunity by the ingestion and absorption of colostrum from the dam.<sup>97,98</sup> Colostrum is a specialized form of milk containing immunoglobulins, which are produced during the last 2 weeks of gestation under hormonal influences. Colostrum contains primarily IgG<sub>a</sub>, IgG<sub>b</sub> (IgG<sub>a</sub> plus IgG<sub>b</sub> is the equivalent of IgG) and IgG(T), with smaller quantities of IgA and IgM, all of which have been concentrated into mammary secretions from the mare's blood.<sup>13,99</sup> Colostrum is produced only one time each pregnancy and is replaced by milk that contains negligible immunoglobulins within 24 hours of the initiation of lactation.<sup>13,97,99</sup> Normal foals suckle within 1 to 3 hours of birth, and the absorptive capacity of the foal's gastrointestinal tract for immunoglobulins is greatest during the first 6 hours after birth, and then steadily declines until immunoglobulins can no longer be absorbed, when the foal is 24 hours old. The incidence of failure of passive transfer is highly variable among groups of horses and seems to depend primarily on management factors that ensure early colostrum ingestion.<sup>100</sup> The reported prevalences of at least partial failure of passive transfer have ranged between 3% to 37%.<sup>22,84,95,100</sup>

### CLINICAL SIGNS AND LABORATORY FINDINGS

Failure of passive transfer does not directly cause any clinical signs of disease. Failure of passive transfer is suspected when signs of generalized or localized bacterial infections such as septicemia, pneumonia, enteritis, and arthritis develop during the first 3 weeks of life. Routine laboratory findings may suggest sepsis, but the presence of infection in the neonatal period is not pathognomonic for failure of passive transfer. Common abnormalities include neutropenia or neutrophilia, hypoglycemia, and hyperfibrinogenemia. The total plasma protein may be low, normal, or elevated in foals with failure of passive transfer because of the wide variation in normal

presuckle total plasma protein and the confounding effects of dehydration secondary to sepsis.

### ETIOLOGY AND PATHOGENESIS

Causes for failure of passive transfer in foals include (1) failure of the foal to ingest an adequate volume of colostrum in the early postpartum period; (2) loss of colostrum via premature lactation; (3) inadequate immunoglobulin content of the colostrum; and (4) insufficient immunoglobulin absorption via the intestine.<sup>2,101</sup> There is a highly negative correlation between foal serum IgG concentration and the incidence of severe infections;<sup>95</sup> however, the minimum amount of IgG necessary for protection of a foal from infection varies with the amount and virulence of environmental pathogens, concomitant stress factors, and colostrum antibody titer against specific pathogens. Although a serum IgG concentration of at least 400 mg/dl has been considered evidence of adequate passive transfer, most normal foals attain values more than twice this high<sup>95,100</sup> and serum IgG greater than 800 mg/dl may be required for adequate immunity.<sup>96</sup> Numerous other colostrum factors may be important for the immune protection of foals. Colostrum has been variously shown to regulate cell-mediated immunity, activate granulocytes, promote intestinal absorption of macromolecules, decrease intestinal colonization by pathogens, and contain constituents of innate immunity (e.g., lactoferrin, complement) and leukocytes that have a local protective role in the neonatal digestive tract and may be systemically absorbed.<sup>102,103</sup> At this time the significance of these various phenomena for the health of neonates and their immunologic development is largely unknown. The one exception is the finding that colostrum ingestion suppresses *de novo* antibody responses in foals in both a nonspecific and an antigen-specific manner.<sup>97,104</sup>

Neonatal weakness or lack of maternal cooperation (common in maiden mares) are common reasons for the foal to ingest an inadequate volume of colostrum. If colostrum ingestion is delayed beyond 6 hours, the absorption of immunoglobulins is significantly reduced. Lactation before parturition is another common reason for failure of passive transfer because colostrum is produced only one time each gestation. The causative factors for premature lactation are unknown at this time, but foals from mares that "leak" milk hours to days before parturition are likely to suffer failure of passive transfer.<sup>101</sup>

Subnormal colostrum immunoglobulin content (<3000 mg/dl) is rare in mares that do not prelactate,<sup>100</sup> but wide individual variation in colostrum concentration of immunoglobulins does occur.<sup>100,105-107</sup> Poor-quality colostrum will undoubtedly cause failure of passive transfer. Colostrum immunoglobulin content can be estimated by specific gravity or sugar (Brix) refractometry or quantitated by RID.<sup>101</sup>

Malabsorption is implicated as a cause of failure of passive transfer when foals are known to have ingested an adequate volume of good-quality colostrum within 12 hours of birth. Because glucocorticoids hasten the maturation of specialized enterocytes, stress-causing endogenous corticosteroid release may be a cause of reduced immunoglobulin absorption. However, obvious stress factors are often not found in foals with apparent impaired ability to absorb IgG.<sup>6</sup>

### DIAGNOSIS

Subnormal serum IgG concentration 24 hours after birth is the basis for diagnosis of failure of passive transfer. Serum IgG of less than 200 mg/dl indicates complete failure of passive

transfer, whereas 200 to 800 mg/dl should be considered partial failure of passive transfer. Many foals under good management conditions may remain healthy if the serum IgG concentration is at least 400 mg/dl, and consequently this cut point is measured by several rapid diagnostic tests. The most quantitatively accurate method to determine serum IgG is the SRID test (VMRD, Pullman, Wash.); however, this assay is time consuming and expensive, thus inappropriate for the diagnosis of failure of passive transfer when timely therapeutic intervention is paramount.<sup>108</sup> Numerous field screening procedures for IgG have been evaluated.<sup>2,15,16,22,108-110</sup> Criteria for selecting a screening test for equine failure of passive transfer must include accuracy, the time necessary to perform the test, ease of performance, and cost. Although the zinc sulfate turbidity, turbidimetric immunoassay, and glutaraldehyde coagulation tests are inexpensive and provide results within 1 hour, the ease and reported accuracy of membrane-based ELISA tests often makes them the test of choice in many practice situations. However, results of a recent study suggest that the choice of screening test is not so straightforward.<sup>111</sup> Although a variety of screening assays produced acceptable screening results, a membrane-based ELISA assay (SNAP test; Idexx, Westbrook, Me.) gave the greatest sensitivity, specificity, and accuracy at a cutoff of 400 mg/dl. However, at a cutoff of 800 mg/dl, this same test had a lower specificity that would have led to unnecessary treatment of some foals if that cutoff had been used. These data highlight the difficulty faced by equine clinicians in selecting a rapid diagnostic test for failure of passive transfer. Because failure to diagnose and treat the condition could result in the death of many foals, a sensitive test is required. However, specificity is also important, particularly given the cost of treatment (plasma transfusion) and the fact that treatment is not without its own inherent complications. Individual clinician judgment is therefore important in test selection, although at this time the relatively good performance of semiquantitative SNAP test, and its convenience, may continue to make it a popular choice.<sup>112</sup> Turbidimetric immunoassays offer a somewhat more complex but potentially more accurate assay that can be conducted at the point of care.<sup>16,110</sup> Generally, all screening tests are relatively accurate in identifying foals with complete failure of passive transfer; however, there is variation in their ability to detect marginally deficient foals.<sup>2</sup> In the future new technologies such as infrared spectroscopy have considerable promise for providing accurate and economical results.<sup>17</sup>

## TREATMENT

If failure of passive transfer is anticipated because of premature lactation, neonatal weakness, dam death, or low-specific-gravity colostrum, an alternative colostrum source can be given orally. A minimum of 2 L of equine colostrum given in 500-ml increments during the first 8 hours after birth is optimal. Bovine colostrum may be safely substituted if equine colostrum is not available;<sup>61,113</sup> however, foals given bovine colostrum may also require plasma transfusion because bovine immunoglobulins have a very short half life in foals and are not specifically directed against equine pathogens.

If the foal is more than 12 hours old when failure of passive transfer is suspected or diagnosed, an intravenous plasma transfusion is indicated. There are numerous commercial sources of equine plasma. Use of these products is convenient, saves time, and is safe because donors are free of alloantibodies

and negative for infectious diseases. The only potential drawback to the use of commercial plasma is that antibodies specific for pathogens in the foal's environment may be lacking. Optimal plasma would be obtained from a local blood-typed donor, one that is known to lack serum alloantibodies and alloantigens Aa and Qa. The volume of plasma necessary to bring serum IgG into an acceptable range cannot be accurately predicted because it depends on the severity of failure of passive transfer, the immunoglobulin content of the plasma, and on concomitant diseases, which may hasten immunoglobulin catabolism. Generally, 1 L of plasma will increase the serum IgG concentration of a 50-kg foal by 200 to 300 mg/dl;<sup>40</sup> thus 2 to 4 L may be necessary to achieve serum IgG greater than 800 mg/dl. A therapeutic dose of plasma should be administered, and then foal serum IgG remeasured. If the desired concentration has not been attained, more plasma is necessary. Some foals with partial failure of passive transfer (IgG >400 and <800 mg/dl) may do well without plasma therapy if there are no preexisting infections and exposure to pathogens is minimized. These foals should be monitored closely for the development of infections.

## CLIENT EDUCATION

The prognosis for foals with failure of passive transfer depends on the degree of failure, the environment to which the foal is exposed, the foal's age at the time of diagnosis, and the presence and severity of secondary infections. Management factors that ensure the ingestion of at least 2 L of high-quality colostrum within 6 hours of birth are paramount in failure of passive transfer prevention. Foaling should be witnessed so that any mispresentations can be corrected, and foals that do not readily nurse within 3 hours can be given colostrum via nasogastric tube. The evaluation of colostrum specific gravity with a hydrometer (Lane Manufacturing, Denver, Colo.) or Brix 0-50% sugar refractometer may aid in prediction of failure of passive transfer.<sup>101</sup> A colostrum specific gravity of 1.060 measured with a hydrometer corresponds to approximately 3000 mg/dl IgG, which is the minimum acceptable value. When dam colostrum specific gravity is less than 1.060, some degree of failure of passive transfer should be suspected in the foal and corrected. A Brix % sugar reading of 20% to 30% correlates with adequate colostrum quality and a reading of >30% indicates very good-quality colostrums. A commercial kit based on glutaraldehyde coagulation (Gamma-Check-C, Veterinary Dynamics, Inc., San Luis Obispo, Calif.) is also available for stallside screening of immunoglobulin concentrations in mare colostrums.

Routine screening of foal serum IgG at 24 to 48 hours after birth allows necessary plasma therapy before the onset of infections. This can be done with any of a variety of stallside or laboratory tests described earlier in this chapter. Ideally, foals should have an IgG concentration of >800 mg/dl at 24 to 36 hours of age.

Foals that are born prematurely, are weak, or from pre-lactating mares should be provided with an alternative colostrum source within 6 hours of birth. A colostrum bank can be established by collecting and freezing ( $-20^{\circ}\text{C}$ ) 250 ml of colostrum from mares that have not pre-lactated within 6 hours of foaling, once their own foals have suckled. Ideally, banked colostrum should be screened for alloantibodies, although they are unlikely if the mare's own foal remains healthy. The immunoglobulins in banked frozen colostrum are stable for at least 1 year.

## EXERCISE

Exercise, when conducted at a stressful level, can significantly affect equine immune function.<sup>114</sup> Strenuous exercise significantly suppresses lymphoproliferative responses, while increasing lymphokine activated killer cell activity.<sup>53,115</sup> In racehorses decreased lymphoproliferative responses can be demonstrated 12 to 16 hours after racing.<sup>116</sup> Protracted high-intensity training results in decreased phagocytosis and oxidative burst activity in neutrophils and lymphocytes, although pulmonary alveolar macrophage function was unaffected.<sup>51</sup> Other studies have demonstrated decreased neutrophil and pulmonary alveolar macrophage (PAM) function in response to single bouts of intense exercise<sup>117,118</sup> and prolonged suppression of innate immunity after exercise of long duration.<sup>119</sup> In unconditioned ponies strenuous exercise increases susceptibility to experimental infection with equine influenza virus.<sup>120,121</sup> In an influenza infection study in trained horses, moderate exercise led to increased signs of clinical disease, although duration of disease was unaffected.<sup>121</sup>

Overall, these various studies have demonstrated a clear immunomodulatory effect of exercise, with some specific evidence for increased susceptibility to infectious disease. Although this remains an active area of investigation with much to be learned, it is clear that the potentially immunosuppressive effect of high-intensity exercise, particularly of protracted duration or in unconditioned animals, needs to be recognized.

## AGE

There is a high incidence of *respiratory infections in foals and weanlings*, which frequently relapse on cessation of antibiotic treatment.<sup>122</sup> It is also possible that the normal level of immunocompetence in this age group leads to increased susceptibility to pyogenic respiratory infections, particularly under group housing conditions. Features of the foal's immune system that may predispose to such infections are discussed earlier in this chapter.

Old age has the potential to result in relative immunodeficiency, although there have been few equine studies to investigate this possibility. Older horses display decreased lymphoproliferation to mitogens,<sup>123</sup> and in an exercise study they demonstrated reduced immunologic response to exercise.<sup>115</sup> The implications of such phenomena for disease risk in older horses remains uncertain. The high incidence of pituitary pars intermedia dysfunction in older horses is a risk factor for infectious disease, as a consequence of high steroid levels.

## LEUKOPROLIFERATIVE DISEASE-ASSOCIATED IMMUNODEFICIENCY

Lymphosarcoma is often associated with IgM deficiency<sup>2,85</sup> and can also be associated with decreased lymphocyte blastogenesis.<sup>124,125</sup> Affected horses were diagnosed with bacterial pneumonia in some instances, and in another report a horse suffering from myelomonocytic leukemia was found to be suffering from pulmonary aspergillosis.<sup>126</sup> These cases demonstrate the importance of considering leukoproliferative disease, and particularly lymphosarcoma, in cases of persistent infections that are refractory to treatment.

## DRUG-INDUCED IMMUNODEFICIENCY

The most common iatrogenic cause of immunosuppression is corticosteroid treatment, often given with the specific aim of treating a hypersensitivity disorder. The mode of action and the effects of corticosteroids are reviewed later in this chapter, but there is evidence for the capacity of corticosteroids to induce recrudescence of viral diseases such as equine infectious<sup>127</sup> anemia or EHV-1 infection<sup>128</sup> and to lead to development of life-threatening bacterial infection.<sup>129</sup> There is also evidence that corticosteroid treatment can bias adaptive immune responses to vaccination in horses, specifically suppressing IgG<sub>a</sub> and IgG<sub>b</sub> responses without affecting IgG(T) responses.<sup>39</sup> This phenomenon may be consistent with the capacity of corticosteroids to specifically suppress Th1 immune responses without affecting Th2 responses.<sup>130,131</sup>

## INFECTIOUS DISEASE

Several infectious diseases have been associated with immunodeficiency in horses. The best-characterized example may be perinatal EHV-1 infection.<sup>132</sup> Foals that are infected late in gestation with EHV-1 are often born weak, with interstitial pneumonia, and develop a variety of bacterial diseases.<sup>133</sup> Affected foals have profound lymphopenia and generally die, despite therapy. The immunodeficiency is thought to be due to viral-induced lymphoid damage because necropsy reveals marked necrosis of lymphoid tissue in the thymus, spleen, and lymph nodes.

## UNDIFFERENTIATED IMMUNODEFICIENCIES

A group of *foals with oral candidiasis and bacterial septicemia* between 2 weeks and 4 months of age had laboratory or histologic evidence of immunodeficiency that did not fulfill diagnostic criteria for any of the recognized primary immunodeficiencies.<sup>134</sup> Oral lesions ranged from focal white plaques on tongue margins to a generalized thick, white pseudomembrane covering the tongue and gingiva. Affected foals showed bruxism, ptyalism, fever, and depression in addition to pneumonia, arthritis, or diarrhea, singly or severally. The lymphocyte counts of the foals were usually normal. Several foals had IgM deficiency coupled with depressed blastogenesis, suggesting cellular immune dysfunction. Many of the foals had low or marginally reduced serum IgG in addition to IgM deficiency or reduced blastogenesis. It was not determined whether the immunologic defects were primary or secondary. All foals died despite extensive therapy with parenteral antimicrobials, topical antimycotics, and intravenous plasma. Localized or systemic candidiasis has also been described in neonatal foals receiving broad-spectrum intravenous antimicrobials for treatment of presumed bacterial sepsis. This may represent an opportunistic infection in foals with loss of normal bacterial flora secondary to antimicrobial use and exacerbated by immune suppression secondary to the underlying primary disease process.

*Acquired immunodeficiency* was identified in a 7-year-old Appaloosa gelding that had no history of previous illness.<sup>135</sup> Clinical signs included lethargy, anorexia, and dyspnea. Pneumonia and septicemia caused by *Rhodococcus equi* were confirmed by tracheal wash and blood culture, respectively. Immunologic evaluation revealed marked lymphopenia, subnormal serum IgG and IgA with marginally low IgG

concentrations, failure to respond serologically to immunization, and reduced *in vitro* lymphocyte blastogenesis. Histologic examination of lymph nodes and spleen revealed lymphoid atrophy.<sup>117,118</sup>

## IMMUNOMODULATORS

Clinicians frequently seek to increase normal, restore deficient, and temper over exuberant host immune responses. For these reasons modulation of the immune system, which provides critical defense against many types of disease, has become an area of intense interest in clinical medicine. Both immunostimulants and immunodepressants are considered immunomodulators. There are a variety of ways to classify immunomodulators beyond this distinction, but for practical purposes they may be best classified on the basis of their origin (i.e., physiologic products [actual normal components of the immune response], microbial products, and chemically defined agents). Immunomodulation can also result from modes of therapy not considered here, including bone marrow transplantation and irradiation.

Although a scientific rationale for the use of immunomodulators exists, a major limitation is the complexity of the immune response to be modulated. We are faced with several major problems in the rational clinical application of immunomodulators. Our current diagnostic methods do not allow us to precisely identify the *in vivo* defects, deficiencies, or excesses of substances or regulators present within the immunoregulatory network. Consequently, our attempts to intervene with immunomodulators are often relatively crude and nonspecific. Some of the information on which we base our use of immunomodulators has come from controlled, experimental studies, some performed *in vitro* and others *in vivo*. In clinical patients expectations based on these types of studies are frequently not realized. Reasons for this include the timing of the administration of the immunomodulator during the course of disease, and the fact that observation of a single immunologic phenomenon resulting from use of an immunomodulator, for example, an increase in lymphocyte count or lymphoproliferative responses, does not necessarily translate into improved clinical performance in the face of an infectious disease. Because of the complexity of the immune network, the rational use of immunomodulators can be considerably more difficult than the use of antimicrobial agents. An example of the importance of timing in immunomodulatory intervention is the relative success of immunosuppressive therapy in the context of organ allografts, compared with the frequent treatment failures experienced in treating autoimmune disease. In the former case, therapy is planned in advance of the introduction of the allograft, whereas in the case of autoimmunity the immune response and resulting disease are well established before they are detected and therapy is initiated.

Immunomodulators have been embraced by clinicians with great enthusiasm, and the concept of their use remains appealing. However, although the clinical value of immunosuppressive drugs such as corticosteroids and immunostimulant adjuvants in vaccines is clearly established, evidence for the clinical value of many immunostimulants is sparse. It is

important to look critically at the immunomodulatory drugs on the market and objectively evaluate the effects of therapy. Many agents that have been discarded for use in humans are now being resurrected for veterinary use. Is it realistic to expect better results in veterinary patients?

This discussion will be limited to drugs currently marketed for use as immunomodulators or for which there is published evidence of activity. Advances in genetic engineering have made available recombinant forms of many cytokines with immunomodulatory potential, but only those with some established value will be discussed.

## IMMUNOSUPPRESSORS

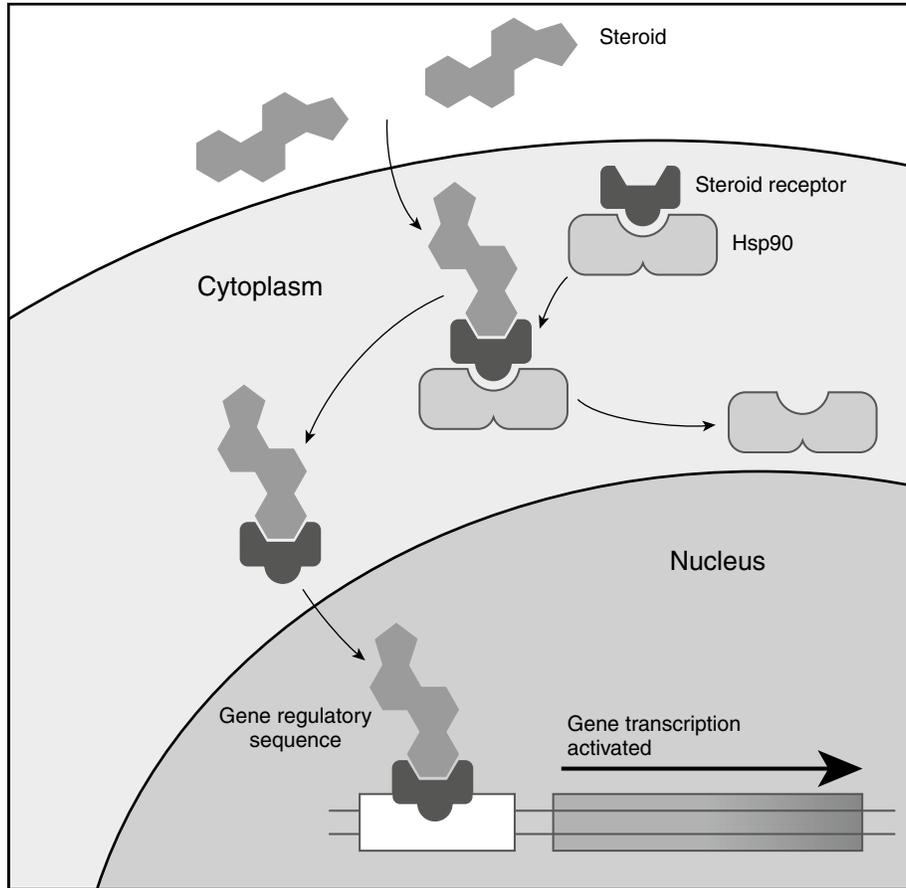

### CORTICOSTEROIDS

Corticosteroids are classic examples of immunosuppressive agents. Corticosteroids exhibit an extensive range of effects on elements of both the innate (inflammatory) and adaptive immune response. The mechanism of action of corticosteroids is illustrated in Figure 1-24. Corticosteroids, acting through their cytoplasmic steroid receptors, directly regulate as many as 1% of genes in the genome, usually resulting in induction of transcription.<sup>1</sup> The useful antiinflammatory effects of corticosteroids are summarized in Table 1-9. The effect on the adaptive immune response is complex.<sup>2</sup> For example, in cases of autoimmune disease such as autoimmune hemolytic anemia, corticosteroids may act by reducing phagocytosis of antibody-coated cells by the reticuloendothelial system rather than decreasing antibody production. Nevertheless, corticosteroids have been shown to have effects on antibody production, and in the horse they can suppress *de novo* antigen-specific IgG<sub>a</sub> and IgG<sub>b</sub> responses while sparing IgG(T) responses.<sup>3</sup> This may be consistent with the action of corticosteroids to suppress Th1 responses while sparing Th2 responses.<sup>4-7</sup> Cell migration is significantly affected by corticosteroids, and in the horse corticosteroids suppress neutrophil migration, together with phagocytic and bactericidal activity.<sup>8</sup> The mechanism whereby migration is decreased involves decreased expression of integrin molecules, including selectins and integrins.<sup>9</sup>

Although corticosteroids are powerful immunosuppressive agents, they may also predispose patients to life-threatening opportunistic infections<sup>10</sup> or recrudescence of viral infection.<sup>11-13</sup> Additional extensive undesirable side effects include fluid retention, decreased wound healing, and the concern that their use can be associated with the development of laminitis in some circumstances.<sup>14-17</sup> For this reason prolonged or high-dose corticosteroid therapy must be used judiciously.

### CYTOTOXIC DRUGS

The two commonly used immunosuppressive cytotoxic drugs, *azathioprine* and *cyclophosphamide*, interfere with DNA synthesis and act primarily on dividing cells.<sup>1</sup> This activity is useful for treatment of cancer and for suppression of dividing lymphocytes. Toxicity limits the use of these drugs, although at lower doses they can be used in combination with corticosteroids. Two case reports describe the use of these drugs in horses suffering from immune-mediated hemolytic anemia or thrombocytopenia when corticosteroid therapy alone had failed, with some success.<sup>18,19</sup>

**FIGURE 1-24** Lipid soluble corticosteroid molecules diffuse across the plasma membrane into the cytosol and bind to steroid receptors. This displaces a heat-shock protein (Hsp90) normally bound to the nascent steroid receptor, exposing a DNA binding region. The new complex enters the nucleus and binds to specific regulatory DNA sequences, resulting in modulation of transcription of a wide variety of genes.

**TABLE 1-9**

### Antiinflammatory Effects of Corticosteroid Therapy Mediated by Regulation of Gene Transcription

#### ACTION OF CORTICOSTEROIDS

##### Direct Effect

- ↓ IL-1, TNF- $\alpha$ , GM-CSF, IL-3, IL-4, IL-5, IL-8
- ↓ NOS
- ↓ Phospholipase A2, Cyclo-oxygenase type 2
- ↑ Lipocortin-1
- ↓ Adhesion molecules
- ↑ Endonucleases

##### Physiologic Effects

- ↓ Inflammation caused by cytokines
- ↓ NO
- ↓ Prostaglandins, Leukotrienes
- ↓ Emigration of leukocytes from vessels
- ↑ Apoptosis in lymphocytes and eosinophils

From Murphy KM, Travers P, Walport M: *Janeway's Immunobiology*, 7<sup>th</sup> ed. New York, 2007, Garland Science, New York, 2008, Garland Science. IL, Interleukin; TNF, tumor necrosis factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; NOS, nitric oxide synthase; NO, nitric oxide.

## BACTERIAL AND FUNGAL DERIVATIVES

Bacterial and fungal derivatives are a class of drugs that includes relatively nontoxic alternatives to immunosuppressive cytotoxic drugs. *Cyclosporine* is a fungal derivative and has emerged as a major immunosuppressive agent for allograft survival; it selectively inhibits proliferation, cytotoxicity, and lymphokine production of T cells by binding to intracellular proteins known as immunophilins and interfering with signaling pathways that are important for clonal expansion of lymphocytes.<sup>1</sup> Cyclosporin is efficacious in suppressing specific immune responses with minimal nonspecific toxic effects on polymorphonuclear leukocytes, monocytes, and macrophages. Thus immunosuppressed patients suffer fewer severe secondary infections. The drug is not hazard free; in addition to suppressing lymphocyte responses in general, it is also toxic to the kidneys and other organs.

In horses the use of cyclosporin has been limited to topical therapy for ocular inflammatory disease, including keratitis<sup>20</sup> and uveitis.<sup>21,22</sup> In the treatment of uveitis, numbers of infiltrating T lymphocytes and IL2 and  $\gamma$ -IFN levels were suppressed by cyclosporin treatment.<sup>23</sup>

## IMMUNOSTIMULANTS

### PHYSIOLOGIC PRODUCTS

#### IMMUNOGLOBULINS

The use of immunoglobulins for treatment of failure of passive transfer of immunity is discussed earlier in this chapter, and antigen-specific passive immunoglobulin therapy is discussed later. Other forms of immunoglobulin immunomodulation include the use of monoclonal or polyclonal sera directed against components of the immune system. This type of therapy has still found limited practical application in the 30 years since the advent of monoclonal antibody technology, largely as a result of the immunogenicity of the antibodies themselves. Although recombinant technology now has the prospect of resolving this problem, there are no current examples of clinical applicability in the horse.

Another mode of immunoglobulin therapy is polyclonal intravenous immunoglobulin (PIVIG) therapy using pools of immunoglobulin derived from several thousand donors.<sup>24,25</sup> It was serendipitously observed that PIVIG administration was useful for treatment of autoimmunity;<sup>26,27</sup> proposed mechanisms include idiotype-antiidiotype network regulation,<sup>28</sup> cytokine regulation, specific antibody interactions, Fc-receptor blockade, inhibition of activated complement deposition, and long-term selection of immune repertoires.<sup>29</sup> Although the exact mechanisms underlying the effects of PIVIG are uncertain, there are good examples of therapeutic success in patients with immunothrombocytopenic purpura.<sup>30</sup> However, diseases such as autoimmune diabetes mellitus are resistant to therapy.<sup>31</sup> There are no publications describing PIVIG therapy in horses, although this treatment modality remains an intriguing possibility in this species.

#### CYTOKINES

Given the central role of cytokines in immunoregulation, their potential as immunomodulators is obvious and a discussion of the possible use of cytokines as therapeutic agents in this regard would be extensive, although largely hypothetical. Therefore consideration will be limited to the two

cytokines that have found clinical application in horses to date.

**Interferon- $\alpha$**  The clinical application of interferon- $\alpha$  in the horse has been extensively reviewed.<sup>32,33</sup> Interferon- $\alpha$  has antiviral and immunostimulant properties, and oral administration of interferon- $\alpha$  reduces inflammatory airway disease (IAD)<sup>34</sup> in racehorses.<sup>35</sup> The treatment employed was low-dose (50 to 150 IU) "natural" human interferon- $\alpha$ , and it resulted in decreased BAL cell counts and a noninflammatory cytologic profile.<sup>36</sup> Higher doses (450 IU) were less effective, consistent with results in other species.<sup>33</sup> The efficacy of oral therapy probably depends on effects mediated through oropharyngeal lymphoid tissue, as the agent is destroyed in the stomach.

**Granulocyte-colony Stimulating Factor** The clinical application of granulocyte colony-stimulating factor (G-CSF) in the horse has been extensively reviewed.<sup>33</sup> Treatment with G-CSF in neonatal foals results in a sustained, dose-dependent increase in neutrophil count and a left shift<sup>37,38</sup> by increasing neutrophil production in the bone marrow and shortening the time to release into the circulation; half life remains unchanged at 8 hours. In horses, canine recombinant G-CSF (Amgen) has been used to treat sepsis and endotoxemia with some success.<sup>33</sup>

## BACTERIAL, VIRAL, AND PLANT PRODUCTS

A variety of bacterial and fungal microorganisms or microbial products have been identified that have an immunomodulating effect on the immune system. A common feature of many of these products is a nonspecific immunostimulant effect, purportedly due to macrophage activation and release of cytokines, including interferons, IL-1, TNF, or IL-6.<sup>33,39</sup> Consequently, mild fever and malaise may be associated with this form of treatment. In the horse these treatments are most commonly used in cases of respiratory infection or sarcoids. An extensive review of the use of these and other immunostimulants in the horse has been published.<sup>33</sup>

### MYCOBACTERIAL PRODUCTS

A wide range of mycobacterial fractions have been identified with immunomodulating ability.<sup>33,39</sup> The minimal structure with immunologic (adjuvant) activity is muramyl dipeptide (MDP), which is a potent adjuvant.<sup>40</sup> Preparations commercially available for use in horses include BCG (bacille Calmette-Guérin), a modified live human tuberculosis vaccine, and protein-free mycobacterial cell wall extracts (Nomagen, Fort Dodge Laboratories, Inc., Fort Dodge, Iowa; Equimune, Vetrepharm Inc., London, Ont.). Efficacy is claimed for treatment of equine respiratory disease. Adverse reactions have been reported after multiple intravenous treatments in horses, resulting in marked interstitial lung infiltration and progressive pulmonary fibrosis. As a result, caution should be exercised before selecting this treatment modality. In horses the major successful application of these products has been in the intralesional treatment of sarcoids, particularly periocular sarcoids, and this is discussed elsewhere in this text.

### PROPIONIBACTERIUM ACNES (CORYNEBACTERIUM PARVUM)

*Propionibacterium acnes* is a gram-positive anaerobe, marketed for use in horses as a killed preparation under the tradename EqStim (Immunovet, Inc., Tampa, Fla.) for treatment of equine respiratory disease.<sup>39</sup> It is recommended for use prophylactically before weaning, transport stress or co-mingling, or for

the therapy of chronic infectious respiratory disease. In a blind randomized clinical trial, *P. acnes* treatment resulted in early resolution of spontaneously occurring respiratory disease.<sup>33</sup> In healthy horses *P. acnes* resulted in increased CD4+ T lymphocyte numbers and LAK activity in peripheral blood and BAL fluid, increased nonopsonized phagocytosis in peripheral blood leukocytes, and decreased pulmonary cellularity.<sup>41</sup> Overall, this agent is one of the most popular immunostimulants currently marketed for horses, but substantive peer-reviewed evidence to confirm its value is lacking.

### CpG DNA

In recent years an extensive literature has developed describing the immunomodulatory effects of certain bacterial DNA motifs.<sup>42</sup> The specific immunostimulatory DNA motifs are called *CpG sequences*, and appropriate sequences for immunostimulation of domestic species have been identified.<sup>43</sup> Much work has been done on examining the efficacy of CpG sequences as vaccine adjuvants,<sup>44</sup> immunomodulators for hyposensitization, or cancer therapy.<sup>45</sup> The value of CpGs in horses as both vaccine adjuvants<sup>46</sup> and as potential nonspecific immunomodulators<sup>47</sup> has been demonstrated, although commercial products are not yet available.

### ACEMANNAN

Acemannan is an extract of the aloe vera plant mostly used for treatment of fibrosarcomas in dogs and cats.<sup>33</sup> It can also be used as a vaccine adjuvant and, in addition, has antiviral activity. Anecdotal reports describe efficacy for treatment of equine respiratory disease (intravenous) and sarcoids (intralesional), although both forms of treatment are associated with side effects, including syncope, tachycardia, tachypnea, and sweating. Controlled studies of efficacy in the horse are lacking.

### PARAPOXVIRUS OVIS

Marketed under the trade name Baypamun (Bayer Animal Health, Del.), and currently in the United States as Zylexis (Pfizer Animal Health), inactivated parapoxvirus ovis has been used extensively in Europe for prophylaxis and treatment of infectious disease in companion animals (including horses) and pigs.<sup>33</sup> The immunostimulant properties depend on a component of the viral envelope and increase NK activity and macrophage activation. Efficacy has been demonstrated against viral and bacterial disease in several species,<sup>33</sup> and there is some evidence in horses that prophylactic administration before weaning reduces signs of respiratory disease after weaning.<sup>48</sup> In studies of treatment of sarcoid, there was no evidence of efficacy.<sup>49</sup> In a model of transport stress, treatment with Zylexis led to restoration of suppressed antibody responses to influenza virus infection in horses.<sup>50</sup>

### ECHINACEA

Extracts of *Echinacea angustifolia* are reported to be immunostimulatory. One study in horses evaluated the effect of an experimental oral *Echinacea* sp. extract on neutrophil number and phagocytosis and lymphocyte count.<sup>51</sup> Findings provided only limited evidence of immunostimulation based on changes in cell count and behavior.

### CHEMICALLY DEFINED AGENTS

**Levamisole** Levamisole is a synthetic anthelmintic used for treatment of nematode infections that has also been reported to restore impaired host immune defenses.<sup>33</sup> Levamisole

appears to have little effect on the normal immune system, but it appears to stimulate a subnormal response and suppress hyperactive responses. The effects are dose related, and low doses are reported to enhance, whereas higher doses suppress, responses. In cattle levamisole enhances lymphoproliferative responses in vitro, although in vivo co-administration with a vaccine had no immunostimulant effect.<sup>52</sup> Similarly, levamisole did not prevent corticosteroid-mediated immunosuppression in cattle<sup>53</sup> or enhance postpartum lymphoproliferative responses in pigs.<sup>52</sup> Aside from anecdotal reports, there are no published controlled studies of its value in horses.

## ANTIGEN-SPECIFIC IMMUNOMODULATION

### VACCINATION AND ADJUVANTS

Vaccination is a critically important tool in preventing infectious disease in humans and animals, and both passive and active vaccination are extensively employed in the horse. Specific equine vaccination strategies are presented elsewhere in this book, and the scientific principles and practice of equine vaccination have been extensively reviewed.<sup>54</sup> Active vaccination induces an antigen-specific immune response in the vaccinated animal by administration of dead or live antigen or DNA capable of expressing protein antigens in vivo. Success of all these forms of vaccination often depends on the use of an effective adjuvant, a compound capable of amplifying and directing immune responses.<sup>55</sup> As such, adjuvants are one of the most important forms of immunomodulation agents in use in equine medicine.

Passive vaccination is accomplished by administering preformed antibodies either as a plasma transfusion or in a concentrated form, as in commercially available tetanus antitoxin. This strategy can be highly effective in diseases for which there is no available form of active vaccination (e.g., *Rhodococcus equi*) or in high-risk situations when there is inadequate time for protection to be generated by active vaccination. Generally, passive vaccination should be avoided when possible because of the risk of transmission of infection in serum-derived products. An example of this is the association of acute hepatic necrosis with a previous administration of tetanus antitoxin.<sup>56</sup>

### HYPOSENSITIZATION

Because horses suffer from a number of hyposensitivity diseases, attempts have been made to perform antigen-specific immunosuppression. Examples include insect bite hypersensitivity (IBH) and recurrent airway obstruction (RAO).<sup>57</sup> The principle of this type of therapy is that the immune response to an allergen can be redirected in order to reduce hypersensitivity disease.<sup>58</sup> For example, Type 1 hypersensitivity disease may depend on a Th2 immune response, and treatments that can change this to a Th1 immune response may eliminate or control the hypersensitivity disease by changing the immune response from one dominated by IgE to IgG.<sup>1</sup> Typically, hyposensitization treatments use injections of the allergen itself, starting with very small doses and gradually increasing the dose over time. This form of treatment depends on correct identification of the allergen against which the hypersensitivity disease is directed, and the difficulty in identifying these allergens using available intradermal testing methodologies.<sup>59,60</sup>

may provide an explanation for the mixed success of hyposensitization treatment in horses.<sup>61</sup> Prospects for hyposensitization therapy may be improved by new techniques to produce large numbers of recombinant allergens.<sup>62,63</sup> These allergens are far better defined than conventionally prepared allergen extracts, and in initial experimental studies of RAO they were found to be far superior in terms of specificity and sensitivity for detection of allergen-specific IgE. Such developments, together with the developments of DNA vaccination strategies incorporating CpG immunomodulation for hyposensitization,<sup>64-66</sup> and additional therapeutic vaccination strategies<sup>67</sup> targeting MHC II antigen presentation<sup>68,69</sup> and formation of Tregs,<sup>70</sup> mean that there is a good chance that new and effective therapies will be developed in the future.

## CONCLUSION

The properties and efficacy of immunosuppressive agents are generally well documented, as are the effects of antigen-specific immunostimulant adjuvants. Of all the nonspecific equine immunostimulants described in the literature, only interferon- $\alpha$  and *P. acnes* are supported by well-designed and well-performed studies.<sup>35,36,41</sup> Given the interest in this modality of therapy, this is regrettable and evidence of the difficulty in designing studies to establish immunostimulant efficacy, possible lack of efficacy of such products in some instances, and the dire need for additional scientific research.

# MECHANISMS OF INFECTIOUS DISEASE

## CHAPTER

Maureen T. Long

## 2

### MECHANISMS OF ESTABLISHMENT AND SPREAD OF BACTERIAL AND FUNGAL INFECTIONS

Maureen T. Long

#### ☞ NORMAL FLORA

Dermal and mucosal surfaces provide a life-preserving protective barrier composed of physical, chemical, and microbial defenses.<sup>1</sup> *Normal flora* is an essential component of this protective barrier against pathogens yet paradoxically provides a source for opportunistic invasion. *Commensal bacteria* are those living on or within a host in a way such that both derive mutual benefit and in which interruption of this association results in abnormal host development or overt disease.<sup>1</sup> A pathogen is any disease-producing organism; thus a commensal is potentially pathogenic. Colonization is infection without disease; colonization of skin, gastrointestinal, respiratory, and urogenital tracts occurs early in life and persists during the healthy lifetime of the host.

#### SKIN FLORA

The combination of normal flora and mucosal immunity provides an effective barrier against infectious colonization of nondisrupted skin surfaces. Specific bacteria are stratified by site, and certain bacteria multiply and colonize depending on associated adnexa.<sup>2</sup> Most bacteria and fungi on the surface of the skin are not associated with disease; however, yeast and bacteria associated with hair follicles are more likely to be related to a disease process.<sup>3</sup> Even though horses inhabit an environment heavily contaminated with fecal flora, normal dermal flora in the horse is surprisingly devoid of members of the Enterobacteriaceae.<sup>4</sup> Normal inhabitants include mixed populations of bacteria of species of *Acinetobacter*, *Aerococcus*, *Aeromonas*, *Bacillus*, *Corynebacterium*, *Flavobacterium*, *Micrococcus*, *Nocardia*, coagulase negative *Staphylococcus*, *Staphylococcus aureus*, *Streptomyces*, and nonhemolytic *Streptococcus* genera.<sup>2</sup> Certain *Staphylococcus* spp. have been associated with skin disease in the horse, and these include *S. aureus*, *S. intermedius*, and *S. hyicus*, whereas species such as *S. xylosus* and *S. sciuri* were more associated with normal skin.

More than 30 species of fungi can inhabit the skin and *Alternaria*, *Aspergillus*, *Candida*, *Fusarium*, *Rhizopus*, and *Trichophyton* spp. are commonly present.<sup>2</sup> Until recently the presence of *Malassezia* yeast species has been considered pathogenic. Recent fungal culturing of the skin of normal, healthy horses has confirmed colonization by a species of *Malassezia* yeast that is novel to the horse (tentatively named *M. equi*). Colonized sites include groin, axilla, and perineal regions.<sup>5</sup>

#### ORAL, PHARYNGEAL, AND RESPIRATORY FLORA

Oral and pharyngeal mucosal flora is associated with both health and disease of the upper and lower respiratory system. The oral and pharyngeal mucosa is richly populated with many bacteria, including obligate aerobes, anaerobes, and facultative anaerobes.<sup>6</sup> Gram positive and negative anaerobes are the predominant flora in the mouth and pharyngeal tonsils of the normal horse, with *B. fragilis* and *Bacteroides* spp. most commonly found. Genera consisting of *Fusobacterium* spp., *Eubacterium* spp., *Clostridium* spp., *Veillonella* spp., and *Megasphaera* spp. are also cultured. Aerobic and facultative anaerobic populations mostly comprise *S. zooepidemicus*, *Pasteurella* spp., *E. coli*, *Actinomyces* spp., and *Streptococcus* spp. Because these same genera are also consistently found in horses with lower respiratory infections, opportunistic colonization by pharyngeal flora is the likely mechanism of disease.<sup>6</sup> Contamination of the trachea of the horse is a frequent occurrence, as evidenced by the fact that trans-tracheal aspiration (TTA) yields positive bacterial cultures in approximately 30% of both normal adult horses and foals.<sup>7</sup> As with skin flora, normal horses have multiple fungal species inhabiting conjunctival, nasal, and oral mucosa.<sup>8</sup> Stabling increases the frequency of ocular fungi in normal horses.<sup>8</sup>

#### INTESTINAL FLORA

In animal models and chronic human conditions, normal flora is considered important for intestinal maturity and containment of disease. Changes in cecal weight, villus: crypt ratio, and volatile fatty acid production and the development of gut IgA responses are all affected by suboptimal cecal colonization in germ-free animals.<sup>9</sup> A relationship between severity of mucosal disease and normal flora has also been demonstrated in models of inflammatory bowel disease of humans.<sup>10</sup>

Bacteria are present in all parts of the intestinal tract of the horse, and the microbial fauna increases in complexity and density aborally.<sup>11</sup> The stomach of the horse is not a sterile environment. A dense population of gram positive bacterial rods, primarily composed of *Lactobacillus* spp., colonizes the nonsquamous portion of the equine stomach. Substantial colonization of the duodenum is present with a large population of proteolytic bacteria, and this colonization increases by tenfold in the ileum.<sup>12</sup>

Microbial degradation and fermentation of plant material in the large intestine are important components of nutrient acquisition in the equid. The consumption of cellulose and starch results in the production of volatile fatty acids (VFAs).<sup>13</sup> The major cellulolytic bacterial strains in the horse produce arrays of fermentation products that differ from those of cattle.<sup>14</sup> The common bovine rumen bacteria *Ruminococcus flavefaciens* is one of the most predominant cellulolytic bacteria of the equine cecum based on standard microbiologic techniques.<sup>15</sup> Genetic techniques also demonstrate that the predominant flora are the low GC-content bacteria, which include *Cytophaga-Flexibacter-Bacteroides* and *Clostridium* bacteria; the actual species are completely novel.<sup>15</sup> Standard microbiologic techniques specifically demonstrate Enterobacteriaceae, *Butyrivibrio* spp., *Streptococci* spp., *Bacteroides* spp., *Lactobacilli* spp., *Selenomonas* spp., *Eubacterium* spp., *Propionibacterium* spp., and *Staphylococcus* spp. in residence.<sup>16</sup> In addition, there are completely different compositions of bacteria between the differing segments of the colon, especially between the ascending colon and cecum, indicating highly specialized digestive functions associated within the large intestine itself.<sup>15</sup> Yeasts and fungi of the order *Mucorales* have been identified in the cecum of normal horses and are capable of digesting cellulose and starch.<sup>17</sup>

Routine surveillance demonstrates a relative lack of intestinal pathogens in the flora of normal horses. In the largest study to date, fecal shedding of *Salmonella enteritidis* as detected by fecal culture in normal horses from farms without evidence of salmonellosis was 0.8% in resident horses.<sup>18</sup> Molecular diagnostics, once hoped to provide a tool for understanding the incidence of *Salmonella* spp. in the clinically normal horse, has provided inconsistent information, and polymerase chain reaction (PCR) is most useful for identification of subclinical shedders and environmental contamination during an outbreak.<sup>19,20</sup> On the basis of limited investigations, the carriage rates of *C. difficile* in normal horses and foals appear to be low (<1.5%).<sup>21</sup>

Intestinal flora in the horse is an important source for extraintestinal pathogens. In studies examining the carriage rate of *Rhodococcus equi*, all horses cultured carried the bacteria regardless of age.<sup>22,23</sup> Furthermore, if the farm had endemic *R. equi* and respiratory isolates contain the 90 kDa plasmid, which has been associated with disease, fecal isolates also contained this plasmid.

## UROGENITAL FLORA

By far, most of the work that characterizes equine normal flora has focused on urogenital flora to address infertility and fetal loss. Although vaginal and vestibular mucosa of mares should be colonized with normal mucosal flora, the uterus is considered sterile. However, typical culturing techniques result in frequent isolation of what could be considered pathogens, and cytology and bacterial counts are essential supplemental

tests for detecting true uterine infection. Counts less than 10 colony-forming units and lack of inflammatory cells indicate uterine or technical contamination.<sup>24</sup>

Many bacteria inhabit the external genitalia of stallions, including bacteria considered to be associated with metritis in mares. The predominant aerobe isolated is coagulase-negative *Staphylococcus* spp., followed by *Corynebacterium* spp.,  $\alpha$ -hemolytic *Streptococcus* spp., and *Lactobacillus* spp. Pathogens such as  $\beta$ -hemolytic *Streptococcus* spp., *Pseudomonas aeruginosa*, and *Klebsiella* spp. can be frequently found in servicing stallions.<sup>25,26</sup> Pregnancy rates appear to be the same in mares bred to *P. aeruginosa* semen-infected stallions.<sup>27</sup>

## FUNGAL FLORA

Essentially the same principals apply regarding normal flora, host immunity, and specific virulence factors for the pathogenesis of fungal infection. Fungal infections can be divided into primary or opportunistic pathogens. True pathogens are less dependent on host status than opportunistic pathogens, although even a true pathogen may require some degree of alteration of normal flora or host immunity to become established. Long-term antibiotic use, immunosuppression, and compromised organ function (especially involving the pulmonary or endocrine system) are three primary host factors highly associated with establishment of opportunistic fungal infection. Fungi in particular can adapt to the mammalian environment over a relatively short course in order to become established. Establishment usually requires a change in thermal range, oxygen requirements, and resistance to host defenses.

## POPULATION BIOLOGY OF BACTERIAL INFECTIONS

Inoculum size, virulence of the organism, and microbial resistance are three important determinants in the outcome of infectious challenge. Minimizing the size of bacterial challenge by controlling environmental contamination must be the primary goal for successful disease control in the natural environment and hospital settings.

## INOCULUM SIZE

Little dose-response work has been published that demonstrates a clear relationship between frequency or severity of disease and dose for many equine bacterial pathogens. In general, for systemic infections, inoculum size has been shown to be the most important determinant of disease in hematogenously disseminated infections such as meningitis and, in rodent models, osteomyelitis.<sup>28</sup> The equine literature emphasizes animal and environmental risk factors<sup>29</sup> as important determinants in survival for conditions such as neonatal osteomyelitis, but these factors ultimately control the degree of bacterial challenge at birth. For skin infections, colonization of experimentally induced wounds with *Staphylococcus* spp. is historically dependent on inoculum size. However, attainment of antibiotic resistance and new virulence factors are predominant factors in the development of human *S. aureus* colonization and disease.<sup>30,31</sup> The occurrence of diarrhea is dose dependent in salmonellosis in calves,<sup>32</sup> but little is known regarding challenge dose in the foal or the adult horse. Very small numbers of *Streptococcus equi* subsp. *equi* inoculated intranasally result in

rapid colonization of the equine lingual and nasopharyngeal tonsils within hours.<sup>33</sup> Minimal inoculum size is required for certain pathogens that form toxins, such as *E. coli* O157H7 and *Clostridium* spp. in humans.<sup>34</sup>

## VIRULENCE

Virulence is the relative ability of an organism to cause disease.<sup>1</sup> Virulence of an organism is frequently tested by inoculation of different strains or genetically modified organisms of a pathogen into groups of a rodent species (or cell culture), and lethality or invasiveness is evaluated. When this particular methodology is used, the severity of many diseases frequently is found to be strain dependent and virulence is commonly associated with certain phenotypic characteristics of a particular strain.

## ANTIBIOTIC RESISTANCE

Widespread use of antibiotics in both animal and human infection occurred after World War II.<sup>35,36</sup> Within 30 years resistance of gram positive organisms was already occurring in human pneumococcal infections.<sup>37</sup> From the 1960s to the 1980s, staphylococcal resistance progressed from initial methicillin-resistant organisms to vancomycin-resistant organisms.<sup>36</sup> Specific types and mechanisms of bacterial resistance are discussed in association with particular diseases. Briefly, there is intermediate resistance that occurs in geographically defined isolates in a step-wise fashion resulting from genetic changes under antibiotic pressure.<sup>37,38</sup> Thus proper dose and length of antibiotic exposure are important in preventing the development of these isolates.<sup>37,38</sup> In high-grade and multidrug-resistant (MDR) forms of antibiotic resistance, there is clonal expansion of small numbers of isolates.<sup>39</sup> In addition to selective antibiotic pressure, individual carrier animals and people are important for development and maintenance of high-grade and MDR resistance. Virulence and antibiotic resistance are not synonymous; commensal or relatively noninvasive pathogens have higher rates of resistance,<sup>40</sup> whereas more highly pathogenic or invasive organisms have less resistance. Because commensal organisms are ubiquitous, with a higher likelihood of contact with bacteria that have multiresistance genes, commensal organisms become a reservoir for resistance genes.<sup>40</sup>

## DEVELOPMENT OF DISEASE AND THE ROLE OF NORMAL FLORA

### DISRUPTION OF NORMAL FLORA

The pathophysiology of certain types of equine colitis and pleuropneumonia is consistent with either disruption of normal flora and invasion by a pathogen or the conversion of a common commensal organism into a pathogen. Development of colitis in the horse has been associated with feed change, antibiotics, surgery, nonsteroidal inflammatory drugs, and transport, all events that disrupt flora.<sup>41,42</sup> Rapid change from a roughage diet to concentrate results in increased anaerobes, decreased cellulolytic bacteria, decreased cecal protozoa diversity, and decreased pH in the equine cecum.<sup>41</sup> Isolation of *Clostridium difficile* is more likely from horses treated with antibiotics, and clinical disease has been associated with ampicillin, erythromycin, penicillin, and potentiated

sulfonamide administration in adult horses.<sup>43,44</sup> In ponies infected with *Salmonella* spp., transport and surgery reactivated infection and diarrhea, and antibiotics (oxytetracycline) prolonged shedding but did not induce recrudescence.<sup>42</sup> In a case control study, use of potentiated sulfonamides was not significantly associated with the development of diarrhea in hospitalized horses; however, overall antibiotic use was highly associated with the occurrence of diarrhea.<sup>45</sup>

There are several mechanisms by which antibiotics disrupt normal gastrointestinal flora and function.<sup>46</sup> The most important include (1) disruption of carbohydrate metabolism, (2) decreased metabolism of bile acids, (3) direct effects on intestinal motility, and (4) shortening of intestinal villi. Changes in carbohydrate metabolism are a large intestinal event secondary to reduced microbial reduction of carbohydrates to short-chain fatty acids (SCFAs). Because SCFA metabolism and absorption result in fluid and electrolyte absorption, a sudden decrease in SCFA leads to osmotic diarrhea with an intraluminal accumulation of organic acids, cations, and carbohydrates. In human studies, reduced SCFAs have been demonstrated with many antibiotics, including ampicillin, metronidazole, and erythromycin.<sup>46</sup> Bile acids, reduced in the colon by dehydroxylating bacteria, are potent colonic secretagogues. Increases in fecal bile acids have been demonstrated in humans with the use of ampicillin and clindamycin.<sup>46</sup> Erythromycin and amoxicillin directly affect colonic motility.<sup>46</sup> Erythromycin is a motilin receptor agonist resting in contraction of antral and duodenal smooth muscles.<sup>47</sup> In the horse erythromycin results in a dose-dependent increase in ileocecal emptying.<sup>48</sup> Motility enhancing effects have also been observed in human patients treated with amoxicillin.<sup>46</sup>

## DISEASE CAUSED BY COLONIZATION OF COMMENSAL FLORA

Occurrence of infectious lower respiratory disease in adult horse is an example of how contamination of a normally sterile site with several commensal bacteria results in disease. Changes in upper respiratory mucosal flora and transportation are two important elements that contribute to the development of pleuropneumonia in the horses. The tonsillar mucosa of the oropharynx is heavily colonized with *S. equi* subsp. *zoepidemicus*, and necrosis of this tissue occurring during viral infection is associated with spread to the lower respiratory tract.<sup>6</sup> Transport of horses (especially for distances >500 miles) is a primary risk factor for pleuropneumonia as demonstrated in a large retrospective study.<sup>49</sup> Elevation of the head for an extended period of time is likely a contributing factor. Horses normally feed from the ground for most of the day, and this posture promotes effective tracheal clearance of inhaled debris and particulate matter. Under experimental conditions elevation of the head for prolonged periods of time results in an increase in the variety and multiplication of oral/pharyngeal commensal bacteria within the trachea. *Pasteurella*, *Actinobacillus*, and *Streptococcus* spp. are the most frequent and prolific colonizers of the trachea after prolonged head elevation.<sup>50,51</sup> In addition to prolonged head elevation imposed by extended transport periods, there is decreased phagocytosis of equine peripheral neutrophils in these horses.<sup>51</sup> As a result, common commensal bacteria of the nasal and oropharyngeal mucosa become opportunistic pathogens.

## NOSOCOMIAL INFECTIONS

Nosocomial infection (health care–associated infections) is defined by the Centers for Disease Control and Prevention (CDC) as a localized/systemic condition resulting from an adverse reaction to the presence of an infectious agent or its toxin. There must be no evidence that the infection was present or incubating at the time of hospital admission.<sup>52</sup> Nosocomial infections are becoming a major problem for large animal veterinary teaching and private referral hospitals. Infections with *Serratia marcescens*, *Acinetobacter baumannii*, *S. aureus*, methicillin-resistant *Staphylococcus* spp., *Enterococcus* spp., and various *Salmonella enteritidis* serovars have all been reported in association with nosocomial infection in equine patients.<sup>53,54</sup> Surgical incision infection, joint sepsis, catheter phlebitis, wounds, and diarrhea represent the common clinical syndromes reported in horses.<sup>53-55</sup> When nosocomial infection involves the acquisition of isolates from the hospital environment, these isolates are more difficult to treat because they frequently undergo high-level antibiotic pressure and attain multiresistance. Nosocomially transmitted salmonellosis in equine hospital wards is increasingly reported, with *Salmonella enteritidis* serotypes Krefeld, Saint Paul, DT104, and Anatum all demonstrating attainment of MDR over the course of the outbreak.<sup>56,57</sup> Only one study of a nosocomially transmitted *Salmonella enteritidis* (serotype Heidelberg) did not demonstrate significant acquisition of multidrug resistance over time.<sup>58</sup>

## ☞ PATHOGENESIS OF BACTERIAL INFECTIONS

The ability of bacteria to gain entry and cause disease results from a combination of factors possessed by the agent itself, environmental conditions, and status of host defenses. Bacteria either gain entry through a body surface by direct inoculation or colonize and damage a dermal or mucosal barrier to cause disease. Environmental or risk factors specific for individual diseases increase the probability of successful penetration or colonization and are discussed for specific diseases in various chapters. Innate immunity and specific immunity, which alter host susceptibility to disease, are also discussed elsewhere in this chapter. General mechanisms that are specific to bacteria and enhance disease are virulence factors that enhance the entry, spread, and damage to host tissues (Table 2-1). Virulence factors may either allow bacteria an advantage to gain entry and disseminate or directly cause damage to the host once entry has been gained. Major virulence factors are listed for specific equine pathogens.

## ☞ FACTORS THAT ENHANCE ENTRY OF BACTERIA

### ADHESION, ENTRY, AND SECRETION

Protein secretion systems (PSSs) are a structurally diverse complex of essential virulence factors for bacteria that allow specialized interactions between cells.<sup>59</sup> Classifications of associated pili are separated on the basis of their biogenesis by a particular PSS and their resulting final structure, which accounts for their wide diversity. These main systems function to translocate various sized molecules and are important in the formation of adhesins upon attachment to host cells.

TABLE 2-1

General Mechanisms of Bacterial Pathogenesis		
Action	Mechanism	Examples
Entry of bacteria	Adhesion	Fibrillar adhesins
	Entry	Nonfibrillar adhesins Curli fimbriae Lipoteichoic acid Biofilm adhesion proteins Membrane ruffling
Enhancement of spread	Immune resistance	Capsule
	Host substrate utilization	Lipopolysaccharide Anticomplement Resistance to phagocytosis Phagolysosomal survival Iron acquisition
Damage to host membranes	Toxins	Exotoxin
		Endotoxin Apoptosis

Fibrillar adhesins (FAs) and nonfibrillar adhesins (NFAs) are the most important PSS subgroup not used for bacterial conjugation. They specifically target host cells and biofilms for enhancement of colonization and invasion.

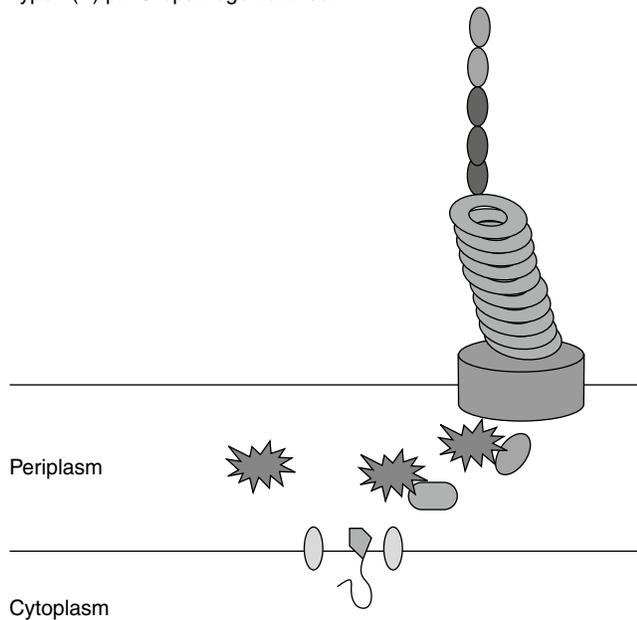

## FIBRILLAR ADHESIONS

There are multiple types of FAs in both gram positive and gram negative bacteria, with gram negative the most well characterized (Table 2-2).<sup>60-62</sup> Pili or fimbriae are rod-shaped structures composed of an orderly array of a single protein usually arranged in a helical fashion to form a cylinder. The tip of the fimbria mediates attachment to carbohydrate moieties on cell surfaces and is integral to bacterial invasion and colonization. Bacteria can also contain multiple types of pili. Both the bacterial pili themselves and the cellular pathways they use for secretion and formation of pili are targets for pharmacologic intervention, and there are multiple subclasses depending on their configuration.<sup>60</sup>

Type I fimbriae (Figure 2-1) are distributed in the periplasmic space and translocated to the cell surface by a chaperone-usher (C-U) pathway.<sup>62-65</sup> These pili are made up of multiple major pilin subunits compiling a rigid shaft with minor pilin proteins composing the flexible tip. These require a C-U secretion system for biogenesis. The C-U prevents the pili from achieving their final figuration while in the periplasmic space located between the inner and outer membrane before assuming their position on the outer membrane. Although once considered Type I, the formation of the pili associated with enterotoxigenic *E. coli* (ETEC) is now considered an alternate C-U pathway, which functions to confer species-specific binding to intestinal epithelium and mediate agglutination of erythrocytes. In gastrointestinal and urinary tract infection, fimbriae are likely one of the most important virulent factors for successful invasion.<sup>61</sup> Although the importance of *E. coli* adhesive fimbriae is questionable in equine disease and

TABLE 2-2

Major Types of Bacterial Adhesins		
Adhesin	Definition	Example
Type 1 fimbriae	Cell surface structure primarily on gram (–) bacteria that bind to the terminal mannose of glycoproteins on cells	<i>Escherichia coli</i>
Type 4 pili	Cell surface structure primarily on gram (–) bacteria that function in adhesion, twitching, and DNA uptake, which bind on CD46 and other glycolipids	<i>Pseudomonas aeruginosa</i>
Curli fimbriae	Coiled aggregative fimbrial structures that bind to fibronectin, laminin, and plasminogen and function in adhesion, aggregation, and biofilm formation	Enterohemorrhagic <i>Escherichia coli</i> (EHEC) Salmonella
Fibrils and flexible rods	Short, thin rodlike adhesins that bind to fibronectin for adhesion to host tissues	<i>Streptococcus</i> species
(Lipo) Teichoic acid	Part of the peptidoglycan layer of cell walls	Gram positive bacteria
Biofilm	Exopolysaccharide produced by bacteria that allows matrix formation of embedded material	Gram positive and negative bacteria

Type I (P) pili-Uropathogenic *E. coli*

**FIGURE 2-1** Idealization of Type 1 fimbrial adhesion where pilus subunits are ushered from the cytoplasm to the periplasmic space and secrete through the cell membrane.

specific receptors for these fimbriae have not been identified, their action provides the general framework of bacterial-host cell interaction. Once receptor-mediated attachment occurs, intracellular calcium increases in the host cell.<sup>61</sup> Proteins and protein kinases involved in the breakdown of actin are activated, resulting in the disruption of microvilli. There is a change in the cytoskeleton of the cells and permeability to ions and water. Ions are secreted, resulting in the classic secretory diarrhea.

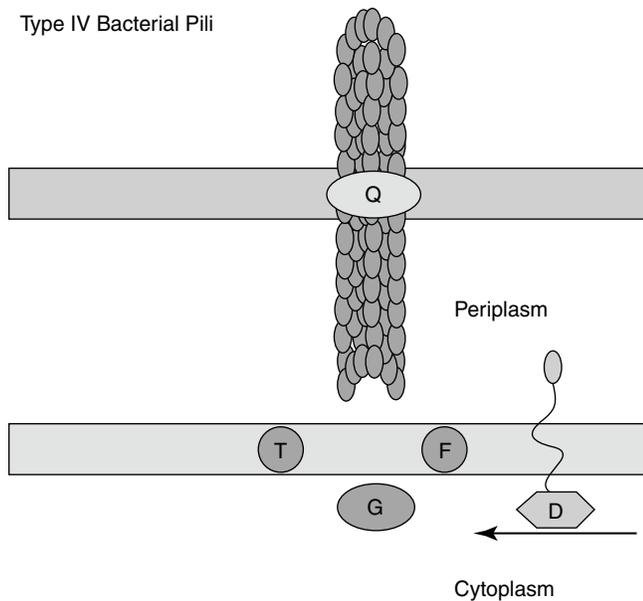

Type IV pili (Figure 2-2) are located at the pole of the cell and assembled via the Type II secretion system that is called the *general assembly pathway*.<sup>62,63</sup> These pili are flexible fibers

of variable length that can aggregate, are important in the formation of microcolonies, and are responsible for the twitching motion of bacteria. The proteins are secreted into the periplasmic space but remain anchored to the inner membrane. The protein is then assembled and passed through a pore formed in the outer membrane. Curli fimbriae are solid surface structures that use the extracellular nucleation-precipitation pathway.<sup>63</sup> This pilus is secreted as a soluble protein extracellularly with a second protein, the nucleator, for stability. These have been identified as important for binding to extracellular matrix proteins and biofilm formation.

Although discussed in greater detail later, the antiphagocytic M-protein of *Streptococcus* spp. is actually a fibrillar protein and also assists, but is not essential for, adhesion. In anaerobic bacteria, antibodies to flagella proteins can block *Clostridium difficile* adhesion.<sup>66</sup> These proteins are thought to mediate intestinal adherence and colonization.<sup>66</sup>

## AFIMBRIAL ADHESINS

Afimbrial adhesins are cell proteins that enhance the binding of bacteria to host cells. They are also called *microbial surface components recognizing adhesive matrix molecules*.<sup>67,68</sup> Gram positive organisms possess afimbrial proteins on their surfaces that presumably aid in binding to host cells. The three most commonly studied afibrillar adhesins are those that bind salivary glycoprotein, bind fibronectin, or are composed of lipoteichoic acid (LTA).<sup>68,69</sup> Salivary binding proteins are commonly found in pathogens and commensals of the oral cavity. Both *Streptococcus* spp. and *Actinomyces* spp. possess these proteins. Fibronectin binding protein (FBP) is necessary for *S. aureus* invasion and binds both fibronectin and collagen to form a bridge between the FBP and the host cell integrin (integrin  $\alpha_5\beta_1$ ).<sup>70,71</sup> The FBPs are essential for invasion of both epithelial and endothelial cells in *S. pyogenes*.<sup>67-68</sup> Heterologs of FBP have been demonstrated in *S. pneumoniae* of humans, *S. equi* subsp. *equi*, and *S. equi* subsp. *zooepidemicus*. Other potential equine pathogens that have FDPs on their surface include *Actinomyces* spp. *E. faecalis*, and *L. monocytogenes*.<sup>69,72</sup> Lipoteichoic acid (LTA), a common binding factor found in *Streptococcus* group A bacteria, is important in adhesion of bacteria to cells.<sup>73</sup> This

**FIGURE 2-2** Idealization of Type IV fimbrial adhesion where pilus subunits are secreted through the membrane by an adenosine triphosphate-mediated process.

protein is also important in stimulation of cytokine secretion from the cells during infection and has been demonstrated in group B *Streptococcus*, including *S. equi* subsp. *equi*.<sup>74</sup> A less commonly described afibrillar adhesin is composed of surface polypeptide chains in *Corynebacterium* that binds to lectin.<sup>75</sup> Binding of these proteins can be abolished by trypsin treatment. Afibrillar adhesins are also present in gram negative organisms; the most commonly studied are conserved high molecular weight adhesion proteins of *Haemophilus influenzae* and *Bordetella pertussis*.<sup>73</sup>

### BIOFILM ADHESINS

Bacterial ecology has emphasized the importance of biofilm for colonization of both biotic and abiotic surfaces of bacteria.<sup>59</sup> A requirement for biofilm formation is a tight interaction of bacterial adhesins with surface receptors that promote further bacterial aggregation. The most important family of biofilm adherence proteins (BAPs) is that of *Staphylococcus aureus*. These proteins have high molecular mass and repetitive structures whose size and number can be varied during the course of infection, possibly allowing for immune evasion.

### CYTOSKELETAL CHANGES

Binding of bacteria frequently results in cytoskeleton changes within the host cell in order to enhance susceptibility to invasion. "Membrane ruffling" is a virulence factor that results in either internalization or breakdown of intracellular components to allow for invasion of tissues. Once bacteria attach, the change in the membrane itself (ruffling) aids in colonization of host surfaces or even uptake of the bacteria. The most common virulence proteins of both gram positive and gram negative are bacteria lectins.<sup>63-76</sup> Although attachment is thought to be the primary role of these proteins, attachment itself results in an intracellular change, including actin rearrangements, cell

signaling regulation, or actual secretion of bacterial substances into the host cell. These proteins are highly conserved in bacteria and are important targets for immunophylaxis.

Membrane transformation for uptake of intracellular bacteria such as *Yersinia* spp., *Listeria monocytogenes*, *Salmonella* spp., and *Shigella flexneri* can be either zipperlike or triggerlike. Binding results in actin rearrangement and engulfment of these intracellular bacteria by both phagocytic and non-phagocytic cells. *Yersinia* and *Listeria* spp. form a zipper-like relationship wherein the tightly adhered bacteria result in actin polymerization and formation of a phagocytic cup through actin nucleation, polymerization, and depolymerization.<sup>77</sup> Alternatively, *Salmonella* and *Shigella* bacteria adhere and secrete proteins that are translocated into the host cell cytoplasm and trigger actin polymerization.<sup>78</sup> In addition to membrane ruffling, *Mycobacterium avium* and *Salmonella* spp. also rely on activation of intracellular GTPases, leading to phagocytosis.<sup>79,80</sup>

## FACTORS THAT ENHANCE SPREAD OF BACTERIA

Once colonization occurs, multiplication and spread of bacteria are enhanced through virulence factors. These factors assist bacteria in survival in the hostile host environment and breakdown of tissue barriers. Many of these defenses overlap, but the result is avoidance of destruction by the host and sublimation of host tissues into a new bacterial niche.

### SURVIVAL IN HOST ENVIRONMENT

#### CAPSULE

One of the most common and potent strategies for avoidance of phagocytosis is the presence of a capsule. Despite the remarkable diversity of bacteria, assembly and structure of capsule are remarkably similar across species.

It was observed as early as 1928 that engulfment and digestion of *S. pneumoniae* were associated with lack of capsule,<sup>81</sup> and by 1940 it was clear that this virulence factor was genetically encoded.<sup>82</sup> Early studies with *S. equi* subsp. *equi* demonstrated that resistance to phagocytosis was associated with an increase in capsule and M-protein,<sup>83</sup> and in a model of *S. equi* subsp. *zooepidemicus* infection in mice, enhancement of virulence was associated with increased amount of capsule, which increased resistance to phagocytosis.<sup>84</sup> Although colonization of the guttural pouch occurs with nonencapsulated *S. equi* subsp. *equi* strains, induction of lymphadenopathy is associated with capsular strains.<sup>85</sup> In more recent studies of *S. equi* subsp. *equi* infection, rapid colonization in the lingual and pharyngeal tonsil is dependent on genetically associated virulence factors that control colony morphology, with the mucoid strain having enhanced virulence.<sup>33</sup>

*Escherichia coli* capsule is the "prototype" capsule of gram negative bacteria.<sup>86</sup> Ultrastructurally, this capsule forms a fine fibrillar meshwork covering the bacteria surface.<sup>87</sup> The K antigen is one of the major antigens, is temperature dependent in its antigenic structure and amount,<sup>88</sup> and is highly associated with increased pathogenicity and resistance to phagocytosis.<sup>89,90</sup> The other major antigen for gram negative bacteria is the lipopolysaccharide (LPS) minus the lipid A component of the molecule. A third minor component, colanic acid, appears to exhibit antiphagocytic activity in some *E. coli*. Classically, the presence of capsule on *E. coli* prevents

complement mediated phagocytosis.<sup>91</sup> The LPS itself activates complement, and the capsule prevents immune activation by concealing the LPS molecule.<sup>92</sup>

Capsules of anaerobic bacteria are unique, and these structures may directly account for the formation of abscesses within the host. The capsule of *B. fragilis* has two distinct polysaccharides composed of repeating subunits with oppositely charged groups (Zwitter ion).<sup>93</sup> This polysaccharide complex injected alone promotes the induction of abscess. Infection of rodents with the encapsulated form of *Bacteroides* and *Fusobacterium* spp. results in the formation of intraperitoneal abscesses, whereas nonencapsulated bacteria do not cause abscessation.<sup>94-96</sup> Synergism of capsular anaerobes with other bacteria occurs; nonencapsulated bacteria have enhanced survival in abscesses and produce capsule when cultured or inoculated with encapsulated bacteria.<sup>95</sup>

### ANTICOMPLEMENT FACTORS

Similar to and overlapping with capsule are structural proteins that block complement. The O side chain of LPS on gram negative bacteria is an anticomplement factor.<sup>97</sup> The longer the side chain, the greater the distance between phagocytes and bacteria. The capsular component, sialic acid, interacts with O antigen to prevent the formation of C3 convertase.<sup>98</sup> Bacterial enzymes are formed by *Streptococcus* spp. and other organisms that damage the polymorph chemoattractant, C5a.<sup>99,100</sup> Production of a protein in *Salmonella* spp., encoded by the *rck* gene, prevents insertion of the C9 fragment of complement into the bacterial membrane.<sup>9</sup> The M protein of *S. equi* subsp. *equi* appears to decrease deposition of complement on the surface of bacteria.

### RESISTANCE TO PHAGOCYTOSIS

Recent studies of streptococci have shown that when M-protein content is kept constant, the amount of capsule is actually correlated with resistance to phagocytosis.<sup>85</sup> Resistance to in vitro phagocytosis can be abolished with treatment with hyaluronidase and induction of specific immunity against M-protein of *S. equi* subsp. *equi* and *S. equi* subsp. *zooepidemicus*.<sup>101</sup> The M proteins of *Streptococcus* spp. are also essential for resistance to phagocytosis blocking complement.<sup>83,102-104</sup> This mechanism for complement resistance appears to be through enhancement of binding of fibrinogen to the bacteria in the presence of M protein.<sup>105-107</sup>

### PHAGOLYSOSOMAL SURVIVAL

The intracellular environment should be inhospitable for bacteria, yet many organisms are ingested by phagocytic cells and utilize this environment to multiply and disseminate. In normal phagolysosomal fusion, the phagocytic vesicle first becomes fused with a host cell endosome. Shortly thereafter, fusion with the lysosome occurs. Several digestive proteins are released within the lysosome, and there is a decrease in pH, resulting in inactivation and digestion of a foreign protein or microorganism. Bacteria have devised ways to escape the phagosome or use the phagosome as a niche for extended survival. *Shigella* spp. and *Listeria monocytogenes* are bacteria that escape the phagocytic vesicle to multiply in the host cell cytoplasm.<sup>108</sup> Before escape from the phagosome, *Listeria* modulates maturation of the phagosome by delaying fusion with the lysosome.<sup>109</sup> Both *Mycobacterium* and *Legionella* spp. cause a change in the maturation of the phagosome leading

to uninhibited replication within macrophages.<sup>110,111</sup> Engulfment of *Salmonella* spp. in the phagosome appears to induce formation of an actual phagolysosome, but the organism survives acidification and reactive oxygen intermediates (ROIs), likely through production of catalase and superoxide dismutase.<sup>112,113</sup> The acid tolerance response (ATR) is important primarily for intracellular bacteria that are able to withstand highly acidic environments, including *L. monocytogenes*, *R. equi*, and *Salmonella* spp.<sup>114,115</sup> Genes that control virulence in *Salmonella* are actually upregulated by an acidic environment. *Rhodococcus equi* suppresses acidification of the phagolysosome in addition to inhibiting phagolysosomal fusion.<sup>116</sup> Recently, homologous genes that regulate survival under high temperature and oxidative stress were also determined to be essential for phagolysosomal survival in *R. equi*.<sup>117</sup> Although the mechanism by which *R. equi* inhibits phagolysosomal fusion is unknown, opsonization by an *R. equi*-specific antibody results in enhanced fusion and killing.<sup>115,118</sup> Resistance to phagolysosomal fusion and replication in the phagolysosome appears dependent on the presence of the 90 kDa virulence plasmid.<sup>114</sup> *Rickettsia*, *Neorickettsia* (formerly *Ehrlichia*), and *Rhodococcus* bacteria appear to inhibit phagolysosomal fusion.

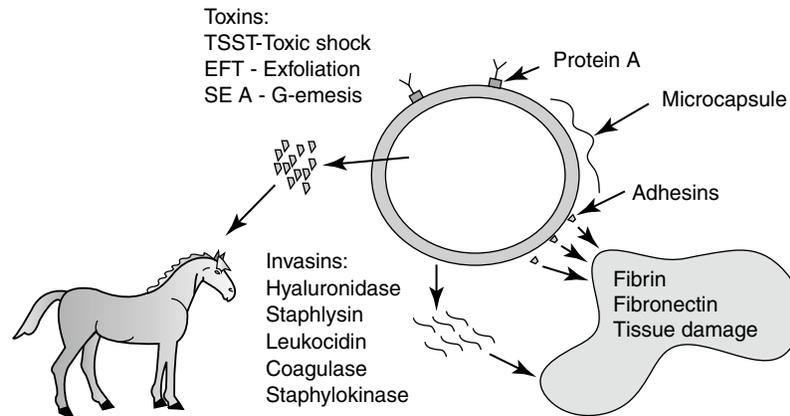

### HOST SUBSTRATE UTILIZATION

Nutrition of bacteria is intimately associated with cellular and tissue environments. The proper level of iron is important because iron is required for the production of reactive oxygen intermediates. The *fur* gene in *E. coli* was first identified as the major regulator of iron acquisition.<sup>119</sup> Homologs of this gene have been identified in many other bacteria, including *Salmonella* spp., *Vibrio* spp., *Pseudomonas aeruginosa*, *S. aureus*, and *B. fragilis*.<sup>119,120</sup> *Rhodococcus equi* has its own chromosomally encoded genes (*iupABC*) that allow survival in low iron environments.<sup>121</sup> In addition, bacteria possess siderophores, which are very potent chelators of iron.<sup>122</sup> These siderophores are secreted outside of the bacterial cell, uptake iron, and are taken back up by the cells through a receptor-mediated process. After internalization the iron is cleaved and utilized by the bacteria. Resistance to carbon, nitrogen starvation, and new substrate utilization are also important means by which bacteria survive inhospitable environments. The latter has been demonstrated as important for *R. equi* survival in the phagosome, where bacteria become more efficient at membrane fatty acid and cholesterol utilization under anaerobic conditions.<sup>123</sup>

## DAMAGE TO HOST TISSUES

### TOXINS

Exotoxins are virulence factors secreted by the host that frequently function to aid spread of infection (Figure 2-3). Both gram positive and gram negative organisms secrete an array of exotoxins. Classically, there are three types of exotoxins.<sup>61</sup> The first is the A-B form, in which there are two distinct parts to the toxin: one for binding and one for enzymatic action. The second does not appear to have distinct parts and forms pores within host membranes. The third is superantigen, which forms a bond between the major histocompatibility complex (MHC) class II receptor of macrophages, resulting in release of various T cell helper-mediated cytokine cascades. Several examples of common equine pathogens are discussed.

**FIGURE 2-3** Mechanisms of virulence of *Staphylococcus aureus*. (Redrawn from Todar K: *Todar's Online Textbook of Bacteriology*, [textbookofbacteriology.net](http://textbookofbacteriology.net), © Kenneth Todar Ph.D., University of Wisconsin-Madison.)

### STAPHYLOCOCCUS AUREUS

Toxins of *Staphylococcus aureus* are well characterized, provide examples of several types of toxins produced by the same organism, and are directly associated with the pathogenesis of this disease (see [Figure 2-3](#)).<sup>124</sup> Although there are few overt syndromes recognized in the horse that are specifically caused by *S. aureus*, toxins that may be important for disease in the horse include the four hemolysins, toxic shock syndrome toxin-1 (TSST-1), exfoliative toxins, and leukocidin ([Table 2-3](#)). For example, cellulitis induced by *S. aureus* in the horse may be similar to wound-associated toxic shock in humans. Toxic shock syndrome is a disease of increased capillary permeability characterized by hypotension, hypoalbuminemia, and edema. The toxins of *S. aureus* work in concert to (1) induce massive release of cytokines, (2) increase sensitivity to cytokines, and (3) damage endothelial cells directly. The superantigen toxin of *S. aureus* forms a bridge between the MHC receptor on macrophages and the T cell receptor. This bridge results in a massive release of interleukin-2 with the downstream effect of T cell proliferation and induction of Type 1 cytokines that stimulate release of pro-inflammatory cytokines from macrophages. Exfoliative toxin, which induces T cell proliferation, and TSST-1 have been identified in equine *S. aureus* isolates associated with severe phlegmon and metritis.<sup>125,126</sup>

The enhanced virulence displayed by community-acquired methicillin resistant *Staphylococcus aureus* (CA-MRSA) has been associated with the cytotoxin Panton-Valentine leukocidin (PVL), which is a  $\beta$ -pore former that causes enhanced spread through skin necrosis.<sup>127,128</sup> PVL has been identified in almost all CA-MRSA strains, but a causal role in enhanced virulence is still subject to debate; recent work with this toxin was not proved in in vivo models.<sup>129</sup> Other toxins, such as arginine catabolic mobile elements (ACMEs) and phenol soluble modules (PSMs), are under intense scrutiny. Deletion of ACME from MRSA strains greatly decreased in vivo virulence, and acquisition of this genetic element likely confers a more robust ability to colonize over non-ACME strains, giving rise to an epidemic-prone bacterial clone.<sup>128-130</sup> The PSM- $\alpha$ protein demonstrates enhanced destruction of white blood cells.<sup>127</sup>

### CLOSTRIDIUM INFECTIONS

*Clostridium* bacteria mediate clinical disease by producing exotoxins. The *Clostridium* bacteria causing botulism and tetanus excrete neurotoxins to which horses are highly susceptible. The main toxins of botulism (BNT) and tetanus (TNT) are remarkably similar even though both toxins exert effects that appear to be polar opposites, with botulism causing a flaccid paralysis and tetanus a spastic paralysis.<sup>131</sup> Both toxins share amino acid sequences of metalloproteinases that are most similar to zinc-requiring endopeptidases. With botulism there are six serologically different neurotoxins, with most reports in horses caused by type B toxin, although A, C, and D have also been identified.<sup>131-135</sup> There is only one tetanus neurotoxin that is responsible for the clinical signs of spastic paralysis.

Neurotoxin is secreted as a progenitor and must be cleaved by proteases (trypsin) to the derivative toxin to produce clinical signs. The active toxin consists of a light and heavy chain (A-B type toxin) that mediates paralysis by blockage of acetylcholine esterase in a three-step process.<sup>61,136</sup> The first step is the rapid step, which is involved in recognition by the neurotoxin of the receptor on the nerve and rapid binding. In the second, translocation occurs as the active site of the molecule is internalized into the nerve cell ending by endocytosis. The acidified vesicle induces a conformational change in the toxin so that it can be translocated to the cytosol. The third and final step is the slow step, wherein cell neuroproteins called *synaptopeptidases* are cleaved and acetylcholine release prevented. Neurotoxin cleaves the proteins synaptobrevin (SNAP), synaptosome associated membrane proteins (VAMP), and syntaxin, which are involved with neurotransmitter release, exocytosis of the neurotransmitter vesicle, and vesicle-cell membrane fusion, respectively. The inactivation of one or more of these proteins accounts for the prevention of release of synaptic vesicles. The different botulinum neurotoxins exhibit variable specificity to these proteins. Types B, D, F, and G are active against VAMP, whereas A, C, and E are active against SNAP, and C is the only form that cleaves syntaxin.

The difference in clinical signs noted between the *C. tetanus* and *C. botulinum* is a reflection of the binding and level of activity of the respective toxin. *Clostridium botulinum* binds

to peripheral nerves and *C. tetanus* to cells within the CNS. Further, *C. botulinum* toxin binding results in prevention of downstream release of other neurotransmitters, such as  $\gamma$ -aminobutyric acid. Injection of *C. tetanus* toxin intravenously in low doses results in flaccid paralysis.

TABLE 2-3

<b>Mechanisms of Virulence of <i>Staphylococcus aureus</i></b>	
<b>Factor</b>	<b>Mechanism of Action</b>
Toxic shock syndrome toxin	Hemolysin
Exfoliative toxin	Hemolysin, T cell proliferation
Leukocidin	Hemolysin
Superantigen	Cross linking and activation of macrophages and T cells
Staphylokinase	Plasminogen activator (lysis of fibrin clots)
$\alpha$ toxin	Damage to erythrocytes, skin, nerve, lethal  Edema formation: forms pores in cells, activation of arachidonic acid cascade and release of procoagulant factors.
$\beta$ hemolysin (Sphingomyelinase C)	Toxic to erythrocytes
$\delta$ toxin	Erythrocytes, cellular
$\gamma$ -hemolysin	Degranulation of leukocytes
Leukocidin	Degranulation of leukocytes
Panton-Valentine leukocidin	Pore former in white blood cells; skin necrosis
Arginine catabolic mobile elements	Increased colonization of community-acquired methicillin resistant <i>Staphylococcus aureus</i> (CA-MRSA)
PSM-alpha	Enhanced destruction of white blood cells in CA-MRSA

The main pathologic features of disease cause by *C. perfringens* are edema, necrosis, and death regardless of the site of action.<sup>136</sup> Toxins elaborated by these clostridia include both lethal and nonlethal toxins that cause necrosis and hemolysis and frequently contain lecithinases and lipases. *Clostridium perfringens* has four major lethal toxins, including an enterotoxin and three minor toxins. Thus far genetic characterization of equine isolates associated with diarrhea indicate that the majority are type A, the toxic effects of which are mediated in part by  $\alpha$ -toxin.<sup>137</sup> The *cpe*-toxin or enterotoxin has been detected by enzyme-linked immunosorbent assay (ELISA) in approximately 16% to 19% of equine isolates, so disease has been linked to both enterotoxigenic type A and nonenterotoxigenic type A strains.<sup>21,138</sup> There are individual case reports of neonatal diarrhea associated with Type B ( $\beta$  and  $\epsilon$  toxins), Type C ( $\beta$  toxin), and Type D ( $\epsilon$  toxin) strains that also carry the  $\alpha$  toxin.<sup>139,140</sup> Table 2-4 is a summary of the mechanisms of actions of the toxins of *Clostridium perfringens*.<sup>136,141-145</sup>

*Clostridium difficile* has five toxins, although disease causation is thought to rely on the production of toxins A and B.<sup>146,147</sup> The evidence to date indicates that both toxin A and B mediate the pathogenesis of *C. difficile* diarrhea.<sup>147</sup> Research suggests that the formation of the classic pathologic lesion, the pseudomembrane, is a result of the combined actions of toxin A, toxin B, and interleukin-8. Classically, toxin A is considered an enterotoxin and lethal, whereas toxin B is a virulent cytotoxin. Toxin A appears to be the primary mediator of fluid accumulation; injection of toxin A results in fluid accumulation, cell necrosis, and recruitment of inflammatory cells.<sup>148,149</sup> One mechanism of this fluid accumulation appears to be by interruption of actin filaments and destruction of tight junctions. Toxin A also results in neutrophil recruitment, and evidence suggests that this is mediated through the direct action of the toxin on macrophages to release interleukin-1, tumor necrosis factor  $\alpha$ , and leukotrienes. In cell culture toxin A can cause interleukin-8 secretion (a potent recruiter of neutrophils), cell detachment, and apoptosis of separated cells. This direct activation of macrophages and secretion of IL-8 is through a calcium- and calmodulin-dependent mechanism that results in direct nuclear upregulation after nuclear translocation of transcription factors NF- $\kappa$ B and AP-1.<sup>148</sup> Toxin B is more cytotoxic than toxin A, especially to human epithelial cells.

TABLE 2-4

<b>Mechanisms of Virulence of <i>Clostridium perfringens</i> Toxins</b>	
<b>Factor</b>	<b>Mechanism of Action</b>
$\alpha$	Zinc metalloproteinase: hemolysis, lethality through cardiovascular collapse and death, disruption of endothelium and erythrocytic cell membranes by <i>hydrolyzation</i> of lecithin and sphingomyelin, platelet aggregation. Stimulates the release of massive amounts of inflammatory cytokines. Activation of coagulation, aggregation of red blood cells, which occurs throughout body, including muscle cells, which results in myositic syndromes
$\beta$	Massive catecholamine release with drop in heart rate and blood pressure. Forms pores especially in neurons, resulting in neurotoxicity
$\epsilon$	Pore former within neuronal cell membrane, resulting in irreversible cell membrane damage and death
Enterotoxin	Change in ion movements of enterocytes affecting cellular metabolism
$\beta$ -2	Mechanism of action in dispute; associated with enteritis of large animals

## CELL DEATH

Apoptosis is a distinctive morphologic process that results in cleavage of nuclear material and scavenging of unwarranted cells without immune activation.<sup>150</sup> Apoptosis or programmed cell death is an important pathway for complex organisms to deal with damaged and diseased tissue. Apoptosis avoids the release of the tissue-damaging enzymes and nonspecific elimination of tissue that occurs in cellular necrosis. Several bacteria have modulated the host apoptotic pathways for enhancement of survival.<sup>151</sup> *Shigella flexneri*, *S. typhimurium*, and toxins of *S. aureus*, *Pseudomonas* spp., and *C. diphtheriae* have demonstrated programmed cell death as a consequence of cellular infection or exposure.<sup>150,152</sup> The protein of *S. flexneri*, IpaB, induces apoptosis by binding to and activating the cellular enzyme caspase 1, which induces apoptosis of macrophages.<sup>108</sup> *Staphylococcus aureus*  $\alpha$  toxin, which is similar to listeriolysin O (LLO) presumably escapes the macrophage after engulfment and induces host cell apoptosis.<sup>124</sup> The TSST toxin of *S. aureus* induces B cell apoptosis and blocks immunoglobulin production.

## ☞ PATHOGENESIS OF FUNGAL INFECTIONS

Of the 250,000 species of fungi, fewer than 200 are true pathogens.<sup>1</sup> Superficial mycoses affect the hair shaft and the superficial epidermis. Cutaneous mycoses (dermatophytosis) infect the epidermis, dermis, hair, and nails of animals, and *Microsporum*, *Trichophyton*, and *Epidermophyton* spp. are the most commonly associated pathogenic genera. Subcutaneous tissues can become infected with *Sporothrix*, *Conidiobolus*, *Basidiobolus* spp., and members of the Dematiaceae fungi, including the *Chromoblastomycosis*, *Mycetoma*, and *Phaeoerythromycosis* spp. infections. Most of these infections are introduced by penetration through skin or opportunistic invasion of damaged skin surfaces. *Histoplasma capsulatum*, *Coccidioides immitis*, *Blastomyces dermatitidis*, and *Paracoccidioides brasiliensis* are the four most important fungal pathogens that can cause systemic infection. The most common opportunistic infections include *Candida albicans*, *Aspergillus* spp., *Cryptococcus neoformans*, *Mucor* spp., and *Pneumocystis carinii*.

## ☞ FACTORS THAT ENHANCE ENTRY OF FUNGI

### ADHERENCE

Fungal virulence factors may be more complex than those of bacteria because of the higher degree of opportunism that occurs with a change in host status. There may be subtle factors that, combined with host status, result in a certain fungus attaining a virulent state. For instance, the typical fungal wall is composed of three major polysaccharides: mannose;  $\beta$ -1,3 and  $\beta$ -1,6 linked glucans; and chitin. Chitin mutants in *C. albicans* are less virulent when tested in rodent models than are wild-type fungi.<sup>153</sup> Further, a mutant *C. albicans* that cannot synthesize complex mannose oligosaccharides does not adhere to other yeast and epithelial cells and has lost virulence in a guinea pig model.<sup>154</sup> Both of these mutants can proliferate in vitro normally, and whether or not this is an actual virulence factor is unclear.

As with bacteria, cellular adherence is an important prerequisite for infection and colonization of the host. Adhesins have been identified in *C. albicans* and *B. dermatitidis*. Two genes have been associated with adhesion in *C. albicans*. The first is a glycoprotein that has sequences consistent with agglutinating activity. Transformation of this gene into other nonadherent fungal species results in adhesion of the transformed yeast to cells.<sup>155</sup> *Candida albicans* also has integrin-like proteins, the disruption of which results in diminished hyphal growth, adhesion to cells, and loss of virulence in mice.<sup>156,157</sup> The *B. dermatitidis* adhesin mediates binding to human monocyte-macrophages through the CD14 receptor.<sup>158</sup>

## ☞ FACTORS THAT ENHANCE SPREAD OF FUNGI

### EVASION OF IMMUNE DEFENSES

#### CAPSULE

Many fungi have polysaccharide capsules that, like bacteria, help resist phagocytosis and immune activation. The capsule of *C. neoformans* inhibits leukocyte accumulation, cytokine secretion, and macrophage phagocytosis.<sup>159</sup> Mutants without capsule are highly infective and avirulent. As indicated earlier, many fungi are engulfed by macrophages, and intracellular survival is mediated by virulence factors. Macrophages are decimating cells for *C. albicans*,<sup>160</sup> *H. capsulatum*,<sup>161</sup> and *B. dermatitidis*. *Histoplasma capsulatum* is primarily a yeast in vivo, and this form infects macrophages. Phagolysosomal fusion occurs at a normal rate,<sup>162</sup> but blockage of acidification of the phagolysosome occurs.<sup>163</sup>

### ADAPTATION TO HOST ENVIRONMENT

#### MORPHOLOGY AND TEMPERATURE

Adaptability to the host environment is also a trait that enhances fungal virulence. Fungal dimorphism, which is the ability to adopt another morphologic state, is clearly tied to virulence. Mutants of *C. albicans* that cannot switch to the hyphal form are avirulent in certain in vivo models, although both forms likely contribute to pathogenesis.<sup>164</sup> A second adaptation is called phenotypic switching, in which colonies of fungi change during in vitro growth. *Candida albicans*, *C. neoformans*, and *H. capsulatum* all display phenotypic switching, and these different phenotypes are associated with degrees of virulence.<sup>165,166</sup> *Histoplasma capsulatum* spontaneously gives rise to mutants that have less capsule, are less virulent, and are not cytotoxic to macrophages.<sup>167</sup> The signal for dimorphic fungi to change form is usually temperature change. Many fungal species germinate within the host with increased temperature, allowing for dissemination within the host. Calcineurin is found in many yeast and mammalian cells, and in *C. neoformans* this protein mediates the ability of this fungus to grow at 37°C.<sup>168</sup> Temperature and heat shock are also mediated by the calcium-dependent protein cyclophilin B in *Aspergillus*.<sup>169</sup> Adaptation to mammalian pH is genetically controlled in *C. albicans*. Mutants display abnormal cell morphology at physiologic pH ranges.<sup>170</sup>

#### NUTRIENTS

Nutrient requirements that affect virulence include primarily melanin, iron, and calcium. Melanins are present in the wall of *C. neoformans*, and melanin can scavenge ROI intermediates,

making the organism resistant to the oxidative burst of neutrophils.<sup>171</sup> Pathogenic fungi have siderophores and high affinity ferric iron reductase to acquire iron from low iron environments.<sup>172,173</sup> *Histoplasma capsulatum* secretes a calcium-binding protein that enhances calcium uptake from calcium-poor environments.<sup>174,175</sup> Without this protein *H. capsulatum* cannot form colonies and does not survive in cultured macrophages.

## ☞ DAMAGE TO HOST TISSUES

### TOXINS

Exposure to both pathogenic and saprophytic fungi is an everyday occurrence. Respiratory contamination and infection are important for many pulmonary species, but skin penetration and dissemination from necrotic gut are important portals for large animals also. Dissemination after the initial infection is dependent on previous damage to host tissues, deeper mechanical penetration, or actual invasion of new tissues. *C. albicans* can actually grow through and replace cell membranes.<sup>160</sup> True molds invade blood vessels and grow along the intima of the vessels. Fungi secrete many degradative enzymes, including proteinases, phosphatases, and DNases in order to surmount structural barriers.<sup>176</sup> A group of genes called *secreted aspartyl proteinase* (SAP) genes allow more persistent colonization of host surfaces and deeper penetration.<sup>177</sup>

When *C. immitis* invades the host, the fungi form endospores. These endospores secrete a proteinase and a urease that likely aid in the breakdown of pulmonary tissues.<sup>178-180</sup> The two proteinases of *A. fumigatus* break down elastin, a major component of lung tissues.<sup>181,182</sup> Phospholipase activity has been demonstrated in *C. albicans*, *C. neoformans*, and *A. fumigatus*.<sup>183</sup> Strains of *Candida* spp. with high amounts of this enzyme have higher virulence,<sup>184</sup> and abolishing this activity results in decreased adherence of the organism.<sup>185</sup> Host eicosanoids enhance fungal colonization. Recent evidence demonstrates production of eicosanoids by both dermatophytosis and systemic fungi.<sup>186</sup>

### APOPTOSIS

Fungi induce apoptosis, which may be due either to the direct effect of a fungal toxin or secondary to host cell cytoskeleton rearrangements.<sup>187</sup> The gliotoxin of *A. fumigatus* can induce DNA fragmentation and apoptosis in macrophages.<sup>188</sup> This toxin also has many other immunosuppressive qualities, which include inhibition of the neutrophil respiratory burst and T cell activation.

## MECHANISMS OF ESTABLISHMENT AND SPREAD OF VIRAL INFECTIONS

J. Lindsay Oaks

Viral infections are responsible for some of the most medically and economically important diseases of horses. A few notable examples include influenza, equine rhinopneumonitis and abortion (Herpesviridae), African horse sickness (Reoviridae), equine infectious anemia (Retroviridae), various encephalitis viruses (Alphaviridae), and most recently in the United States

the West Nile virus (Flaviviridae). Specific therapy of viral infections remains a significant challenge because antiviral drugs are generally ineffective, impractical, or prohibitively expensive for the treatment of horses. Treatment of most viral infections focuses on supportive care of the affected organ systems and control of secondary complications such as bacterial infection. Currently control of most clinically significant viral diseases in horse populations relies on vaccination, quarantine, or even destruction of infected animals.

Despite the great significance of some viral infections, recognizing that many equine viruses are ubiquitous, weakly pathogenic, or not associated with any known disease under normal circumstances is also important. Some examples include equine adenovirus,<sup>1</sup> respiratory and enteric reoviruses<sup>2</sup> (the term *reo* is derived from the acronym for respiratory enteric orphan, indicating that these isolates have not been associated with disease), and equine herpesvirus (EHV) type 2.<sup>3</sup> Some host-virus relationships may be mutualistic in that virally derived genetic elements are theorized to benefit the host by facilitating genetic variability and evolution.<sup>4</sup> Thus many viruses are of no practical clinical significance, and no control efforts are warranted. For this reason, the veterinarian should never assume that the recovery of a virus from a clinical specimen is significant without proof that the virus can cause the disease in question.

Veterinary virology is a rapidly changing field. New diseases continue to emerge or be discovered; a dramatic example is the Hendra paramyxovirus that appeared in Australia in 1994, killing horses and human beings.<sup>5</sup> More recently, another paramyxovirus, the Salem virus, has been identified in the United States, although the clinical importance of this virus is unclear.<sup>6</sup> Less dramatic, but of more relevance to most equine veterinarians, is the association of bovine papillomavirus with sarcoids.<sup>7,8</sup> A number of equine diseases occur in which viral involvement has yet to be excluded, including Theiler's hepatitis<sup>9</sup> and lymphosarcoma.<sup>10</sup> Viral origins also likely will be discovered for diseases in which viruses were not suspected previously to play a role; in human beings and mice, viruses have been proposed to have a role in everything from diabetes to obesity.<sup>11,12</sup> However, the greatest advances in veterinary virology are in understanding the molecular biology of viral replication, virus-cell interactions, and virus-host interactions. Related advances in molecular biology techniques, such as PCR and immunohistochemistry, also are providing sensitive, specific, and rapid tools for the diagnosis of viral infections. In the realm of antiviral drugs, aggressive searches are ongoing for effective and economical drugs for treatment of human beings, and in the near future antiviral drugs likely will be a realistic therapeutic option for equine veterinarians.<sup>13,14</sup> Finally, significant advances in the design of vaccines likely will improve the efficacy of immunization.

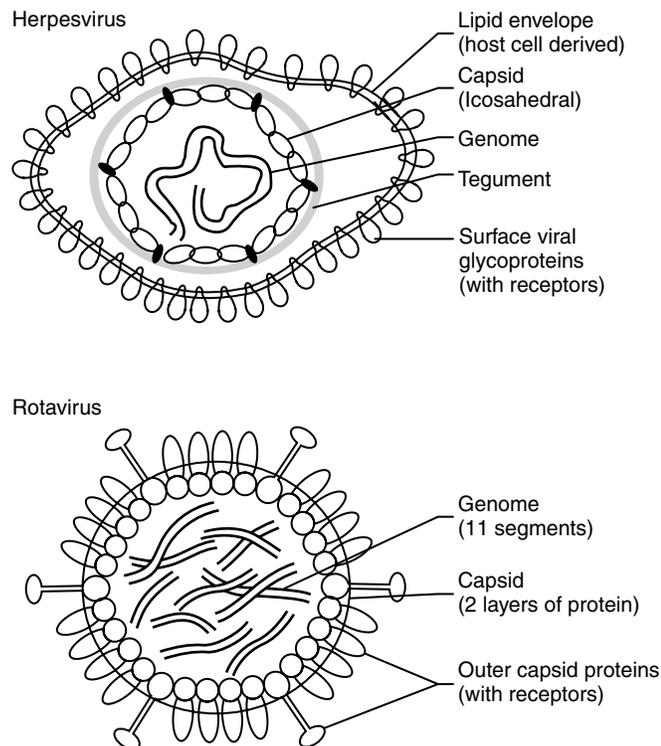

This chapter outlines the general ways that viruses cause disease and describes the most important virus-cell and virus-host interactions that result in pathologic conditions. Although the focus is on equine viruses whenever possible, the principles described are generally not species dependent, and no attempt is made to limit the discussion to recognized equine viral pathogens or diseases. Discussion of a particular mechanism or virus also should not be taken to suggest that this mechanism or type of virus has been documented in horses. When possible, supporting references have been selected to include review articles or texts for additional information about key concepts.

## ☞ VIRUSES AND VIRUS-CELL INTERACTIONS

An in-depth discussion of viral structure, taxonomy, and replication is beyond the scope of this chapter, and the reader is referred to textbooks of veterinary or human virology for more detailed information.<sup>15,16</sup> However, a brief overview is presented to emphasize those features that have clinical relevance.

### VIRUS STRUCTURE, TAXONOMY, AND REPLICATION

The fundamental structure of all viruses is a DNA or RNA genome enclosed by a coat of protein called the *capsid* (Figure 2-4). For viruses that are enveloped, the capsid is enclosed further by a host cell–derived lipid membrane into which viral proteins have been incorporated. In addition to protecting the viral genome, the capsid and other associated structural proteins (e.g., matrix proteins) are important for virus assembly, packaging the viral genome, releasing the genome into a target cell, and for nonenveloped viruses, providing receptors that bind to host cells. For enveloped viruses the receptors are incorporated into the lipid membrane. The primary clinical significance of these features is that enveloped viruses, because of their fragile lipid membrane, are highly susceptible to inactivation by heat, desiccation, or detergents, and transmission typically requires direct exchange of body fluids, short distance aerosols, or arthropod vectors.

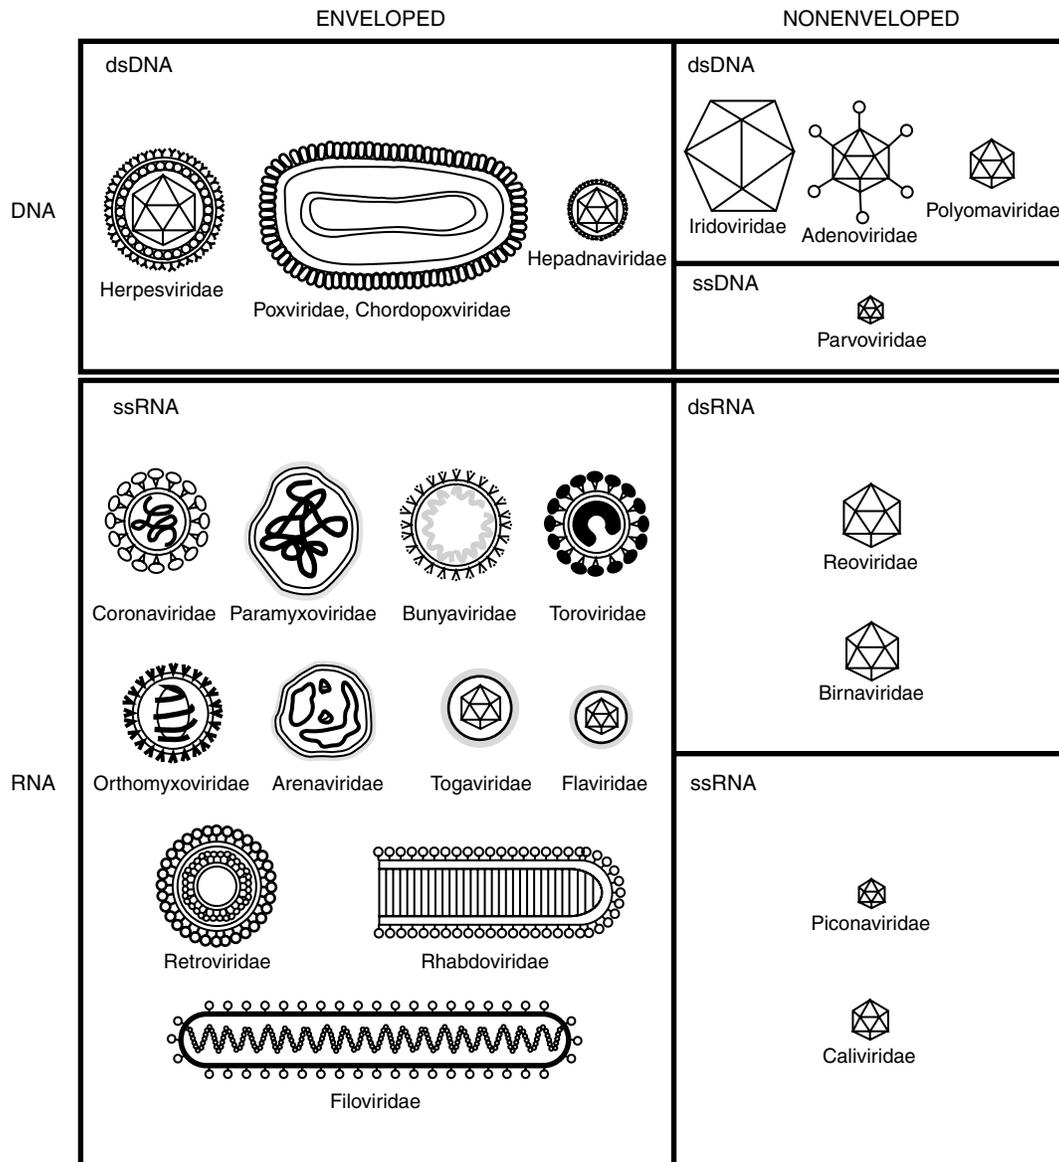

**FIGURE 2-4** Schematic representations of basic viral structure. The basic structure of an enveloped virus is shown by the drawing of a herpesvirus. The basic structure of a nonenveloped virus is shown by the drawing of a rotavirus.

In contrast, nonenveloped viruses (e.g., equine rotavirus) are resistant to physical inactivation, and environmental contamination is more likely to be a significant factor in their transmission.

The composition of the viral genome is an important basis for virus classification (Figure 2-5). The type of viral genome also determines the strategies required to replicate the genome and transcribe messenger ribonucleic acid (mRNA; Figure 2-6). Viral genomes may be single-stranded RNA, double-stranded RNA, single-stranded deoxyribonucleic acid (DNA), or double-stranded DNA. The genomes of single-stranded RNA viruses may have positive polarity, in which the genome also serves directly as mRNA for translation of viral proteins. To replicate genomes, these viruses must first synthesize a strand of complementary RNA that can be used as a template to replicate genomes and transcribe new mRNA. Retroviruses are a subset of single-stranded, positive polarity RNA viruses that use their RNA genomes as templates to produce double-stranded DNA, which in turn is used for the transcription of mRNA and new viral genomes. Single-stranded RNA viruses may also have negative polarity, in which the genome is antisense to mRNA, and synthesis of a complementary RNA strand is required to serve as mRNA and as a template for new genomes. The clinical significance of these types of replication strategies is that they require polymerases and other enzymes not normally found in eukaryotic host cells. Eukaryotic cells, which exclusively use DNA as genetic material and as templates for mRNA transcription, use DNA-dependent DNA polymerases and DNA-dependent RNA polymerases for these functions, respectively. RNA viruses require RNA-dependent RNA polymerases to replicate or transcribe RNA, or RNA-dependent DNA polymerase (reverse transcriptase) to produce DNA from an RNA template. These unique viral enzymes are important targets for antiviral drugs because they can be used selectively to inhibit viral replication. The most common antiviral drugs currently available are nucleotide analogs that are used selectively by viral but not cellular enzymes and result in defective DNA or RNA.<sup>17,18</sup> Although most DNA viruses follow the eukaryotic pattern of replication and transcription, in many cases these viruses produce homologs of host cell enzymes that are sufficiently unique to make them selectively susceptible to nucleotide analogs. Additional targets for current and future antiviral agents are viral proteins used for translation and post-translational protein processing.<sup>17</sup>

Viral polymerases and the genetic organization of viruses are also important for rapid antigenic variation and immunologic evasion. Viral RNA polymerases are low fidelity and lack proofreading functions and thus randomly introduce errors into new RNA at an average rate of about one nucleotide mismatch per 10,000 bases copied.<sup>19</sup> Therefore in a population of viruses, virtually every individual virus differs slightly, and this population is referred to as a *quasi species*. Although many of these mutations are neutral or even deleterious, in the face of selective pressures such as the host immune response or antiviral drugs, this genetic plasticity allows rapid development of resistant virus populations.<sup>20</sup> Secondary structures or certain sequences in the viral genome may facilitate polymerase errors further at selected regions that are important for immune evasion, such as in sequences that code for neutralizing epitopes.<sup>19</sup> The genomes of some viruses, such as influenza, comprise separate segments, which allows reassortment of entire gene segments and sudden and dramatic changes in antigenicity.<sup>21</sup>

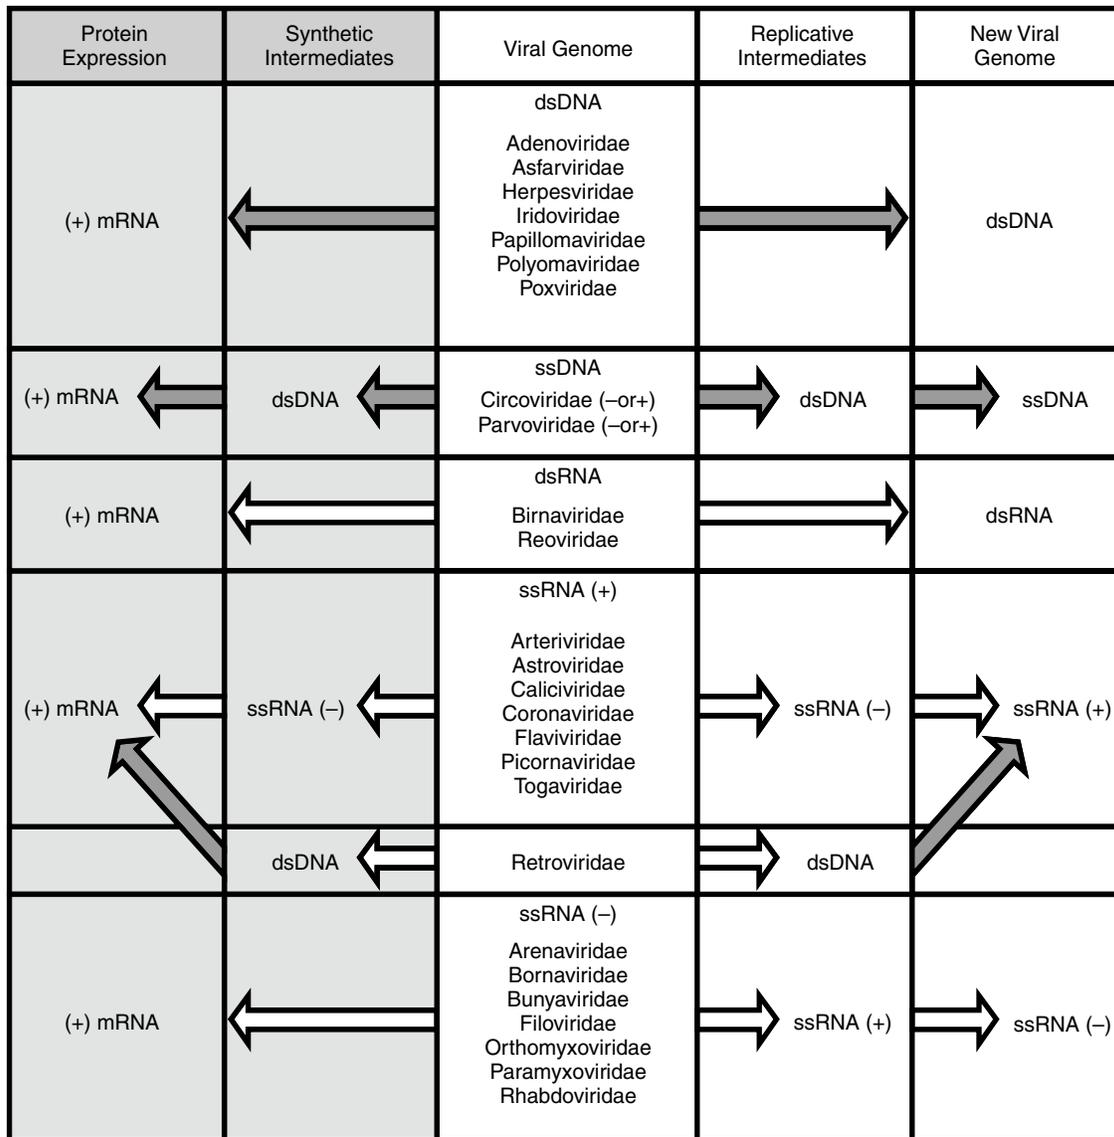

**FIGURE 2-5** Virus family classification based on genome composition and presence of envelope or absence of envelope. The relative size of the viruses to each other is also shown.

## VIRUS LIFE CYCLE

All viruses are obligate intracellular parasites. Viral replication can occur only within living cells, and all viruses to some extent depend on the host cell synthetic machinery. The life cycle of all viruses includes the following steps: attachment to the target cell, entry into the cell, uncoating and release of the viral genome, transcription and translation of viral proteins, replication of the viral genome, assembly of new virions, and release of progeny virions<sup>15,16</sup> (Figure 2-7). Although the biochemistry of these steps is beyond the scope of this discussion, recognizing that they are all specific, energy-requiring interactions between the virus and the host cell is important. The inability of the virus to interact appropriately with a cell at any of these steps prevents replication in that cell type and defines the tropism of the virus. All of these steps are also important potential targets for antiviral drugs and host immune responses.

One of the most critical virus-cell interactions is attachment and entry. This initial step is one of the most important determinants of species susceptibility and host cell tropism and is an important target for antiviral antibodies that neutralize infectivity. Attachment and entry requires a specific interaction between a viral receptor and a cell-surface protein that acts as the host cell receptor. Many viruses also require interaction with additional cell surface molecules (co-receptors) for successful attachment and entry. Influenza provides a good example of this process. The influenza virus hemagglutinin molecule binds to sialic acid residues of cell-surface glycolipids or glycoproteins. Binding induces a conformational change in the hemagglutinin protein, exposing a cleavage site to a host cell protease. Cleavage of hemagglutinin induces fusion of the viral envelope to the host cell membrane and release of the capsid into the cytosol.<sup>22,23</sup> Equine influenza does not infect human beings because the hemagglutinin molecules do not recognize human sialic acid molecules.<sup>24</sup>

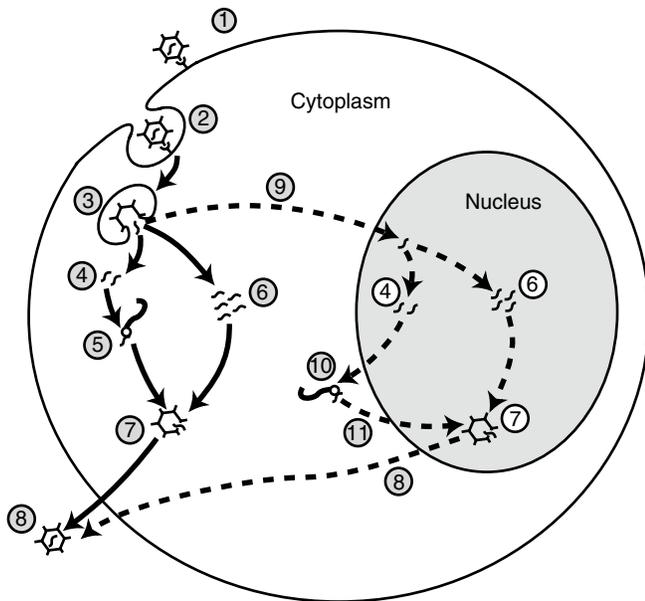

**FIGURE 2-6** Summary of the main virus families that infect vertebrates and general strategies employed by these viruses to produce mRNA for protein expression and to replicate genomes. Required intermediate molecules are indicated. *White arrows* indicate the need for unique viral polymerases, including RNA-dependent RNA polymerase and RNA-dependent DNA polymerase (reverse transcriptase). *Dark arrows* indicate the use of cellular polymerases or viral homologs of cellular polymerases. *ds*, Double-stranded; *ss*, single-stranded; (+) for RNA = positive polarity, polarity of RNA used for protein translation; (+) for DNA = coding strand, sequence same as for (+) RNA; (- or +) DNA = contains single strands of DNA of both polarities. (Modified from Baltimore D: Expression of animal virus genomes, *Bacteriol Rev* 35:235-241, 1971.)

Within the horse equine influenza infection is restricted to respiratory epithelial cells by the distribution of the appropriate host cell protease.<sup>22</sup> Viruses may infect other cell types by using a different host cell receptor for attachment and entry. Highly pathogenic strains of avian influenza are able to spread systemically because of mutations in the hemagglutinin that allow cleavage by host cell proteases found on cells outside of the respiratory tract.<sup>22</sup> Other ways in which a virus can infect multiple cell types are using a host cell receptor that is present on different cell types or infecting a single cell type that is present in different tissues (e.g., macrophages and vascular endothelium). Host cell receptors also may be present in an

age-dependent fashion, accounting for age-related differences in susceptibility to diseases such as polioencephalomyelitis and rotaviral enteritis.<sup>25,26</sup>

Once the viral nucleocapsid gains entry to the cytosol of the cell, the viral genome is released through the process of uncoating. After uncoating, depending on the genetic composition of the virus, the viral genome localizes to the appropriate regions of the cell for replication and mRNA transcription. DNA viruses typically replicate genomes and transcribe mRNA in the nucleus and then transport the mRNA to the cytoplasm for translation. RNA viruses typically replicate, transcribe mRNA, and translate viral proteins in the cytoplasm. These

**FIGURE 2-7** Schematic representation of the general virus life cycle. Both RNA and DNA viruses share the initial steps, including attachment (1); entry/fusion (2); and uncoating and release of viral genome into the cell (3). *Solid arrows* indicate remaining steps for RNA viruses, which all occur in the cytoplasm, including transcription of mRNA (4); translation of viral proteins (5); replication of the viral genome (6); assembly of new virions (7); and release of progeny virions (8). *Dashed arrows* indicate steps for a DNA virus. The life cycle is similar except that the DNA genome is translocated to the nucleus (9) for transcription (4) and replication of viral genomes (6). Viral mRNA is then translocated back to the cytoplasm for translation (10), and newly synthesized viral proteins are translocated back to the nucleus (11) for assembly (7); new virions are then released from both nuclear and cytoplasmic membranes (8).

sites of replication account, respectively, for the location of viral inclusion bodies that are diagnostically useful in histopathologic sections. In general, the first viral proteins expressed are regulatory factors, enzymes, and polymerases required for initiation of viral gene expression and diversion of host cell resources to viral replication. Subsequently, viral structural proteins are expressed and assembled with new viral genomes into virions. Enveloped viruses require the additional step of acquiring a lipid envelope by budding the nucleocapsid through areas of the nuclear or plasma membrane into which viral proteins have been incorporated. Viruses then are released, usually in association with death of the host cell, into the extracellular space and blood. Some viruses, such as herpesviruses and paramyxoviruses, also may transfer progeny virions directly into an adjacent cell by inducing fusion between the two cells, a strategy that allows the virus to avoid contact with neutralizing antibodies in the extracellular space.

### VIRUS-CELL INTERACTIONS

After a cell is infected, the process of viral replication may have a number of effects on the host cell. Viruses have evolved a number of strategies and host cell interactions to facilitate their own replication and circumvent host responses that may eliminate the infected cell. In general, virally driven effects

favor viral replication, transmission, and persistence and often result in death or dysfunction of the infected cell. Cellular or host responses generally favor control and elimination of the virus from the host. These responses may block viral replication, may initiate innate and specific host immune responses, and are frequently evident clinically as inflammation.

### CELL CYCLE AND VIRAL REPLICATION

Viral replication requires that the host cell support high levels of nucleic acid replication, mRNA transcription, and protein translation. The growth and division phase of the cell cycle (S phase) is most suited for this purpose. However, many cells infected by viruses already are differentiated fully and in the resting phase ( $G_0$  or  $G_1$  phase). Some of the more complex viruses, such as herpesviruses, poxviruses, and adenoviruses, have virally encoded proteins that activate the cellular systems for growth and division, thus manipulating the cell to create an environment favorable for viral replication. This ability allows tropism for cells that otherwise might not be able to support viral replication. The “immediate early” genes expressed by herpesviruses, which initiate viral replication in differentiated cells, induce progression of the cell cycle from  $G_0$  to the S phase.<sup>27,28</sup> Other viruses, particularly the genetically simpler viruses such as parvoviruses, lack the ability to activate resting cells.<sup>27,29</sup> Thus their tropism is restricted to cells that naturally go through a growth and division phase, such as intestinal crypt cells and hematopoietic cells. Consequently, parvoviral diseases such as feline panleukopenia typically involve replication in the rapidly dividing cells of the intestine (diarrhea) and bone marrow (pancytopenias). If infection occurs in utero during development of tissues such as the cerebellum, neurologic disease also may be observed.

### CELL KILLING

Cells that replicate virus often are killed as a direct consequence of infection. One mechanism by which viruses kill cells is lysis, often associated with the release of progeny virions. Insertion of viral proteins into cell membranes, budding, direct toxicity of viral proteins, and diversion of normal host cell homeostatic processes to viral replication may result in death of the cell.<sup>15,16,30</sup> Viruses also may activate the cellular self-destruct mechanism of programmed cell death (apoptosis). Although cells may induce apoptosis in an attempt to prevent completion of the virus life cycle, viruses also may use this mechanism to kill the cell and facilitate release of virions.<sup>31</sup>

### NEOPLASIA

Viral infection can cause neoplastic transformation of infected cells. The most common examples in horses include warts (equine papillomavirus) and sarcoids (bovine papillomavirus). Virally induced invasive neoplastic diseases such as leukemia or lymphosarcoma have not been recognized in the horse, unlike other species. However, these types of diseases may be identified. Viral proteins that activate the cell cycle into the growth and division phases may lead to neoplastic transformation if expressed in a cell that is not killed by the infection. Papillomavirus infections induce epithelial neoplasms (fibropapillomata) using a virally encoded protein (E5 oncoprotein) that induces proliferation of normally quiescent cells and that presumably is needed for viral replication.<sup>8</sup> The E1A oncoproteins and immediate early proteins of adenoviruses and herpesviruses, respectively, are highly oncogenic in cells that do

not allow full virus expression.<sup>32,33</sup> Adenoviral and herpesviral infections in horses currently are not recognized as oncogenic. The lack of oncogenic transformation by these viruses is most likely because abortive infections may not occur in vivo, transformed cells are always removed by the immune system, or the requisite co-factors for transformation are not present. As an example of the role of co-factors, infection of human beings with human herpesvirus 4 (Epstein-Barr virus, the cause of infectious mononucleosis) is not associated commonly with neoplasia in North America or Europe, whereas infection with this virus in Africa is associated strongly with Burkitt's lymphoma and in China with nasopharyngeal carcinoma.<sup>34</sup>

Oncogenic retroviruses, including leukemia and sarcoma viruses, induce neoplastic transformation in several ways but in all cases do so by integration into the host cell genome and activation of cellular oncogenes.<sup>35</sup> Specifically, a retrovirus and its viral promoter sequences may insert upstream from and activate a normally quiescent cellular oncogene in the process of viral gene expression. Other retroviruses, such as the bovine leukemia virus, produce a virally encoded protein, tax, which transactivates and upregulates the expression of cellular oncogenes. These are believed to be the primary mechanisms of transformation by the leukemia viruses. Integration of the retroviral genome also may inactivate by insertion host cell repressors required to actively suppress the expression of cellular oncogenes. Some retroviral genomes, such as those of the rapidly transforming sarcoma viruses, may transform the cell by acquiring cellular oncogenes that are then co-expressed along with other viral gene products during replication.

### INTERFERENCE WITH DIFFERENTIATED CELL FUNCTION

Although not described in horses and still poorly documented in other species, such as humans, some viral infections are theorized to play a role in chronic diseases such as diabetes and obesity. For example, the hepatitis C virus may infect the B cells of the pancreas and interfere with the production of insulin.<sup>11</sup> In experimental infections of rodents, canine distemper virus and Borna disease virus cause obesity, possibly by infection of the hypothalamus and downregulation of leptin receptors.<sup>12</sup> Although the role of viruses in these types of infections is still controversial, advances in the detection of viruses are likely to uncover unusual and previously unsuspected roles for viruses in chronic diseases, including those of horses.

### INTERACTIONS WITH HOST IMMUNE RESPONSES

One of the main obstacles to successful viral replication in vivo is the host immune response. In response to infection, cells can react in a number of ways to block viral replication, initiate the expansion of specific antiviral immune responses, and target the infected cell for immunologic recognition and destruction. As a result, many viruses have developed counterstrategies to block cell signals that promote these host cell responses.

Interferons induce the expression of a number of cellular proteins that inhibit viral replication in the cell. Secreted interferons similarly impart resistance to viral replication in adjacent cells and are an important mechanism for controlling the local spread of infection. Some viruses, including paramyxoviruses, adenoviruses, and herpesviruses, produce proteins that interfere with the cell signaling mechanisms required for the expression of interferon-induced proteins.<sup>36,37</sup>

One of the most important systems for recognition of virally infected cells by cytotoxic lymphocytes is endocytic

processing of viral proteins followed by expression of the resultant viral peptides on the cell surface complexed with MHC class I molecules. Viral products may interfere directly with the processing, transport, or cell surface expression of MHC I molecules or viral peptides, thereby preventing recognition by cytotoxic, CD8<sup>+</sup> T lymphocytes.<sup>36,38</sup> In antigen-presenting cells, cell surface expression of viral peptides with MHC II molecules to immune regulatory cells, mainly CD4<sup>+</sup> helper T lymphocytes and B cells, is required for initiation and upregulation of antibody- and cell-mediated antiviral immune responses. Similar interference with the processing, transport, or cell surface expression of MHC II molecules or viral peptides can interfere with antiviral immune responses.<sup>36</sup> Some herpesviruses also have been shown to interfere with recognition of virally infected cells by natural killer cells, an early, nonspecific cell-mediated immune response.<sup>39</sup>

An interesting and more recently recognized viral mechanism for interference with host immune responses is the use of virally encoded cytokine mimics. Cytokines are critical cell signaling molecules that coordinate and regulate the development of host immune responses. Some viruses, including poxviruses, herpesviruses, and adenoviruses, express cytokine homologs that mimic and interfere with the activity of interferons, interleukin-1, interleukin-8, interleukin-10, tumor necrosis factor, epidermal growth factor, and granulocyte-macrophage colony-stimulating factor.<sup>36,40</sup> Although the role of these homologs in natural disease is not clear, experimentally they can modulate immune responses and affect disease severity.<sup>36</sup>

### VIROLOGIC LATENCY

At the host level viruses may use several mechanisms to establish persistent infections and avoid immune clearance. Some persistent infections are characterized by continual replication despite the presence of antiviral immune responses. If these types of persistent infections are subclinical, they often are described as clinically latent. However, the viral dynamics at the host level should be differentiated from events at the cellular level. In cells virologic latency is a specific type of cell interaction and an important mechanism of persistence for some viruses. *Virologic latency* is defined as the presence of a viral genome that is not producing infectious virus.<sup>41</sup> The genomes of latent viruses are transcriptionally suppressed and translationally silent so that no viral proteins are expressed that may identify the cell to the immune system as infected. The definition of *latency* also stipulates that on reactivation, viral gene expression and the production of infectious progeny virions can be resumed, differentiating latently infected cells from cells infected with defective viruses.

The classic latent infection is that of the herpesviruses. For the  $\alpha$  herpesviruses, such as EHV1 and EHV4, latent infections are established in the nuclei of sensory neurons and can be maintained indefinitely, and infected animals serve as the reservoir of the virus.<sup>42-44</sup> The only detectable viral gene products in latently infected neurons are a small RNA message called *latency-associated transcripts*, which are required for maintenance of latency.<sup>41</sup> On reactivation viral nucleic acids are translocated across synapses to epithelial cells of the nasopharynx, which produce infectious virus. In adult horses the amount of viral replication in the nasopharynx is usually not sufficient to result in clinical disease.<sup>44</sup> The stimuli that induce reactivation are poorly defined, but reactivation can be induced by immunosuppression (e.g., corticosteroids) and presumably by other stressors, such as pregnancy, transport, and social stress.<sup>44,45</sup>

## ☉ MECHANISMS OF DISEASE: VIRUS-HOST INTERACTIONS

Viral interactions with individual cells are the basis for viral pathogenesis. However, for the whole animal, the severity of disease, or whether infection even results in clinical disease at all, is a much more complex interaction between the classic triad of virus, host, and environment. More specifically, these factors include viral virulence, viral spread within the animal, the intensity of direct and immune-mediated pathologic response elicited by the virus, and the ability of the virus to avoid clearance by the host. Other than the virulence of the virus, which is strictly a property of the virus, the other virus-host interactions can be influenced by the age and genetics of the host and by environmental factors such as stress and nutrition. These factors account for the observation that considerable variation in disease signs can occur among a group of animals infected with the same viral strain.

### VIRAL VIRULENCE

Certain strains of a virus are well recognized as causing more severe disease. Although many host factors may influence the severity of clinical disease, virulence per se is strictly a property of the virus. The main properties of a virus that may affect virulence include host cell tropism and replication rate. A tropism change that leads to involvement of additional tissues or facilitates virus spread generally results in more severe disease. The systemic spread of highly pathogenic avian influenza strains described earlier is one example. Outbreaks of EHV1 abortion or neurologic disease strongly suggest that EHV1 strains exist that have a tropism for these tissues compared with EHV1 strains that cause respiratory disease. However, the appropriate studies have not been performed yet to determine the exact basis for this observation. Limited studies of EHV1 genetics and virulence in mouse models have not identified differences between the abortigenic, neurogenic, and respiratory strains.<sup>46</sup> However, the severity of EHV1 respiratory disease in experimentally infected foals can be decreased by deletion of genes that facilitate cell-to-cell spread.<sup>47</sup>

An increase in the viral replication rate is usually associated with an increase in virulence, presumably because of the greater number of infected cells and amount of tissue damage. The virulence of equine infectious anemia virus strains can be correlated directly to plasma virus titers and numbers of infected cells, without any changes in tropism.<sup>48,49</sup> The molecular basis for the increased replication rate is not clear but most likely is caused by variation in viral regulatory sequences and proteins.<sup>50,51</sup>

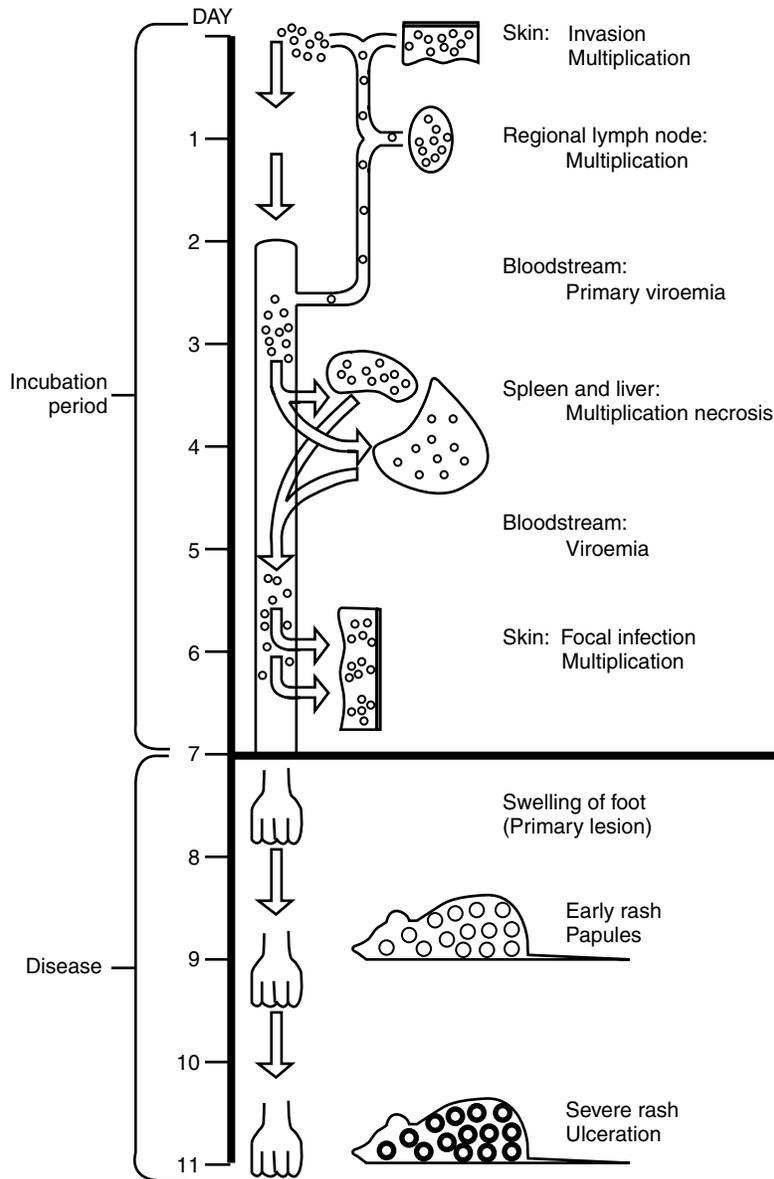

### SPREAD OF INFECTION IN THE HOST

Viral infections generally are regarded as localized or systemic. Localized viral infections are those that are restricted to a single organ system, often at the site of entry. Because infection of the tissue is direct, the incubation period for localized viral infections is usually short, often only a few days. Many infections of the skin or mucosal surfaces are localized, and examples in the horse include infections with enteric rotavirus and influenza. For influenza, virus is inhaled into the nasopharynx and replicates in epithelial cells of the upper respiratory tract and trachea. Virus is not present in the blood or tissues outside

of the respiratory tract. In general, viruses remain localized because they lack the receptors to infect cells of other tissues or circulating cells, such as monocytes or lymphocytes, that can disseminate the virus. Some viruses are temperature sensitive and remain localized because they are unable to replicate efficiently at core body temperatures. EHV3, the cause of coital exanthema, is restricted to the surface of the genitalia in horses because of its temperature sensitivity.<sup>52</sup> EHV1 and EHV4 are not temperature sensitive, however, and systemic infection may occur with these viruses. The feline respiratory herpesvirus is also temperature sensitive and normally is restricted to the cooler mucosal surfaces. However, hypothermia may lead to dissemination and multiorgan infections.<sup>53</sup> Temperature sensitivity is also a means by which some viruses, such as equine influenza and infectious bovine rhinotracheitis virus, may be attenuated for use as modified-live intranasal vaccines. Infection by the vaccine strain is limited to the cooler mucosal surfaces; the inability to spread systemically prevents sequelae such as abortion and pneumonia.<sup>54,55</sup>

Systemic infections are those in which virus is disseminated to multiple tissues by blood or lymph. This viremia may exist in the form of cell-free virions in the plasma or lymph or may be cell associated in circulating blood cells, usually monocytes or lymphocytes. The classic paradigm for a systemic infection is infection of mice with ectromelia virus<sup>56</sup> (Figure 2-8). Localized viral replication first occurs at the site of entry and in regional lymph nodes. Depending on the level of replication, clinical disease may be present. The virus then enters the blood or lymphatics and spreads to other tissues, such as spleen and liver, in which clinical disease may occur. Virus is amplified and then released again for a second, usually higher-titered, viremia that further disseminates the virus to other organs. Each viremic episode is associated with a febrile response and is the basis for the biphasic fever response associated with some viral infections. Because systemic infections require multiple steps, the incubation periods are longer than for localized infections, typically 1 to several weeks. Infections in the horse by eastern, western, or Venezuelan equine encephalitis virus closely follow this paradigm. Localized viral replication occurs at the site of entry (mosquito bite) followed by viremia and dissemination to the central nervous system.<sup>57</sup> For most horses, even non-vaccinated horses, dissemination is controlled before infection of the brain, and neurologic disease is a rare outcome of infection. A variation on the theme is infection of horses with EHV1. The most common clinical disease associated with EHV1 infection is rhinopneumonitis caused by a localized infection of the nasopharyngeal mucosa.<sup>58</sup> In almost all cases, a cell-associated viremia also occurs in lymphocytes, but in most infected horses this does not result in disease. However, in some cases, viremia is associated with infection of endothelial cells, and in the pregnant mare vascular damage to the uterus and placenta may lead to abortion.<sup>58,59</sup> Similarly, infection of the vascular endothelium in the central nervous system results in neurologic disease.<sup>60</sup>

Some viruses also may spread in the host through nerves. In the horse rabies is the best known infection that relies on neural spread. Following local replication in myocytes at the site of entry, usually a bite wound, rabies virus ascends peripheral nerves into the central nervous system, where it replicates in neurons, and then egresses by way of cranial nerves to the salivary gland.<sup>61</sup> EHV1 and EHV4 establish latency in the nuclei of sensory neurons that innervate the nasopharynx

**FIGURE 2-8** Schematic representation of the pathogenesis of mousepox (ectromelia), illustrating the classic paradigm for the events in a systemic infection. (From Fenner F: The pathogenesis of the acute exanthems, *Lancet* 255:915, 1948.)

and reach the nucleus by ascending nerve axons. Similarly, on reactivation these viruses egress back down the axon to infect epithelial cells.<sup>43,62</sup>

## VIRAL PATHOLOGY

Once a virus reaches a target organ, virally mediated cell death is the fundamental source of pathologic response, disease, and clinical signs observed by the veterinarian. Despite the great complexity of virus-host interactions and the many factors that influence the expression of clinical disease, in actuality viruses have a limited number of ways by which to cause infection. Cells and tissues may be destroyed directly by cytolytic viral infections or by infections that affect the differentiated function of target cells (e.g., neoplasms and immunodeficiencies). Viral infections of organ systems with bacterial flora

(e.g., intestinal and respiratory tracts) can disrupt the normal barrier functions of these organs and result in secondary bacterial infections and toxemia that may contribute significantly to the pathologic response. Cell death and pathologic response also may be caused by host immune responses specifically directed against virally infected cells or by indiscriminate inflammatory responses. Virally induced autoimmune diseases have not been described in horses but are another potential source of pathologic response that may be identified in the future.

For most of the clinically important viral diseases of horses, disease manifestation results from some combination of cytolytic infection and immune-mediated tissue destruction. The relative contribution of these mechanisms is primarily a function of viral virulence and host factors that influence the type and intensity of immune responses. The predominant

mechanism of pathologic response also can vary with different stages of the same disease, as seen in acute versus chronic equine infectious anemia. In acute disease most of the disease manifestation is caused by direct viral damage and cytokines, whereas in chronic disease immune complex-mediated anemia and glomerulonephritis become more significant.

### DIRECT VIRAL PATHOLOGY

The most straightforward cause of damage and disease in an organ system is for the virus directly to kill or cause dysfunction in the infected cells. As described previously, cell death may be caused by cytolysis resulting from viral replication and interference with normal cell homeostasis or by initiation of apoptosis. Cell dysfunction usually is observed as neoplastic transformation, although more vague effects on other differentiated cell functions, such as insulin secretion, remain possibilities.

The disease associated with a given viral infection is related to the affected organ system(s), the number of cells destroyed, and the sensitivity of the affected organ system to dysfunction. If the number of infected cells is not sufficient to lead to clinically significant organ dysfunction, then the result is a subclinical infection. Vaccination and naturally acquired immunity are important factors that limit the number of infected cells. However, epidemiologically these infections may still be important because these animals may still be infectious. When enough cells are infected to lead to overt organ dysfunction, then clinical disease becomes apparent. The threshold for clinically significant damage varies considerably between organs and the types of cells. EHV1 infections of the respiratory epithelium, which has a large number of cells with a high turnover rate, produce mild clinical disease even with a high rate of infection. On the other hand, much more significant clinical manifestations of EHV1 infection such as abortion and neurologic disease are caused by infection of a few endothelial cells because minimal vascular damage can lead to thrombosis, ischemic necrosis, and damage to large amounts of tissue. If viral infection results in neoplastic transformation of a cell type, then disease may progress according to the characteristics of the neoplasm, whether or not the virus remains associated with the tumor.

Of particular importance are infections of the respiratory and intestinal tracts that contain normal bacterial flora and have important barrier functions to prevent access of bacteria and toxins to deeper tissues. Consequently, complications of bacterial infection and toxemia are important secondary problems of viral infections.<sup>63,64</sup> For example, upper respiratory viral infections damage the ciliated epithelial cells that function to move mucus and other respiratory secretions outward and provide a barrier between the mucosal bacterial flora and the underlying subepithelial tissues. Damage to this barrier may lead to opportunistic bacterial pneumonias by normal bacterial flora such as *Streptococcus equi* subsp. *zooepidemicus* or *Mannheimia haemolytica* in horses or cattle, respectively.

### IMMUNE-MEDIATED VIRAL PATHOLOGY

In most viral infections immune-mediated pathologic response contributes significantly to disease and in some cases may be the predominant cause of disease manifestation. This paradigm has been documented elegantly in classic experiments with lymphocytic choriomeningitis virus infections of mice in which immunodeficient mice develop persistent infections but do not develop disease and do develop disease if their

immune systems are reconstituted.<sup>65</sup> Equine immune and inflammatory responses are covered in detail in Chapter 1 and are described in this section only in general terms and as they relate to viral infections.

The primary antiviral immune responses initiated in viral infections include natural killer cells, virus-specific cytotoxic (CD8<sup>+</sup>) T lymphocytes, and to a lesser extent antibody-mediated lysis of infected cells (antibody-directed cellular cytotoxicity, complement fixation, and phagocytosis by macrophages and neutrophils). These immune responses detect and selectively kill virally infected cells and are a significant cause of cell death. Indiscriminate inflammatory responses also may kill uninfected cells in the vicinity of infected cells, primarily from activation of monocytes and granulocytes with release of a wide array of cytotoxic molecules (e.g., lysozyme, proteases, lipases, and oxygen radicals). Secondary bacterial infections greatly exacerbate indiscriminate tissue damage, not only from the direct effect of bacterial toxins but also because of extensive recruitment of neutrophils and complement, which are highly nonselective components of the antibacterial immune response.

Antibody-mediated immune complex hypersensitivity reactions also may play a major role in the genesis of viral disease. Antibodies bound to soluble viral antigens fix complement and opsonize neutrophils, again leading to indiscriminate cell and tissue destruction. Viral antigens may be on the surface of cells, such as erythrocytes or platelets, resulting in immune-mediated anemia and thrombocytopenia, respectively.<sup>66</sup> When viral antigen is in excess relative to antibody, circulating immune complexes are formed that can be deposited in the capillary beds of tissues such as joints and renal glomeruli. In chronic equine infectious anemia virus, with persistent viral replication and antigenemia in the presence of antiviral antibodies, these mechanisms are primarily responsible for the characteristic lesions of anemia, thrombocytopenia, and glomerulonephritis.<sup>66,67</sup> Non-neutralizing antiviral antibodies actually may serve to increase the number of infected cells and the severity of disease through the mechanism of antibody-dependent enhancement. This enhancement occurs when antibodies bind to the virus and facilitate attachment and entry into Fc receptor-bearing cells such as macrophages by serving as a form of alternative receptor.<sup>68</sup> Antibody-dependent enhancement has been shown to be involved in the pathogenesis of a number of diseases, including feline infectious peritonitis,<sup>69</sup> human respiratory syncytial virus,<sup>70</sup> and dengue hemorrhagic fever.<sup>71</sup>

Soluble inflammatory mediators released by infected cells and inflammatory cells in response to viral infections are also significant contributors to clinical signs and disease manifestation. These mediators include a wide array of cytokines, interleukins, and other pro-inflammatory molecules with potent systemic and local effects. The most evident of these is the febrile response caused by interleukin-1 released by macrophages in response to virally infected cells. Increased levels of other soluble factors, including interferons, interleukins, transforming growth factor, and tumor necrosis factor, are also present in many viral infections.<sup>72,73</sup> These cytokines are primarily proinflammatory and immunoregulatory and are generally important for the control of viral infections but also can be responsible for many of the nonspecific clinical signs of viral infection, such as depression; malaise; and, in chronic infections, cachexia. Soluble mediators also may have important local effects. Vasoactive factors such as prostaglandins and leukotrienes cause edema and swelling. In equine infectious anemia virus, tumor necrosis factor  $\alpha$ , transforming

growth factor  $\beta$ , and interferon- $\alpha$  have been shown to suppress hematopoiesis and contribute to the development of anemia and thrombocytopenia.<sup>74</sup>

### AUTOIMMUNITY

Although not described in horses, viral infections in other species can induce immune-mediated responses to host cell antigens and autoimmune diseases. The best documented human autoimmune disease suspected to be initiated by viral infections is Guillain-Barré syndrome, in which infection with cytomegalovirus or Epstein-Barr herpesvirus elicits antinerve ganglioside immune responses and demyelinating disease.<sup>75</sup> Postinfluenza myocarditis is an occasional sequela in horses and human beings and is a potential autoimmune disease. Although no direct evidence supports this theory, influenza virus is not identified consistently in affected heart muscle and the pathogenesis is not known.<sup>76</sup>

### IMMUNE AVOIDANCE

A key requirement for viruses to be maintained in nature is to persist successfully in a reservoir host (if the reservoir is an infected animal) and to be transmitted to another susceptible host. One of the most important obstacles to persistence and transmission is detection and elimination by the host immune system. Transmission to a new host also may require that the virus avoid preexisting immunity from prior natural exposures or vaccination. Within the host rapidly replicating viruses such as influenza may shed and transmit virus before the host can mount specific antiviral immune responses. Herpesviruses avoid detection during latency by not expressing any viral proteins. For persistent viral infections that continually replicate within a host, such as retroviruses, evasion of developing immune responses is necessary. Immunodeficiency viruses may cripple antiviral immune responses by directly infecting immunoregulatory CD4<sup>+</sup> T lymphocytes. As described previously, many other viruses can dysregulate host immune responses by expressing cytokine mimics.

One of the most important mechanisms of immunologic avoidance is antigenic variation in which neutralizing viral antigens are altered so that they are no longer recognized or accessible by host immune responses. The most important of these antigens includes viral proteins bound by neutralizing antibodies (e.g., virus receptors) and any peptides presented in the context of MHC I or II cell surface molecules for recognition by cytotoxic (CD8<sup>+</sup>) T lymphocytes or helper (CD4<sup>+</sup>) T lymphocytes, respectively. Antigenic variation is generated by nucleotide errors during transcription or replication, which result in amino acid substitutions in the relevant epitopes. This process is facilitated by viral polymerases that are inherently error prone and lack proofreading functions and by placing the sequences for the relevant epitopes adjacent to other genomic sequences or structures that further predispose to transcriptional errors.<sup>19</sup> Other mechanisms by which some viruses may modify their antigenicity is through intramolecular recombination/duplication or reassortment of segmented genomes (e.g., influenza and African horse sickness).<sup>19,21</sup> For reassortment, co-infection of a single cell with genetically different virions may result in a progeny virion with segments derived from both virions and a major change in antigenicity. In influenza these are called *antigenic shifts*, and the radical change in the antigenicity of the virus may render preexisting immunity in the host population ineffective at preventing

outbreaks of disease with high morbidity and mortality.<sup>21</sup> Viruses also may facilitate the production of non-neutralizing antibodies that sterically interfere with the ability of neutralizing antibodies to bind. Although the mechanism of antigenic variation is primarily random, immunologic selection determines which variants successfully emerge and are capable of replicating within the host or the host population.

### HOST GENETICS

Genetic differences in susceptibility to disease have been well documented. In an outbred population of animals, the considerable variation in the type or severity of clinical disease is well recognized, even when animals are infected with the same virus strain and have no recognizable differences in other factors such as age, challenge dose, nutrition, and general health status. Conversely, highly inbred populations may be more uniformly susceptible to a viral disease.<sup>77</sup> Thus inbreeding can pose problems for endangered species, such as Przewalski's horse, or other populations with limited genetic variability, which may incur high rates of morbidity or mortality if the animals are infected with a virulent virus.

Although in many virus-host interactions the basis for genetic resistance to disease is not well defined, host genetics have been shown to affect the tropism of the virus and influence the type and intensity of immune responses to a viral infection. In human immunodeficiency virus infections, genetically determined absence or presence of certain co-receptors has a significant effect on susceptibility to disease.<sup>78,79</sup> Immunologically, host genetics defines the repertoire of antigen-specific recognition molecules (antibodies and T cell receptors) and antigen-presenting molecules (MHC I and II). Consequently, genetically different animals respond to different subsets of viral antigens. The relative inability to react to a neutralizing epitope prevents or delays effective control of viral replication.<sup>80</sup> Different subsets of viral antigens may favor the development of a type 1 T helper cell (cell-mediated) or type 2 T helper cell (antibody-mediated) immune response, which has implications for the ability to control infection and for immune-mediated pathologic response.<sup>81-83</sup>

## ADVANCES IN THE DIAGNOSIS OF VIRAL DISEASES

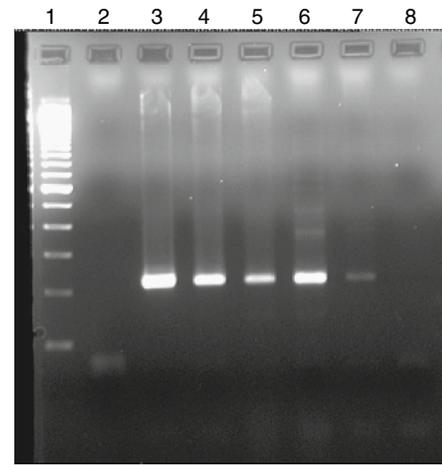

The diagnosis of viral infections traditionally has relied on the detection of antiviral antibodies by serologic tests and the direct demonstration of virus by isolation in cultures of living cells or in laboratory animals. Although these principles are still the foundation for the diagnosis of viral diseases, recent molecular biology advances have greatly improved the clinical use of viral diagnostics.

The sensitivity and specificity of antibody testing have been enhanced by the recombinant viral proteins or peptides for use as antigens in serologic tests. One example is the use of recombinant antigens in antibody tests for equine infectious anemia virus. The replacement of whole-virus antigen preparations with recombinant viral proteins has improved the sensitivity and specificity of the agar gel immunodiffusion (Coggins) and enzyme-linked immunosorbent assay tests.<sup>84,85</sup> The improvement in specificity is especially important when screening for a low-prevalence disease in which the predictive value of a positive result is low, as is the case for equine infectious anemia in the United States.

However, the greatest advances have been in the area of detection of virus in clinical specimens. The clinical utility of traditional methods of virus isolation in cell culture often is limited by the sensitivity, specificity, predictive value, or the length of time needed to perform this type of assay. Another significant limitation of virus isolation, particularly for the more labile enveloped viruses, is the requirement for viable virus, which may be compromised by autolysis or transport to the laboratory. In many diagnostic laboratories, virus isolation in cell culture has been replaced by immunohistochemistry and the PCR, both of which are sensitive and specific tests that can be completed in one or two days. Immunohistochemistry is a method that detects viral antigens in formalin-fixed tissue samples. Although immunohistochemistry technology has been available for many years, this assay has become more widely used because of improvements in the methods for antigen retrieval and the greater availability of antiviral monoclonal or polyclonal antibodies. The aldehydes in formalin cross-link proteins during the fixation process and prevent the recognition of epitopes by antibodies. For many viruses reliable protocols now have been established that use carefully controlled protease digestion of the tissue sections so that the availability of epitopes is restored.<sup>86</sup> The tissue sections then can be incubated with antiviral antibodies, and bound antibodies can be visualized with a variety of colorimetric systems. The specificity of immunohistochemistry depends highly on the antiviral antiserum and has been improved greatly by the availability of antiviral monoclonal antibodies and recombinant viral proteins that can be used to generate monospecific antisera.<sup>87-89</sup>

The PCR is a nucleic acid amplification method that detects viral DNA or RNA extracted from fresh or formalin-fixed tissue samples. Only a few years ago the techniques used to purify nucleic acids and perform the PCR reaction were limited by expense and practicality to the research laboratory. However, the simplification and commercialization of these procedures have made this type of test economical and clinically useful for diagnostic laboratories.<sup>90,91</sup> The PCR test uses oligonucleotide primers and a thermostable DNA polymerase (Taq polymerase) to amplify exponentially the viral nucleic acids. The basis for specific amplification in the PCR assay is the sequence of the oligonucleotide primers, which are produced synthetically to be complementary and thus bind to the viral nucleic acid sequences. To produce complementary primers, the sequence of the viral DNA or RNA must be known. Consequently, this assay is only useful for testing for viruses that have been sequenced, and in the past sequence data limited the ability to design PCR primers. However, because of advances in the technology for sequencing and database management, virtually all of the significant equine pathogens now have complete sequence data available. At the end of the PCR procedure, the amplified nucleic acids (i.e., a positive result) are visualized most commonly with agarose gel electrophoresis in which the amplicons in the gel are viewed with a fluorescent dye, and the product presumptively is confirmed as the correct one on the basis of its molecular size (Figure 2-9).

Immunohistochemistry and PCR are now routine tests that generally are sensitive, specific, and rapid. However, care must be taken not to make assumptions about the performance characteristics of new tests. For example, although PCR assays are often more sensitive than virus isolation, this is not automatically true. The sensitivity and specificity of any new test must be evaluated individually and with respect to the performance of the previous test. Also, the significance of any

**FIGURE 2-9** Analysis of polymerase chain reactions (PCRs) for equine infectious anemia virus. PCR products are electrophoresed in an agarose gel. DNA in the gel is stained with ethidium bromide and visualized with ultraviolet light that causes the DNA to fluoresce and appear as white bands in the gel. Lane 1 is a size standard to determine the size of the DNA amplicons. Lane 2 is a negative control, and lane 3 is a positive control. The samples in lanes 4, 5, 6, and 7 are positive; the sample in lane 8 is negative.

virus identified in a specimen still must be interpreted in the context of the pathogenicity of the virus and clinical disease, regardless of the method used to detect the virus.

## INTERNAL PARASITE INFECTIONS

*Thomas R. Klei*

Horses serve as hosts for numerous parasites, which induce a wide range of pathologic and immunologic responses.<sup>1,2</sup> Many of the latter are of a hypersensitive nature and also result in disease conditions. Immune responses leading to protective resistance against reinfection occur, but the level of this resistance is most often incomplete. Mechanisms associated with these responses have not been investigated extensively in the horse, but information is available from other host-parasite systems that may be relevant to the equine. The purpose of this section is to acquaint the reader with contemporary thoughts on host-parasite interactions. Because of their prevalence, major importance to equids, and information available, coverage is limited to helminth parasites that occur in most developed and nontropical countries.

## ☞ PARASITE-INDUCED LESIONS

Infection with most metazoan parasites results in inflammation and structural and functional changes of the organs invaded. The outcome of these changes is an alteration of the host's physiologic state. The degree of alteration depends on the existing physiologic condition of the animal, which is dictated to a great degree by its age, nutritional status, and previous immunologic experience with the parasite. The numbers of parasites introduced and the specific parasite also affect the degree of physiologic change that occurs.

When these factors favor major alterations, the results are readily identifiable clinical signs of infection. Subclinical infections, although less apparent, are potentially important to the general health of the animal and continued transmission of the agent. The pathophysiologic effects of infection by ectoparasites, helminths, and microorganisms are in many cases similar.<sup>3,4</sup> Abnormalities in weight gain, skeletal growth, reproduction, and lactation may result from infections with any of these agents. These changes are often directly related to parasite-induced anorexia, disruption of metabolic processes, and anemia. An understanding of the morphologic and biochemical lesions produced by specific parasites clarifies the role of these agents in clinical and subclinical conditions associated with the infections. A majority of detailed studies on the pathophysiology of parasitic infections have been conducted in laboratory animal models and domestic animal species other than the horse.<sup>3</sup> However, the classical pathology of parasitic infections of the horse has been reviewed.<sup>2,5</sup> The following discussion outlines some recent observations on host-parasite interactions that may be of significance to equine medicine. Examples of host-parasite interactions responsible for alterations in host homeostasis are presented as they relate to the gastrointestinal tract, lungs, and skin.

## GASTROINTESTINAL TRACT

Internal parasites are most important to equine health as mediators of gastrointestinal problems, including colic and diarrhea. Although almost all internal parasites have been inferentially implicated as causative agents of colic at some time, significant evidence-based experimental or field observations have emerged to support this contention for some parasites. The helminth parasites include large strongyles, principally *Strongylus vulgaris*, *Parascaris equorum*, *Anoplocephala perfoliata*, and as a group the cyathostomins.

### STRONGYLUS VULGARIS

Details of the pathogenesis of colic associated with migration of *Strongylus vulgaris* through the mesenteric arteries and the resultant thrombosis, infarctions, and necrosis of the intestine have been described in detail elsewhere.<sup>2,5</sup> Large strongyles are easily controlled with currently available macrocyclic lactone anthelmintics and are rare in horses kept on well-managed farms in developed countries. Nonetheless, this parasite-host interaction has arguably been experimentally studied in more detail than other internal parasites of the horse and some points are particularly noteworthy. Histologic studies of experimentally infected parasite-free pony foals during the initial stages of infection indicate that the severity of lesions produced in the intestine cannot be attributed solely to mechanical disruption caused by larval migrations and that these larval stages induce some biologic amplification system within the mucosa, which results in the degree of inflammation observed.<sup>6</sup> Although the mechanisms involved in this response have not been investigated, the histologic nature of the lesion is characteristic of an Arthus reaction, suggesting an involvement of the immune response. Other experimental studies using the parasite-free pony-*S. vulgaris* system have implicated a role for the immune response in the mediation and regulation of the arterial lesions produced by this parasite. Passive transfer of immune serum but not normal serum reduced the severity of

arteritis seen and clinical signs associated with experimental infections without reducing the numbers of parasites that develop in these ponies.<sup>7</sup> However, treatment with immune serum also induced an anamnestic eosinophilia and marked perivascular infiltration of eosinophils in the cecum. The reduction in intravascular lesions may have been associated with an inactivation of parasite-secreted inflammatory factors either by antibody or serum enzymes or circulating cytokines. This serum may also have contained nonspecific host-derived anti-inflammatory substances. The exacerbation of the eosinophil response may have been associated with the formation of immune complexes. Although the mechanisms are unknown, the results suggest that the immune response may simultaneously modulate and potentiate inflammation. It has been postulated that larvicidal treatment of *S. vulgaris*-infected horses and killing of intravascular larvae may release a bolus of antigenic factors from these larvae within the mesenteric vasculature, resulting in an exacerbation of arterial and intestinal lesions and colic. Experimental testing of this hypothesis indicates that this phenomenon does not occur and further that viable larvae are necessary to maintain the arteritis and eosinophilia seen.<sup>8,9</sup> Experimental studies using parasite-free ponies that were immunized with crude adult worm antigens and subsequently challenged with *S. vulgaris* larvae showed an exacerbation of the pathologic responses seen in the mesenteric vasculature and including an anamnestic eosinophilia, further suggesting a role for the immune response in the development of these lesions.<sup>10</sup>

### PARASCARIS EQUORUM

Colic associated with *Parascaris equorum* infection in foals has been related to intestinal impaction and rupture and is not considered to be of major significance in adult horses.<sup>11</sup> These conditions in foals may become more important with the widespread identification of *P. equorum* resistance to ivermectin.<sup>12</sup> However, ascarid nematodes are particularly potent sources of allergens, and it is not inconceivable that the hypersensitized mature horse may respond to low-level infections with this parasite. Observations made in the author's laboratory are noteworthy in this regard. Two mature *Parascaris*-free adult horses were inoculated intradermally with less than 90 µg of saline-soluble somatic extract of adult *P. equorum* in order to test for immediate hypersensitivity to this antigen. Both horses experienced an immediate systemic response and colic. One of the horses died within 3 hours of intradermal inoculation. Necropsy results were consistent with the diagnosis of acute severe colitis. Because of the allergic potential of ascarid nematodes and the sensitivity of the equine gut to immediate hypersensitivity reactions, this potential is worthy of further characterization and consideration.

### ANOPLOCEPHALA PERFOLIATA

Clinical observations have maintained an interest and concern over the pathogenic potential of *Anoplocephala perfoliata* infections. Earlier case reports have described cecal ruptures and intussusceptions of the cecum and colon associated with these infections.<sup>13,14</sup> However, detailed retrospective analyses of the concomitant occurrence of intussusception and colic with *A. perfoliata* infections have failed to consistently demonstrate any causal relationship between these conditions and tapeworm infections.<sup>15</sup> These parasites inhabit the region of the ileocecal junction and produce ulcerated lesions of the

mucosa and submucosal inflammation. However, the parasites are not uncommon, and it is possible that the association of tapeworm infections and clinical signs attributed to them are caused by chance alone. Detailed experimental investigations of these infections have not been conducted, and thus specific details on the pathogenesis and relevance of these lesions are lacking. However, an association between tapeworm infections and colic of ileocecal origin has been suggested in a case control study of 231 horses.<sup>16</sup> The development of a test to measure IgG(T) levels to specific secreted *A. perfoliata* antigens was shown to correlate to parasite burdens. Use of this method in the United Kingdom has shown by a matched case control study that *A. perfoliata* is a significant risk factor for spasmodic colic and ileal impactions. The risk of spasmodic colic was also associated in these studies with increased numbers of parasites.<sup>17</sup>

### CYATHOSTOMINS

Cyathostomins (cyathostomes or small strongyles) have not generally been considered to be of major importance, particularly as causative agents of colic. In this regard, field studies of Uhlinger are of particular importance.<sup>18</sup> In these controlled experiments different anthelmintic treatment regimens were used to test their efficacy in reducing the incidence of colic. The more efficacious treatment programs significantly reduced the incidence of colic by 2 to 13 times of that seen in the same herds before implementation of the more efficacious treatment. Because of the management programs used before the initiation of this study and the results of fecal cultures, it can be assumed that the primary parasites present in these horses were cyathostomes. These data strongly implicate a role for cyathostomins in a substantial proportion of colics observed under field conditions. The parasite or host factors involved in these colic cases are unknown but may be the dynamic turnover of parasites during the life cycle in the mucosa and the related inflammatory responses seen that they induce.

Cyathostomins have been implicated in numerous case reports with seasonal diarrhea in adult horses, which is a condition called *larval cyathostominiasis*. These cases are characterized by a sudden onset of diarrhea during the late winter or spring. Mature horses are usually affected, and these cases are often fatal. These are difficult to diagnose, and the only consistent signs are weight loss and diarrhea.<sup>19</sup> Large numbers of larval cyathostomes are found in the feces or in intestinal contents and within the mucosa of these horses. These symptoms are related to the synchronous emergence of fourth-stage larvae of these parasites from the mucosa. These larvae build to potentially large numbers within the mucosa owing to the arrested development of infective larvae. The seasonality of the occurrence of this condition at present does not appear to vary in different climatic regions as does the analogous bovine condition of type II ostertagiasis. Specific parasite or host factors associated with the regulation of the hypobiotic state of the larvae or the inflammatory response initiated at parasite emergence have not been described. Other clinical reports have suggested that cyathostome-related diarrhea and weight loss are not related to the seasonal presentation described previously.<sup>20</sup> This is supported by experimental studies demonstrating that pathophysiologic effects occur as large numbers of parasites enter the intestine as well as when they leave.<sup>21</sup>

In view of the paucity of specific mechanistic information on the pathophysiologic effects of equine gastrointestinal parasites, a synopsis of relevant information gathered from other

model systems is warranted, particularly for nematodes.<sup>3,22</sup> Parasitic organisms may induce changes in gastrointestinal function directly by mechanical disruption of tissues and cells or by the release of factors that directly alter cell function. Induction of the immune response serves as an anamnestic amplification system. The result of these changes is an alteration in function of the smooth muscle and epithelium of the bowel.

A number of helminth parasites, including *P. equorum*, have been demonstrated to produce intestinal smooth muscle hyperplasia. Evidence suggests that this response may be induced by intestinal inflammation or stenosis associated with parasitism. Contractility of these muscles has also been demonstrated to be induced in a Schultz-Dale reaction by stimulation with parasite antigens. This response is mediated in rats by mast-cell-derived 5-hydroxytryptamine (5-HT) and in guinea pigs by histamine. A regulatory relationship of myenteric neurons to these antigen-induced changes has also been demonstrated in this model system. These latter experiments suggest that antigen-induced stimulation of smooth muscle contractility may be correspondingly blocked by  $\gamma$ -aminobutyric acid similarly stimulated by mast cell products. This complex system may be an adaptation by the host to maintain homeostasis in the face of continued antigenic stimulus. It is noteworthy that strongyle-induced alterations in myoelectric activity of the equine small intestine and colon have been demonstrated in vivo.<sup>23,24</sup> In some of these experiments, dead *S. vulgaris* larvae evoked an alteration of the smooth muscle response in previously exposed ponies, suggesting a role for the immune response in the stimulation of the hyperactivity.<sup>25</sup>

There is a rapidly growing literature on the host-parasite interactions of a number of mouse models of gastrointestinal nematode infections.<sup>26-29</sup> The mouse models include infections of *Trichinella spiralis*, *Nippostrongylus brasiliensis*, *Heligmosomoides polygyrus*, and *Trichuris muris*. Because of the use of the mouse the most contemporary of immunologic, genetic, molecular, and cell biologic techniques are available and may provide useful insights into potential explanations of immunologic and pathophysiologic responses of the horse to nematode parasites, particularly the cyathostomins. Although differences in specifics exist between these murine models, it is clear that these worms induce a type 2 T helper cell cytokine response consisting of IL-4, IL-5, IL-9, and IL-13. IL-4 and IL-13 induction of the Stat6 pathway is central to most of the resulting responses. There is a consistent mastocytosis and eosinophil infiltration of the intestine. The resulting responses also involve goblet cells, the enteric nervous system, epithelial cells, and alternately activated macrophages as effector cells. Cell junctions are disrupted, smooth muscle hypercontractility is stimulated and epithelial cell secretion increased, and goblet cell productions of mucus production stimulated. Although these mechanisms are used most often to explain expulsion of the nematodes in question, they could be equally important in the disruption of the homeostasis seen in the parasitized equine intestine.

### RESPIRATORY SYSTEM

Several nematode parasites infect the equine lung. These include *S. westeri* and migrating stages of *P. equorum* en route to the small intestine. Migrating stages of aberrant parasites, such as *Habronema* sp., *Draschia megastoma* and *Strongylus* spp.,

which induce granulomatous foci in the lung parenchyma, and adults and larvae of the lungworm *Dictyocaulus arnfieldi*, which inhabit the bronchi, also occur. Host responses to two of these are noted.

*Parascaris equorum* larval migrations in the lungs of yearling horses produce more severe clinical signs and inflammatory responses than in foals that are reared parasite free. These infections in yearlings are accompanied by focal accumulations of lymphoid tissue, indicating an induction of an active local immune response. It is suggested that this is an age-related phenomenon.<sup>11</sup> However, it is likely that more severe reactions could be the result of previous sensitization to *P. equorum* antigens. Increased responses of this nature have been described in the livers of pigs immunized with *Ascaris suum* antigens following challenge infections.

*Dictyocaulus arnfieldi* infections of donkeys rarely produce clinical signs, and it has been suggested that these equids are the natural host for this parasite. Infections of horses produce a more severe and prolonged bronchial inflammatory response similar to *Dictyocaulus* sp. infection in other hosts. The mechanisms associated with this differential response have not been defined but are not uncommon in unadapted host-parasite associations. It is possible that the more marked inflammatory reaction of the horse to these parasites is due to the absence of downregulatory mechanisms that are established in the more adapted natural host, the donkey.

## SKIN

Whereas *Onchocerca cervicalis* infections in horses are rare where macrocyclic lactone anthelmintics are regularly used, reactions to the filarial nematode illustrate variations seen in responses to chronic parasite infection. Focal, alopecic, depigmented, pruritic lesions are often seen in infected horses. Not all infected horses react to this infection, and the appearance of clinical signs is often seasonal. Detailed studies have not been conducted on the pathogenesis of these lesions in horses. However, similar conditions occur in human onchocerciasis,<sup>30</sup> and it is likely that the host-parasite responses active in humans are also present in the horse. Lesion development is associated with immune-mediated killing of microfilariae in the skin. Parasites appear to be killed in an antibody-dependent cell-mediated reaction. In this response antimicrofilarial surface IgG and IgE antibodies mediated adherence and degranulation of granulocytes, which are predominantly eosinophils. Major basic protein of eosinophils has been demonstrated in the tissues of patients with dermal lesions, and it has been suggested that eosinophil toxic enzymes and proteins are responsible for many of the changes seen. The reason for the absence of these lesions in most horses is unclear. Human onchocerciasis and filariasis are spectral diseases. In these diseases regulation of immune responses has been associated with the lack of pathologic responses to the parasites.<sup>31,32</sup> Immune regulatory mechanisms associated with these infections include immune tolerance, anergy, induction of immune regulation involving Treg cells or macrophages, and the production of IL-10 and TGF  $\beta$ -altering Th cell subsets and the production of specific cytokines during different phases of the infections. Recent studies have also focused on the role of an intracellular commensal microorganism, *Wolbachia*, which is a parasite of *Onchocerca* and other filarial nematodes. These bacteria have been shown to mediate type 1 inflammatory lesions in humans and mouse models.<sup>32</sup>

The presence of these types of parasite-associated immune regulatory events has yet to be critically studied in the horse. However, the seasonal variability in skin responses to the *Onchocerca microfilariae* by horses in some regions has been investigated. In this instance the onset of ventral-midline dermatitis during the summer may be related to a seasonal fluctuation in microfilarial burdens of the skin, which have been demonstrated to correspondingly peak at this time.<sup>33</sup> Not only do total numbers increase, but microfilariae are also found more commonly in the surface layers of the skin. Interestingly, this period of abundant microfilariae corresponds with the seasonal peak in numbers of the vector, *Culicoides varripennis*. Although speculative, correlations in the peak availability of microfilariae and vectors may be an evolutionary adaptation by these parasites to maximize transmission and survival of this parasite species.

## ☞ PROTECTIVE RESISTANCE

Resistance to infection may be innate or acquired. In some instances innate resistance to equine parasites has been attributed to age, with older individuals being resistant. Most equine helminth parasites develop only in the horse, and conversely the horse exhibits an innate resistance to most nonequine parasites. Exceptions to this rule are parasites with a broader host range that occasionally infect horses, such as larvae of the tapeworm *Echinococcus granulosus* and the liver fluke *Fasciola hepatica*. *Trichostrongylus axei*, a parasite of ruminants, establishes readily in the equine stomach and produces significant lesions only when present in large numbers. In some cases parasites that develop in the horse induce more severe lesions and clinical signs than in their apparent normal host, as has been described for *D. arnfieldi*.

Age resistance to *P. equorum* and *S. vulgaris* has been described in horses by comparing susceptibility of young and old ponies reared under parasite-free conditions. It is apparent that the reaction of the lung to migrating *P. equorum* larvae is more marked in mature horses and suggests that an immune response occurs in this site.<sup>13,14</sup> Initial reports on age-acquired resistance to *S. vulgaris* infection<sup>34</sup> have not been substantiated, and experimental observations in our laboratory indicate that this does not occur.

The occurrence of acquired resistance to equine parasites can be inferred from the observation that older chronically exposed horses generally have lower burdens of parasites than do similarly exposed young horses. On the basis of these criteria, acquired resistance is apparent to infections of *S. westeri*, *P. equorum*, *Strongylus* spp., and cyathostome species. Extensive experiments are limited, however, to those on *S. vulgaris* and to some degree cyathostomins.

Although *S. vulgaris* has been largely eliminated from well-managed horse farms, examination of details of the immune response to it illustrates some equine immune mechanisms. Resistance that is acquired to *S. vulgaris* in most cases is partial and of a concomitant type; that is, some stages of the parasite, such as arterial larvae of *S. vulgaris*, may reside within the horse in the face of an active acquired resistance against newly acquired infective stages.

Resistance to infection with *S. westeri* adult parasites is inferred by the short duration of their life cycle within the small intestine and the failure of subsequent exposures to establish patent infections. Mares, however, remain infected with arrested third-stage larvae, which subsequent to foaling

are transmitted to the foals in milk 4 days postpartum. Although not studied in horses, similar phenomena occur in swine strongyloidosis. In these infections there is apparent protective resistances against the migrating L<sub>3</sub>, which is effective in preventing re-establishment of the intestinal infection but is ineffective against L<sub>3</sub>, which are sequestered in the abdominal fat of the sow.<sup>35</sup> Similar epidemiologic phenomena occur in *S. westeri* infection of horses, and it may be implied that similar immunologic mechanisms are also active.

Immunologic mechanisms associated with protective resistance are presented primarily as they relate to parasites that inhabit the lumen of the gastrointestinal tract and secondly as those that undergo extraintestinal tissue migration.

## GASTROINTESTINAL PARASITES

Immune responses directed toward gastrointestinal nematodes vary significantly among hosts and against different parasite species within a given host. However, some generalities may serve as a background for understanding these responses in the horse. A phenomenon termed *self-cure* has been described in sheep, in which the ingestion of significant numbers of infective larvae induces the expulsion of existing adult parasites. This expulsion is initiated by a species-specific immediate-type hypersensitivity response that may cause the nonspecific expulsion of other nematode species. Although this phenomenon has not been examined in the horse, experimental infections of naturally parasitized ponies with large numbers of *S. vulgaris* L<sub>3</sub> induced a dramatic decrease in preexisting strongyle fecal egg counts, suggesting that a self-cure-like reaction may occur under some conditions.

More typically, establishment of primary infections results at some time in spontaneous expulsions of these worms as a result either of senility or, as demonstrated in laboratory animal model systems, of active acquired immune responses. This phenomenon occurs experimentally in the absence of reinfection and is thus separate from the self-cure phenomenon. A large number of immune effectors has been identified with this phenomenon in various model systems, and it is likely that some if not all are at some time active in the equine intestine. The mechanisms involved are T cell dependent. Antibodies may be involved but are not sufficient in themselves to induce expulsion. T cell-mediated mastocytosis, eosinophilia, and goblet cell hyperplasia have all been demonstrated to be related to expression of expulsion in some systems. These accessory cells are involved in the nonspecific efferent arm of this response. Mediators of inflammation, such as vasoactive amines, prostaglandins, and increased production of mucus, have been linked to immune elimination of primary infections in some but not all model systems. The increased secretion and hyperreactivity of intestinal smooth muscle associated with worm expulsion have been termed “weep and sweep” phenomena. It is likely that a number of specific immunologic events initiate several nonspecific effector mechanisms, resulting in this expulsion. These mechanisms vary with the species of parasite involved. The elimination of adult *S. westeri* and *P. equorum* from maturing horses and the hypothetical seasonal turnover in *Strongylus* spp. and cyathostome spp. may be mediated by such responses.

In addition to immune responses that occur during tissue migrations, protective resistance to reinfection by gastrointestinal nematodes occurs at the surface of the epithelium. This reaction, termed *rapid expulsion* or *immune exclusion*, is

separate from self-cure or immune expulsion of primary infection. Infective larvae are expelled from the intestine in a matter of hours. Again, mechanisms of expulsion described vary between parasite and host species. However, anaphylactic reactions and mucus entrapment have been observed. Some experiments using the *T. spiralis*–rat system suggest that alterations in the epithelial cells in immune animals are directly involved in the exclusion of these parasites. Although immune-mediated damage of intestinal helminths such as decreased fecundity, reduced size, and morphologic alterations have been noted, infective larvae expelled by rapid expulsion mechanisms remain viable and undamaged. It may be speculated that reactions of this nature are responsible, in part, for resistance to reinfection of equines with cyathostomes.

Some specific observations have been made on the equine acquisition of resistance to reinfection with cyathostomins.<sup>36</sup> This resistance is acquired over time with continued exposure to pasture L<sub>3</sub>; is incomplete; and, like other parasitic helminth infections, appears to be genetically regulated in that parasite numbers are overdispersed within a given herd of adult animals. The limited number of experimental and field studies completed to date suggest that immunity may be directed toward all stages of the parasite life cycle. Challenge infections of previously exposed and naïve ponies with mixed strongyle infections indicate that a nonspecific self-cure-like phenomenon occurs, reducing numbers of adult and fourth stage larvae (L<sub>4</sub>) in the lumen as well as within the mucosa.<sup>10</sup> Fecal egg counts are significantly reduced in older animals when compared with yearlings even when adult parasite numbers are similar. These observations suggest that immune responses are directed at female fecundity or that the species of cyathostomins present in the older animals are inherently less fecund. Numbers of early L<sub>3</sub> (EL<sub>3</sub>) are reduced following challenge infections of previously exposed adult ponies when compared with previously exposed young animals or age-matched naïve controls.<sup>37</sup> Other studies have suggested that acquired resistance is important in the induction of hypobiosis.<sup>38,39</sup> Resistance to acquisition of EL<sub>3</sub> was not seen when numbers were compared in young previously exposed and age-matched ponies raised under parasite-free conditions. However, these previously exposed young animals demonstrated significantly fewer developing larvae (DL) in the mucosa, suggesting that once the EL<sub>3</sub> began to develop, they were susceptible to immune attack.<sup>37</sup> This response is likely driven by cytokines produced by T cells of the Th<sub>2</sub> lineage with demonstrated increases in IL-4 and IL-5.<sup>40</sup> This response mimics in some ways the results described in studies of murine nematodes.<sup>29</sup>

## TISSUE-MIGRATING PARASITES

A number of intestinal helminths as well as others migrate through extraintestinal tissues as part of their life cycle. These include parasites such as *P. equorum*, *S. westeri*, and *Strongylus* spp., all of which stimulate an acquired immune response in the horse. During this migration these larvae are vulnerable to attack by immune effectors that may either encapsulate them in an immune-mediated inflammatory response, disrupt their migrations by interfering with important metabolic or invasive processes, or inhibit molting from the L<sub>3</sub> to L<sub>4</sub> stages. The most studied phenomenon in this regard is antibody-mediated adherence of inflammatory cells, which may result in killing of the larvae. This phenomenon involves many cell types and immunoglobulin isotypes in different host-parasite systems.

In vitro studies of this nature have been conducted using *S. vulgaris* third-stage larvae and equine immune effectors.<sup>41</sup> In these experiments an antibody-dependent adherence of cells was demonstrated and shown to be parasite species-specific. In vitro killing was mediated by eosinophils and not by neutrophils or monocytes. Activated eosinophils were necessary to mediate this response, and *S. vulgaris* infections have been demonstrated to activate eosinophils and neutrophils in vivo.<sup>42</sup> Although it is not certain that eosinophils are essential in this protective immune response, an anamnestic eosinophilia is characteristic in immune ponies but not nonimmune ponies following experimental *S. vulgaris* challenge.<sup>10</sup> Because of its prominence and compelling in vitro and correlative in vivo data, the eosinophil is considered a major effector in immune-mediated helminth killing. However, recent studies in murine parasite model systems in which eosinophilia was blocked by anti-IL-5 treatment suggest that this type of cell is not essential for protective resistance in some systems.<sup>43</sup> Significant increases in equine IL-5 have been measured in ponies vaccinated against *S. vulgaris*. It is possible, in vivo, that a number of cells function as effectors and may overcome the absence of sufficient eosinophils under some circumstances. Antibody reactivity with parasite-secreted enzymes and molting fluids, factors important in parasite homeostasis, has been demonstrated in vitro; similar reactions may be important in vivo.

T-cell responses are essential for the induction of protective resistance to tissue-migrating helminths in most systems studied, including the experimental *S. vulgaris* pony model. This dependency is likely due to the T cell dependency of the antibody response and to the mediation of secondary effector cell responses. It is likely that antigenic substances secreted or excreted (ES) by migrating nematodes are important in the induction of these responses. It is probable that a combination of immune responses elicited by a combination of specific parasite antigens, including surface antigens and ES products, is necessary to induce an immune response sufficient to provide protective resistance.

## ☞ PARASITE-INDUCED REGULATORY RESPONSES

Helminth parasites have evolved elaborate mechanisms to evade the host's immune responses, live in the face of an active specific host response, and yet establish chronic infections. These immune evasion strategies include the production and secretion of molecules such as proteases, protease inhibitors, antioxidants, prostaglandins, and phosphocholin-antigens, which disrupt host effector responses.<sup>44,45</sup> Other molecules that mimic host immune regulatory factors, such as TGF $\beta$  and MIF, have also been identified in parasitic helminth genomes.<sup>45</sup> These mimics likely downregulate host-parasite-directed protective response and add to immune evasion.

Helminth parasites can induce a regulatory immune response, which promotes their survival but also has bystander effects on host responses to other infectious agents, vaccines, allergic responses, and autoimmune diseases. These observations have progressed to the point that helminth therapy is being developed for the treatment of human inflammatory bowel disease and ulcerative colitis.<sup>46,47</sup> In this situation infection with the swine whipworm *T. suis* impedes the regulation of type 1 inflammatory responses responsible for these conditions and reduces disease activity. The generally accepted and simple model that has emerged for this type of helminth-induced regulation is that parasite factors stimulate dendritic cells that

activate regulatory T cells and alternately activated macrophages. These cells, through the production of TGF $\beta$  and IL-10, may suppress both Th1- and Th2-mediated inflammatory responses.<sup>48-50</sup>

Detailed studies of the effects of equine helminths on the regulation of parasite-induced responses or to heterologous immunogens have not been reported. The effects of different levels of gastrointestinal helminth infection on the response of ponies to keyhole limpet hemocyanin immunization was measured.<sup>51</sup> Antibody levels determined by ELISA showed that animals with low levels of parasites had a trend toward increased KLH specific total immunoglobulin, IgG(T) and IgA compared with heavily parasitized ponies. Medium and heavily parasitized ponies demonstrated a trend toward reduced lymphoproliferative response to KLH that was not restored after the addition of IL-2. Cells from these ponies also produced significantly lower levels of IL-4 compared with lightly parasitized ponies. These data indicate that heavily parasitized animals have uniformly decreased cellular and humoral immune responses to soluble protein immunization. The mechanisms involved are unknown. The significance of these observations, particularly to vaccination against specific pathogens and the subsequent protective response to challenge infection, should be considered in the future.

# CLINICAL APPROACH TO COMMONLY ENCOUNTERED PROBLEMS

## CHAPTER 3

*Melissa T. Hines*

### CHANGES IN BODY TEMPERATURE

*Melissa T. Hines*

Assessment of body temperature is an essential part of every physical examination. As with all mammalian species, horses normally maintain their core body temperatures within a narrow range despite extremes in environmental conditions. The core temperatures may vary by approximately 1° C (2° F) between individuals. In adult horses the average normal body temperature is 38.0° C (100.5° F), whereas in neonatal foals the temperature tends to be slightly higher, ranging between 37.8° to 38.9° C (100.0° to 102.0° F). A diurnal variation of up to 1° C (2° F) may occur, with the low point typically in the morning and the peak in the late afternoon.

#### ☞ CONTROL OF BODY TEMPERATURE

The set-point is the crucial temperature that the body attempts to maintain, primarily via neuronal control operating through temperature centers in the hypothalamus.<sup>1,2</sup> Peripheral and central thermoreceptors sense changes in ambient and core body temperatures and activate feedback mechanisms that bring the temperature back to the set-point. Specifically, the anterior hypothalamic-preoptic area contains large numbers of heat-sensitive neurons and lower numbers of cold-sensitive neurons that function as temperature detectors. Peripheral receptors, which are generally most sensitive to low temperatures, are located in the skin and in some deep tissues, such as the spinal cord and abdominal viscera, and around certain great veins. The anterior hypothalamic-preoptic area and the peripheral receptors transmit signals into the posterior hypothalamic area, subsequently activating autonomic and behavioral effector responses to regulate body temperature.

When the body temperature is too high, heat loss increases and heat production diminishes. Increasing blood flow to the skin is an effective mechanism for heat transfer from the body core to the surface. In response to changes in core body temperature and environmental temperature, the sympathetic nervous system regulates the degree of vasoconstriction and thus the amount of blood flow. Heat is lost from body surfaces to the surroundings by several physical mechanisms, including radiation, conduction, and convection. Evaporation is also

an important mechanism of heat loss in horses.<sup>3</sup> The rate of sweating controls to some extent the amount of evaporative heat loss. However, even when the animal is not sweating, water evaporates insensibly from the skin and lungs, causing continual heat loss. In horses evaporative heat loss, primarily through increased sweating but also through increased respiration, becomes more important as the ambient temperature rises and during exercise.<sup>3,4</sup> In addition to increased heat loss when the body temperature rises, the horse also decreases temperature further by inhibiting means of heat production, such as shivering, and by behavioral responses, such as seeking shade and wind currents and wading into water.

Mechanisms that increase body temperature come into play when the body temperature is too low.<sup>2</sup> Heat is conserved by stimulation of the posterior hypothalamic sympathetic centers, leading to cutaneous vasoconstriction and piloerection. Heat production also increases and may occur through increased muscle activity ranging from inapparent contractions to generalized shivering. Shivering may increase heat production by four to five times baseline. The primary motor center for shivering is in the posterior hypothalamus, which normally is stimulated by cold signals from the peripheral receptors and to some extent the anterior hypothalamic-preoptic area. Signals from heat-sensitive neurons in the anterior-hypothalamic-preoptic area inhibit the center. Digestion of food also contributes to total body heat. Sympathetic stimulation may increase the rate of cellular metabolism, increasing heat production by chemical thermogenesis. Cooling also increases the production of thyrotropin-releasing hormone, ultimately increasing thyroid hormones and cellular metabolism and further contributing to chemical thermogenesis. In addition to these physiologic adaptations, behavioral responses to conserve heat also occur, such as adopting a huddled stance, aggregating in groups, and seeking shelter.

#### ☞ CONDITIONS OF INCREASED BODY TEMPERATURE

Elevation of the body temperature above normal is one of the most common clinical problems encountered, and although classically associated with infection, a variety of disorders may cause increased body temperature. Veterinarians should distinguish between conditions of hyperthermia, in which the

temperature set-point is unaltered, and true fever, in which the set-point actually increases.

## **HYPERTHERMIA**

The body temperature may become elevated without an increase in the set-point when a loss of equilibrium occurs in the heat balance equation. Increased heat production or absorption of heat beyond the ability of the body to dissipate heat may occur. In some conditions impaired heat loss also may occur. Hyperthermic conditions include problems such as exercise-related hyperthermia, heat stroke, malignant hyperthermia, anhidrosis, central nervous system disorders, and reactions to certain toxins or drugs. In general, these conditions do not respond to treatment with antipyretic drugs.

### **EXERCISE-RELATED HYPERTHERMIA**

During sustained or high-intensity exercise, increased heat production is associated with muscular activity.<sup>3,4</sup> The heat produced may exceed the ability of the body to lose heat, resulting in an increased core body temperature. Typically, the temperature returns to normal with rest as heat loss mechanisms remain activated. Elevated temperature also may occur with the intense muscle activity associated with generalized seizures.

### **HEAT STROKE**

Heat stroke occurs when the body temperature rises above a critical temperature, leading to multisystemic problems. In horses signs of heat stroke may develop when the body temperature is above 41.5° C (107° F), which most often occurs in association with exercise in environmentally stressful conditions. Although horses can acclimatize to various weather conditions to some extent, the efficiency of evaporative heat loss may be compromised significantly in hot, humid weather.<sup>4,5</sup> Susceptibility to heat stroke may increase if sweating leads to dehydration and electrolyte imbalances. Once the body temperature reaches the critical point, the homeostatic mechanisms of thermoregulation fail, resulting in peripheral vasoconstriction, decreased cardiac output, and decreased blood pressure. Affected horses are lethargic, with weak, flaccid muscles. Prostration, circulatory shock, disseminated intravascular coagulation, multiple organ failure, and death may occur.

### **ANHIDROSIS**

Especially in hot, humid climates, horses may develop anhidrosis, which is characterized by a partial or total loss of the ability to sweat.<sup>6</sup> Because of the resulting impaired heat loss, hyperthermia may develop. Clinical signs of poor performance, increased respiratory rate, and poor hair coat also are observable.

### **MALIGNANT HYPERTHERMIA**

Malignant hyperthermia encompasses a group of inherited skeletal muscle disorders in which calcium metabolism is altered.<sup>7</sup> Although the condition is most common in human beings and pigs, it has been reported in several species, including horses.<sup>8,9</sup> The disorder is characterized by a hypermetabolic state of muscle that generally is induced by halogenated inhalation anesthetics, depolarizing skeletal muscle relaxants, and occasionally local anesthetics or stress. Clinical

signs include a rapid increase in core body temperature, skeletal muscle rigidity, and tachycardia. Affected animals may develop significant acidosis and muscle necrosis and in some cases may die. In pigs, malignant hyperthermia has been linked to a single point mutation in the gene for the skeletal muscle ryanodine receptor, but a genetic basis has not yet been established in horses.<sup>7</sup>

### **CENTRAL NERVOUS SYSTEM DISORDERS**

Any condition affecting those areas of the hypothalamus involved in thermoregulation may alter the body temperature, with hyperthermia being more common than hypothermia.<sup>1,2</sup> Thus central hyperthermia occurs in association with a variety of conditions, including hemorrhage, neoplasms or abscesses, infectious/inflammatory changes, and degenerative disorders. Central hyperthermia usually is characterized by a lack of any diurnal variation, absence of sweating, resistance to antipyretic drugs, and excessive response to external cooling.

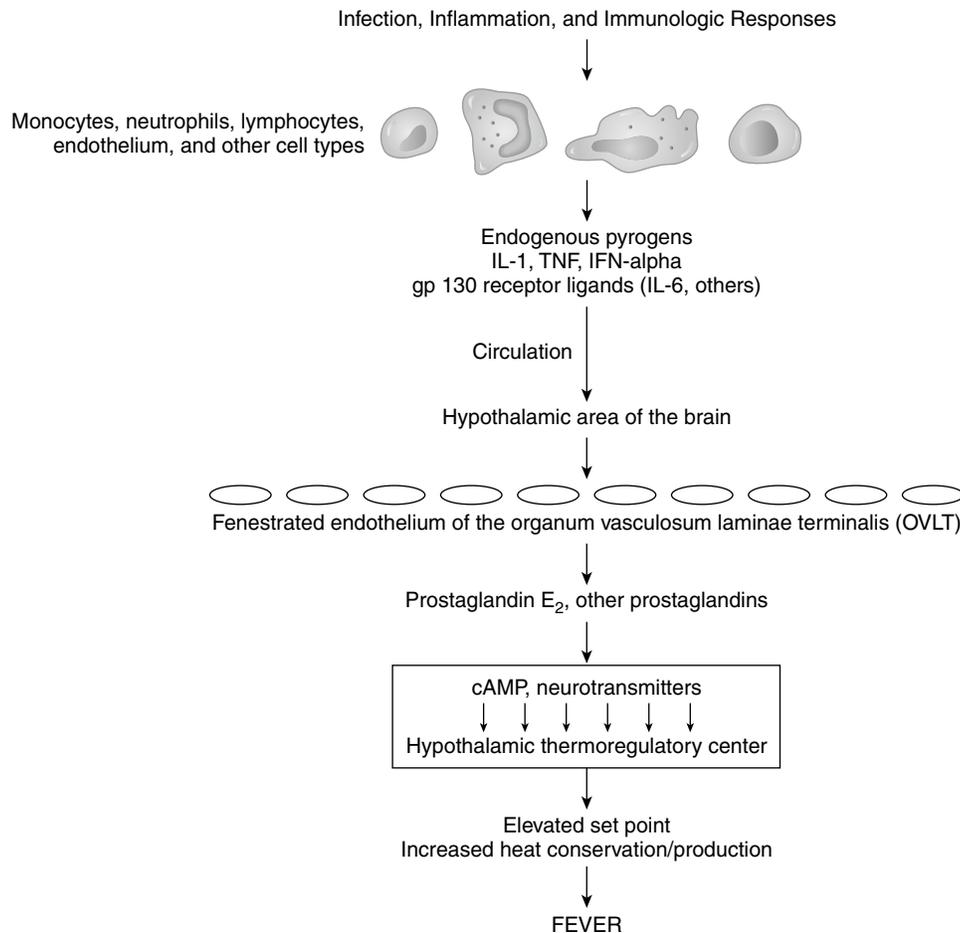

### **CERTAIN TOXINS OR DRUGS**

Occasionally, hyperthermia has been associated with toxins or drugs. Exposure to compounds that act to uncouple oxidative phosphorylation, such as the wood preservative pentachlorophenol, potentially could cause a significant rise in body temperature.<sup>10</sup> Foals treated with the antibiotic erythromycin and possibly other macrolides are at risk of developing hyperthermia.<sup>11</sup> Such predisposition has been attributed to a reaction to the erythromycin itself or to an alteration of the thermoregulatory system of the foal by mechanisms not yet described. Environmental conditions may exacerbate the development of hyperthermia, with foals exposed to high ambient temperatures and direct sunlight being at greatest risk.

## **☞ PATHOGENESIS OF TRUE FEVER**

In true fever the set-point for the desired core body temperature increases and then is maintained by the same mechanisms that maintain the normal body temperature. Although primarily associated with infectious diseases, fever is also a prominent component of many inflammatory, immunologic, and neoplastic conditions. Although the pathogenesis of the febrile response is complex, essentially all of these conditions initiate fever by stimulating the release of endogenous pyrogens (Figure 3-1).

Endogenous pyrogens are substances with the biologic property of fever induction.<sup>12,13</sup> Initially endogenous pyrogen was assumed to be a single molecule produced by leukocytes—thus the name *leukocytic* or *granulocytic pyrogen*. Now, multiple cytokines are known to act as pyrogens, and a variety of cell types produce them, with monocytes and macrophages predominating. Currently, the following cytokines are thought to be intrinsically pyrogenic in that they produce a rapid-onset fever via direct action on the hypothalamus without requiring formation of another cytokine: interleukin-1 $\alpha$  (IL-1 $\alpha$ ) and IL-1 $\beta$ , tumor necrosis factors (TNF)  $\alpha$  and  $\beta$ , interferon- $\alpha$ , and IL-6. IL-1 $\alpha$  and IL-1 $\beta$  and TNF- $\alpha$  appear to be among the most potent pyrogens. Many endogenous pyrogens use the cell-signaling apparatus gp130. Cytokines that act through this receptor include IL-6, IL-11, oncostatin M, ciliary neurotrophic factor, cardiotropin-1, and leukemic inhibitory factor. From a clinical standpoint, several pyrogenic cytokines

**FIGURE 3-1** Schematic representation of the pathogenesis of fever. *cAMP*, Cyclic adenosine monophosphate; *IFN*, interferon; *IL*, interleukin; *TNF*, tumor necrosis factor.

are produced during most febrile diseases and contribute to the febrile response.

The precise mechanism of action of pyrogenic cytokines in the central nervous system is still unclear. Endogenous pyrogens probably act on the circumventricular organs or organum vasculosum laminae terminalis (OVLT), a rich vascular network associated with neurons of the preoptic anterior hypothalamus.<sup>13-15</sup> Ablation of the OVLT prevents fever after a peripheral injection of endogenous pyrogens but has no effect when endogenous pyrogens are injected directly into the brain tissue.<sup>14</sup> In the region of the OVLT the blood-brain barrier is minimal, and endothelial cells lining this region may allow direct movement of endogenous pyrogens into the brain or may release arachidonic acid metabolites in response to endogenous pyrogens, which then move into the brain. The production of arachidonic acid metabolites, particularly prostaglandin  $E_2$  via the cyclooxygenase 2 (COX-2) pathway, is clearly important in the pathogenesis of fever because COX inhibitors, and specifically COX-2 inhibitors, effectively reduce the febrile response but have no effect on the normal body temperature. The prostaglandins do not act directly but initiate neuronal signaling by producing a cascade of changes in cyclic nucleotides, calcium, and monoamines leading to a higher set-point in the hypothalamic thermoregulatory center.

Physiologic mechanisms exist to control the febrile response and prevent extremes that are incompatible with life. Multiple feedback mechanisms limit the activity of the pyrogenic cytokines, and many endogenous cryogens or antipyretics have been identified.<sup>16,17</sup> For example, IL-10, which can be induced by pyrogenic cytokines, inhibits further production of IL-1 and TNF. Arginine vasopressin and  $\alpha$ -melanocyte-stimulating hormone act within the brain to decrease fever.<sup>16-19</sup> When administered to human beings,  $\alpha$ -melanocyte-stimulating hormone is a much more potent antipyretic than acetaminophen. Nitric oxide also has been shown to have an antipyretic role, mediated by cyclic guanosine monophosphate, in the anterior hypothalamic-preoptic region.<sup>20</sup>

The cytokines that act as endogenous pyrogens have a variety of biologic effects. Therefore the onset of fever is accompanied by several hematologic, immunologic, and metabolic changes referred to as the *acute phase response*. In particular, IL-6 and IL-11 induce the synthesis of acute phase proteins by hepatocytes, including fibrinogen, C-reactive protein, haptoglobin, and others. Similarly, hypoferrinemia, hypozincemia, and hypercupremia are cytokine mediated, as is the activation of lymphocytes, which in turn produce additional cytokines.

Pyrogenic cytokines, particularly IL-1 and TNF- $\alpha$ , cause membrane perturbation with an increase in phospholipases and the production of arachidonic acid.<sup>12,13</sup> The subsequent production of mediators depends on the metabolic pathways

for arachidonic acid in the target tissue. Prostaglandins induced by endogenous pyrogens stimulate the muscle catabolism associated with fever and induce collagenase synthesis from synovial cells, contributing to the muscle and joint pain often seen with fever. Local tissue responses to IL-1 $\beta$  and TNF- $\alpha$  may stimulate afferent neural impulses that lead to behavioral responses associated with fever, such as lethargy and anorexia. As expected, treatment with COX inhibitors can diminish many of the signs of fever.

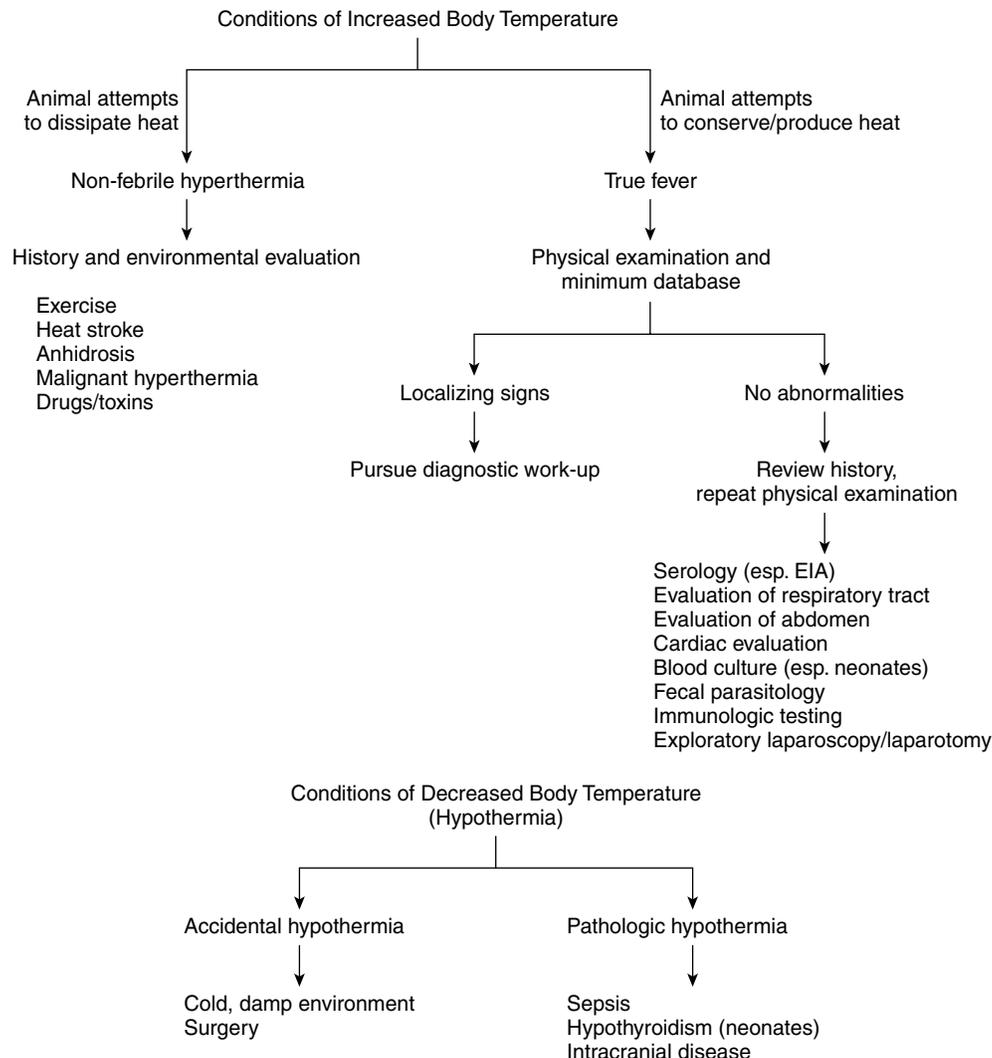

## ☞ EFFECTS OF FEVER

Fever is a normal physiologic response with beneficial and adverse effects to the animal. With the exception of some viral infections, the elevation in temperature is generally not high enough to affect pathogens directly. However, studies on bacterial infections in several species have demonstrated an increase in survival with fever, which is thought to be caused primarily by enhanced host defenses.<sup>21-23</sup> In addition, the concentration of iron, which is required by many bacteria for multiplication, decreases during the acute phase response.<sup>24-26</sup> If the temperature becomes extremely high, many of the beneficial effects are reversed.<sup>2,27,28</sup> In rabbits

the severity of bacterial infection increases when the body temperature is more than 3° C (5° F) above normal. The increased catabolism, variable anorexia, and increased metabolic rate can lead to muscle wasting and weakness when fever is prolonged. Although seizures induced by fever are uncommon in horses, they can be seen in neonates when the temperature is above 42° C (108° F).<sup>29</sup> In debilitated animals prolonged fever has been associated with cardiovascular failure.

## ☞ APPROACH TO FEVER

Increased body temperature is a common clinical sign with diverse causes (Figure 3-2). Fortunately, in many cases the cause may be readily apparent on the basis of the signalment, history, and physical examination. Conditions of increased temperature, such as exercise-related hyperthermia and malignant hyperthermia, are often apparent from the history. Infectious diseases remain the most common cause of fever, and often localizing clinical signs such as nasal discharge or diarrhea aid in the diagnosis. In other cases an increased temperature may be one component of another obvious condition, such as neoplasm, immune-mediated disease, or a drug reaction.

**FIGURE 3-2** Approach to changes in body temperature.

## ☞ FEVER OF UNKNOWN ORIGIN

Fever of unknown origin exists when fever is prolonged with no other specific signs. In many cases the cause is a common disease with an unusual presentation. The specific criteria used to define fever of unknown origin in the horse in a review of 63 cases included the following: (1) illness of at least 3 weeks' duration associated with nonspecific signs, (2) body temperature of at least 38.6° C (101.5° F) on several occasions, and (3) no clear diagnosis after an initial complete blood count and serum biochemical profile.<sup>30</sup> The most common cause was found to be infection, which was responsible for 43% of the cases. Other causes included neoplasms in 22% of cases; immune-mediated diseases in 6.5%; and miscellaneous diseases such as toxic hepatopathy, parasitism, and others in 19%. In 9.5% of cases no diagnosis was made. Therefore diagnosis of fever of unknown origin requires a systematic approach with emphasis on the evaluation of infectious disease.

The clinician can have the body temperature taken twice daily over a period of time to document fever and identify any pattern. Although some inconsistencies in the precise terminology used to define patterns of fever exist, intermittent fevers generally are characterized by recurring paroxysms of elevated temperature followed by periods of normal temperature, such as those fevers that demonstrate diurnal variation. Intermittent fevers most often are associated with infectious causes, particularly viral infections, although they may be seen with a variety of other conditions. In most cases of intermittent fever the temperature tends to peak in the late afternoon or evening, though this is not always the case. Remittent fevers are those in which diurnal variation is exaggerated without a return to normal body temperature or those with a cyclic pattern in which the temperature elevation lasts for several days, such as may be seen with equine infectious anemia virus. Biphasic fevers, in which an initial rise in body temperature precedes a period of normal temperature and then a second rise, are characteristic of certain diseases such as equine monocytic ehrlichiosis (Potomac horse fever). Sustained fevers are those in which the elevation of temperature is consistent.

A complete history is important when investigating fever of unknown origin. Any exposure to *Streptococcus equi* ssp. *equi* (strangles) may be significant because of the association of this organism with internal abscessation. Travel history may be relevant, especially regarding diseases with a geographic influence such as babesiosis and coccidioidomycosis.

The clinician always should perform a careful physical examination, including rectal palpation. Repeating the physical examination may yield new information. The clinician also should perform a complete neurologic examination because disorders of the central nervous system may cause aberrations in temperature through pyrogenic cytokines or in some cases through direct effects on thermoregulatory centers.

Ancillary diagnostic tests usually are required to diagnose fever of unknown origin. A database, including complete blood count, fibrinogen, biochemical profile with bile acids, and urinalysis, should be obtained. Hemoparasites occasionally may be seen on the blood smear, but the apparent absence of organisms does not rule out a parasitemia that is below readily detectable limits. Abnormalities consistent with chronic infection or inflammation, including anemia, hyperfibrinogenemia, and hyperglobulinemia, are common

but nonspecific findings. If an elevation of serum protein occurs, further assessment by serum protein electrophoresis and specific immunoglobulin quantitation may be indicated. A monoclonal gammopathy is characteristic of plasma cell myeloma and other tumors of the reticuloendothelial system, both of which may initiate fever directly and increase susceptibility to bacterial infection. In general, immunodeficiencies may be associated with chronic infections. If the serum albumin is low, the veterinarian should investigate the causes of hypoalbuminemia, including decreased production because of significant hepatic disease, increased gastrointestinal or renal loss, or loss into a third space. The presence of hypercalcemia can be helpful in establishing a diagnosis because in horses hypercalcemia most often is linked with renal disease or neoplasms.

Infections of the respiratory tract and abdomen frequently are associated with fever of unknown origin in the horse, and therefore these systems should be thoroughly evaluated. Careful auscultation of the thorax using a rebreathing bag should be performed at rest and, if possible, after exercise. Endoscopy, including examination of the guttural pouches, can be useful. Diagnostic imaging of the thorax, including radiographs and ultrasound, often is indicated. The clinician also should include thoracocentesis in evaluation of the thorax because abnormalities occasionally are apparent even without increases in the volume of pleural fluid. Pleuroscopy, which allows direct visual examination of the pleural space and which may facilitate biopsy of any masses, can be helpful in establishing a diagnosis, especially when neoplasia is suspected.

Peritonitis and abdominal abscessation are common causes of fever of unknown origin, and the veterinarian should include abdominocentesis in the diagnostic plan. The peritoneal fluid should be evaluated for protein, cellularity, and cell morphology, and culture should be performed. The veterinarian should remember that although many neoplastic conditions involve the abdomen, neoplastic cells are not always observed in the peritoneal fluid. In cases of gastric squamous cell carcinoma, gastroscopy is helpful in establishing the diagnosis. Radiographs of the abdomen may be useful, especially in neonates, and ultrasound of the abdomen may help identify fluid for collection or abnormalities that indicate further evaluation, such as abdominal masses or pathologic liver conditions.

Gastrointestinal parasitism is a common clinical problem in the horse, although it is associated only occasionally with fever. However, feces should be examined for parasite ova in horses with fever of unknown origin. In cases of suspected gastrointestinal protein loss, diarrhea, or melena, one should consider diagnostic procedures such as fecal culture, polymerase chain reaction for *Salmonella*, rectal mucosal biopsy, or absorption tests.

Bacterial endocarditis can cause a fever of unknown origin, although the condition is not as common in horses as in some other species. In the study by Mair, Taylor, and Pinsent, the authors identified endocarditis in 3 of 63 cases of fever of unknown origin.<sup>30</sup> In each case a murmur they did not identify initially became apparent several weeks after the onset of illness. Therefore a thorough cardiac evaluation, including echocardiography, is indicated.

Blood cultures are generally most useful in neonates but can yield valuable information in adult horses with fever as well. Ideally, collect three to five samples at least 45 minutes

apart when the horse is not on a regimen of antibiotic therapy. Sampling just before and during a temperature rise is most likely to yield a positive culture.

The clinician should consider equine infectious anemia as a differential diagnosis for horses with fever of unknown origin and should perform a serologic examination. Recently, a serologic test for detection of antibodies to the M protein of *Streptococcus equi* ssp. *equi* was developed as an aid in the diagnosis of internal abscessation.<sup>31</sup> Serologic tests for equine babesiosis, brucellosis, and coccidioidomycosis are also available.

Immune-mediated disorders such as immune-mediated hemolytic anemia, immune-mediated thrombocytopenia, systemic lupus erythematosus, vasculitides, and rheumatoid arthritis have been implicated as causes of fever of unknown origin, but more commonly in human beings and small animals than in horses. However, appropriate diagnostic tests, such as the Coombs' test, skin biopsy, and antinuclear antibody testing, may be useful in some cases.

Exploratory laparoscopy or laparotomy is indicated when abdominal involvement is evident or the animal is becoming progressively debilitated. Occasionally, bone marrow aspiration may be useful, particularly in those horses with persistent abnormalities in circulating cell populations. In cases in which a specific diagnosis has not been made, therapeutic trials with antimicrobials may help, and in cases of suspected immune-mediated disease, corticosteroids may help.

## ☞ HYPOTHERMIA

Hypothermia occurs when the core body temperature drops below accepted normal values. In clinical cases hypothermia can be characterized as accidental or pathologic (see [Figure 3-2](#)). In accidental hypothermia a spontaneous decrease in the core body temperature occurs independent of actual disruption to the thermoregulatory system. These cases often can be identified from the history. Mild accidental hypothermia sometimes occurs with surgical procedures. Most often, accidental hypothermia is associated with exposure to cold or cold, damp environments, which can lead to severe hypothermia and death. Neonates are particularly susceptible to hypothermia, although central thermoregulation through the hypothalamus is normal.<sup>29</sup> Sick foals often decrease their activity and nutritional intake and have alterations in circulation. They also have a large ratio of surface area to body weight, enhancing heat loss. Geriatric and otherwise debilitated animals are also at increased risk of hypothermia.

One should consider pathologic causes of hypothermia when no clear reason for accidental hypothermia is evident. Pathologic hypothermia occurs in association with disorders that decrease metabolic activity or directly affect the thermoregulatory center and occurs with endocrine disorders, sepsis, and intracranial disease. In horses hypothyroidism is probably an uncommon clinical problem; however, impaired thermoregulation has been seen in foals with congenital hypothyroidism.<sup>32</sup> Lesions of the thyroid gland also have been associated with hypothermia in donkeys.<sup>33</sup> Hypothermia has been observed with septicemia and shock, especially in neonates, in which 24% of septic foals were found to have a decreased body temperature.<sup>29</sup>

The ability to generate heat through shivering is impaired or lost when the body temperature becomes too low. The animal experiences a decrease in the metabolic rate of most

tissues. Heart rate, cardiac output, glomerular filtration, and blood pressure may decrease.

## CHANGES IN BODY WEIGHT

*Jonathan H. Foreman*

An unwelcome or unexpected change in the body weight of a horse is a commonly encountered problem in equine practice. Although obesity may be a more common problem, weight loss often represents a more serious situation, with potentially severe consequences. Normal or acceptable body weight is also in the eye of the beholder because a horse with a given body weight might look overweight as an endurance horse, appropriate as a Thoroughbred racehorse, or too thin as a show hunter.

Whether dealing with a problem of weight loss or weight gain, the veterinarian always should investigate the feeding practices of the horse. Not uncommonly the owner reports that the horse is receiving 3 lb of grain twice daily when the actual measuring device (usually the everyday coffee can) differs in net grain weight once the volume of the measuring device and grain density are taken into account. Observing firsthand the feeding practices of the stable may be necessary to document that the horse actually is getting the reported amount of grain 2 or 3 times daily. Hay should be examined for type, quality (color, texture, leafiness, and steminess), mold, weeds, and potentially toxic plants. Hay analysis will help in the accurate assessment of the nutritional value of the hay. The horse in question should be observed eating hay and grain to ensure that it really does consume the amounts the owner or feeder reports.

The veterinarian also should observe nursing foals when they suckle. The udder should be examined before and after nursing to ensure that the mare actually is producing sufficient milk and that the foal actually is nursing the mare completely until her udder is empty. The milk itself should be examined from both halves of the udder to see that it appears grossly normal (no evidence of mastitis). The nostrils of the foal should be examined after nursing to determine the presence of milk reflux caused by dysphagia, esophageal obstruction, or gastric reflux associated with gastrointestinal ulcers.

## ☞ DECREASED BODY WEIGHT

Losses in body weight are usually insidious and chronic but may be surprisingly rapid in the face of acute overwhelming systemic infections ([Table 3-1](#)). Causes have been classified variously as gastrointestinal, nutritional, infectious, or hypoproteinemic.<sup>1,2</sup> Differential mechanisms include decreased feed intake, decreased absorption of nutrients, decreased nutrient utilization, and increased loss of energy or protein leading to a catabolic "sink."<sup>1-3</sup>

Decreased feed intake may be caused by management factors, poor dentition, dysphagia, or esophageal obstruction. Management factors leading to weight loss may be multifactorial and include inadequate amounts of feed, inadequate quality of feed, or inability of the horse to eat the proper amounts of the feed given. A horse with severe lameness (e.g., chronic laminitis) may not be able to ambulate to the feed source. A horse low on the pecking order in a pasture hierarchy may be unable to eat because it cannot approach the feed without

TABLE 3-1

**Mechanisms and Selected Differential Diagnoses for Decreased Body Weight**

Mechanism	Differential Diagnoses
Lack of access to appropriate food	Unappetizing or inappropriate types of feed Poor-quality feed Insufficient quantity of feed Inability to access the available feed: <i>Lameness, other musculoskeletal abnormality</i> <i>Social factors within the herd (“pecking order”)</i>
Lack of ingestion of available nutrients	Lack of appetite Inadequate prehension <i>Nigropallidal encephalomalacia</i> <i>Masseter myodegeneration</i> Abnormal mastication <i>Poor dentition</i> <i>Masseter myodegeneration</i> Abnormal swallowing <i>Dysphagia</i> Abnormal esophageal transit <i>Esophageal abnormalities</i>
Abnormal digestion, absorption, or metabolism of nutrients	Gastrointestinal dysfunction <i>Gastrointestinal ulceration</i> <i>Inflammatory bowel disorder</i> <i>Neoplasia</i> <i>Parasitism</i> Hepatic dysfunction Toxicities
Inadequate delivery of nutrients to peripheral tissues	Cardiovascular disease <i>Heart failure</i> Respiratory disease <i>Recurrent airway obstruction (chronic obstructive pulmonary disease)</i> Hepatic disease
Increased rate of protein and energy use or loss	Unusual levels of physical activity Late gestation, early lactation Adaptation to environmental conditions (e.g., cold) Neoplasia Infection, inflammation <i>Pneumonia</i> <i>Pleuritis</i> <i>Peritonitis</i> <i>Equine infectious anemia</i> Pain Heart failure Endocrine disorder <i>Pituitary pars intermedia dysfunction</i> Gastrointestinal disease Renal disease
Primary muscle wasting disorders	Neurogenic muscle atrophy Primary muscle disease <i>Equine motor neuron disease</i> <i>Immune-mediated myopathy</i> <i>Polysaccharide storage myopathy</i>

the other horses bullying it and fending it away. The feed must be palatable and digestible. Appropriate amounts and types of concentrates must be fed with consideration to the work schedule or pregnancy status of the horse. Proper investigation of stable feeding practices is described earlier.

Poor dentition may cause the horse not to eat some or all of its grain or hay. Parrot-mouthed horses or aged horses with receding incisor teeth (more than 25 years old) may have difficulty in tearing off grass when grazing. A horse with one or more oral sores from a poorly fitting bit or sharp cheek teeth

may exhibit partial or complete inappetence because of pain associated with chewing. Sharp cheek teeth, wave mouth, or step mouth may lead to poor digestion and incomplete absorption of nutrients because of inadequate mastication of hay leading to poor fiber use during the hindgut (cecum) fermentation process.

Dysphagia has many causes, including abnormal prehension, chewing, or swallowing.<sup>4</sup> Abnormal prehension can be caused by tongue lacerations; dental, mandibular, or maxillary fractures; damage to nerves supplying the tongue or facial musculature (local trauma, equine protozoal myelitis, or polyneuritis equi); or central neurologic disease (equine protozoal myelitis). Basal ganglia lesions caused by poisoning by ingestion of yellow star thistle or Russian knapweed prevent normal prehension in the pharynx.<sup>4</sup> Swallowing abnormalities may be caused by neurologic (equine protozoal myelitis, viral encephalitis, or guttural pouch infection); muscular; or physical obstructions such as strangles, abscesses, or guttural pouch distention.<sup>4</sup> Muscular causes include hyperkalemic periodic paralysis in Quarter Horse foals, vitamin E or selenium deficiency in neonates, botulism in neonates and adults, and local trauma subsequent to laryngeal surgery (laryngoplasty).

Esophageal obstruction usually presents acutely because an apparently dysphagic horse regurgitates food from its nostrils while attempting to eat or drink. Chronic choke, or anorexia related to painful swallowing caused by partial esophageal obstruction, may lead to weight loss without the owner realizing that the horse is not eating adequately. Megaesophagus and esophageal diverticula may also result in dysphagia, intermittent obstruction, aspiration pneumonia, and chronic weight loss. The accurate diagnosis of some esophageal disorders may require esophageal endoscopy or contrast radiography.

If the horse with weight loss has been observed to fully ingest adequate amounts of good-quality hay and grain, then decreased feed absorption must be considered the reason for weight loss. Maldigestion and malabsorption are not easily confirmed diagnoses, but tests based on luminal absorption of simple sugars (xylose or glucose tolerance tests) have been used to document malabsorption syndromes.<sup>3,5,6</sup> These tests are described in greater detail in Chapter 15. Malabsorption may be caused by parasitism, diarrhea, and inflammatory or neoplastic intestinal disease.

Gastrointestinal parasitism results in weight loss because of several mechanisms.<sup>2</sup> Parasites may compete directly for nutrients within the lumen of the bowel. Malabsorption may result from a lack of mucosal integrity, a decrease in intestinal villi size and number (and subsequent decrease in mucosal absorptive surface area), and a decrease in digestive enzymes that originate in the mucosa. Competition of parasites for protein sources may result in decreased availability of amino acids for production of digestive enzymes or mucosal transport proteins. Increased mucosal permeability caused by leakiness in mucosal intercellular bridges may result in mucosal edema and increased transudation of intercellular fluid and its associated electrolytes, amino acids, and sugars into the lumen of the intestine.

Chronic diarrhea may result in partial or complete anorexia, which contributes directly to weight loss. More rapid (decreased) gastrointestinal transit time results in increased losses of incompletely digested dietary feedstuffs. Malabsorption may result from decreased transit time and from villus blunting caused by specific pathogens, such as in viral diarrhea (see Chapter 15). Bacterial pathogens may compete directly

for luminal nutrients. Mucosal invasion by viral and bacterial pathogens may cause mild to severe degrees of mucosal sloughing (ulcers), which results in maldigestion, malabsorption, and increased mucosal losses of intercellular fluid (e.g., in parasitism).

Assuming that the horse has adequate feed intake and absorption, inappropriate hepatic use of amino acids and sugars must be considered as a differential diagnosis for weight loss. Chronic liver disease may result in weight loss because of inappetence, maldigestion (caused by inadequate bile acid production), and inadequate or improper processing of amino acids into normal plasma proteins in the liver. These abnormalities may result in lowered concentrations of serum albumin, liver-dependent clotting factors (factors II, VII, IX, and X), and total plasma or serum protein. Lowered circulating proteins (especially albumin) may result in decreased plasma colloid osmotic pressure and thus may manifest as peripheral dependent edema in the distal limbs, pectoral region, and ventral midline. This peripheral edema may mask further weight loss by making the torso of the horse appear to be heavier than it actually is. Decreases in clotting factors may result in bleeding diatheses. Hyperlipemia, hyperlipidemia, fatty liver syndrome, and ketosis may be seen in poorly fed ponies and in miniature horses with acute anorexia or overwhelming energy demands, such as pregnancy or lactation.<sup>7</sup>

Increased loss of protein or energy is a common cause of decreased body weight in horses. Luminal losses of fluid, electrolytes, and nutrients were described earlier for intestinal parasitism and diarrhea. Acute inflammatory protein losses may occur into major body cavities in overwhelming infections such as pleuritis or peritonitis. Chronic abscessing pneumonia, pleuritis, and peritonitis often result in increased, rather than acutely decreased, serum total protein because of increased  $\gamma$ -globulin production in response to chronic antigenic stimulation from the chronic infection. These chronic infections also usually have weight loss as an additional clinical sign because of the continuing catabolic processes associated with the infection itself. Equine infectious anemia is a type of persistent systemic infection that in its symptomatic form may result in chronic weight loss and varying levels of anemia.<sup>8</sup> Asymptomatic equine infectious anemia carriers may have no weight loss or other obvious clinical signs but can infect pasture mates via vector transmission.

Protein-losing enteropathy is not a definitive diagnosis but rather is a group of diseases, each of which results in luminal losses of fluid, electrolytes, plasma proteins, and nutrients. Mechanisms of protein and fluid loss were described earlier for intestinal parasitism and diarrhea. Gastrointestinal ulcers, especially in the right dorsal colon, have been reported to result in lowered serum total protein and weight loss.<sup>9</sup> One of the early indications of nonsteroidal anti-inflammatory drug toxicity is detection of a lowered serum total protein. Horses with such a condition also may manifest varying degrees of inappetence and colic, especially during the immediate postprandial period. Intestinal neoplasms (usually lymphosarcoma) often manifest as a protein-losing enteropathy with weight loss.<sup>10</sup>

Acute or chronic renal diseases, especially involving glomerulonephritis, can result in urinary protein loss and subsequent body weight loss.<sup>2</sup> Horses with this condition may have polyuria and polydipsia as associated clinical signs. Owners or handlers often report polyuria as increased wetness in stall bedding. The veterinarian should question owners thoroughly

regarding the water intake of the horse. The veterinarian may need to observe stable watering habits, often including actually measuring the volume of the water buckets to establish definitively the presence of polydipsia. Turning off automatic water feeders in the stall or pasture and offering the horse measured volumes of water from additional buckets may be necessary to establish a diagnosis of polydipsia. Urine puddles in stalls or collected urine samples may foam excessively because of increased protein concentrations. Increased urinary protein concentrations can be diagnosed quickly on the farm with the proper interpretation of urine dipstick protein indicators.

Neoplasms or abscesses within the thorax or abdomen serve as catabolic energy and protein sinks, resulting in chronic weight loss.<sup>2,10,11</sup> Chronic pain, such as that associated with severe, unresponsive laminitis, results in increased catabolism and weight loss, probably because of chronically elevated systemic catecholamine levels. Increased circulating epinephrine and norepinephrine levels result in a whole-body catabolic state with increased breakdown of stored energy sources and ultimately result in chronic weight loss. Similar weight loss caused by systemic catabolism can result from chronically elevated serum cortisol associated with pituitary adenoma and secondary hyperadrenocorticism.

Heart murmurs and resultant heart failure can cause weight loss because of inefficiency of circulation of nutrients and oxygen to peripheral tissues. Chronic obstructive pulmonary disease or heaves may result in weight loss because of an increase in the work of breathing and poor oxygenation of peripheral tissues. Although ventral abdominal musculature may hypertrophy and result in a heave line, weight loss is manifested by increased depth between the ribs and decreased muscular thickness and definition along the dorsal midline. Suckling foals with severe pneumonia may manifest weight loss if they become inappetent because of decreased suckling related to their severe dyspnea.

## APPROACH TO THE DIAGNOSIS OF WEIGHT LOSS

An appropriately taken history should document the type, amount, and quality of feed and hay being provided daily. Documentation of deworming products used and intervals of administration is critical. The history also may document the presence of anorexia, depression, polyuria, polydipsia, diarrhea, and other important historical signs that may point more quickly toward a specific cause of the weight loss.

The physical examination should reveal the presence of weight loss, a cardiac murmur, pneumonia or pleuropneumonia (increased lung sounds), chronic obstructive pulmonary disease (increased abnormal expiratory lung sounds), dental abnormalities, peripheral edema, urine staining on the hindlimbs, diarrhea, icterus, nasal discharge (dysphagia, pneumonia), fever, or hirsutism (secondary hyperadrenocorticism). The rectal examination may document the presence of intra-abdominal masses (abscesses or neoplasms), enlarged left kidney, thickened intestinal or rectal wall, colonic displacement, gritty peritoneal surfaces (peritonitis), gritty feces (sand impaction), or diarrhea.

Fecal flotation may serve as an adequate screening tool to determine whether any evidence of parasitism exists. In the event of a positive fecal flotation, Baermann sedimentation may be necessary to determine quantitatively the severity of the patent parasitic load in the horse with weight loss. Fecal

occult blood may be positive with gastrointestinal ulceration or neoplasms, but parasites or a recent rectal examination also may result in positive results.

Routine hematologic testing (complete blood count and fibrinogen) should assist in diagnosing infectious conditions such as pleuritis or peritonitis. Decreased serum or plasma total protein and albumin concentrations are evidence of hypoproteinemia and make the following conditions more likely: severe malnutrition, protein-losing enteropathy (diarrhea, parasitism, ulceration, intestinal neoplasms, or inflammatory intestinal disease), glomerular disease, acute pleuritis or peritonitis, and chronic liver disease. Increased total protein concentrations, especially  $\gamma$ -globulins, make chronic closed-cavity infections such as abscesses, peritonitis, or pleuritis more likely. Increased  $\gamma$ -globulin fractions suggest the presence of parasitism.

Routine serum biochemistries should aid in diagnosing renal (renal azotemia, electrolyte abnormalities) and liver disease (increased  $\gamma$ -glutamyltransferase, aspartate aminotransferase, serum alkaline phosphatase, and lactate dehydrogenase). Urinalysis should reveal increased protein levels on dipstick or quantitative analysis in the event of glomerular protein losses. Metabolic alkalosis may be evident in the aftermath of salivary bicarbonate losses caused by dysphagia or esophageal obstruction.

Endoscopy may aid in diagnosing causes of dysphagia or esophageal obstruction. Lengthy endoscopes are necessary for examination of large adult horses for suspected gastrointestinal ulcers, but shorter endoscopes may suffice for foals or shorter-necked adults (e.g., Arabians and ponies).

Peritoneal fluid analysis documents the presence of a transudate (equivocal infection) or exudate (probable infection).<sup>12,13</sup> Aerobic and anaerobic peritoneal fluid cultures should be performed if intra-abdominal infection is suspected. Exfoliative cytologic examination rarely may document the presence of neoplastic cells from intra-abdominal neoplasms.<sup>2,10-14</sup>

Nonroutine tests should be performed only as indicated and should include oral absorption tests (see Chapter 15) and biopsies of the liver, kidney, or intestinal wall. Abdominal or thoracic ultrasonography should help in ruling out abnormalities of the liver or kidneys and may document the presence of abnormal fluid (peritonitis or pleuritis) or masses (abscesses or neoplasms). Cardiac ultrasound should be definitive in the event of a murmur and suspected heart failure. Radiography also may be helpful to document the presence of thoracic masses or chronic obstructive pulmonary disease, but increased pleural fluid obscures visualization of other intrathoracic structures.

## ☞ INCREASED BODY WEIGHT

Overfeeding may be the most common cause of obesity in horses and also may be the easiest to correct. The veterinarian should investigate the feeding practices of the stable and feed and hay sources thoroughly. Novice horse owners, single-horse owners, and pony owners commonly overfeed their animals.

Ponies seem to be particularly susceptible to obesity, perhaps because their size renders them more easily overfed. However, at least one author has proposed that this tendency toward obesity in ponies receiving modern confinement diets may be because of their having evolved in the inhospitable ice age climates of northern Europe.<sup>15</sup> In that era the lack

of readily available grazing feedstuffs might have placed greater selection pressure on survival of ponies with more efficient dentition and better nutrient and fluid absorption from the gastrointestinal tract. The author argues that those ponies that had greater feed conversion efficiency would have been stronger, had longer lives, and been more available for breeding. Current illustrations of this theory may lie in the Welsh and Connemara pony breeds that still thrive and flourish in the wild in the inhospitable north Atlantic climates of the western coasts of Wales and Ireland, respectively.

Obesity has also been associated with equine metabolic syndrome, also known as *peripheral Cushing's disease* or *prelaminitic metabolic syndrome*.<sup>16-18</sup> Affected horses are insulin resistant and at increased risk of developing laminitis. They may exhibit either generalized obesity or regional adiposity, typically manifested as a cresty neck or fat pads next to the tailhead. Although equine metabolic syndrome has been recognized in many breeds, some breeds, including ponies, Morgans, Paso Finos, and Norwegian Fjords, appear to be predisposed. Certain management practices, such as the provision of a starch-rich, high glycemic-index diet to horses that are relatively inactive, may contribute to the development of the syndrome. Previously, affected horses were sometimes assumed to suffer from hypothyroidism, but recent studies do not support a primary role for thyroid dysfunction in equine metabolic syndrome.

Horses with pituitary pars intermedia dysfunction (PPID; equine Cushing's syndrome) may also have insulin resistance and abnormal accumulation of fat.<sup>19</sup> Although horses with PPID often have loss of muscle mass or weight loss, some individuals will also have excess fat deposition, especially along the crest of the neck, over the tailhead, in the sheath or in the supraorbital fossa. The presence of additional clinical signs, such as hirsutism, as well as specific testing for PPID, will help to differentiate these horses from those with insulin resistance and fat accumulation resulting from metabolic syndrome.

Hypothyroidism has been reported to be associated with weight gain in horses and obesity and infertility in broodmares.<sup>15,20</sup> However, evidence for hypothyroid-associated weight gain and infertility was lacking in surgically created hypothyroid pony<sup>21</sup> and Quarter Horse<sup>22</sup> subjects. Also, a clinical study demonstrated that decreased thyroid function was uncommon in broodmares and was not a common cause of infertility.<sup>23</sup> In general, hypothyroidism remains a somewhat controversial disorder in adult horses, both because of difficulties in accurately diagnosing the condition and the numerous extrathyroidal factors that can affect thyroid function.<sup>24-27</sup> Because resting thyroid hormone concentrations can vary widely depending on a number of factors, documentation of hypothyroidism may require performance of a thyroid-stimulating hormone or thyroid-releasing hormone stimulation test or determination of thyroid-stimulating hormone concentrations.<sup>25-27</sup> The diagnosis and treatment of thyroid dysfunction is described in greater detail elsewhere in this text.

Pregnancy in mares is a normal physiologic event that leads to increased body weight. Surprisingly, many new owners of mares may not know that their new purchase is pregnant. For an earlier negative pregnancy diagnosis to have been in error is not uncommon. Any mare that is gaining weight in an unexpected manner should be examined rectally, and by ultrasonography if necessary, for a possible pregnancy.

## APPROACH TO THE DIAGNOSIS OF INCREASED BODY WEIGHT

Major differential diagnoses for increased body weight include overfeeding; pregnancy; metabolic syndrome; and other conditions that result in abdominal distention, such as bloat, ascites, uroperitoneum, fetal hydrops, and rupture of the prepubic tendon or abdominal wall musculature. The latter conditions are described in greater detail in Chapter 18.

Feeding practices should be investigated and observed firsthand if necessary. A positive pregnancy status should be an easy historical and rectal diagnosis. Most hematologic and biochemical tests are normal in the pregnant or simply overweight horse. Horses should be evaluated for insulin resistance and PPID. Thyroid status should be assessed appropriately, not by simple resting thyroid hormone concentrations.<sup>24-26</sup>

Education of the client regarding feeding practices is important, especially if the overweight horse is determined simply to have been overfed by a novice owner. Dangerous consequences, including colic and laminitis, should be explained to the client.

### CLINICAL ASSESSMENT OF POOR PERFORMANCE

*Melissa T. Hines*

Any decrease in performance may be critical to the equine athlete. Numerous factors influence performance, including genetics, training, desire, and overall health. Peak athletic performance requires optimal function of all body systems, particularly those involved in locomotion and oxygen transport.

## ☞ APPROACH TO POOR PERFORMANCE

Determining the cause of poor performance in those horses without overt clinical disease often is challenging.<sup>1-4</sup> In a study by Martin, Reef, Parente, et al. of 348 cases of poor performance, a definitive diagnosis was established in 73.5% of cases after in-depth examination, which included the use of a high-speed treadmill.<sup>3</sup> Subtle abnormalities may be sufficient to impair performance, and in some cases problems may be evident only during exercise, contributing to the difficulty of making a diagnosis. Additionally, multiple problems may occur concurrently. In a study by Morris and Seeherman of 275 racehorses with a history of poor racing performance, 84% were found to have more than one abnormality.<sup>2</sup> Therefore determining the actual clinical significance of any given problem may be difficult.

Equine athletes presented for poor performance should undergo a comprehensive evaluation, the basic components of which include a history, detailed physical examination, and laboratory screening. The clinician should emphasize examination of the respiratory, musculoskeletal, and cardiovascular systems because these systems most often are linked to performance problems. In many cases standardized exercise testing, generally on a high-speed treadmill, is critical in identifying the problem. Endoscopic examination of the upper airways during exercise has proved particularly useful.

## 🌀 HISTORY

Obtaining a complete history is a fundamental part of evaluating poor performance. The clinician should establish the use of the horse, the time in training, and the specifics of the training program. Determining whether the horse has never performed as expected or has experienced a decline in the level of performance is crucial. If the horse has never performed as expected, the veterinarian should consider a lack of ability, congenital abnormalities, and training problems. A change in performance, either sudden or insidious, often is associated with an acquired problem. The clinician should characterize specifically the decline in performance, including the intensity of exercise at which signs are observed and whether performance is abnormal from the onset of exercise or declines during an exercise bout. In those cases in which performance drops off during exercise, the clinician should determine whether the decline is acute or gradual and whether any other signs, such as stridor, are associated with it.

Other elements of the history with particular relevance to athletic performance include any previous respiratory disease, respiratory noise, or respiratory distress associated with exercise. Any change in gait also may be significant. Establishing the feeding practices, changes in appetite or body condition, the type of tack used, and whether sweating is appropriate is important. The clinician should determine the response to any medications that have been used, such as phenylbutazone or furosemide. The information obtained in the history may help direct the investigation.

## 🌀 GENERAL PHYSICAL EXAMINATION AND LABORATORY SCREENING

The clinician should perform a complete physical examination in all cases. Hematologic testing and a biochemical profile are indicated, although in most horses presented for poor performance without obvious clinical abnormalities, routine evaluation of a single sample is within normal limits. Because exercise can induce some changes in laboratory parameters, such as an increase in the packed cell volume and neutrophil count, considering the time of sample collection relative to exercise is important.<sup>5-7</sup> Potentially significant findings include changes consistent with chronic inflammation, such as anemia, hyperglobulinemia, and possibly hyperfibrinogenemia. Subclinical infections may have only slight alterations in the leukocyte count and differential. Viral infections, especially in the early stages, may be associated with a leukopenia and neutropenia. A decrease in the neutrophil-to-lymphocyte ratio has been associated with overtraining, although this is not a reliable correlation.<sup>7</sup>

Horses at rest normally maintain a significant proportion of red blood cells and hemoglobin in the splenic reserve.<sup>5,6,8</sup> Thus although total body hemoglobin increases in response to training and may correlate with performance, this cannot be determined from a resting sample. Special techniques must be used to document total red cell mass or hemoglobin.<sup>8,9</sup> Anemia can decrease the oxygen-carrying capacity during exercise, resulting in suboptimal performance.

Signs of organ dysfunction in horses presented for poor performance are not common findings. Muscle enzymes may be elevated, although many cases of myopathy are subclinical and require evaluation of muscle enzymes after exercise.<sup>10</sup> Much attention has been paid to the importance of electrolytes

and exercise; however, abnormalities seldom are found. In general, circulating electrolyte concentrations are regulated tightly and may not reflect closely the total body electrolyte status.<sup>11</sup> However, a concentration of potassium consistently below 3 mEq/L may suggest a potassium deficit. Chronic electrolyte deficiencies may be detected by performing renal fractional excretion of electrolytes.

## 🌀 EVALUATION OF THE RESPIRATORY SYSTEM

The clinician should give careful attention to examining the respiratory tract because abnormalities of this system frequently influence performance. The examination should include evaluation of air flow from the nares and percussion of the sinuses, as well as assessment of any cough or nasal discharge. Careful palpation of the larynx may reveal an increase in prominence of the muscular process of the left arytenoid cartilage resulting from a loss of mass of the left dorsal cricoarytenoid muscle associated with idiopathic hemiplegia. The clinician can use the laryngeal adductor response test, or slap test, to evaluate adduction of the arytenoid cartilages by slapping the withers during expiration and evaluating movement of the contralateral arytenoid by endoscopy or palpation. The clinician should perform a thorough auscultation of the trachea and lungs. Having the horse rebreathe from a plastic bag placed over the nostrils increases the respiratory rate and tidal volume, thus accentuating sounds. In addition to auscultation, the clinician should note the character and pattern of respiration, including the presence of any abdominal component, and the recovery time. Percussion of the thorax may be useful in establishing the lung border and any dull or hyperresonant areas, as well as in detecting pleural pain.

Dynamic obstruction of the airway is among the most common causes of poor performance in the equine athlete.<sup>2,3,12-14</sup> In the study by Morris and Seeherman of 275 racehorses evaluated for poor performance, 40% were found to have dynamic obstruction.<sup>2</sup> Similarly, in the study by Martin, Reef, Parente, et al. of 348 racehorses and show horses with poor performance, 148 (42.6%) had dynamic obstruction of the airways.<sup>3</sup> Of these 148 affected horses, 39 were found to have multiple airway abnormalities. An additional 22 horses had dynamic airway obstruction concurrently with a cardiac arrhythmia. In both studies of poor performance, the most common conditions causing airway obstruction were dorsal displacement of the soft palate and idiopathic left laryngeal hemiplegia with arytenoid collapse. Other conditions diagnosed included dynamic pharyngeal collapse, epiglottic entrapment, subepiglottic cyst, rostral displacement of the palatopharyngeal arch, and redundant alar folds. An important note is that many of the horses with airway obstruction did not have a history of abnormal respiratory noise and did not have abnormalities at rest. Also, not all abnormalities observed at rest caused obstruction. Therefore these studies emphasize the importance of treadmill videoendoscopy as a component of the evaluation of poor performance. In most cases the clinician should perform a treadmill videoendoscopy regardless of the history and physical examination findings.

Endoscopy also can be useful in identifying respiratory problems other than dynamic airway collapse. For example, the clinician can identify narrowing of the ventral nasal

meatus associated with sinusitis, nasal masses, and pharyngitis. If the endoscope is sufficiently long, tracheal injury and secretions in the lower respiratory tract can be visualized. Sampling of airway secretions by bronchoalveolar lavage may aid in the diagnosis of low-grade respiratory infections, small airway inflammatory disease, or exercise-induced pulmonary hemorrhage. In some cases evidence of inflammation and retropharyngeal lymphadenopathy on endoscopic examination of the guttural pouches has been associated with dorsal displacement of the soft palate, which may result from neuropathy of the pharyngeal branch of the vagus nerve.<sup>15</sup>

Radiographs and ultrasound may be indicated on evaluation of the respiratory system of horses with poor performance, especially in those horses with evidence of lower respiratory tract disease. Radiographs also can be useful in assessing upper respiratory disorders, allowing for the evaluation of soft tissue masses or fluid accumulations. In addition, sometimes the clinician can identify abnormalities of the pharyngeal and laryngeal structures such as thickening of the soft palate or hypoplasia of the epiglottis.

## ☞ EVALUATION OF THE CARDIOVASCULAR SYSTEM

Any decrease in cardiac output potentially can limit performance, making thorough evaluation of the cardiovascular system essential. On basic physical examination the clinician should evaluate the mucous membrane color, capillary refill time, and arterial and venous peripheral pulses, although finding abnormalities in these parameters in horses presented for decreased performance is uncommon. The clinician should perform careful auscultation of the heart on both sides of the thorax to evaluate the cardiac rhythm and murmurs. Many horses have murmurs that are of little clinical significance.<sup>2,16</sup> In the study by Martin, Reef, Parente, et al., 102 of the 348 horses were found to have murmurs, the most common being mitral regurgitation.<sup>3</sup> In all cases the murmur was determined to be clinically unimportant.

The clinician can use electrocardiography to evaluate the cardiac rhythm further and ideally should perform the procedure before, during, and after exercise using radiotelemetry. Cardiac arrhythmias were the only abnormality found in 33 of the 348 horses evaluated by Martin, Reef, Parente, et al. and were found in conjunction with dynamic airway obstruction in 22 horses.<sup>3</sup> However, in the study by Morris and Seeherman, arrhythmias were noted in just 2 of 275 horses.<sup>2</sup> The most frequent arrhythmias observed include atrial and ventricular premature depolarizations. Ventricular tachycardia and paroxysmal atrial fibrillation also have been noted. Changes in the T wave, once thought to be related to poor performance, and second-degree atrioventricular block have been found to have no effect on exercise capacity.<sup>17</sup>

Echocardiography before and after exercise helps to evaluate cardiac function. Martin, Reef, Parente, et al. found decreased fractional shortening indicating left ventricular dysfunction after exercise in 19 horses, only 8 of which had echocardiographic changes at rest.<sup>3</sup> Six of the 19 horses had clinically significant arrhythmias. Myocardial disease may contribute to left ventricular dysfunction and arrhythmias. Elevations in myocardial fractions of creatine kinase, lactate dehydrogenase, and troponin support myocardial disease but are not present in all cases.

## ☞ EVALUATION OF THE MUSCULOSKELETAL SYSTEM

A surprising number of horses presented for poor performance are found to be lame, even when lameness is not part of the presenting complaint.<sup>1,2,4</sup> Therefore the clinician should perform a complete lameness examination in all cases. In some horses presented for poor performance, the gait asymmetry may be subtle and only discernible at high speed, making diagnosis by traditional methods difficult. In these cases gait analysis on the treadmill and advanced diagnostic techniques such as nuclear scintigraphy, thermography, and computed tomography or magnetic resonance imaging may be useful. The clinician also should perform a neurologic examination to identify any deficits that could contribute to poor performance.

Myopathy can lead to decreased performance. In many cases the condition is subclinical and requires an exercise challenge test to make the diagnosis.<sup>3,10</sup> The clinician should measure creatine kinase before exercise and ideally 4 to 6 hours after an exercise bout consisting of 15 to 30 minutes at the trot. In normal horses this light exercise rarely causes more than a threefold increase in creatine kinase. An increase of fivefold or more indicates exertional rhabdomyolysis. A muscle biopsy can help to define the myopathy. In the study by Martin, Reef, Parente, et al., 10 of 348 horses developed clinical exertional rhabdomyolysis after exercise, and an additional 53 demonstrated subclinical myopathy as demonstrated by increased creatine kinase levels after exercise.<sup>3</sup>

## ☞ EXERCISE TESTING

Exercise testing provides a mechanism for evaluating a range of body systems under standard exercise conditions. In particular, measurements of cardiorespiratory and metabolic function taken during an exercise test provide information about the capacity and efficiency of key body systems involved in energy production. From a clinical standpoint exercise testing is generally most useful in assessing the effect on performance of abnormalities found on a physical examination. Testing also may help to establish the reason for reduced athletic capacity in horses that have no abnormalities on basic examinations. Exercise testing can be done in the field, which mimics the condition in which the horse actually performs. However, most testing is currently done on a treadmill, which provides more consistent conditions and an opportunity to perform a greater range of measurements. The specific protocol used for exercise testing may vary somewhat.<sup>1,18,19</sup> Occasionally a high-speed test is performed in which the horse is accelerated rapidly to maximal speed and run to fatigue. However, the most common type of test is an incremental test in which the speed increases every 1 to 2 minutes until the horse reaches fatigue, allowing for the generation of data during submaximal and maximal exercise. In most cases the test is performed with the treadmill at a slope of 10%. This slope is not so steep as to be completely unrepresentative of normal exercise, and yet it ensures that maximum-intensity exercise can be performed without reaching speeds that may be too fast for horse safety. Some parameters that can be assessed in an exercise test include heart rate, blood lactate level, arterial blood gases, total red cell volume, stride length, and oxygen uptake. Various spirometers, which are masks for measuring pulmonary ventilation, can be used to measure parameters

such as air flow rates, tidal volume and the durations of phases of the respiratory cycle.<sup>20</sup> As previously discussed, treadmill videoendoscopy is often valuable.

### HEART RATE DURING EXERCISE

Evaluation of the heart rate during exercise provides an indirect index of cardiovascular capacity and function. Several heart rate monitors are available.<sup>21</sup> Radiotelemetry also can be used to evaluate the heart rate and rhythm, particularly at the end of exercise. Because the stroke volume does not change greatly with increasing exercise speed, the heart rate provides a guide to changes in cardiac output. In general, a linear increase in heart rate occurs with increasing exercise speed up to the point at which the maximal heart rate is reached.<sup>22-24</sup> The maximal heart rate (HR<sub>max</sub>) is identified when no further increase in heart rate occurs despite an increase in exercise speed. The HR<sub>max</sub> does not change with training state, although the speed at which it is reached increases with increasing fitness.

One reference point for comparison of cardiovascular capacity is the treadmill speed at a heart rate of 200 beats/min ( $V_{200}$ ). At a heart rate of 200 beats/min, most horses are close to the point of onset of blood lactate accumulation. The  $V_{200}$  can be calculated by linear regression analysis or plotted using measurements taken at three to four submaximal exercise speeds, without the horse reaching maximal exercise. The clinician should take care when using the  $V_{200}$  to assess exercise capacity because at a heart rate of 200, horses may be exercising at different proportions of their HR<sub>max</sub> and therefore their maximal oxygen uptake ( $VO_{2max}$ ). In general, however, horses with the highest cardiovascular and metabolic capacities have the highest  $V_{200}$  values; that is, the better horses reach a heart rate of 200 at higher speeds than those with a lower exercise capacity. The  $V_{200}$  increases with training and can be useful for monitoring changes in fitness. The better-quality Thoroughbreds have a  $V_{200}$  of 8 to 9 m/sec in an exercise test with the treadmill set at a 10% slope. Values less than 7 m/sec are abnormal and if found in a fit horse indicate decreased cardiac capacity.

Another measurement of cardiovascular capacity is the treadmill speed at which the horse reaches HR<sub>max</sub>, known as  $V_{HRmax}$ . This value correlates with  $VO_{2max}$  and exercise capacity but requires the horse to exercise up to maximal speeds so that a plateau in heart rate can be identified.

Heart rate measurements are helpful in determining the actual significance of cardiac abnormalities such as murmurs and arrhythmias. In horses with functional cardiac disease, the reduced stroke volume necessitates higher heart rates to maintain adequate cardiac output. Also, studies in Standardbred racehorses have suggested that horses with musculoskeletal problems have an increased  $V_{200}$  and that monitoring the  $V_{200}$  may help to identify subclinical lameness.

### BLOOD OR PLASMA LACTATE MEASUREMENT

Exercising muscles produce lactate to some extent during all intensities of exercise, but production increases exponentially with the intensity of exercise.<sup>24-26</sup> As exercise becomes more intense, the aerobic energy contribution becomes insufficient to meet total energy requirements, and increased anaerobic metabolism results in increased lactate production. Lactate diffuses from muscle to blood, and therefore blood or plasma concentrations of lactate reflect muscle lactate. Some evidence

suggests that whole blood concentrations most accurately measure lactate accumulation because red blood cells actively take up lactate.<sup>26-29</sup>

The rate of increase of lactate in the blood may be used as an indirect indicator of cardiovascular and metabolic capacity. Horses with the highest aerobic capacities because of a high maximal cardiac output tend to have lower lactate values at submaximal exercise intensities than those with lower aerobic capacities. Lactate values can be used to compare horses or to evaluate training in the same horse. The treadmill speed at which a plasma lactate of 4 mmol/L ( $V_{LA4}$ ) is reached is one measure of lactate production, and a high value reflects good aerobic capacity. The  $V_{LA4}$  has been used to monitor changes in fitness. In fit Thoroughbred horses 3 years of age and older, values for  $V_{LA4}$  range from 8.0 to 9.5 m/sec. Horses that are not fit or that have respiratory disease have lower values. Another useful reference is the blood or plasma lactate at conclusion of the 10 m/sec exercise step of the incremental test, and highly fit, athletic horses usually have values below 5 mmol/L. High-quality sprint horses, which perform largely under anaerobic conditions and have a high anaerobic capacity, may have high peak lactate values.

### OXYGEN UPTAKE

The measurement of oxygen uptake ( $VO_2$ ) is critical to assessing athletic performance.<sup>22,23</sup> The  $VO_{2max}$  has been used as a key indicator of exercise capacity in human athletes since the 1950s. As the  $VO_2$  increases linearly with increasing treadmill speed,  $VO_{2max}$  can be identified when  $VO_2$  reaches a plateau despite an increase in speed. The Thoroughbred horse has  $VO_{2max}$  values that are higher than those of many other mammalian species when expressed on a mass-specific basis. The major factor responsible for the high  $VO_{2max}$  in athletic horses is their high oxygen-carrying capacity, which arises from a high maximum stroke volume and to some extent a large arteriovenous oxygen content difference. The  $VO_{2max}$  is a good index of changes in fitness and a measurement of exercise capacity in performance horses.

### MAXIMUM OXYGEN PULSE

The oxygen pulse is defined as the  $VO_2$ /heart rate and is expressed as ml/kg/beat. This value provides an indication of the maximum stroke volume, and in high-quality horses values range between 0.66 to 0.76 ml/kg/beat. Those horses with cardiac problems resulting in low cardiac outputs and individuals with low  $VO_{2max}$  values usually have values in the range of 0.5 to 0.56 ml/kg/beat. The maximum oxygen pulse also has been shown to correlate with treadmill total run time.

### ARTERIAL BLOOD GAS ANALYSIS DURING EXERCISE

Arterial blood gas analysis during exercise may be indicated, especially in horses in which respiratory disorders are the suspected cause of poor performance. For an accurate blood gas analysis, the clinician should take into account the temperature of the blood because it may reach 42° C during maximal exercise. At exercise intensities above 65%  $VO_{2max}$ , athletic horses become hypoxemic, although the extent varies between individuals.<sup>30-33</sup> Horses with low  $VO_{2max}$  values do not necessarily have a significant decrease in arterial oxygen tension.

## HEMATOCRIT AND TOTAL RED CELL VOLUME DURING EXERCISE

The total volume of red cells is a major determinant of oxygen-carrying capacity, and therefore measurement of red cell volume can give some index of exercise capacity. A postexercise packed cell volume test is not a reliable indicator of total red cell volume primarily because of plasma volume variations, but it does provide a rough estimate of total circulating red cells.

The clinician can make an accurate determination of red cell volume by techniques that use dye dilution after mobilization of the splenic erythrocyte pool to measure the plasma volume. Although total red cell volume increases with training, some evidence indicates that Standardbred racehorses with overtraining syndrome may develop an abnormal red cell hypervolemia that contributes to poor performance.<sup>9</sup>

## PEAK RUNNING SPEED AND TOTAL RUN TIME

The peak treadmill running speed and the total run time may indicate exercise capacity. In some studies of human athletes, the peak treadmill running speed during an exercise test was shown to be a predictor of performance. Athletic Thoroughbred racehorses can complete 60 seconds at 13 m/sec during an incremental exercise test at a 10% slope.

## STRIDE LENGTH

Athletic horses are thought to have better stride characteristics.<sup>4,34</sup> Some studies have shown a correlation between maximum stride length and the treadmill run time. An accelerometer device has been used to provide quantitative information about locomotory variables that may be useful in evaluating performance.<sup>34</sup>

## DYSPHAGIA

Laurie A. Beard

## ☞ NORMAL EATING

Normal eating is complex and requires normal anatomic structures and neurologic function. The process of eating can be divided into prehension (uptake of food into the oral cavity) and deglutition (transport of food from the oral cavity to the stomach). Prehension requires the lips to grasp and the incisors to tear the food.<sup>1</sup> Motor innervation to the tongue, lips, and muscles of mastication is provided by the hypoglossal, facial, and trigeminal nerves. Sensory input is important for successful prehension and requires intact olfactory, optic, and trigeminal nerves, providing smell, sight, and sensation of the rostral oral mucosa and lips. Normal prehension depends on the central nervous system to coordinate movements of the tongue and lips.

Deglutition involves mastication, swallowing, and transport of food through the esophagus to the stomach. Mastication initiates mechanical digestion and insalivation. Mastication is specifically a function of the molars to grind feed and the tongue and buccal muscles to position the food. The facial nerve provides motor and sensory fibers to the tongue and

pharynx. The glossopharyngeal nerve provides sensory fibers to the caudal third of the tongue. The trigeminal nerve is sensory to the teeth and provides the important parasympathetic fibers to the parotid salivary gland. Function of this gland is critical to help liquefy food and provides a small amount of digestive enzymes.

Swallowing is complex and is performed in a series of steps. Initially, food must be moved to the base of the tongue and formed into a bolus. This action requires coordinated movements of the tongue and pharynx. Second, the bolus is forced caudally. As this action takes place, the oropharynx relaxes and the soft palate elevates to seal the palatopharyngeal arch and nasopharynx.<sup>1</sup> Next, the bolus enters the oropharynx and the hyoid apparatus swings rostradorsally, which draws the larynx and the common pharynx forward.<sup>1,2</sup> The epiglottis is tipped caudally and prevents the bolus from entering the larynx. Finally, the bolus is moved into the common pharynx with pharyngeal muscle contractions and enters the open cranial esophageal sphincter. The sphincter closes to prevent esophagopharyngeal reflux and aerophagia. Herbivores are unique in that breathing continues uninterrupted during swallowing, unlike as in other animals.<sup>1</sup> The glossopharyngeal, vagus, and spinal accessory nerves provide sensory and motor fibers to the pharynx, larynx, and soft palate.

The esophageal phase of eating involves the transport of the food bolus to the stomach, with primary peristaltic waves, which are generated by continuous contraction of the pharyngeal peristalsis. The bolus is transported to the caudal esophageal sphincter, which relaxes to allow the bolus to enter the stomach and then contracts to prevent gastroesophageal reflux. If reflux does occur, esophageal clearance is achieved by secondary peristaltic waves. Antiperistalsis is normal in ruminants during eructation and regurgitation but is not normal in horses.<sup>1</sup>

## ☞ DYSPHAGIA

*Dysphagia* is defined as difficulty in swallowing but often is used to describe problems with eating.<sup>2</sup> Problems with eating may include problems with prehension, mastication, swallowing, and esophageal transport. In this section the term *dysphagia* is used in the broader sense to describe problems with eating. Dysphagia can result from a number of disorders affecting any part of the upper gastrointestinal system (i.e., oral cavity, pharynx, and esophagus). Clinical signs of dysphagia vary depending on the cause and the location of the problem but may include ptyalism (excessive salivation), gagging, dropping food, nasal discharge, and coughing. Dysphagia can result from morphologic or functional disorders. The causes of these diseases may be acquired or congenital. Morphologic causes of dysphagia include abnormal anatomy, obstruction of the upper gastrointestinal tract, inflammation, and pain. Examples of anatomic abnormalities include a cleft palate and subepiglottic cysts.<sup>3,4</sup> Obstruction of the upper gastrointestinal tract most commonly includes feed impactions of the esophagus but also can include pharyngeal obstructions secondary to retropharyngeal lymph node masses or severe guttural pouch tympany.<sup>1,2,5-8</sup> Inflammatory conditions resulting in pain and dysphagia include periodontal diseases, foreign bodies, pharyngitis, epiglottitis, and mandibular or maxillary fractures.<sup>1,3</sup>

Functional disorders resulting in dysphagia include neurologic, neuromuscular, and muscular diseases. Functional

disorders frequently result in problems with swallowing but less commonly involve mastication and prehension and rarely occur with esophageal transport. Neurologic diseases resulting in dysphagia may be peripheral or central. Peripheral neurologic problems frequently result from abnormalities of the guttural pouch but also can include toxic peripheral neuropathies, such as lead toxicity. Problems of the guttural pouch include infection (tympy, empyema, or mycosis), iatrogenic problems (infusion of caustic substances), and trauma (rupture of the longus capitis muscle from the basisphenoid bone and hemorrhage into the guttural pouch).<sup>2,9,10</sup> Central neurologic diseases may result in problems in prehension, mastication, or swallowing. Specific examples include equine protozoal myelitis, viral encephalitis (rabies and eastern and western encephalitis), toxic neuropathies (leukoencephalomalacia and nigropallidal encephalomalacia), and cerebral trauma.<sup>1,2,5,11,12</sup> Neuromuscular problems resulting in dysphagia generally manifest as a systemic disease and include diseases such as botulism and organophosphate toxicity.<sup>1,2,13</sup> Muscular diseases resulting in dysphagia are rare but include nutritional muscular dystrophy (white muscle disease).<sup>14</sup> Although reported more frequently in foals, nutritional muscular dystrophy is also seen in adult horses, and in some cases signs are limited to dysphagia associated with myodegeneration of the masseter muscles or tongue.<sup>15,16</sup>

### **BASIC APPROACH TO DYSPHAGIA**

The initial evaluation of dysphagia focuses on determining whether morphologic or functional abnormalities exist. To answer these questions best, the signalment, history, physical examination (including observation of the horse eating), and additional tests (e.g., endoscopic examination and radiographs) should be considered. Some morphologic abnormalities, such as a cleft palate, will be apparent at an early age. There is some evidence that esophageal disorders may be more common in Friesian horses.<sup>17</sup> A history of an acute onset of dysphagia is often consistent with trauma, whereas a slow, progressive onset of clinical signs is more consistent with a neurologic problem such as guttural pouch mycosis, equine protozoal myelitis, or toxicities. The clinician should assess exposure of the horse to toxic substances or plants (lead or yellow star thistle). A history of treatment before the onset of dysphagia suggests trauma or injury to the pharynx. Use of a balling gun or flushing of guttural pouches may result in iatrogenic injury to the pharynx, esophagus, and guttural pouches. The clinician should determine concurrent problems in other horses (e.g., strangles or other bacterial infections of the submandibular lymph nodes).

In performing the physical examination, the clinician should pay close attention to the head and neck. Because rabies is a potential cause of dysphagia, protective measures should be taken while performing a careful and thorough physical examination. Ideally, all clinicians working on horses should have an adequate rabies antibody titer. An examination of the oral cavity is best accomplished with a mouth speculum; good light; and, if necessary, the administration of sedation. The teeth should be examined carefully for retained deciduous caps, sharp points or hooks, wave mouth or step mouth, dental fractures, and patent infundibula.<sup>3</sup> Foreign bodies may become wedged between the molars or under the tongue. The tongue should be examined for lacerations, foreign bodies, and evidence of neoplasia. The throat latch area and neck should

be examined for heat or swelling, which might be caused by a ruptured esophagus. The lungs should be auscultated carefully to determine if the horse shows evidence of aspiration pneumonia resulting from dysphagia.

A valuable activity is to watch the horse eat. The distinction between dysphagia and anorexia is important. Dysphagic horses usually are hungry and will attempt to eat. Problems with prehension generally suggest a primary neurologic problem. Watching the horse try to graze and eat hay or grain may be necessary. Ingestion of yellow star thistle or Russian knapweed results in basal ganglia lesions (nigropallidal encephalomalacia). Horses with these lesions are unable to prehend food (with lack of coordination of the lips and tongue), but they can swallow.<sup>2</sup> Their ability to drink water should be evaluated carefully because some horses continue to drink despite swallowing difficulties. Horses that expel food while chewing may have problems with mastication. Coughing and nasal discharge indicate aspiration of food into the trachea. Problems with swallowing or regurgitation may cause aspiration. Esophageal obstruction results in regurgitation of food through the nares. Regurgitation often is observed during feeding but may occur shortly after or even hours after feeding. Ptyalism, without dysphagia, may result from ingestion of legume plants (especially second-cutting red clover) contaminated with *Rhizoctonia leguminicola*. This fungus produces a mycotoxin called *slaframine*, which has parasympathomimetic properties.<sup>2</sup> The excess salivation disappears once the animal stops feeding on the plant.

### **MORPHOLOGIC ABNORMALITIES**

Morphologic abnormalities that cause dysphagia are more easily diagnosed than functional disorders. Morphologic problems of the oral cavity generally result in problems of prehension or mastication. An oral examination (as outlined earlier) is particularly useful. The passing of a nasogastric tube, endoscopic examination, and radiographs (if necessary) are other diagnostic tests that may help to identify the anatomic localization and cause of dysphagia. Complete obstruction of the esophagus can be excluded if a nasogastric tube is passed successfully into the stomach. Feed impactions of the esophagus are common in horses. Esophageal impactions of feed may occur because of poor mastication or esophageal strictures or diverticulum.<sup>1,2,5</sup> The most common sites for obstructions occur in the cranial esophagus, at the thoracic inlet, and at the base of the heart.<sup>5</sup> Other esophageal abnormalities include rupture, fistula, cyst, diverticula, megaesophagus, and neoplasms.<sup>2,18</sup> An endoscopic examination allows visualization of the nasal passageways, nasopharynx, guttural pouches, pharynx, larynx, and esophagus. Inflammation of the pharynx, larynx, or esophagus is assessed best by endoscopic examination. Partial obstructions of the pharynx often result in dyspnea, especially during exercise, and sometimes can cause dysphagia. Retropharyngeal masses, guttural pouch tympany, and rarely neoplasms may result in pharyngeal obstruction and collapse.<sup>2,7,8</sup> Depending on the length of the endoscope available, the clinician can evaluate all or part of the esophagus for inflammation or obstruction.

Although they are not required in all situations, radiographs can provide additional information about horses with morphologic causes of dysphagia. Radiographs of the skull can help demonstrate the presence of periodontal disease, fractures of the mandible or maxilla, lesions of the temporomandibular

joint, or radiopaque foreign bodies.<sup>3</sup> Radiographs of the larynx or pharynx are indicated in cases of pharyngeal obstruction and are especially useful to evaluate retropharyngeal masses, neoplasms, or trauma.<sup>6-8</sup> Radiographs of esophageal perforations reveal subcutaneous air, which shows up as extraluminal radiolucencies.<sup>1</sup> Contrast studies of the esophagus, with the use of barium sulfate, may help differentiate cases of esophageal strictures, dilation, or diverticulum.<sup>2</sup> Radiographs of the thorax are indicated in horses with nasal discharge and abnormal thoracic auscultation because of the concerns of aspiration pneumonia.

## FUNCTIONAL ABNORMALITIES

Functional disorders that cause dysphagia are more difficult to diagnose and should be pursued after morphologic causes are not identified. The clinician also should consider a functional abnormality if the initial physical examination provides strong evidence of a neurologic, neuromuscular, or muscular problem. The initial step to evaluate functional causes of dysphagia is to perform a neurologic examination. The neurologic examination helps establish a neuroanatomic localization by (1) assessing brain, brainstem, and spinal cord functions; (2) determining if the problem is focal, multifocal, or diffuse; and (3) determining if the problem is a peripheral or central problem.

Cerebral disease usually manifests as seizures, head pressing, wandering, depression, and changes in mentation. Brainstem function can be assessed by cranial nerve examination. Evaluation of an abnormal response of the cranial nerves should establish the location of the problem within the brainstem. For example, the optic nerve can be assessed by the menace response (requiring the facial nerve) and by the pupillary light reflex (requiring the oculomotor nerve). Abnormalities of the oculomotor, trochlear, and abducens nerves manifest as strabismus or lack of a pupillary light reflex. Facial nerve paralysis (ear, eyelid, and muzzle droop) and vestibular disease (circling, nystagmus, and head tilt) often occur together because of the close proximity of these nerves as they exit the brainstem.<sup>19</sup> Endoscopic examination is a valuable tool to determine if pharyngeal or laryngeal paralysis is present. These problems may be caused by peripheral or central diseases. The dorso-lateral wall of the medial compartment of the guttural pouch contains a plexus of nerves, including the glossopharyngeal nerve; branches of the vagus, spinal accessory, and hypoglossal nerves; and the cranial cervical ganglion. Mycotic plaques, empyema, and trauma (hematoma) of the guttural pouch can result in pharyngeal paralysis, dorsal displacement of the soft palate, laryngeal hemiplegia, and occasionally Horner's syndrome.<sup>1,2,9,10,19</sup> The clinician should obtain skull radiographs in many horses with dysphagia; these are especially helpful when traumatic injuries are suspected. Rupture of the longus capitis muscle results in ventral deviation of the dorsal pharynx and narrowing of the nasopharynx. Bony fragments may be evident ventral to the basisphenoid bones in these horses.<sup>10</sup> Otitis media and pathologic fracture of the petrous temporal bone frequently result in vestibular disease and facial nerve paralysis and occasionally in glossopharyngeal and vagus nerve involvement. An endoscopic examination of the guttural pouches is helpful with this problem because the distal stylohyoid bone is thickened and irregular. Ventrodorsal, lateral, and rostralateral oblique radiographs also may reveal osseous changes of the stylohyoid bone, tympanic bulla, or petrous temporal bone.<sup>19</sup>

The clinical examination should include an evaluation of gait. Signs of ataxia, generalized weakness, and hypermetria along with cranial nerve signs may be observable with brainstem involvement. The clinician should evaluate the horse at the walk, the trot, down an incline, over a step, and backing and turning in tight circles. The clinician may wish to place the feet of the horse in abnormal positions and determine if the horse can reposition the leg correctly in a reasonable time. Generalized weakness (without ataxia) may manifest with a decrease in tail, eyelid, and tongue tone and muscle fasciculations. Weakness generally suggests a neuromuscular (botulism, organophosphate poisoning) or muscular problem.<sup>2,13,14</sup> Equine lower motor neuron disease results in generalized weakness and weight loss; however, affected horses are not dysphagic and do not exhibit cranial nerve abnormalities.<sup>20</sup> Ataxia or hypermetria along with dysphagia suggests a diffuse or multifocal disease that affects the spinal cord and brainstem. Examples of such diseases include equine protozoal myelitis, rabies, equine herpes myeloencephalopathy, polyneuritis equi, and a migrating parasite.<sup>10,21,22</sup> Further diagnostic tests are indicated in these cases, such as an evaluation of spinal fluid for cytologic abnormalities and chemistry and Western blot analysis for antibodies to *Sarcocystis neurona*.<sup>23</sup> Grass sickness, a disease found in Great Britain and other northern European countries, results in ileus and colic. Grass sickness can result in dysphagia, with problems in swallowing or esophageal transport.<sup>24</sup> Grass sickness is regarded as a fatal disease, resulting in ileus of the gastrointestinal tract, dysphagia, and weight loss, which most likely is caused by an unidentified neurotoxin. *Grass sickness* can be defined as a dysautonomia characterized by pathologic lesions in autonomic ganglia, enteric plexi, and specific nuclei in the central nervous system.<sup>25</sup> Additional information about the specific causes of dysphagia are covered elsewhere in this text.

## ABDOMINAL DISTENTION

Jonathan H. Foreman

Increases in body weight because of overeating or pregnancy must be distinguished from increases in body girth caused by bloat, ascites, uroperitoneum, fetal hydrops, or ruptured prepubic tendon. In each of these conditions body weight actually may increase because of fetal growth or fluid accumulation. More important, however, a perceptible change in the shape of the abdomen of the horse occurs.

Bloat usually is associated with colic signs in horses and is caused by gaseous intestinal distention resulting from ileus or simple obstruction of the large intestine or, rarely, the small intestine. Ileus caused by diarrhea, peritonitis, colic surgery, or parasympatholytic agents (e.g., atropine) can result in sufficient accumulation of intraluminal gas to be manifested as tympany, bloat, and mild to severe abdominal pain.<sup>1</sup> If optic topical atropine application is overly aggressive, secondary ileus and bloat may result. Rapid and severe gas production may follow grain overload; cecal and colonic fermentation of readily available carbohydrate sources results in rapid-onset colonic tympany and abdominal distention.<sup>2</sup> Exhaustion in endurance horses also is associated with intestinal shutdown and subsequent abdominal distention.<sup>3</sup> In any of these bloat conditions, abdominal auscultation in the flank area reveals

decreased or absent intestinal motility sounds (borborygmi) and perhaps increased gaseous distention sounds (pinging). Decreased borborygmi in the right flank are specific for cecal ileus.

Simple colonic obstruction also results in tympany and bloat. Strangulating obstruction results in greater pain than usually is manifested in simple obstruction and bloat. Colonic displacements are more common in older postpartum mares.<sup>4</sup> These horses often initially show mild colic signs and progressively develop more dramatic pain and abdominal distention. Miniature horses with simple obstructions caused by fecaliths often have bloat as the initial clinical sign.<sup>5</sup> Such cases have the additional complication that rectal examination may be impossible for differentiation of the source of the bloat. Even in full-sized horses, rectal examination may reveal that the abdomen is so filled with distended colon that the examiner cannot push an arm into the rectum any farther than wrist-deep. Colonic or cecal bloat can be relieved by trocarization through the flank, but relief is merely palliative and is usually temporary because the cause of the obstruction still has not been resolved.

Ascites does not occur commonly in horses and usually is caused by peritonitis or abdominal neoplasms. Peritonitis is caused by septicemia, laparotomy, intestinal leakage, internal abscess, or a penetrating external wound resulting in inflammation and usually infection of the peritoneal lining of the abdomen. Such inflammation results in increased fluid production by the squamous abdominal epithelium. Initially, this increased abdominal fluid may be characterized as a transudate (low cell count and low total protein). If inflammation with infection persists, the character of the fluid may change to that of an exudate (increased cell count >5000 nucleated cells/ $\mu$ l, increased neutrophil count, increased degenerate neutrophils, microscopically visible bacteria, and increased total protein).<sup>6,7</sup> These increases in abdominal fluid volume can be substantive and can result in abdominal distention that eventually becomes clinically apparent. Fluid ballottement in the equine abdomen is not an easily performed diagnostic technique but may be easier in foals, ponies, or miniature horses than in full-sized horses.

Ascites also may result from abdominal neoplasms. Tumors reported to cause ascites and weight loss in horses include lymphosarcoma, squamous cell carcinoma, mammary adenocarcinoma, and mesothelioma.<sup>8,9</sup> Although rare, mesothelioma may cause the most fluid production because it is a tumor of the fluid-producing cells of the peritoneal lining. Mesothelioma may result in the production of large volumes of fluid (several liters) in a short time (24 hours) after a similarly large volume is drained from the same horse via abdominal catheterization or trocarization.

Ascites also may result from any condition that produces lowered serum total protein and albumin. With lowered intravascular colloid osmotic pressure, fluid diffuses or moves from the vasculature and results in dependent peripheral edema. Fluid also may accumulate within the major body cavities (i.e., the thorax and the abdomen).<sup>7</sup> The mechanisms for such low-protein conditions include poor protein intake, malabsorption, poor hepatic utilization, and increased rate of protein loss such as in glomerular renal disease, peritonitis/pleuritis, or gastrointestinal transudation (diarrhea or ulceration). Causes of peripheral edema are described elsewhere in this text.

Increased preload because of right ventricular heart failure also can result in a transudate fluid accumulation within

the abdomen.<sup>7</sup> A horse with right ventricular heart failure usually has tricuspid insufficiency and manifests other signs of right ventricular heart failure, such as a murmur; exercise intolerance; jugular pulse; and edema of the ventral abdomen, pectoral muscles, and distal limbs. Severe mitral insufficiency also can result in right ventricular heart failure but only after the development of left ventricular heart failure and its associated pulmonary edema, which is manifested by exercise intolerance, coughing, epistaxis, and increased respiratory effort.

Uroperitoneum results from leakage of urine from some part of the urinary tract into the abdomen and most commonly is associated with a ruptured bladder in neonatal foals (usually male). Uroperitoneum also may result from a necrotic bladder caused by neonatal sepsis and urachal abscesses. Such foals often have pendulous, bloated abdomens that ballote more easily than do the abdomens of adult horses with accumulation of fluid. Abdominal fluid actually may smell like urine, and peritoneal fluid creatinine concentrations will be high—often more than twice those of peripheral blood.<sup>10-12</sup> Because most classically described neonatal urinary bladder tears are dorsal near the trigone, the foal still may be able to produce a stream of urine despite having a leaking bladder. A ruptured urinary bladder abscess should be suspected in a foal with sepsis that initially responds to therapy for sepsis and then, several days later, exhibits acute-onset depression, anorexia, ileus, and abdominal distention. Adults horses rarely have uroperitoneum; however, uroperitoneum has been associated with ruptured urinary bladders during stressful parturition in mares that manifest mild postpartum abdominal pain and abdominal distention.<sup>12,13</sup>

Fetal hydrops results from an accumulation of excessive amounts of fluid within the amnion (hydrops amnion) or chorioallantois (hydrops allantois).<sup>14</sup> Hydrops results in a bilaterally pendulous abdomen in a late-term pregnant mare. A rapid accumulation of fluid over 10 to 14 days may make walking or perhaps even breathing difficult for the mare. A diagnosis may be made after taking history and performing a rectal examination, although palpating the fetus is usually difficult because the excess fluid causes the uterus to descend out of reach of the examiner. If necessary, a percutaneous ultrasonographic examination may be used to confirm the diagnosis by documenting the presence of increased intrauterine fluid within the fetal membranes.

A ruptured prepubic tendon results in a unilateral lowering of the abdominal margin and apparent distention of the abdomen only on the affected side. The condition is associated routinely with later-term pregnancy in mares and is thought to occur simply because of the increased weight of the pregnant uterus pressing downward on the abdominal wall. Rupture of the rectus, transverse, or oblique abdominal muscles also can result in ventral dropping or herniation of the abdomen late in gestation.<sup>14</sup> Ruptures may be more common in older or more sedentary mares, probably because of decreased abdominal wall strength and tone. Other than a focal abdominal wall hernia, a unilateral prepubic tendon rupture results in the only form of prominent unilateral abdominal distention in horses. Mares with ruptured prepubic tendons may have elicitable pain in the local abdominal wall and may be reluctant to walk. They may need assistance during parturition because they may have difficulty performing an effective abdominal press to aid in fetal expulsion.

## ☞ APPROACH TO THE DIAGNOSIS OF ABDOMINAL DISTENTION

Pregnancy, diarrhea, colic signs, colic surgery, and the use of parasympatholytic agents should be evident from the history. The rate of onset of abdominal distention may help to distinguish more acute conditions (e.g., gastrointestinal bloat from grain overload) from more chronic conditions (e.g., ascites caused by heart or liver failure). Signalment and history may assist in indicating specific conditions. A depressed, 48- to 72-hour-old male foal with fluid abdominal distention may be a likely candidate to have a ruptured urinary bladder and uroperitoneum. Miniature horses with bloat and colic signs frequently have simple obstructions owing to fecaliths or enteroliths.

A complete physical examination reveals the presence of a murmur that may be associated with heart failure and ascites. Other signs of heart failure also may be evident on physical examination. An actual defect in the integrity of the abdominal wall may be palpable on external examination of the abdomen in a mare with a ruptured prepubic tendon or ruptured abdominal wall musculature.<sup>14</sup> The veterinarian should attempt ballottement to discern the presence of increased free abdominal fluid in suspected ascites or uroperitoneum. Fever may indicate the presence of an infectious peritonitis or umbilical abscess.

A rectal examination is a critical part of examining a horse with bloat or colic but may be difficult to accomplish if colonic distention is dramatic or if the patient is small (i.e., a foal, pony, or miniature horse). A rectal examination may document advanced pregnancy, resulting in mild bilateral abdominal distention (normal pregnancy), abnormal or severe bilateral distention (hydrops or bilateral ruptured prepubic tendon), or unilateral distention (unilateral ruptured prepubic tendon or focal abdominal wall hernia). A rectal examination also may reveal abnormalities of the urinary tract (enlarged kidney or ureter, abscess, or neoplasm), which may result in uroperitoneum in adults.

An ultrasonographic examination may be helpful and is sometimes necessary to examine the distended abdomen and fetus in a pregnant mare. Such an examination must be performed percutaneously in late gestation. Ultrasonography can determine the location of increased abdominal fluid (intrauterine or extrauterine) and the health status of the fetus. Percutaneous placement of base-apex electrocardiographic leads across the abdomen of the mare may help to document that the fetus is still viable if an ultrasound examination does not produce definitive evidence (heart movement or gross fetal movement).<sup>15</sup>

Cardiac ultrasonography may help to document the presence of a cardiac valvular defect that can be the cause of ascites in a horse with heart failure. Abdominal radiography may assist in the diagnosis of abdominal distention caused by intestinal obstruction in a foal or miniature horse. Percutaneous ultrasound examination also may assist in documenting the source of abdominal distention (e.g., intussusception) in smaller horses or foals<sup>3,16</sup> and in characterizing umbilical and urachal abnormalities.<sup>3</sup>

Complete blood counts and plasma fibrinogen concentrations assist in diagnosing inflammatory conditions such as infectious peritonitis. Urachal or urinary bladder abscesses also may be associated with inflammatory leukograms. Blood or peritoneal fluid cultures may assist in documenting the

offending bacterial agent(s). Foals or adults with uroperitoneum have elevated serum urea nitrogen, creatinine, and potassium and decreased serum sodium, chloride, and bicarbonate concentrations.<sup>10,11</sup>

Abdominocentesis should be attempted to distinguish the cause of ascites. Care must be taken, however, when obtaining peritoneal fluid from late-term pregnant mares to avoid penetrating directly into the distended uterus. Analysis of peritoneal fluid reveals abdominal fluid to be a transudate (equivocal infection) or exudate (probable infection).<sup>6,7</sup> Fluid should be cultured aerobically and anaerobically when infectious peritonitis is suspected. Exfoliative cytologic examination rarely may document the presence of neoplastic cells.<sup>8,9</sup> Peritoneal fluid creatinine concentration approaches or often exceeds (more than twice) that of serum if uroperitoneum is present.<sup>10,11</sup> Serum and peritoneal urea nitrogen concentrations are less reliable for such a diagnosis because the peritoneal membrane does not differentially sequester urea nitrogen (but does creatinine) within the abdominal cavity.

## COLIC

*Siddra Hines*

*Colic* is defined as the manifestation of abdominal pain. In horses colic is a serious medical and economic problem worldwide. In the United States the annual incidence of equine colic has been reported to be anywhere between 3.5% and 26%. A study performed by the National Animal Health Monitoring System in 1998 assessed the annual incidence to be 4.2%.<sup>1</sup> In this study only 1.4% of colic episodes resulted in surgery, but the overall fatality rate for all colic was 11%, making colic second only to old age as a leading cause of death in horses.<sup>1</sup> The estimated total cost of colic nationally in 1998 was \$115 million.<sup>1</sup> These numbers illustrate the enormous impact that colic has on the equine population.

Colic encompasses a wide variety of conditions, and determining the specific cause of colic is a complex and sometimes impossible task. Because many cases resolve with minimal intervention, a specific diagnosis is often not made. Most cases of colic, often referred to as “true colics,” are conditions of the gastrointestinal tract. However, disorders of other body systems, such as cholelithiasis and uterine torsion, may also manifest as colic. In addition, a number of other clinical problems may be confused with colic, including pleuritis, exertional rhabdomyolysis, laminitis, hyperkalemic periodic paralysis, renal disease, and even neurologic abnormalities.<sup>2</sup> A thorough physical examination and further diagnostic tests help ascertain whether or not a horse is exhibiting actual gastrointestinal pain.

Horses express clinical signs of colic in a variety of ways. Often, the first sign recognized by owners is inappetence, but other early signs include general restlessness and extended periods of lying down. More overt signs, such as kicking or biting at the abdomen, pawing, and stretching out as if to urinate, may also be observed. As the level of discomfort increases, horses may repeatedly get up and down and try to roll, sometimes violently.<sup>3</sup> The level of stoicism varies widely between individual horses, and the severity of signs does not always correlate to the severity of the lesion.

## ☪ PATHOPHYSIOLOGY

The precise pathophysiologic mechanisms involved in cases of colic may vary because of the myriad causes for colic in the horse. True colic can be classified on the basis of small intestinal versus large intestinal disorders, physical versus functional disorders, obstructive versus nonobstructive lesions, and strangulating versus nonstrangulating lesions. In all of these colic classifications, the simplest basic etiologies for damage to the gastrointestinal tract are inflammation and ischemia. Gastrointestinal distention, ileus, and endotoxemia also play a role in the development of disease in many cases.

Ischemia of the intestine can result from a strangulating lesion or even from a simple obstruction. Strangulating lesions cause acute direct occlusion of vessels leading to rapid tissue hypoxia, ischemia, and ultimately necrosis. With obstructions significant pressure within the distended intestine may lead to venous collapse, which over time may result in ischemia as the intestinal vasculature becomes increasingly compromised.<sup>3</sup>

The mucosa is the layer most sensitive to hypoxia because of its high metabolic activity. Damage to the mucosa can be assessed on a scale of Grade I through Grade V, with Grade V being the most severe.<sup>4</sup> The villous tips are especially sensitive to ischemia and damage typically begins there. Crypt cells are affected later as the ischemia becomes more complete and longer in duration. In the equine colon complete ischemia leads to necrosis and detachment of surface epithelial cells and most likely to capillary thrombosis and occlusion.<sup>4</sup> Smooth muscle is less sensitive to hypoxia, and therefore it is destruction of the mucosa that is the main factor leading to the pathologic changes associated with colic.

Prolonged intestinal distention proximal to an obstructive lesion can eventually lead to tissue ischemia. Distention also results in edema and additional secretion of fluid into the lumen of the gut as venous collapse occurs.<sup>4</sup> As veins are occluded, hydrostatic pressure within the capillaries increases, causing increased filtration. Lymphatic drainage is also often impaired, and the resultant excess fluid becomes edema and secreted intestinal fluid. Distention is one of the main causes of pain associated with colic, as stretch pain receptors are triggered within the wall of the intestine.<sup>4</sup>

Inflammation plays a major role in almost every type of colic and often occurs secondary to ischemia. The inflammatory response is generally meant to protect the intestine against long-term damage. The pathophysiology of inflammation is complex and beyond the scope of this section, but the basic process in the gut is similar to that of other body systems. Almost all cells in the intestine can play a role in the development of inflammation by either cytokine production or cell activation. Some specific cell types involved in the initiation of intestinal inflammation include mucosal cells, endothelial cells, fibroblasts, neutrophils, macrophages, neurons, eosinophils, and mast cells.<sup>5</sup> Cytokines, growth factors, and adhesion molecules produced by these cells are important in the initiation of inflammation. Some important cytokines include interleukin-1, tumor necrosis factor (TNF)  $\alpha$ , platelet activating factor, complement, interferon (IFN), and histamine.<sup>5</sup>

Endothelial cells are stimulated by ischemia or macrophage cytokines to attract neutrophils, which subsequently migrate to the affected tissue facilitated by adhesion molecules. Vascular permeability is also increased, resulting in the formation of edema and facilitating the migration of inflammatory cells. Neurons, fibroblasts, and muscle cells detect and release

other cytokines, leading to the activation of many effector cell types.<sup>5</sup>

Eventually the intestinal barrier is compromised to the extent that endotoxin begins to leak into systemic circulation. Endotoxemia (discussed in detail in Chapter 15) is most common with colitis and to a lesser extent with strangulating lesions. The response to endotoxin is complex, involving a massive release of cytokines and mediators that results in systemic inflammation and fever. Classical endotoxemia has more recently been described as *systemic inflammatory response syndrome* (SIRS), because it appears to involve more than just endotoxin as an initiating factor.<sup>5</sup> The result is hemodynamic responses that include both vasodilation and vasoconstriction, platelet aggregation, and eventual development of a hypercoagulable state and consumptive coagulopathy.<sup>4</sup>

Finally, ileus should be addressed as an important component of the pathophysiology of colic. Ischemic bowel has decreased motility, although bowel more proximal to the lesion tends to have an increase in motility until it becomes so distended that it can no longer contract normally. Postoperative ileus appears to involve both dopaminergic and adrenergic stimulation. It has also been suggested that prostaglandins E<sub>1</sub> and E<sub>2</sub>, as well as nitric oxide, play a role in disrupting intestinal motility patterns.<sup>4</sup>

## ☪ APPROACH TO THE PATIENT WITH COLIC

Colic may be caused by a number of conditions. Fortunately, in most affected horses, such as those with gas or spasmodic colics, the problem can be resolved without extensive intervention. However, in some cases, a delay in surgical exploration can result in increased mortality. Thus the initial goal in the assessment of a horse with colic is often to determine whether the case is an uncomplicated one rather than one requiring either extensive medical management or surgical exploration. Signalment, history, physical examination, clinicopathologic data, and imaging findings may all contribute to the evaluation of a patient with colic.

The signalment of the horse can provide some information that may increase the degree of suspicion for a specific cause of colic. Weanling-age foals are more prone to ascarid impactions,<sup>2,6</sup> whereas younger foals are at higher risk for small intestinal volvulus or intussusception.<sup>7</sup> Older horses have a far greater likelihood of developing strangulating lipomas.<sup>4,8</sup> In general, Arabians are considered to be at higher risk for colic than other breeds and are specifically predisposed to ileal impaction, small colon impaction, and enterolith formation.<sup>2</sup> Miniature horses, especially younger horses, are prone to small colon impactions and fecaliths.<sup>2,4</sup> Standardbreds, Tennessee Walking Horses, and Warmblood stallions have a higher risk of developing inguinal hernias.<sup>2,4</sup>

With regard to sex, stallions are susceptible to testicular torsion in addition to inguinal hernias.<sup>4</sup> Postpartum mares are predisposed to torsion of the large colon,<sup>2,4</sup> whereas colic in a late-gestation mare may indicate normal parturition or dystocia. Pregnant mares also exhibit signs of colic with uterine torsion.<sup>2,3</sup> Nonpregnant mares can have mild transient signs of colic associated with ovarian activity.

The history of the patient can provide vital clues as to the severity and possible etiology of the colic. Previous history of colic, including colic surgery, history of other surgeries, recent management changes, geographic area, breeding

history and pregnancy status, duration and severity of pain, recent defecation, appetite, previous treatment, and response to treatment are all important components in the medical history of a colicky horse. Additionally, specific details as to feed, deworming, dentistry, history of medications (e.g., nonsteroidal anti-inflammatory drugs [NSAIDs], antibiotics), and activity level may also provide valuable diagnostic information. Factors that tend to increase risk of colic include inadequate deworming or dentistry, use of NSAIDs, stall confinement, recent feed changes, feeding of Coastal Bermuda grass hay, feeding of excessive concentrate or infrequent large meals, and off-the-ground feeding.<sup>2,9</sup> A link has also been identified between cribbing and an increased likelihood of developing epiploic foramen entrapment.<sup>10</sup>

A thorough physical examination is essential to the evaluation of colic. It is possible that a horse will be so uncomfortable initially that sedation will be necessary for safe completion of the examination. If possible, heart rate, respiratory rate, and auscultation of gut sounds should be evaluated before sedation because these can change significantly in response to sedation.<sup>11,12</sup> Because rectal temperature can also be significantly decreased after rectal palpation, it is advisable to obtain the body temperature before palpation.<sup>3</sup> A finding of pyrexia may increase suspicion of colitis, enteritis, peritonitis, or intra-abdominal abscessation in the patient, although previous administration of an NSAID may mask this clinical finding.<sup>2,4</sup> Tachycardia is considered to be an indicator of pain, hypovolemia, tachyarrhythmia, or endotoxemia and rates of >80 beats/min generally indicate serious disease.<sup>2,4</sup> During auscultation the patient should be evaluated for the presence of any cardiac abnormalities that would put the horse at increased risk under sedation. Respiratory rate may be increased in horses with colic as a response to some combination of pain, fever, and/or metabolic acidosis. Mucous membranes and capillary refill time (CRT) give a rough assessment of cardiovascular status and peripheral perfusion. Mucous membranes should be pink with a CRT <2 seconds. Prolonged CRT and either grayish or dark red mucous membranes indicate impaired cardiovascular status and poor perfusion. With poor perfusion, there may also be cool extremities and reduced jugular fill. Significant changes in mucous membrane color, often with a dark "toxic" line adjacent to the teeth, may accompany endotoxemia, which is common in gastrointestinal disease, particularly in those horses with colitis, proximal enteritis, and strangulating lesions. Icterus does not always indicate hepatobiliary disease because horses that have been off feed for more than 48 hours will also exhibit hyperbilirubinemia. Finally, tacky mucous membranes are generally observed with dehydration of at least 5% to 7%.<sup>2</sup>

Other important considerations include assessment of hydration status, attitude, abdominal distention, and the presence of injuries that indicate self-trauma. As previously mentioned, in stallions careful palpation of the inguinal region must be performed to identify an inguinal hernia or testicular torsion. Severe abdominal distention may markedly increase the respiratory effort and eventually lead to respiratory distress. During auscultation of gastrointestinal sounds, auscultation of the most ventral part of the abdomen should also be performed to assess for the presence of sand. Although not always present, a characteristic "waves on the beach" sound can sometimes be heard, indicating the presence of sand in the colon.<sup>13</sup> If feces can be collected from the horse, it is very useful to evaluate for the presence of sand. A simple way to

do this is to mix a few fecal balls with warm water in a rectal sleeve and hang the sleeve with the fingers down. After about 5 minutes any sand in the feces should sediment into the ends of the glove fingers.<sup>2</sup>

Adequate restraint is essential for colic diagnostics such as rectal palpation, nasogastric intubation, and abdominocentesis. Not only is the veterinarian at increased risk of injury with an uncooperative horse, but the horse also is at increased risk of rectal tears, significant epistaxis, and abdominocentesis complications such as enterocentesis or contamination of the collection site. Depending on the case, restraint for further examination can be accomplished using sedation or application of a nose twitch. Care should be taken when determining appropriate restraint for an individual animal. The safety of the examiner and the horse must be considered; at the same time, it is important not to further compromise an unstable patient or dramatically affect assessment of the horse's level of pain. Use of xylazine hydrochloride IV at 0.2 to 0.5 mg/kg (typically 100 to 250 mg for a 500-kg horse) is often adequate, but butorphanol tartrate at 0.01 to 0.08 mg/kg IV can be added when necessary.<sup>3</sup> Use of detomidine is usually discouraged in the initial management of colic because of its long duration of action and heightened ability to mask more significant pain that may affect determination of the horse's treatment.<sup>12</sup> However, if indicated, detomidine can be administered at 0.01 to 0.04 mg/kg IV or IM.<sup>3</sup> It is most commonly used when a longer duration of sedation is required to keep a horse quiet during transport to a referral center.

Nasogastric intubation should be performed as a part of a complete colic examination. If a horse is exhibiting significant pain or has a heart rate greater than 60 beats/min on initial evaluation, nasogastric intubation should be performed before other diagnostic procedures because it may have both diagnostic and therapeutic value. It is important to note that if a horse has significant gastric distention, gastric decompression may help prevent gastric rupture and allow for a more thorough physical exam. The nasogastric tube can be left in place if a significant amount of net reflux is obtained to allow for repeated decompression. If no reflux is obtained and a simple colic is suspected, oral fluids with or without electrolytes or magnesium sulfate (Epsom salt) can be administered via the tube. Although mineral oil has long been considered a part of standard colic treatment, its use is controversial. Mineral oil may be valuable as a diagnostic tool, providing an estimate of gastrointestinal transit time. In a normal horse mineral oil can be observed in the feces and on perineum and tail in 12 to 24 hours.<sup>14</sup> The absence of mineral oil after this period indicates delayed gastrointestinal transit. However, mineral oil can sometimes pass around an impaction that is present, thereby falsely suggesting adequate gastrointestinal transit when in fact digesta is not moving normally.<sup>14</sup> In addition, if a horse ultimately requires abdominal surgery, the presence of mineral oil can complicate an enterotomy.<sup>15</sup>

Rectal palpation can be important in the assessment of colic. Even with the use of appropriate sedation, some horses remain resistant to rectal examination, placing them at increased risk for rectal tears. To facilitate palpation per rectum, application of lidocaine within the rectal lumen or intravenous administration of N-butylscopolammonium can help to decrease rectal pressure and peristalsis.<sup>16</sup> Although rectal palpation can provide valuable diagnostic information, the presence or absence of a particular lesion cannot always be definitively determined. For instance, although a pelvic

flexure or cecal impaction may be palpable, if no impaction is palpated, it cannot be ruled out. Additionally, gas distention might be palpable in gas colic, but it may also reflect a more serious problem, such as a displacement or torsion. Rectal palpation therefore can provide evidence to support a diagnosis but is often not diagnostic in itself. Nephrosplenic entrapment may be suspected if the spleen is displaced medially or the gut is palpated between the spleen and kidney.<sup>2</sup> Another useful finding is the identification of distended small intestine. Although small intestinal distention may occasionally occur secondary to a large intestinal problem such as a displacement, it is most often an indication of small intestinal disease. Although rectal palpation cannot differentiate a surgical small intestinal problem such as a strangulating lesion from a medical problem such as proximal enteritis, small intestinal disease is almost always an indication for referral.<sup>17</sup> Therefore palpable loops of distended small intestine are a significant finding on rectal examination. Rectal palpation can also be useful for identifying masses in the abdomen, which may be a cause of chronic colic.

A packed cell volume (PCV) and total protein should ideally be evaluated to assist with an assessment of hydration status and possible protein loss. These values can be affected by stress, which can increase the PCV, anemia, protein loss, or hyperproteinemia, confounding the effects of dehydration.<sup>4</sup> Therefore these values must be evaluated in the context of the history and physical examination of the patient as well as their relationship to each other. In general, the greatest negative indicator is a significantly increased PCV (i.e., >65%) coupled with a significantly low plasma protein concentration (i.e., <4 g/dl), especially if serial values are trending toward these extremes.<sup>2,4</sup>

Although further bloodwork usually is not performed on a standard simple colic, a complete blood count (CBC) and serum chemistry can provide valuable information if a colic goes beyond simple treatment and requires more advanced care. In acute colic, CBC values will typically be normal or reflect stress, but in more chronic conditions nonspecific signs of inflammation such as leukocytosis and hyperfibrinogenemia can develop as well as a possible normochromic normocytic anemia of chronic disease. If significant colon wall compromise occurs, leukopenia with neutropenia and a left shift with toxic changes can occur as a result of endotoxemia.<sup>2,3</sup> Thrombocytopenia may also be present with endotoxemia.

Electrolyte abnormalities, especially hypokalemia and hypocalcemia, are the most common abnormalities observed on a chemistry panel in horses with colic.<sup>18</sup> Anorexia, dehydration, diarrhea, and excessive nasogastric reflux can all contribute to derangement of electrolytes. In addition to calcium and potassium, sodium, chloride, magnesium, and bicarbonate can be lost with diarrhea or significant gastric reflux.<sup>18</sup> Leakage from damaged cells may result in elevated serum phosphate. Metabolic acidosis caused by elevation of lactate, loss of bicarbonate, or both may also be observed. Occasionally, hepatic enzyme activities are increased, especially  $\gamma$ -glutamyltransferase. This most commonly occurs with large colon displacement or proximal enteritis.<sup>19,20</sup> Dehydration often results in elevations in creatinine and serum urea nitrogen, and these parameters should be monitored, especially when NSAIDs or aminoglycoside antibiotics are used.

Abdominocentesis can be performed in the field as well as in a referral setting. Most often the procedure requires either an 18-g, 1.5-inch needle or a teat cannula for the collection of fluid. The typical location in which the procedure is performed

is to the right of midline (to avoid splenocentesis) on the most ventral point of the abdomen at least several inches caudal to the xiphoid.<sup>4</sup> If severe gas distention or small intestinal distention is present, or if a sand enterocolitis is suspected, it may be advisable to forego abdominocentesis in order to avoid puncture of a distended compromised viscus or a heavy sand-filled viscus that is sitting flush with the ventral body wall.

Although a practitioner may not have access to a full fluid analysis and cytology, a basic assessment of abdominal fluid can be made by visual evaluation for color and clarity, and total protein can be evaluated with a refractometer. Normal fluid should be odorless, nonturbid, and a clear to pale yellow color.<sup>4</sup> Increased turbidity can indicate increased protein, increased total nucleated cell count, or both. Total protein should be less than 2.5 g/dL.<sup>4,21</sup> A normal cell count is typically less than 5000 cells/ $\mu$ l, although it may be normal up to 10,000/ $\mu$ l.<sup>4,21</sup> Serosanguinous fluid usually reflects a strangulating obstruction or significant compromise to the bowel wall. With a ruptured gastrointestinal structure, the fluid is generally dark and smells of ingesta. These results should be confirmed, however, because an accidental enterocentesis will appear the same.<sup>4</sup> If the spleen is accidentally punctured, the fluid will look like frank blood and will usually have a PCV equal to or greater than the peripheral PCV.<sup>22</sup>

Ultrasound examination of the abdomen may be useful in the evaluation of horses with colic. It is particularly valuable in the identification of small intestinal distention or nephrosplenic entrapment. With a nephrosplenic entrapment the spleen cannot be visualized against the body wall, or the kidney cannot be visualized on the left side because of the interference of large colon.<sup>23</sup> Small intestine can most reliably be found in the inguinal region or on the ventral abdomen, and it should normally be collapsed or have a very small diameter with frequent peristalsis.<sup>21,24</sup> Small intestine can be evaluated for dilation, motility, and thickening of the intestinal wall.<sup>24</sup> An intussusception may be identified as a target-shaped lesion on cross-sectional view.<sup>25</sup> Ultrasonographic assessment of peritoneal fluid volume and character may be useful in assessing the patient and in identifying pockets of representative fluid for abdominocentesis. The thickness of intestinal wall should be evaluated at numerous locations, especially the right dorsal colon, which may be extraordinarily thickened with right dorsal colitis.<sup>24</sup> Investigation for abdominal masses also is often undertaken using ultrasound, coupled with rectal palpation. Adequate transabdominal ultrasound examination is most easily performed with a 2.5 to 5 MHz curved linear transducer; however, an examination can also be performed using a transrectal probe, which is more likely to be available to the general practitioner.<sup>24,26</sup>

Radiographs of the abdomen are of limited usefulness but may be diagnostic for two problems associated with colic in the adult horse: sand accumulation and enterolithiasis. Sand is usually visualized best in the ventral large colon. It is important to keep in mind that some sand can be visualized in many normal horses, so the presence of sand in and of itself has no diagnostic relevance. Radiographs may, however, provide some information as to the volume of sand present.<sup>27</sup> Enteroliths represent the other main lesion identifiable by radiographs, although, depending on the location, they may be difficult to visualize.<sup>21</sup> In a study of 141 horses evaluated for enterolithiasis, abdominal radiography had a sensitivity of 76.9% and a specificity of 94.4%.<sup>28</sup> The abdomen can be more thoroughly assessed via radiography in a neonate as opposed

to an adult horse, although results still cannot be considered conclusively diagnostic. Radiographs of a foal's abdomen can identify gas distention of the stomach, small intestine, or large colon, which are nonspecific but generally pathologic findings.<sup>7</sup> A radiographic pattern known as *pneumatosis intestinalis*, characterized by linear radiolucencies within the bowel wall, is typical for necrotizing enterocolitis.<sup>7</sup> Excessive peritoneal fluid and pneumoperitoneum can also be identified.

Referral to a secondary care center is indicated when there is a strong likelihood that the horse will require surgery or more extensive medical care is necessary. The most common basis for referral is severe or persistent pain with a lack of response to analgesics.<sup>17</sup> If a horse demonstrates intractable pain or requires repeated doses of analgesics to remain comfortable, referral is warranted. Referral is also indicated when a horse has not resolved the signs of colic in 24 to 48 hours after onset, or if a 1.1 mg/kg dose of flunixin meglumine does not maintain comfort for at least 8 to 12 hours.<sup>17</sup> A persistently elevated heart rate can be a good indicator of pain or endotoxemia and necessitates referral. Other indications of endotoxemia or impaired cardiovascular status include weak pulses, abnormal mucous membrane color (pale, hyperemic, injected, purple, or cyanotic), and delayed capillary refill time. Rectal palpation of a potentially surgical lesion or small intestinal distention, an abnormal abdominocentesis, net nasogastric reflux of >2 to 3 L, or significant depression are all findings that would also support referral.<sup>17</sup> In addition, significant dehydration may require extensive treatment with intravenous or oral fluids or both because dehydration has the potential to exacerbate even apparently simple colic problems and affects the patient's systemic health. Dehydration can result in worsening of an impaction that is already present or contribute to development of an impaction when coupled with ileus and an inciting primary colic problem such as colonic displacement.

## DIARRHEA

Melissa T. Hines

*Diarrhea*, defined as an increase in the frequency, fluidity, or volume of bowel movements, is a commonly encountered clinical problem in the horse. Diarrhea may occur as a primary disease of the gastrointestinal tract or as a secondary response to another disease process, such as sepsis, endotoxemia, or hepatic disease.

The function of the equine gastrointestinal tract is complex and involves maintenance of normal fluid balance and digestion and absorption.<sup>1-3</sup> As a result of dietary intake and endogenous secretions, normally a large volume of fluid enters the gastrointestinal tract, most of which is reabsorbed. In the adult horse absorption occurs predominantly in the large bowel, where a volume of water approximately equal to the total extracellular fluid volume of the animal, or about 100 L, is recovered during the course of the day. Because the large colon is the primary site of water resorption, most significant diarrheal disease in the adult horse involves the colon. In young foals, however, small intestinal disorders such as rotaviral infection also may result in diarrhea.<sup>4</sup>

A second critical function of the large bowel is that of microbial digestion of carbohydrates and, to some extent,

protein or nonprotein nitrogen.<sup>1-3</sup> Microbial fermentation of carbohydrates in the cecum and colon results primarily in the production of volatile fatty acids, which are absorbed readily, providing up to 75% of the energy requirement of the horse. Therefore maintaining a stable environment for the microbial population is important. In general, efficient function of the large bowel requires mechanisms that limit the rate of digesta passage, provide optimal conditions for microbial digestion, and allow for efficient transport of solutes and water.

The characteristics of normal equine feces vary somewhat with diet. Generally, equine feces are tan, brown, or greenish, and, although approximately 75% water, they are well formed. An adult horse on a diet of grass hay and approximately 3 lb of oats per day produces about 20 to 28 g of feces per kilogram of body mass per day, or about 11 to 13 kg of feces per day.<sup>5</sup> In cases of diarrhea the amount of feces may increase up to tenfold, with horses producing more than 200 g/kg/day, or more than 90 L of diarrhea. As a result, diarrhea can cause significant losses of electrolytes and water and significant systemic acid-base imbalances. However, despite large water losses, horses with chronic diarrhea seldom develop severe dehydration or electrolyte abnormalities because they compensate for increased fecal losses.

## MECHANISMS OF DIARRHEA

Inflammation within the bowel plays a central role in the pathogenesis of diarrhea. Several basic mechanisms of diarrhea have been described, and in most diarrheal diseases more than one mechanism is involved. These mechanisms include the following:

1. *Malabsorption*: Malabsorption results from a decrease in the functional absorptive surface area of the gastrointestinal tract. Villus atrophy in the small intestine, seen with rotaviral enteritis and infiltrative bowel disease, can result in malabsorption because of the loss of functional epithelium and maldigestion caused by decreased production of digestive enzymes. A number of insults to the colon result in inflammation and disruption of absorptive cells and tight junctions, leading to decreased absorptive capacity and decreased ability to retain absorbed fluid (i.e., increased loss). Several inflammatory mediators, such as histamines and prostaglandins, contribute to the colonic inflammation. These mediators are produced primarily by inflammatory cells in the lamina propria and inhibit absorption through a variety of mechanisms.<sup>6-10</sup>
2. *Increased secretion*: The increased secretion of solutes and water by the inflamed colon can contribute significantly to the development of diarrhea. Although the precise mechanisms of secretion in the equine colon are not understood fully, active secretion and passive fluid loss occur.<sup>6-12</sup> Control of active secretion is complex, involving two primary pathways: first, the activation of adenylyl cyclase, resulting in an increase of intracellular cyclic adenosine monophosphate concentrations, and second, the activation of calcium channels, leading to increased intracellular calcium concentrations.<sup>11,12</sup> Cyclic adenosine monophosphate and calcium stimulate specific secretory activities, primarily through chloride channels. In some cases of diarrhea, bacterial enterotoxins such as those produced by certain strains of *Escherichia coli* and *Salmonella* spp. stimulate adenylyl cyclase activity, thus

increasing active secretion. This is true hypersecretory diarrhea. Also, a number of inflammatory mediators produced by the inflamed colon, particularly prostaglandin E, increase intracellular concentrations of cyclic adenosine monophosphate and to some extent calcium, thereby increasing active secretion by mucosal cells.<sup>11-13</sup> Inflammation also enhances passive fluid loss through a number of factors, such as changes in hydrostatic pressure in the colonic capillaries, mucosal damage, and loss of tight junctions. In horses with severe mucosal injury, the loss of protein can decrease vascular oncotic pressure and further potentiate fluid exchange across the endothelium.

3. **Decreased transit time (abnormal motility):** Progressive motility must be present for diarrhea to occur. Primary motility disorders causing diarrhea are not well recognized, although diarrhea associated with stress or excitement may represent this phenomenon. Inflammation is known to influence gastrointestinal motility, in addition to altering absorption and secretion. However, the precise significance of the altered motility in the pathogenesis of diarrhea is not clear. Sufficient retention time and thorough mixing are required for digestion and absorption of nutrients and fluid to occur, and decreased intestinal transit time has been recognized in association with many gastrointestinal diseases, including infectious diarrhea. Absorption of endotoxin and the release of inflammatory mediators, including prostaglandins, disrupts normal motility patterns.<sup>14</sup> In some cases of acute colitis, a period of ileus may occur without diarrhea. With diarrheal diseases, the elimination of gut contents is part of the normal host defense mechanism, and thus decreasing motility is not indicated in most cases.
4. **Osmotic overload:** Any increase in osmotically active particles within the intestinal lumen can result in diarrhea. The increase can be associated with the administration or ingestion of osmotically active substances such as magnesium sulfate. The increase also may be associated with overloading of the intestine with carbohydrates or occasionally lipids beyond the amount that can be digested and absorbed. Therefore sudden dietary changes that result in significant shifts in gut flora and changes in fermentation or gastrointestinal diseases that result in malabsorption or maldigestion also may result in an osmotic diarrhea. In foals the loss of villus epithelial cells in the small intestine associated with disorders such as rotavirus infection and clostridiosis may lead not only to malabsorption but also to maldigestion caused by the decreased production of lactase.<sup>4,15</sup> The resulting lactose intolerance allows excess lactose to enter the large intestine, increasing the osmotic load.
5. **Increased hydraulic pressure from the blood to the lumen:** This mechanism of diarrhea is more common in chronic conditions, such as congestive heart failure or inflammatory bowel disease. The condition may result from decreased oncotic pressure associated with hypoproteinemia, increased capillary hydrostatic pressure (as in heart failure), or decreased lymphatic drainage associated with inflammation of lymphatics and lymph nodes.

Understanding the mechanisms of diarrhea can be helpful in directing therapy. However, it is important to remember that most disorders that cause diarrhea, whether infectious or noninfectious, do so through inflammatory mechanisms resulting in multiple functional alterations.

## DIAGNOSTIC APPROACH TO THE PATIENT WITH DIARRHEA

Diarrhea is a common, and sometimes fatal, clinical problem of adult horses and foals. A number of specific causes for acute and chronic diarrhea have been identified (Tables 3-2, 3-3, and 3-4). A comprehensive evaluation may help in establishing a diagnosis and developing a treatment plan (Box 3-1). However, even in severe cases a definitive diagnosis often is not made, making the problem particularly frustrating.<sup>16,17</sup>

### HISTORY AND PHYSICAL EXAMINATION

The veterinarian should consider the signalment and history carefully when evaluating a patient with diarrhea. Age is particularly important because several disorders, such as foal heat diarrhea and rotavirus, are age related. The genetic background also may be significant because diarrhea has been associated with certain heritable immunodeficiencies, and granulomatous bowel disease has been identified in three sibling horses.<sup>18-20</sup> Establishing whether the diarrhea is acute or chronic is important. Other historical questions of particular relevance include dietary changes; deworming program; involvement of single versus multiple animals; exposure to sand; and the use of medications, especially antibiotics and NSAIDs.<sup>21-23</sup> Other concurrent diseases, stress, possible exposure to toxins, weight loss, water consumption, and salt availability also may be significant. The information obtained helps the veterinarian prioritize differential diagnoses and direct further testing.

TABLE 3-2

#### Differential Diagnoses for Acute Diarrhea in Adult Horses

Common Causes	Major Diagnostic Test(s)
Salmonellosis	Fecal culture or polymerase chain reaction (PCR), culture of rectal mucosal biopsy
Potomac horse fever ( <i>Neorickettsia risticii</i> )	PCR (feces, peripheral blood), paired serologic tests
Clostridiosis ( <i>Clostridium difficile</i> , <i>C. perfringens</i> )	Fecal culture, toxin analysis
Antibiotic-associated diarrhea	History
Nonsteroidal anti-inflammatory toxicity (primarily right dorsal colitis)	History and supportive clinicopathologic findings, ultrasonography, exploratory surgery with biopsy
Undiagnosed	Other conditions ruled out
<b>Less Common</b>	
Cantharidin toxicity	
Parasitism (strongylosis, cyathostomiasis, other)	
<i>Aeromonas</i> , <i>Campylobacter</i> spp.	
Sand	
Carbohydrate overload	
Arsenic toxicity, other toxicities	
Thromboembolic disease	
Anaphylaxis	

TABLE 3-3

Differential Diagnoses for Chronic Diarrhea in Adult Horses	
Cause of Diarrhea	Major Diagnostic Test(s)
Chronic salmonellosis	Fecal culture or polymerase chain reaction, culture
Sand	Fecal sedimentation
Parasitism (strongylosis, cyathostomiasis)	Fecal egg count, empirical deworming
Nonsteroidal anti-inflammatory toxicity (primarily right dorsal colitis)	History and supportive clinicopathologic findings, ultrasonography, exploratory surgery with biopsy
Inflammatory or infiltrative disorders	Histopathologic exam, absorption tests (supportive but nonspecific)
Inflammatory bowel disease (granulomatous, lymphocytic-plasmacytic, or eosinophilic enterocolitis)	
Mucosal lymphosarcoma	
Amyloidosis	
Dietary: abnormal fermentation	History
Neoplasms: lymphosarcoma, squamous cell carcinoma	Histopathologic exam
Peritonitis, abdominal abscessation	Peritoneal fluid analysis, ultrasound, exploratory surgery
Nongastrointestinal causes (chronic liver disease, congestive heart failure, renal disease)	Physical exam, clinicopathologic findings

TABLE 3-4

Differential Diagnoses for Diarrhea in Foals	
Cause of Diarrhea	Major Diagnostic Test(s)
Salmonellosis	Fecal culture or PCR
Clostridiosis ( <i>Clostridium difficile</i> , <i>C. perfringens</i> )	Fecal culture, toxin analysis
Endotoxemia, gram negative septicemia	Blood culture, physical examination, complete blood count, sepsis score
Antibiotic-associated diarrhea	History
Foal heat diarrhea	History, physical examination
Viral: rotavirus; rarely coronavirus or adenovirus	Electron microscopy, enzyme immunoassay
Protozoan: cryptosporidiosis	Fecal analysis
Secondary lactose intolerance therapy	Oral lactose tolerance test, response to
<i>Rhodococcus equi</i>	Culture, PCR
<i>Lawsonia intracellulare</i>	Fecal PCR, serologic testing
Gastric ulcer disease syndrome	Gastric endoscopy
<i>Strongyloides westeri</i>	Fecal egg count
Sand	Fecal sedimentation

PCR, Polymerase chain reaction.

The clinician should perform a complete physical examination. The body condition of the horse and the presence of any edema should be noted. The presence of fever, dehydration, or signs of endotoxemia may help in assessing the severity of the disease and differentiating the cause because some causes of diarrhea are not associated typically with systemic

signs of illness. Careful evaluation of the abdomen should be performed. Visible abdominal distention is often an indication of large intestinal distention, which may occur in association with acute colitis. However, distention also may be visible with extreme dilation of multiple loops of small intestine. Careful auscultation of the abdomen can be useful in assessing motility. Generally, progressive borborygmi heard about every 3 to 4 minutes on both sides of the abdomen suggest normal motility of the cecum and colon. Auscultation behind the xiphoid process may help identify the presence of sand or gravel if particles can be heard grinding together during contractions of the colon.<sup>24</sup> Particularly in foals, transabdominal palpation and ballottement may be useful to identify increased abdominal fluid or large masses near the body wall. Transrectal palpation can be helpful in assessing the size of intestinal segments, consistency of contents, and wall thickness as well as in identifying masses, enlarged lymph nodes, or mesenteric arteritis.

## CLINICAL PATHOLOGY

Routine analysis of blood work rarely identifies a specific cause of diarrhea but can be important in directing appropriate supportive care and may help to establish whether diarrhea is caused by another condition, such as hepatic or renal disease. Some important parameters to evaluate include the presence of leukopenia, particularly neutropenia with a left shift and toxic changes in the white blood cells. These abnormalities suggest a systemic inflammatory response, which also may be associated with thrombocytopenia and coagulopathies. The clinician also should evaluate the concentration of protein, as well as the albumin:globulin ratio. Significant hypoproteinemia, especially hypoalbuminemia caused primarily by protein loss, may occur with acute and chronic diarrhea. Hyperglobulinemia may indicate a chronic inflammatory condition. Disturbances in acid-base balance, especially metabolic acidosis, and electrolyte abnormalities frequently occur in horses with acute

## BOX 3-1

OUTLINE OF DIAGNOSTIC APPROACH  
TO DIARRHEA

- I. Signalment, history, and physical examination
- II. Clinical pathology
  1. Minimum database: complete blood count, fibrinogen, and serum chemistry profile
    - a. Assess hydration, acid-base status, electrolyte abnormalities, and protein status.
    - b. Assess renal and hepatic function.
    - c. Assess endotoxemia.
  2. Serum protein electrophoresis and immunoglobulin quantitation
  3. Serologic testing: *Neorickettsia risticii* and *Lawsonia intracellulare*
  4. Peritoneal fluid analysis
- III. Evaluation of feces
  1. Gross appearance: severity, hemorrhage, odor, and presence of sand
  2. Direct smear: evaluation of protozoan populations and presence of leukocytes and epithelial cells
  3. Parasite evaluation: including evaluation for *Cryptosporidium parvum*, especially in foals
  4. Evaluation of bacterial pathogens
    - a. Gram stain and spore stain
    - b. Aerobic and anaerobic culture (culture of multiple samples or rectal mucosal biopsy for *Salmonella* spp.)
    - c. Clostridial toxin analysis
    - d. Polymerase chain reaction: *Salmonella*, spp. *N. risticii*, and *L. intracellulare*
  5. Foals: evaluation of viral pathogens, primarily rotavirus (electron microscopy and enzyme immunoassay)
- IV. Diagnostic imaging: radiography and ultrasonography
- V. Endoscopic examination: stomach, rectum, and descending colon
- VI. Absorption tests (glucose or xylose absorption): primarily for chronic protein-losing enteropathy
- VII. Histopathologic examination
- VIII. Toxin evaluation: cantharidin in urine or gastrointestinal contents, arsenic in liver, or other
- IX. Response to therapy

diarrhea but are uncommon with chronic diarrhea. Because of the dehydration frequently seen with acute diarrhea, prerenal azotemia is common and is important to recognize because some therapies, especially NSAIDs, may worsen the condition. In a study of 122 horses with acute diarrhea, horses with azotemia and clinicopathologic findings consistent with hemoconcentration and hypoproteinemia were less likely to survive.<sup>17</sup>

The diagnostic and prognostic value of serum protein electrophoresis has been evaluated in horses with chronic diarrhea.<sup>25</sup> Significantly higher levels of  $\beta_1$ -globulin were found in horses with larval cyathostomiasis than in other horses, and such values in conjunction with a decreased albumin were helpful in diagnosing intestinal parasitism. However, a normal

$\beta_1$ -globulin concentration was not a reliable indicator of the absence of the disease. Significantly lower albumin concentrations and significantly higher  $\alpha_2$ -globulin concentrations were found in horses that did not survive, suggesting that these parameters are nonspecific indicators of the severity of inflammatory changes within the intestinal wall. Parasitic infections, particularly strongylosis, also may be associated with elevated serum concentrations of immunoglobulin G(T).<sup>26</sup>

Infrequently, immunodeficiencies are associated with diarrhea.<sup>18,19</sup> Therefore in some horses, further evaluation of immune status may be indicated and may include specific immunoglobulin quantitation, evaluation of specific lymphocyte subsets, or functional assays. The clinician should consider genetic testing for severe combined immunodeficiency in sick foals of Arabian breeding.

Analysis of peritoneal fluid may be useful in some horses with diarrhea. Abnormalities in the peritoneal fluid may reflect the severity of inflammation and in some cases may help to establish a specific diagnosis. Increases in protein and sometimes nucleated cell count may be seen in association with ulcerative colitis.<sup>23</sup> In horses with bacterial peritonitis, the veterinarian may find organisms on cytologic examination or culture. Occasionally, the veterinarian may identify neoplastic cells in the peritoneal fluid, although their absence does not rule out the presence of neoplasia.

### EVALUATION OF FECES

Evaluation of the feces may yield important information in cases of diarrhea. Even the gross appearance of the feces can be helpful. For example, profuse, watery diarrhea is not generally consistent with a diagnosis of right dorsal colitis. Frank blood in the feces suggests bleeding into the distal colon from mucosal damage. Hemorrhagic, foul-smelling feces often are seen in association with clostridial diarrhea. The clinician also can assess the feces for the presence of occult blood, which indicates bleeding from any source. Although excess sand in the feces is readily apparent in some cases, other cases require mixing the feces in a rectal sleeve with water and allowing the sand to settle.

Microscopic examination of the feces for evidence of parasitism and evaluation of viable protozoal populations also may be useful. A direct smear of fresh feces allows for observation of the motility of ciliates and can be used as a screen for the presence of ova and oocysts, although more sensitive techniques, including fecal flotation and sedimentation, are recommended for evaluation of parasitism. Ideally, a quantitative method that allows for estimation of the number of eggs per gram of feces, such as McMaster's or Stolley's, is recommended. However, it is important to remember that fecal examination for parasites sometimes can be misleading, giving false-negative results. *Cryptosporidium parvum* infection can be difficult to diagnose, but oocysts can be detected in the feces by acid-fast staining or by immunofluorescence assay.<sup>27</sup>

Fecal samples also can be examined microscopically for leukocytes and epithelial cells. In general, the cellularity increases with the severity of diarrhea. Fecal leukocytes and epithelial cells are increased in salmonellosis but are not specific for this disorder.<sup>28</sup> More than 10 leukocytes per high-power field may indicate salmonellosis.

Evaluation of the feces for infectious agents is essential in the diagnostic evaluation of horses with diarrhea. *Salmonella* and *Clostridium* species are among the most common causes

of bacterial diarrhea in horses. Other, less common bacterial agents include *Campylobacter* spp.; *Aeromonas* spp.; and, particularly in weanling age foals, *Lawsonia intracellulare*.<sup>29,30</sup> Although primarily a respiratory pathogen, *Rhodococcus equi* also can cause diarrhea, particularly in foals 2 to 4 months of age.<sup>31</sup> *Escherichia coli* is an uncommon cause of diarrhea in foals, unlike in calves and piglets. However, enterotoxigenic strains, characterized by the presence of virulence factors, have been identified in foals. Gram stain and spore stain of fecal smears can help to identify and quantitate the bacterial populations present, particularly clostridial species. However, although large numbers of gram positive rods or spores have been identified in foals with clostridial enterocolitis, the results of direct staining may be misleading.<sup>32,33</sup> In one study *Clostridium perfringens* was cultured from 59% of samples in which no gram positive rods were visible. Some clostridial strains also are likely part of the normal microflora.<sup>34</sup> Large numbers of yeast in the feces should alert the clinician to the possibility of candidiasis, especially in compromised neonatal foals.

Fecal culture is used commonly to establish a diagnosis in cases of bacterial diarrhea. When culturing feces, especially if an outside laboratory is used, the clinician must consider proper sample handling, particularly for anaerobic clostridia.<sup>35</sup> *Salmonella* spp. are one of the most significant bacterial pathogens in equine feces.<sup>36</sup> Although the number of *Salmonella* spp. organisms isolated from the feces of horses with clinical salmonellosis is generally greater than from horses with asymptomatic infections, the volume of feces in horses with profuse diarrhea may decrease the likelihood of positive culture. Culture of multiple fecal samples, typically five, is recommended to increase the sensitivity. Culture of a rectal mucosal biopsy or rectal scraping is an alternative to fecal cultures and may increase sensitivity because *Salmonella* spp. are intracellular organisms. Identifying clostridial species requires anaerobic culture. However, evaluating the presence of toxin in cases of suspected clostridial diarrhea also is critical because *Clostridium* spp., particularly *C. perfringens* type A, may be present in normal equine feces.<sup>34</sup> Depending on the clostridial species and the laboratory, toxin can be assessed by detecting preformed toxin in the feces, toxin being produced by the isolate in culture, or the toxin gene in the isolate.<sup>32-35</sup>

An increasing number of polymerase chain reaction (PCR) assays are available for detecting causative agents of equine diarrhea. In comparing a PCR with microbial culture for detection of salmonellae in equine feces and environmental samples, the PCR method was found to be more sensitive and more rapid and required submission of fewer samples.<sup>37,38</sup> Currently, PCR is also available for detection of *Neorickettsia risticii* (*Ehrlichia risticii*), the causative agent of Potomac horse fever, in feces and peripheral blood.<sup>39,40</sup> Fecal PCR analysis also has been shown to be useful in documenting equine proliferative enteropathy caused by *Lawsonia intracellulare*.<sup>30</sup> Serologic methods, evaluating the presence of antibodies, are additional diagnostic tests used for diagnosis of *Neorickettsia* and *Lawsonia*.<sup>30,40</sup>

Rotaviral infection is associated with diarrhea in foals and is most common in foals from 1 to 4 weeks of age.<sup>4,41</sup> The veterinarian generally makes a diagnosis by detecting the virus through electron microscopy or the viral antigen by enzyme immunoassay (Rotazyme, Abbot Laboratories, North Chicago, Ill.), which is generally more sensitive than direct electron microscopy.<sup>42</sup> Coronavirus appears to have a low prevalence in foals but has been isolated from a horse with diarrhea.<sup>43</sup>

Less commonly used tests include evaluation of fecal osmolality and electrolyte concentrations (sodium and potassium). If the concentration of sodium plus potassium is much less than the osmolality, the result indicates the presence of osmotically active nonelectrolytes, confirming an osmotic diarrhea.

## DIAGNOSTIC IMAGING

Diagnostic imaging, although particularly useful in foals, also can be valuable in adult horses. In foals radiographs can detect gas distention in the lumen of the gastrointestinal tract, and the gas pattern may help to differentiate ileus from mechanical obstruction. Occasionally, gas may be seen within the bowel wall in severe cases of clostridial necrotizing enterocolitis. In adult horses abdominal radiography is limited somewhat by having the proper facilities and equipment to perform the procedure safely. However, radiographs can be effective in identifying radiodense material, such as enteroliths and sand. Ultrasonography can be used in horses of all ages to evaluate the amount and character of the peritoneal fluid, masses, intestinal distention, and wall thickness. In horses with right dorsal colitis the diagnosis has been supported by ultrasonographic evidence of thickening of the right dorsal colon. Although isotope-labeled white blood cell scintigraphic scans also may help identify colonic ulcerations, the availability and sensitivity of the procedure are limited.

## OTHER DIAGNOSTICS

Endoscopic examination of the stomach and proximal duodenum may reveal the presence of neoplasms or ulceration. Diarrhea and inappetence are common clinical signs in symptomatic foals with ulceration of the squamous gastric mucosa. Endoscopy also can be used for inspection of the mucosa of the rectum and descending colon, allowing for evaluation of mural masses or mucosal inflammation.

Absorption tests are used primarily in horses with chronic diarrhea or weight loss to evaluate the small intestinal absorptive capacity. Oral glucose and oral xylose absorption tests have been used.<sup>44,45</sup> Although the plasma concentration of glucose may reflect glucose metabolism as well as absorption from the gastrointestinal tract, the assay has been shown to be reliable in the diagnosis of significant malabsorptive conditions. Xylose is influenced less by the metabolic status of the horse, but the compound is more expensive than glucose, and the assay is not available in many laboratories. Results of both assays are nonspecific, but abnormal results support malabsorption and may indicate the necessity of biopsy.

Diagnosing neoplasms and chronic inflammatory or infiltrative disorders often requires histopathologic examination. A rectal mucosal biopsy is easy to collect and also can be cultured, but the area that can be reached for biopsy is limited. Laparoscopy allows for visualization of the abdomen and certain biopsies. The veterinarian can obtain full thickness intestinal biopsy during exploratory celiotomy.

Diarrhea is a component of the clinical syndrome associated with several toxins. Cantharidin (blister beetle toxin) can be detected in urine or gastrointestinal contents.<sup>46,47</sup> The veterinarian can measure lead in the blood and liver, selenium in the blood and liver, or arsenic in the liver if they are suspected.<sup>47,48</sup> He or she should consider oleander toxicity in horses with diarrhea, arrhythmias, and renal disease,

especially if exposure is possible.<sup>47</sup> Oleandrin is detectable in urine and gastrointestinal contents.

## EVALUATION OF RESPONSE TO THERAPY

Evaluating the response to empirical therapy may be helpful in some horses with undiagnosed diarrhea, especially in chronic cases. Dietary changes may decrease diarrhea in some cases, and often a diet of grass hay alone is recommended. In cases in which right dorsal colitis is suspected but cannot be confirmed, using pellet feed may be beneficial. Addition of psyllium mucilloid and corn oil to the diet also may be beneficial in right dorsal colitis. Psyllium mucilloid also has been used in cases in which sand was suspected as contributing to the diarrhea. Any medications that the horse has been receiving, especially NSAIDs or antibiotics, should be discontinued in case they are contributing to the diarrhea.

Transfaunation can be used in an attempt to restore normal flora. Fresh colonic or cecal contents are considered the best source of organisms, but feces can be used. Several commercial prebiotics and probiotics are available, and their efficacy is under investigation. The yeast *Sacchromyces boulardii* may decrease the severity and duration of clinical signs in horses with acute enterocolitis.<sup>49</sup>

A course of corticosteroids can be tried in cases of chronic diarrhea in which infectious causes have been ruled out. Treatment with a larvicidal anthelmintic may be beneficial in some cases and sometimes is used with corticosteroids. Some horses with chronic diarrhea have responded to iodochlorhydroxyquin (10 g/450 kg/day for 2 weeks). This drug sometimes has been used concurrently with trimethoprim-sulfa. Occasionally, transfusion with plasma seems to suppress diarrhea in young horses.

## RESPIRATORY DISTRESS

Bonnie R. Rush

*Respiratory distress* is defined as labored breathing and is characterized by an inappropriate degree of effort to breathe based on rate, rhythm, and subjective evaluation of respiratory effort.<sup>1</sup> *Dyspnea* refers to the sensation of arduous, uncomfortable, or difficult breathing that occurs when the demand for ventilation exceeds the patient's ability to respond.<sup>2</sup> *Dyspnea* describes a symptom rather than a clinical sign, and although the term is used often, dyspnea is not technically applicable in veterinary medicine. The clinical signs of respiratory distress vary with the severity and origin of impaired gas exchange. Clinical signs commonly observed in horses with respiratory distress include flared nostrils, exercise intolerance, inactivity, exaggerated abdominal effort, abnormal respiratory noise (stridor), anxious expression, extended head and neck, cyanosis, and synchronous pumping of the anus with the respiratory cycle.<sup>1</sup> Horses with chronic respiratory distress may develop a heave line resulting from hypertrophy of the cutaneous trunci and abdominal muscles, which assist during forced expiration.<sup>3</sup> Respiratory distress usually results from inefficient exchange of oxygen and carbon dioxide caused by primary pulmonary disease, airway obstruction, or impairment of the muscles and supporting structures necessary for ventilation. In some cases ventilation increases in the absence of impaired gas exchange

in response to pain, metabolic acidosis, or high environmental temperature. Familiarity with the mechanics of breathing and control of ventilation in healthy and diseased lungs facilitates the diagnosis and treatment of respiratory distress.<sup>3,4</sup>

## ☞ CONTROL OF VENTILATION

The partial pressure of oxygen ( $P_{aO_2}$ ) and carbon dioxide ( $P_{aCO_2}$ ) in arterial blood are maintained within a narrow range through rigid control of gas exchange.<sup>2</sup> The central controller of respiration in the medulla alters the rate and depth of respiration via efferent signals to the muscles of respiration in response to afferent signals from chemoreceptors in the peripheral vasculature and central nervous system and mechanoreceptors in the upper and lower respiratory tract, diaphragm, and thoracic wall. The central controller therefore adjusts alveolar ventilation to the metabolic rate of the individual.<sup>4</sup>

## SENSORS

The chemoreceptors identify changes in metabolism and oxygen requirements and provide feedback to the central controller, thus allowing for modification of ventilation. Central chemoreceptors respond predominantly to hypercapnia, whereas peripheral chemoreceptors respond to hypoxia and hypercapnia. Central chemoreceptors, located in the ventral medulla, monitor alterations in the pH of intracerebral interstitial fluid and cerebrospinal fluid. The blood-brain barrier is impermeable to bicarbonate and hydrogen ions but is freely permeable to carbon dioxide. Therefore acidification of the intracerebral interstitial fluid and stimulation of the central chemoreceptors occur predominantly in response to hypercapnia. The severity of acidosis in the intracerebral interstitial fluid caused by hypercapnia is amplified by two features of the central nervous system: (1) hypercapnia produces cerebral vasodilation, increasing the delivery of  $CO_2$  to the central nervous system, and (2) cerebrospinal fluid has poor buffering capacity because of low total protein concentrations.<sup>2</sup>

Peripheral chemoreceptors are located in the arterial circulation and respond to acidemia, hypercapnia, and hypoxemia. The carotid bodies are situated at the bifurcation of the common carotid artery, and the aortic bodies are located near the aortic arch. These receptors relay information to the central controller regarding arterial gas tensions via the glossopharyngeal and vagus nerves. Their responsiveness to alterations in  $P_{aCO_2}$  is less consequential than the central chemoreceptors; however, the peripheral chemoreceptors are solely responsible for the hypoxic ventilatory drive. The peripheral chemoreceptors demonstrate a nonlinear response to low arterial oxygen tension. They are insensitive to alterations in  $P_{aO_2}$  above 100 mm Hg, exhibit moderate response to arterial  $O_2$  tensions between 50 and 100 mm Hg, and demonstrate a dramatic increase in responsiveness when the partial pressure of oxygen falls below 50 mm Hg in the arterial circulation.<sup>2</sup> The respiratory pattern elicited by hypoxia differs from that stimulated by hypercapnia.<sup>5,6</sup> Hypoxia evokes an increase in respiratory frequency, whereas hypercapnia triggers an elevation in tidal volume. In addition, hypoxia stimulates recruitment of the inspiratory muscles, whereas hypercapnia potentiates the activity of inspiratory and expiratory muscles.

The sensitivity of peripheral chemoreceptors should be considered in the treatment of patients with complex acid-base and blood-gas abnormalities. A patient suffering from impaired gas exchange caused by pulmonary disease and metabolic acidosis resulting from shock manifests respiratory distress in response to hypoxemia, hypercapnia, and acidosis. Oxygen supplementation likely will improve the patient's arterial oxygen tension. Such treatment, however, may abolish the hypoxic ventilatory drive and consequently slow the ventilatory rate. This decreased ventilation could exacerbate respiratory acidosis and may result in decompensation of the patient.<sup>4</sup> To prevent life-threatening acidemia, treatment of metabolic acidosis in addition to oxygen supplementation is indicated.

Receptors located in the upper and lower respiratory tract respond to mechanical and chemical stimuli and relay afferent information to the central controller of respiration via the vagus nerve.<sup>1,2</sup> Vagal blockade abolishes tachypnea in horses with pulmonary disease; therefore these receptors are likely to play an important role in development of respiratory distress associated with primary pulmonary disease.<sup>7-9</sup> Pulmonary stretch receptors, also called *slow-adapting stretch receptors*, are located within smooth muscle fibers in the walls of the trachea and bronchi.<sup>1,2,4</sup> These receptors are stimulated by pulmonary inflation and inhibit further inflation of the lung (Hering-Breuer reflex). Conversely, at end expiration these receptors stimulate inspiratory activity. These receptors are considered to be partially responsible for controlling the depth and rate of respiration.

Irritant receptors (rapid-adjusting stretch receptors) are believed to be located between epithelial cells of the conducting airways.<sup>2</sup> They are not likely to function in regulation of breathing in a normal resting horse.<sup>4</sup> Stimulation of these receptors by noxious stimuli triggers bronchoconstriction, cough, tachypnea, mucus production, and release of inflammatory mediators.<sup>1,2</sup> Irritant receptors can be triggered by exogenous stimuli (e.g., smoke, irritant gases, dust) or by endogenously produced inflammatory mediators, including histamine and prostaglandins. Production of histamine, prostaglandins, and other inflammatory mediators increases in horses with recurrent airway obstruction (RAO; chronic obstructive pulmonary disease [COPD]).<sup>10-12</sup> Stimulation of irritant receptors by these inflammatory mediators may be responsible in part for bronchoconstriction, mucus production, and tachypnea observed in horses with allergic airway disease. In addition to their role as chemoreceptors, irritant receptors also function as mechanoreceptors.<sup>1</sup> An abrupt change in end-expiratory lung volume, such as occurs with pneumothorax or pleural effusion, produces tachypnea attributed to stimulation of irritant receptors. Juxtacapillary receptors are believed to be located within the wall of the alveolus. Stimulation by increased interstitial fluid volume triggers the sensation of difficult breathing.<sup>2</sup> Nonmyelinated C fibers are located in the pulmonary parenchyma, conducting airways, and blood vessels. These receptors respond to pulmonary edema, congestion, and inflammatory mediators, and stimulation activates tachypnea. In addition, C fiber receptors may stimulate the release of pulmonary neuropeptides, which produce bronchoconstriction, vasodilation, protein extravasation, and cytokine production.<sup>1</sup> Increased negative pressure (upper airway obstruction) within the airway stimulates mechanoreceptors of the larynx and produces prolongation of inspiratory time and activation of upper airway dilator muscles.<sup>13</sup>

## CENTRAL CONTROL OF RESPIRATION

The central controller consists of a group of motor neurons in the pons and medulla that receive input from the peripheral and central receptors and initiate phasic activity of diaphragmatic, intercostal, and abdominal respiratory muscles.<sup>2</sup> The medullary respiratory center, which is located in the reticular formation, controls the rhythmic pattern of respiration. The dorsal respiratory group coordinates inspiratory activity by assimilating afferent information from the glossopharyngeal and vagus nerves and transmits efferent signals to the muscles of inspiration and neurons in the ventral respiratory group. The ventral respiratory group consists of inspiratory and expiratory motor neurons. This nucleus is relatively inactive at rest and has a more dominant role during exercise. The apneustic center, located in the pons, provides stimulatory input to inspiratory motor neurons. Damage to the apneustic center, from trauma or neonatal maladjustment syndrome, results in prolonged inspiratory gasps interrupted by transient expiratory efforts.<sup>4</sup> The pneumotaxic center, also located in the pons, inhibits the inspiratory centers and regulates the volume and rate of respiration. The pneumotaxic center is not required to maintain a normal respiratory rhythm; instead, this center functions to fine tune the respiratory rhythm,<sup>2</sup> receiving afferent input from the vagus nerve regarding  $P_{aO_2}$ ,  $P_{aCO_2}$ , and pulmonary inflation.

## EFFECTORS OF RESPIRATION

The muscles required for ventilation include the diaphragm, the external and internal intercostal muscles, and the abdominal muscles. The single most important muscle required for the inspiratory phase of the respiratory cycle is the diaphragm. Contraction of the diaphragm forces the abdominal contents back, increasing the length of the thoracic cavity, and pulls the ribs abaxially, increasing the width of the abdominal cavity. In addition, the external intercostal muscles participate in inspiration by pulling the ribs abaxially to increase the width of the thoracic cavity. The net effect is an increase in the size of the thoracic cavity, producing subatmospheric intrathoracic pressure, to drive inspiration and pulmonary inflation. Expiration at rest is a passive process in most species and relies on elastic recoil of the lung to create positive intrathoracic pressure.<sup>2</sup> In horses the first portion of expiration relies on elastic recoil of the lung to the point of relaxation volume, whereby the tendency for pulmonary collapse equals the tendency for expansion by the thoracic wall. However, horses further decrease lung volume by active compression of the chest wall, through contraction of the internal intercostal muscles and muscles of the abdominal wall.<sup>14</sup> Conversely, the first part of inhalation is passive until the relaxation volume is reached, at which point the diaphragm and external intercostal muscles complete the inspiratory phase. Mechanical (abdominal distention, trauma to the thoracic wall) and neuromuscular (botulism, phrenic nerve damage, nutritional muscular dystrophy) dysfunction of the diaphragm and intercostal muscles prevents expansion of the thoracic wall and produces hypoventilation, hypoxemia, and respiratory distress.<sup>4</sup> Horses with torsion of the large colon develop significant abdominal distention and respiratory distress. Respiratory failure caused by impaired diaphragmatic function plays an important role in the pathophysiology and mortality associated with this intestinal accident.

The diameter of the conducting airways is an important determinant of the degree of pulmonary resistance and work of breathing and is controlled by the autonomic nervous system. Vagal-mediated parasympathetic stimulation causes airway narrowing and is one mechanism of bronchoconstriction associated with allergic airway disease. Administration of atropine results in rapid relief of bronchoconstriction in some horses with RAO, demonstrating the important role of parasympathetic bronchoconstriction in the pathogenesis of this disease.<sup>3,4</sup>  $\beta_2$ -Receptor stimulation produces smooth muscle relaxation and bronchodilation.  $\beta_2$ -Adrenergic receptors are abundant throughout the lung; however, sympathetic innervation is sparse, and  $\beta$ -receptors within the lung must rely on circulating catecholamines for stimulation.<sup>4</sup> Airways must be constricted for  $\beta_2$ -receptor stimulation or atropine blockade to produce increased airway caliber.<sup>15,16</sup>  $\beta$ -Adrenergic receptors are less abundant than  $\beta_2$ -receptors and play no important role in the regulation of airway diameter. However,  $\beta$ -receptors appear to be upregulated in horses with RAO and contribute to bronchoconstriction associated with this disease.<sup>17</sup>

Nonadrenergic-noncholinergic (NANC) innervation also contributes to large airway diameter. Smooth muscles of the trachea and bronchi relax in response to activation of the inhibitory NANC system. In RAO-affected horses with clinical signs of airway obstruction, inhibitory NANC function is absent.<sup>18</sup> Failure of the inhibitory NANC system may result from the inflammatory response during acute RAO or may be an inherent autonomic dysfunction of the conducting airways of RAO-affected horses.

## ☉ HYPOXEMIA

Respiratory distress most often originates from inadequate pulmonary gas exchange to meet the metabolic demands of the individual, resulting in hypoxemia and hypercapnia. Hypoxemia results from one or more of five basic pathophysiologic mechanisms: hypoventilation, ventilation-perfusion mismatch, right-to-left shunting of blood, diffusion impairment, and reduced inspired oxygen concentration. The degree of hypercapnia and response to oxygen supplementation varies depending on the mechanism of impaired gas exchange. Determination of these two parameters is useful in identifying the pathophysiologic process predominantly responsible for the development of hypoxemia.<sup>2</sup>

## HYPOVENTILATION

The hallmark of hypoventilation is hypercapnia.<sup>2</sup> The elevation in  $P_{aCO_2}$  is inversely proportional to the reduction in alveolar ventilation; halving alveolar ventilation doubles  $P_{aCO_2}$ .<sup>2</sup> The reduction in arterial oxygen tension is almost directly proportional to the increase in  $CO_2$ . For instance, if  $P_{aCO_2}$  increases from 40 to 80 mm Hg, then the  $P_{aO_2}$  decreases from 100 to 60 mm Hg. Therefore hypoxemia resulting from hypoventilation is rarely life-threatening. In addition, oxygen supplementation easily abolishes hypoxemia caused by pure hypoventilation. Acidosis caused by hypercapnia is the most clinically significant feature of hypoventilation and may threaten the life of the patient.<sup>2</sup> Metabolic alkalosis or central nervous system depression (e.g., from head trauma, encephalitis, narcotic drugs) can produce hypoventilation; however, horses with these disorders may not demonstrate clinical signs of respiratory distress. The following disorders can cause

alveolar hypoventilation, and affected patients usually demonstrate clinical signs of respiratory distress: mechanical (abdominal distention, trauma to the thoracic wall) and neuromuscular (botulism, phrenic nerve damage, nutritional muscular dystrophy) dysfunction of the diaphragm and intercostal muscles, restrictive pulmonary disease (silicosis, pulmonary fibrosis, pneumothorax, pleural effusion), and upper airway obstruction.<sup>4</sup>

## VENTILATION-PERFUSION MISMATCH

Ventilation-perfusion (V-Q) mismatch is the most common cause of hypoxemia and is characterized by unequal distribution of alveolar ventilation and blood flow.<sup>4</sup> Pulmonary regions that are overperfused in relation to ventilation (low V-Q ratio) contribute disproportionate amounts of blood with low arterial oxygen content to the systemic circulation.<sup>2</sup> Respiratory diseases characterized by low V-Q ratios include RAO, pulmonary atelectasis, and consolidation.<sup>4</sup> If ventilation exceeds perfusion (high V-Q ratio), the ventilated pulmonary units are inefficient for  $CO_2$  elimination and  $O_2$  uptake. Ventilation of poorly or nonperfused units is wasted ventilation, termed *alveolar dead space*.<sup>2</sup> Conditions associated with high V-Q ratios include pulmonary thromboembolism and shock (low pulmonary artery pressure). Patients with V-Q mismatch often have a normal arterial  $P_{CO_2}$ . The ventilatory drive to maintain normal  $P_{aCO_2}$  is powerful. Because the  $CO_2$  dissociation curve is basically a straight line (direct relationship), increased ventilation efficiently decreases  $P_{aCO_2}$  at high and low V-Q ratios. Because of the nearly flat shape of the  $O_2$  dissociation curve, increasing ventilation is inefficient for proportionally increasing the arterial  $P_{O_2}$ . Only pulmonary units with moderate to low V-Q ratios benefit from increased ventilation. Therefore the increased ventilatory effort to maintain normal  $P_{aCO_2}$  is wasted and unnecessarily increases the work of breathing. Oxygen supplementation increases  $P_{aCO_2}$  in patients with a V-Q mismatch. However, elevation in arterial  $O_2$  is delayed compared with hypoventilation and in some cases may be incomplete.<sup>2</sup> Compensatory mechanisms are present to minimize unequal distribution of ventilation and perfusion in diseased lungs to prevent the development of hypoxemia until the pulmonary pathologic condition is severe.<sup>23</sup> Reflex pulmonary arterial constriction (hypoxic vasoconstriction) prevents perfusion of unventilated alveolar units and attempts to redirect blood flow to alveoli that are ventilated adequately. Airway hypocapnia causes bronchoconstriction of airways that conduct to unperfused alveolar units, redirecting air flow to better-perfused alveoli.

## SHUNT

*Shunt* is defined as blood that is not exposed to ventilated areas of the lung and is added to the arteries of the systemic circulation.<sup>2</sup> Shunting can occur as an extreme form of V-Q mismatch or with direct addition of unoxygenated blood to the arterial system. *Physiologic shunting* is defined as perfusion of nonventilated or collapsed regions of the lung and occurs with pulmonary consolidation, atelectasis, and edema. Congenital heart disease, such as tetralogy of Fallot and some cardiac septal defects, is an example of a direct right-to-left shunt wherein unoxygenated blood from the right side of the heart is added to oxygenated blood from the left side of the heart. In these conditions hypoxemia cannot be abolished by

increasing the oxygen content of inspired air. The shunted blood is never exposed to the higher concentration of inspired oxygen in the alveolus, and the addition of a small amount of shunted blood with its low  $O_2$  content greatly reduces the  $P_{O_2}$  of arterial blood. Compared with breathing room air, the decrement in  $P_{O_2}$  is much greater at  $P_{O_2}$  levels associated with the inhalation of  $O_2$ -enriched air because the  $O_2$  dissociation curve is so flat at high  $P_{O_2}$  levels. Only hypoxemia caused by right-to-left shunting behaves in this manner when the patient is permitted to inspire high percentages of oxygen (70% to 100%). Shunts do not usually cause hypercapnia.<sup>2</sup> Chemoreceptors detect excess arterial  $CO_2$ , and ventilation increases to reduce the content of  $CO_2$  in unshunted blood until arterial  $P_{CO_2}$  reaches the normal range. In some cases of shunt the arterial  $P_{CO_2}$  is below normal because of hyperventilation stimulated by the hypoxemic ventilatory drive.

### **DIFFUSION IMPAIRMENT**

Gas exchange between the alveolus and the capillary occurs by passive diffusion, which is driven by the property of molecules to move randomly from an area of high concentration to one of low concentration.<sup>2</sup> Factors that determine the rate of gas exchange include the concentration gradient between the alveolus and capillary blood, solubility of the gas, surface area available for diffusion, and the width of the air-blood barrier. Diseases characterized by pure diffusion impairment are rare in veterinary medicine.<sup>4</sup> Diffusion impairment can occur with pulmonary fibrosis, interstitial pneumonia, silicosis, or edema caused by increased width of the barrier or decreased surface area available for gas exchange. The clinician should recognize that the major component of hypoxemia for these conditions is a V-Q mismatch; however, diffusion impairment can contribute to the severity of hypoxemia. Supplemental oxygen therapy is effective in treating hypoxemia caused by diffusion impairment because it creates a more favorable concentration gradient and increases the driving pressure of oxygen to move from the alveolus into the blood. Transport of  $CO_2$  is less affected by diseases of diffusion impairment because of its greater solubility compared with  $O_2$ .<sup>2</sup>

### **REDUCTION OF INSPIRED OXYGEN**

Hypoxemia resulting from decreased inspired oxygen content is uncommon and occurs only under special circumstances. High altitude and iatrogenic ventilation with a low oxygen concentration are the most common circumstances in which hypoxemia is attributed to reduction of inspired oxygen content.<sup>2</sup>

Most pulmonary diseases in horses incorporate more than one of these pathophysiologic mechanisms for the development of hypoxemia. Horses with pleuropneumonia, for example, may develop hypoxemia caused by hypoventilation (extrapulmonary restriction by pleural effusion), V-Q mismatch (accumulation of exudate and edema within alveoli and conducting airways), and diffusion impairment (exudate and edema within the interstitial spaces).

### **☞ OBSTRUCTIVE DISEASE**

The location (intrathoracic or extrathoracic) and nature (fixed or dynamic) of airway obstruction determines whether impedance to air flow occurs during inspiration, expiration, or both.<sup>3</sup>

The phase of the respiratory cycle affected by air flow obstruction is prolonged and may be associated with a respiratory noise (stridor or wheeze).<sup>2,19</sup>

The horse is an obligate nasal breather and can breathe efficiently only through the nares.<sup>4</sup> Therefore upper airway obstruction within the nasal passages cannot be bypassed by mouth breathing. In addition, approximately 80% of the total airway resistance to air flow is located in the upper airway.<sup>19</sup> A 50% decrease in the radius of an airway increases its resistance by 16-fold (Poiseuille's law).<sup>2</sup> Therefore small changes in the upper airway diameter dramatically affect the overall resistance to air flow and work of breathing for the horse. Extrathoracic airway pressures are subatmospheric during inspiration; therefore poorly supported structures in the upper airway narrow or collapse during inspiration (dynamic collapse). The most common cause of non-fixed upper airway obstruction in horses is laryngeal hemiplegia, which produces inspiratory stridor during exercise. Intraluminal masses and arytenoid chondritis cause fixed upper airway obstruction and produce inspiratory and expiratory respiratory distress.<sup>3</sup>

Of the total airway resistance 20% is attributable to the small airways.<sup>19</sup> Although the radius of individual bronchioles is small, many of them exist and the sum or collective radius is large, with the result that their overall contribution to pulmonary resistance is low.<sup>2</sup> Because the resistance of the bronchioles is low, advanced disease must be present for routine measurements of airway resistance to detect an abnormality, and obstruction of these airways must be extensive before a horse would suffer from respiratory distress. During pulmonary inflation intrathoracic pressures are subatmospheric. Small airways are pulled open by negative intrathoracic pressure and stretched parenchymal attachments at high lung volumes. Thus resistance to air flow in small airways is low during the inspiratory phase of respiration.<sup>2</sup> During exhalation intrathoracic pressure is positive and the diameter of small airways is decreased, and bronchioles may even close at low lung volumes. Therefore resistance to air flow in small airways is greatest during the expiratory phase. In horses with RAO the airway diameter is reduced by inflammatory exudate, edema, and bronchoconstriction.<sup>3,4</sup> As lung volume decreases during expiration, the narrowed bronchioles are compressed shut (dynamic airway collapse) and trap air distal to the site of closure.<sup>4</sup> This is an example of severe flow limitation, which may lead ultimately to the development of emphysema. Flow limitation forces horses with RAO to breathe at higher lung volumes and maintain a higher functional residual capacity to reduce or prevent dynamic airway collapse. Affected horses attempt to reduce the end-expiratory lung volume by recruiting abdominal muscles to increase the intrathoracic pressures during expiration. However, the greater the end-expiratory pressure, the greater is the likelihood of small airway compression and collapse. Hypertrophy of the cutaneous trunci and expiratory abdominal muscles, especially the external abdominal oblique, produces the characteristic "heave line" associated with RAO.<sup>4</sup> Because dynamic airway narrowing and collapse occur during exhalation, wheezes are typically loudest at end expiration in horses with RAO.<sup>3,4</sup>

### **☞ RESTRICTIVE DISEASE**

Restrictive disease is less common than obstructive pulmonary disease in horses.<sup>4</sup> By definition, restrictive disease inhibits pulmonary expansion and leads to inspiratory respiratory distress.<sup>2</sup>

The vital capacity and compliance (pulmonary or chest wall) decrease, expiratory flow rates and elastic recoil increase, and airway resistance is normal. The characteristic respiratory pattern in horses with restrictive pulmonary disease is rapid, shallow respiration at low lung volumes.<sup>4</sup> This strategy takes advantage of high pulmonary compliance at low lung volumes and decreases the work of breathing. This respiratory pattern has the disadvantage of increased ventilation of anatomic dead space.<sup>2</sup> Restrictive diseases may be classified as intrapulmonary (pulmonary fibrosis, silicosis,<sup>20</sup> and interstitial pneumonia<sup>21,22</sup>) and extrapulmonary (pleural effusion, pneumothorax, mediastinal mass, botulism, and nutritional muscular dystrophy).<sup>4</sup> Hypoxemia observed in horses with intrapulmonary restrictive disease is attributed to V-Q mismatch and diffusion impairment. Stimulation of juxtacapillary receptors may contribute to respiratory distress observed in these patients.<sup>2</sup> The pathophysiologic mechanism for hypoxemia in horses with extrapulmonary restriction is hypoventilation.<sup>4</sup> In horses with pleural effusion and pneumothorax, respiratory distress is likely to be exacerbated by thoracic pain.

## ☞ NONPULMONARY RESPIRATORY DISTRESS

Respiratory distress does not always originate from dysfunction of the pulmonary system and its supporting structures. Nonpulmonary respiratory distress can occur because of inadequate oxygen-carrying capacity of the blood, compensation for metabolic acidosis, pain, and hyperthermia.

Impaired oxygen-carrying capacity of the blood may occur because of anemia (blood loss, hemolytic, or aplastic) or dysfunction of red blood cells (methemoglobinemia, carbon monoxide toxicity). In these cases the arterial  $P_{O_2}$  tension (quantity of dissolved oxygen) is normal; however, the total oxygen content of the blood is reduced greatly.<sup>2</sup> Tachypnea and respiratory distress occur in response to impaired oxygen delivery and tissue hypoxia.<sup>3</sup>

The respiratory system can compensate for metabolic acidosis by increasing ventilation to lower  $P_{aCO_2}$  and attenuate acidemia.<sup>2</sup> The ventilatory drive increases in response to stimulation by peripheral chemoreceptors by circulating hydrogen ions. Hypocarbic compensation for mild to moderate metabolic acidosis is effective in returning blood pH to normal until renal compensatory mechanisms can be established.<sup>2</sup>

Pain and anxiety are physiologic causes of tachypnea and hyperpnea. Horses with musculoskeletal pain are unlikely to demonstrate significant respiratory distress; however, rhabdomyolysis and laminitis are painful musculoskeletal conditions that may produce tachypnea.<sup>3</sup> Marked respiratory distress is observed frequently in horses with abdominal pain; however, the respiratory distress is not caused solely by pain and is exacerbated by abdominal distention, shock, acidosis, and endotoxemia.

Hyperthermia caused by fever, high environmental temperature, exercise, and heat stress can produce respiratory distress in horses. Tachypnea and elevation in body temperature are the most prominent clinical signs in horses with anhidrosis.<sup>23</sup> Hyperpnea is an effective mechanism for heat dissipation in human beings, dogs, and ruminants.<sup>3</sup> Unfortunately, increased ventilation is an inefficient mechanism for heat dissipation in horses and appears to be wasted effort.<sup>3,4</sup>

## ☞ CLINICAL EVALUATION OF RESPIRATORY DISTRESS

A thorough physical examination is essential to determine the origin of respiratory distress, identify concurrent disease, and direct further diagnostic testing. Prolonged inspiration is consistent with restrictive or extrathoracic, nonfixed, obstructive disease, whereas horses with intrathoracic airway obstruction exhibit expiratory difficulty.<sup>2,3</sup> Respiratory distress associated with inspiration and expiration may indicate an extrathoracic fixed obstruction. Stridor is an abnormal respiratory noise that usually is generated by obstruction of the upper airway and is audible most often during inspiration.<sup>3</sup> Horses with nonpulmonary respiratory distress demonstrate increased rate and depth of respiration without producing abnormal respiratory noise.

Thoracic auscultation identifies abnormal respiratory sounds (crackles and wheezes) or regions of decreased breath sounds caused by pleural effusion, pneumothorax, or pulmonary consolidation. Percussion of the thoracic wall generates a resonant and hollow sound when performed over regions of normal lung. Pleural effusion and pulmonary consolidation sound dull and flat during thoracic percussion, whereas pneumothorax produces a hyperresonant sound.<sup>4</sup>

Normal air flow occurs in laminar flow; therefore normal horses at rest do not generate easily audible sounds.<sup>4</sup> Respiratory sounds are generated from vibration in tissue and sudden changes in pressure of gas moving within the airway lumen. Airway narrowing and exudate generate audible sounds by creating disturbances in laminar flow, turbulence, and sudden changes in pressure of moving gas.<sup>2</sup> Crackles are intermittent or explosive sounds, generated by bubbling of air through secretions or by equilibration of airway pressures after sudden opening of collapsed small airways. The generation of crackles requires an air-fluid interface, and these abnormal lung sounds occur in horses with pneumonia, interstitial fibrosis, RAO, pulmonary edema, and atelectasis.<sup>4</sup> Wheezes are continuous, musical sounds that originate from oscillation of small airway walls before complete closing (expiratory wheeze) or opening (inspiratory wheeze).<sup>2</sup> Expiratory wheezes are the hallmark of obstructive pulmonary disease.<sup>2</sup>

Arterial blood gas determination provides a quantitative evaluation of pulmonary function, alveolar ventilation, and acid-base status and may identify the origin of respiratory distress (hypercapnia, hypoxemia, or acidemia).<sup>2</sup> The clinician may determine the pathophysiologic mechanism of hypoxemia by examining the  $P_{aCO_2}$  level and by investigating the response of  $P_{aO_2}$  to supplemental oxygen therapy. In addition, serial blood gas monitoring can determine response to bronchodilator, parasympathomimetic, or anti-inflammatory therapy.

Additional diagnostic tests that may be indicated in horses with respiratory distress include thoracic radiography, thoracic ultrasonography, endoscopic examination of the upper airway, and atropine challenge. The findings during thoracic auscultation and percussion are valuable in determining whether ultrasonography rather than radiography is indicated. Pulmonary consolidation, abscessation, fibrosis, interstitial pneumonia, peribronchial infiltration, and mediastinal mass are differentiated and diagnosed readily via thoracic radiography. Thoracic ultrasonography is superior to radiography in detecting and characterizing pleural fluid

and peripheral pulmonary abscessation and consolidation in horses. Air reflects the ultrasound beam; therefore ultrasonography does not image deep pulmonary lesions if the overlying lung is aerated.<sup>24</sup> An endoscopic examination of the upper airway is indicated in horses with inspiratory stridor and suspected upper airway obstruction.<sup>4</sup> Horses with extreme respiratory distress may resent endoscopic examination, and forced examination may precipitate a respiratory crisis. Atropine administration in horses with RAO may provide rapid relief of respiratory distress if the major component of airway obstruction is reversible bronchoconstriction. Horses that respond to an atropine challenge likely will respond favorably to bronchodilator therapy. Incomplete response to atropine in horses with RAO indicates that exudate or fibrosis is contributing to airway obstruction, and limited response to bronchodilator therapy is anticipated.<sup>3,4</sup>

## COUGH

Catherine W. Kohn

Cough, a sudden explosive expulsion of air through the glottis, is a common sign of respiratory disease and a reflex pulmonary defense mechanism. Coughing facilitates the removal of noxious substances and excessive secretions from the airways by creating maximum expiratory airflow. A high-velocity airflow generates the shear forces required to separate mucus from the airway walls, enabling expulsion of exudate and debris from the airway.<sup>1</sup> An understanding of the cough reflex provides insight into the pathophysiology of diseases characterized by cough.

The cough reflex has been studied infrequently in horses. Descriptions of the cough cycle and the neural basis of cough presented in this section are based on data from other species. The author infers that similar events occur in horses. Because differences exist among species regarding the cough reflex,<sup>2</sup> studies on horses will be required to define the physiologic events of the cough reflex in this species.

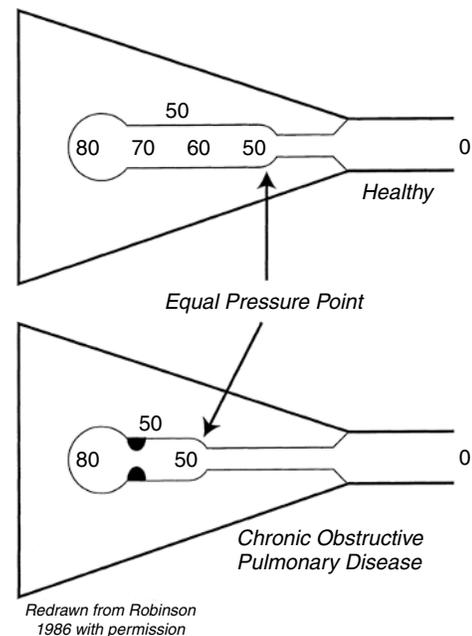

### ☞ COUGH CYCLE

The cough cycle has four phases: inspiration, compression, expression, and relaxation.<sup>1</sup> Deep inspiration, which immediately precedes cough, increases lung volume. As lung volume increases, the ability to generate maximum expiratory airflow increases because of the greater force of contraction achieved by the muscles of respiration when their precontraction length increases and because of the greater elastic recoil pressure of the lung at high lung value.<sup>3</sup> Thus precough expansion of lung volume maximizes the velocity of expiratory airflow. Achievement of maximum expiratory airflow rates requires a relatively gentle expiratory effort, and airflow maxima are therefore independent of effort.<sup>2</sup>

After deep inspiration the glottis closes. While the glottis remains closed, compression of the chest cavity occurs by contraction of the thoracic and abdominal musculature during an active expiratory effort. Compression of the chest results in an increase in pleural pressure from 50 to 100 mm Hg.<sup>2</sup> This increase in pleural pressure is transmitted to pressure in the intrathoracic airways and trachea. Intra-alveolar pressures actually exceed intrapleural pressures by an amount equal to the elastic recoil pressure of the lung.<sup>4</sup>

Expression occurs when the glottis opens abruptly, thus producing a gradient in airway pressure (atmospheric at the pharynx and high in the alveoli), and air is expired forcefully. The occurrence of dynamic airway compression in larger airways maximizes the velocity of airflow toward the mouth (Figure 3-3). The intra-airway pressures vary in the respiratory system according to the instantaneous transpulmonary pressure.<sup>3</sup> At the equal pressure point the airway pressure equals the pleural pressure. Toward the mouth from the equal pressure point (downstream), the pleural pressure is greater than intrathoracic airway pressure, and the intrathoracic airways therefore are compressed dynamically. Partial collapse of the airways downstream of the equal pressure point maximizes airflow velocities in these airways by decreasing their diameter. At high lung volumes the equal pressure point likely is in the larger airways and therefore only the intrathoracic trachea may be subject to dynamic compression and maximal airflow velocity.<sup>4</sup> Maximum airflow velocity produces high shearing forces that dislodge mucus and debris from airway walls, thus facilitating expectoration. Cough is therefore most effective as a defense mechanism for clearing the larger airways in healthy animals. Removal of noxious substances from the smaller peripheral airways depends on the presence of mucus in the airways, and irritants that stimulate cough also may stimulate mucus production.<sup>5</sup>

In diseases characterized by increased resistance in small peripheral airways caused by partial obstruction (e.g., RAO), maximal expiratory flow rates are reduced. When small airways are obstructed partially, the equal pressure point moves toward the periphery of the lung during coughing because

**FIGURE 3-3** Dynamic airway compression during cough or maximum expiratory airflow. Lungs are represented at total lung capacity. When chronic obstructive pulmonary disease is present, the equal pressure point moves toward the alveoli. This peripheral migration of the equal pressure point results in dynamic compression in more peripheral airways during cough than would be found in a healthy individual. Redrawn from Robinson NE: Pathophysiology of coughing, Proceedings of the thirty-second convention of the American Association of Equine Practitioners, Nashville, 1986.

pressures in airways downstream of the partial obstruction are lower than are pressures in those airways in healthy lungs (see Figure 3-3). This shift in the equal pressure point subjects more peripheral airways to dynamic compression. Coughing is likely to be less effective as a clearance mechanism when obstructive diseases of the small airways are present. Bronchodilator therapy may increase the effectiveness of cough in such patients by increasing expiratory airflow rates.<sup>4</sup>

The sound of cough is generated by vibration of laryngeal and pharyngeal structures caused by the rapid expulsion of air immediately after opening of the glottis,<sup>3</sup> by narrowing and deformation of airways, and by vibration of surrounding lung tissue. Variations in the sound of cough most likely relate to the quantity and quality of mucus in the airway.<sup>6</sup>

At the end of cough relaxation occurs. Intrapleural pressure falls, and the muscles of expiration relax. Transient bronchodilation occurs.<sup>1</sup>

## ☞ NEURAL BASIS OF THE COUGH REFLEX

The afferent input for the cough reflex is carried predominantly in the vagus nerves, and the cough reflex depends uniquely on vagal afferents in the species studied.<sup>5,7,8</sup> Sensory myelinated nerves in the larynx respond to mechanical and chemical irritation and mediate cough and changes in airway diameter.<sup>7</sup> The identity of receptors that initiate cough in the lower airways is subject to debate; however, all of the receptors described in this section likely contribute to the cough response.<sup>8</sup> Rapidly adapting receptors are located in the airway mucosa in the region of the carina and are stimulated primarily by mechanical deformation produced, for example, by inhaled particles, mucus, or cellular debris accumulating near the carina. Chemical irritants (e.g., ammonia fumes, ozone, and inflammatory mediators) evoke cough by stimulation of receptors located in the peripheral airways. Pulmonary C fibers may mediate a chemically evoked cough, although this issue is currently under debate. Chemical mediators known to stimulate pulmonary C fibers and cough when inhaled as aerosols by human beings include bronchodilator prostaglandins, bradykinin, and capsaicin.<sup>8</sup> Forced expiration during coughing may be facilitated by the modulating effects of information from these receptors on central respiratory neurons.

Bronchoconstriction is a constant component of cough,<sup>3,6</sup> and stimuli of cough also may cause bronchoconstriction; however, cough and bronchoconstriction are separate airway reflexes. Inhalation of dust and irritant gases causes reflex bronchoconstriction in the species studied. Reflex bronchoconstriction has a slow onset and is long lasting compared with the cough reflex.<sup>2</sup> Bronchoconstriction may increase the efficiency of cough by decreasing airway diameter and therefore increasing airflow velocity. In some cases bronchodilating drugs may suppress the cough reflex by desensitizing airway receptors that elicit cough.<sup>6</sup>

Sensory nerves mediating bronchoconstriction and cough are distributed unevenly along the airways.<sup>7</sup> Laryngeal receptors and sensory nerves in the extrapulmonary airways may be more sensitive to mechanical stimuli, whereas intrapulmonary receptors may respond preferentially to chemical mediators and irritants.

Little is known about the brainstem neuronal pathways of the cough reflex. In the cat the cough center is reported to be in the medulla at the level of the obex, alongside the solitary

nucleus of the vagus and close to the expiratory neurons of the respiratory center. On the motor side of the cough reflex, the vagal, phrenic, intercostal, and lumbar nerves and motor portions of the trigeminal, facial, hypoglossal, and accessory nerves are distributed to the striated and smooth muscles of respiration, the vocal fold abductors and adductors, and glands of the respiratory tract.<sup>3</sup>

## ☞ STIMULI OF COUGH

Cough may be stimulated by airway smooth muscle contraction (bronchoconstriction), excessive mucus production, presence of inhaled particles in the airways, release of inflammatory mediators (infectious diseases), exposure to cold or hot air, intramural or extramural pressure or tension on the airways (tumor, granuloma, abscess, or decreased pulmonary compliance caused by restrictive disease such as interstitial fibrosis or pleuritis), sloughing of airway epithelial cells, and enhanced epithelial permeability (pulmonary edema).<sup>5</sup> Epithelial sloughing and enhanced epithelial permeability theoretically increase the accessibility of cough receptors to the mechanical or chemical agents that stimulate them. Loss of the integrity of the epithelial lining of the respiratory tract is a common feature in many respiratory diseases associated with cough (infectious diseases); however, a cause-and-effect relationship between alterations in respiratory epithelium and cough has not been established.<sup>5</sup>

Diseases of the respiratory tract may alter the sensitivity of the cough reflex.<sup>5</sup> For example, viral diseases may increase the responsiveness of cough receptors to stimuli.

## ☞ DELETERIOUS CONSEQUENCES OF COUGH

Although cough is an important defense mechanism of the respiratory system that promotes expectoration of inhaled noxious substances and voluminous airway secretions, cough may lose its original defensive function and may contribute to the morbidity and discomfort associated with bronchopulmonary disease.<sup>8</sup> This is especially true when the effort to cough is intense and when multiple coughs occur sequentially. Chronic coughing is exhausting and, especially in foals, may decrease food intake. Paroxysmal or persistent cough may impair respiration. Coughing may have profound effects on the cardiovascular system. During the deep inspiratory phase of cough, the rise in intra-abdominal pressure because of contraction of the diaphragm and the fall in intrathoracic pressure combine to aspirate blood from the vena cava to fill the right atrium and ventricle abruptly.<sup>3</sup> Because the pleural pressure decreases, the pulmonary artery pressure also decreases. During the expiratory phase of cough, an initial increase in systemic arterial blood pressure and a simultaneous and commensurate increase in cerebral venous and cerebrospinal fluid pressures occur. However, venous return to the heart soon decreases, and within a few heartbeats filling of the heart and stroke volume decrease.<sup>2,3</sup> Hypotension ensues. Falling arterial blood pressure in the face of high cerebral venous pressures reduces the effective perfusion pressure of the brain. Cerebral hypoperfusion and anoxia may occur. Cough-induced syncope has been reported in human beings<sup>2</sup> and in dogs.<sup>9</sup>

In chronic cough bronchial muscular hypertrophy may develop. Bronchial mucosal edema or emphysema may accompany chronic cough. During cough inspiration inflammatory

debris may be aspirated into previously uncontaminated areas of the lung. Cough in dogs has been associated with pneumothorax (from rupture of preexisting pulmonary bullae) and lung lobe torsion.<sup>10</sup> Rib and vertebral fractures have been reported in human beings with powerful coughs but have not been reported in horses.<sup>2,3</sup>

## ∞ CLINICAL APPROACH TO THE COUGHING HORSE

Cough is a common sign of respiratory disease in horses (Figure 3-4). Cough is an indication of mechanical or irritant stimulation of cough receptors for which the potential causes are diverse. Many clinical approaches exist for anatomic localization of the origin of the cough stimulus in respiratory disease and for discovery of the cause. All methods have in common a systematic and thorough evaluation of the history and physical examination of the patient. To aid the clinician in formulating a rational approach to diagnosis, diseases associated with cough may be grouped according to those characterized by fever (current or historical) and those characterized by lack of an elevated body temperature. The clinician should keep in mind that exceptions to generalizations always occur concerning disease processes, and the following discussion therefore serves only as a guide to develop a logical approach to differentiating diseases characterized by cough.

### COUGH WITH FEVER

Horses with cough and fever should have a thorough physical examination (see Chapter 9 for a complete description of a physical examination for horses with respiratory disease). A minimal laboratory database for the coughing horse with fever should include the results of a hemogram and a fibrinogen determination. The clinician carefully should auscultate the thorax of the horse in a quiet room with the horse breathing quietly. If the horse is not dyspneic or hypoxemic, the clinician also should undertake auscultation during forced breathing. A plastic bag loosely held over the nostrils of the horse forces the horse to increase tidal volume and respiratory rate. This maneuver causes many horses with exudate in the airways to cough, and deep breathing may be frankly painful for some horses with pleuropneumonia. Auscultation during forced breathing is not necessary in horses with obviously abnormal lung sounds during quiet breathing and is not advisable in horses with pneumonia (especially aspiration pneumonia) or in horses with foreign material in the trachea. Crackles and wheezes heard repeatedly during the inspiratory and early expiratory phases of breathing suggest that pulmonary parenchymal disease is present.

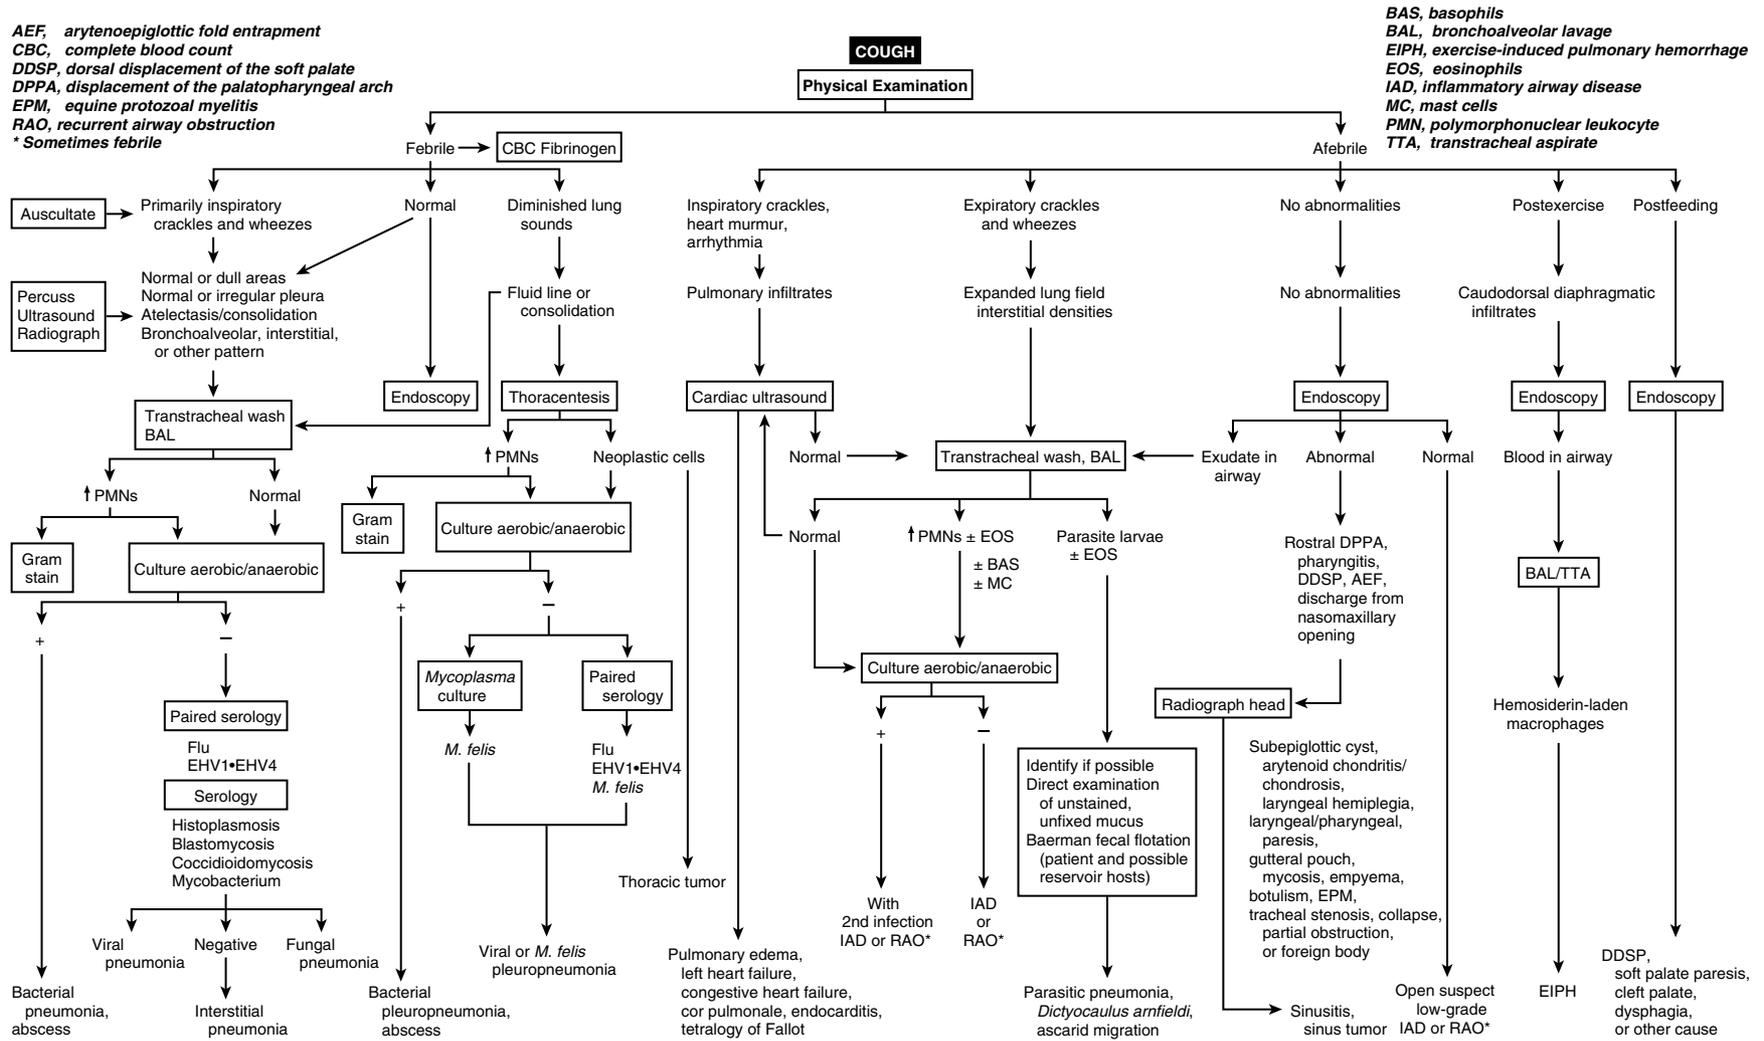

Accentuated normal bronchovesicular sounds sometimes are present in horses with pulmonary consolidation because of referral of sounds from the aerated lung. Absence of lung sounds in dependent portions of the thorax indicates that pulmonary consolidation, atelectasis, or fluid in the pleural cavity may be present. Thoracic percussion and sonographic evaluation are particularly helpful in documenting the presence of fluid in the pleural cavity. Ultrasonography also may show pleural irregularities and superficial parenchymal abscessation, atelectasis, or consolidation. Thoracic radiographs are especially helpful in demonstrating deeper parenchymal disease. Many equine practitioners do not have access to thoracic radiography but can perform thoracic ultrasonography.

Abnormal lung sounds, percussion irregularities, and sonographic evidence of fluid or consolidation are indications for performing transtracheal aspiration (TTA) and bronchoalveolar lavage (BAL). When both procedures are to be performed on the same patient, the clinician should perform TTA first to obtain a sample for culture before the airway is contaminated by the BAL tube. Many practitioners prefer to obtain TTA samples transendoscopically to prevent percutaneous aspiration. Despite the development of guarded culture swabs for transendoscopic use, this technique does not always prevent contamination of lower airway fluid samples. One study demonstrated that *Pseudomonas* spp. and anaerobic bacteria in cultures of tracheal fluid obtained transendoscopically should be viewed as potential contaminants.<sup>11</sup>

Cytologic evaluation of the TTA/BAL, indicating an increase in polymorphonuclear leukocytes (PMNs), is consistent with parenchymal disease. Some PMNs may be degenerate. Although some clinicians believe that PMNs may be seen in the tracheal aspirates of normal horses, few PMNs are found in bronchoalveolar lavage fluids from healthy horses ( $4.4 \pm 3.3$  cells to  $8.9 \pm 1.2$  cells/ $\mu$ l).<sup>12</sup> How well the results of cytologic evaluation of BAL fluids represent the environment of the lower airways is a matter of some debate. BAL fluids are harvested from a focal area of the lung. If parenchymal disease is not generalized, BAL may miss the diseased region. Results of BAL fluid analysis are normal in some horses with pneumonia and pleuropneumonia. Transtracheal wash fluid consists of secretions from both lungs, and TTA cytologic examination was abnormal in all horses with pneumonia and pleuropneumonia in one study.<sup>13</sup> The prevalence of PMNs in TTA fluid from horses without lower respiratory tract disease has not been determined.

The presence of degenerate PMNs and extracellular or intracellular bacteria in TTA/BAL fluid is consistent with the diagnosis of a septic process. The clinician should evaluate a Gram stain to guide the initial choice of antimicrobial agents while awaiting results of culture and sensitivity determinations. Growth of aerobic or anaerobic bacteria in a culture of TTA fluid confirms the presence of bacterial pneumonia if clinical and radiographic findings are also consistent with this disease process. Contamination of cultures of airway secretions obtained via TTA occasionally may occur. Lack of growth of bacterial pathogens from TTA fluid suggests that viral, interstitial, or fungal pneumonia might be present. These possibilities should be investigated by evaluating paired serum samples taken 10 to 14 days apart for influenza virus, equine herpesvirus 1 (EHV1), EHV4, rhinovirus, and equine viral arteritis. Identification of virus by DNA or antigen detection (PCR, immunofluorescence) or virus isolation may also be indicated. Serologic testing for histoplasmosis, blastomycosis, coccidioidomycosis (especially in the southwestern United States), and possibly mycobacteria should be evaluated. Fungal cultures of tracheal fluid should be evaluated when other, more common causes of pneumonia have been ruled out and if the clinical signs of the patient are consistent with this diagnosis. Negative results on serologic tests and fungal cultures in patients with a significant interstitial pattern on thoracic radiographs should prompt consideration of the diagnosis of interstitial pneumonia, a condition for which the inciting cause has not been established and for which the prognosis is grave.

Percussion, radiographic, or ultrasonic evidence of increased intrapleural fluid is an indication for thoracocentesis. Many horses with bacterial pleuropneumonia have elevated pleural fluid PMN concentrations, and PMNs may be

\* IAD (as compared to RAO) is characterised by less neutrophilic inflammation and is more likely to have increased numbers of EOS, BAS, and MØ in BAL fluid samples.

FIGURE 3-4 Approach to cough. EHV1, 4, Equine herpesvirus 1 or 4.

degenerate. Intracellular or extracellular bacteria may be seen on cytologic evaluation. Occasionally, frankly neoplastic cells may be identified in thoracic fluid (usually squamous cells or lymphocytes). Many cytologists are uncomfortable diagnosing thoracic neoplasia solely on the basis of an evaluation of pleural fluid. Thoracic fluid should be cultured aerobically and anaerobically. A positive culture identifies the cause of bacterial pleuritis; however, pleural fluid cultures often may be negative. Cultures of TTA fluid are more likely to be positive in horses with pleuropneumonia, and TTA cultures should be performed routinely for these patients. Primary viral pleuritis, although rare in the author's experience, has been reported in horses, and paired serologic examinations for influenza virus and EHV1/EHV4 may be helpful when cultures are negative. One case of pleuritis caused by *Mycoplasma felis* has been reported.<sup>14</sup> Culture of pleural fluid and paired serologic examinations for this organism should be performed in patients for which other tests have not proved diagnostic.

Intrathoracic neoplasms may cause cough with or without accompanying fever. Confirmation of a thoracic tumor may require an ultrasound-guided biopsy or an exploratory thoracotomy and a biopsy. Secondary bacterial pleuritis may complicate thoracic neoplasms, and aerobic and anaerobic cultures of thoracic fluid from patients suspected of having thoracic neoplasms should be performed.

Some febrile coughing horses have no abnormalities on auscultation, percussion, thoracic radiography, or ultrasound. In such patients occult pulmonary disease may be present and TTA/BAL and culture of TTA fluid are indicated. Alternatively, such horses may have upper airway disease (sinusitis, sinus tumor, guttural pouch empyema), and an endoscopic evaluation is also indicated.

## COUGH WITHOUT FEVER

When auscultation of the thorax demonstrates primarily expiratory crackles and wheezes, thoracic percussion often reveals a caudoventral expansion of the lung borders. These findings suggest that RAO may be present. Thoracic radiographs usually show increased interstitial densities; radiographs are useful to rule out occult underlying pulmonary disease (such as a well walled-off abscess) but are not required for diagnosis in most cases. TTA and BAL are indicated. Horses with RAO usually have an increase in well-preserved PMNs, and sometimes eosinophils, in TTA and BAL fluids. Growth of pathogens in aerobic or anaerobic culture of TTA fluid identifies secondary bacterial infection. No growth in cultures of TTA fluid is also consistent with the diagnosis of RAO.

Inflammatory airway disease (IAD) is a syndrome most often associated with chronic intermittent cough, decreased performance and increased mucoid airway secretions.<sup>15</sup> However, the absence of a cough does not rule out IAD. Evaluation of BAL fluid reveals nonseptic inflammation. IAD and RAO share a number of clinical, cytologic, and functional characteristics. In general, IAD is not associated with the labored breathing and severe exercise intolerance seen with active cases of RAO. Also, in horses with IAD the BAL fluid tends to have less pronounced neutrophilic inflammation and is more likely to have increased mast cells, basophils, or eosinophils compared with BAL fluid from horses with RAO.

TTA/BAL fluids may occasionally contain parasite larvae or many eosinophils. If horses historically have been housed with donkeys or mules, the veterinarian should suspect

*Dictyocaulus arnfieldi* infestation. Coughing horses younger than 18 months of age with eosinophilic TTA fluid may be experiencing migration of *Parascaris equorum* larvae. The clinician should attempt to identify the larvae, although this may be difficult. A direct cytologic evaluation of unfixed, unstained, or iodine-stained mucus may be helpful to identify larvae of *D. arnfieldi*. The clinician should perform a Baermann flotation on feces from the patient and potential reservoir hosts, but the test may not demonstrate ascarid larvae because pulmonary migration occurs early in the prepatent period.<sup>16</sup> The diagnosis of pulmonary ascarid migration is based on ruling out other causes of pneumonia.

When TTA/BAL fluids have no abnormal cells, cultures still should be assessed. For afebrile coughing horses with thoracic auscultation findings of inspiratory crackles and wheezes and cardiac murmur or arrhythmia, thoracic radiographs are appropriate. The presence of diffuse pulmonary infiltrates in a bronchoalveolar pattern suggests that pulmonary edema may be present. A complete ultrasonic evaluation of the heart is indicated.

Some coughing, afebrile horses have no abnormalities on auscultation or percussion, and endoscopy of the upper airway and trachea is indicated. Some horses have endoscopic evidence of exudate in the trachea and likely have low-grade RAO. The clinician should take thoracic radiographs of these horses if possible and perform TTA/BAL testing followed by culture of TTA fluid. A transtracheal aspirate should not be obtained immediately after tracheoscopy because bacteria on the endoscope may contaminate airway cultures.

In other patients, cough may be a symptom of upper airway obstructive disease (dorsal displacement of the soft palate; rostral displacement of the palatopharyngeal arch; arytenoepiglottic fold entrapment; subepiglottic cyst; arytenoid chondritis/chondrosis; laryngeal hemiplegia; or tracheal stenosis, collapse, or partial obstruction) or maxillary or frontal sinusitis with discharge into the nasal passages via the nasomaxillary opening or laryngeal/pharyngeal paresis. The latter may be a symptom of guttural pouch mycosis, empyema, or systemic disease (e.g., botulism or equine protozoal myelitis). Cough also may be a symptom of a tracheal foreign body (e.g., a twig or TTA catheter) in the airway. The veterinarian should suspect low-grade RAO or IAD in horses with cough but no abnormalities on endoscopic examination.

Cough after exercise or feeding also should prompt an endoscopic evaluation. Evidence of hemorrhage in the trachea after exercise indicates that exercise-induced pulmonary hemorrhage is likely. This diagnosis can be confirmed by finding hemosiderin-laden macrophages in BAL or TTA fluid. Thoracic radiographs may show interstitial densities and pleural thickening in the caudodorsal lung field. Postprandial cough may be associated with soft palate paresis, dorsal displacement of the soft palate, cleft palate (neonates and foals), or dysphagia of any cause. A detailed description of diagnostic and therapeutic strategies for diseases of the respiratory system can be found in Chapter 9.

## POLYURIA AND POLYDIPSIA

Catherine W. Kohn, Bernard Hansen

The complaint of excessive urination and drinking may be heard with some frequency in equine practice. Before pursuing a lengthy diagnostic workup, the veterinarian should

TABLE 3-5

**Voluntary Water Consumption in Healthy Horses**

Ambient Temperature	WATER CONSUMPTION	
	ml/kg/day	L/450 kg
5° to 16°C (41° to 61° F)	44 to 61	19.8 to 27.5
25° C (77° F)	70	31.5

(Data from Tasker JB: Fluid and electrolyte studies in the horse, III. Intake and output of water, sodium, and potassium in normal horses, *Cornell Vet* 57: 649-657, 1967; Rose BD: *Clinical physiology of acid-base and electrolyte disorders*, New York, 1989, McGraw-Hill Information Services; and Groenedyk S, English PB, Abetz I: External balance of water and electrolytes in the horse, *Equine Vet J* 20: 189-193, 1988.)

confirm that 24-hour urine production and voluntary water consumption exceed reference ranges. Urine production in adult horses may range from 15 to 30 ml/kg/day, and values as high as 48 ml/kg/day have been reported.<sup>1-4</sup> Daily urine volume is affected by diet; more water is lost in the urine of horses fed pelleted diets and legume hays than in that of horses fed grass hay. The latter excrete more water in feces.<sup>5,6</sup> Generally, any component of the diet that increases renal solute load increases urine volume (e.g., high salt content in the diet). Voluntary water intake also is affected by the ambient temperature (Table 3-5). When temperatures are high and evaporative water losses increase to cool the horse, voluntary water intake also increases. Diet and climatic conditions therefore must be considered when interpreting water consumption and urine production data. Water requirements are proportional to metabolic body size rather than to body mass. Thus larger horses, particularly draft breeds, require less water per kilogram than do smaller horses, ponies, or miniature horses. In addition, fat is low in water content compared with lean body tissue, and fat animals require proportionately less water than do lean animals.<sup>7</sup>

Some owners may misinterpret pollakiuria (frequent urination usually of small volume) as polyuria. Quantitative collection of urine for a 24-hour period may be required to verify excessive urine production. Several simple collection apparatuses have been described.<sup>8,9</sup>

## ☞ MAINTENANCE OF WATER BALANCE IN HEALTH

Maintenance of water homeostasis depends on establishing a balance between intake and excretion such that plasma osmolality remains constant (within approximately 2% of normal).<sup>10</sup> The primary determinant of renal water excretion is antidiuretic hormone (ADH).<sup>11</sup> ADH is a polypeptide synthesized in three nuclei in the hypothalamus (suprachiasmatic, paraventricular, and supraoptic nuclei)<sup>12</sup> and transported from the latter two nuclei in secretory granules down axons of the supraopticohypophyseal tract into the posterior lobe of the pituitary, where ADH is stored. Some ADH enters the cerebrospinal fluid or portal capillaries of the median eminence from the paraventricular nucleus.<sup>11</sup> In addition, neurons from the supraoptic nucleus deposit ADH in other areas in the central nervous system.<sup>12</sup> In human beings lesions of the

posterior pituitary or supraopticohypophyseal tract below the median eminence usually do not lead to permanent central diabetes insipidus because ADH still has access to systemic circulation in these cases.<sup>11</sup> The clinical importance of these anatomic relationships in horses is not known.

ADH increases renal water reabsorption and urine osmolality by augmenting water permeability of luminal membranes of cortical and medullary collecting tubules. ADH augments urea, and in some species NaCl, accumulation in the interstitium, therefore promoting medullary hypertonicity. The primary stimuli for ADH release are plasma hyperosmolality and depletion of the effective circulating blood volume. Osmoreceptors in the hypothalamus detect changes in plasma osmolality of as little as 1%.<sup>11</sup> Although the threshold for ADH release in the horse is not known, 24-hour water deprivation in healthy ponies resulted in approximately an 8 mOsm/kg increase in plasma osmolality (about 3%), from 287 ± 3 mOsm/kg to 295 ± 4 mOsm/kg, which was associated with an increase in plasma ADH concentration between 1.53 ± 0.36 pg/ml to 4.32 ± 1.12 pg/ml.<sup>13</sup> In another study of ponies water deprivation for 19 hours resulted in an increase in plasma osmolality from 297 ± 1 mOsm/L to 306 ± 2 mOsm/L.<sup>14</sup> In human beings plasma osmolalities of 280 to 290 mOsm/L stimulate ADH release. The organs that sense changes in effective circulating blood volume include arterial and left atrial baroreceptors. These stretch receptors function indirectly as volume sensors by responding to the reductions in intraluminal pressure that typically accompany loss of plasma volume. Reduced activation of these receptors by hypovolemia or heart failure is a potent cause of ADH release, even in the absence of increased plasma osmolality. ADH secretion also may be stimulated by stress (pain), nausea, hypoglycemia, and certain drugs (e.g., morphine, lithium).<sup>11</sup>

When the need for water in body fluids cannot be met by conservation via the renal/ADH axis, thirst is stimulated. Thirst is regulated primarily by plasma tonicity; however, in human beings the threshold for stimulation of thirst is approximately 2 to 5 mOsm/kg greater than that for stimulation of ADH release.<sup>11</sup> Thirst is controlled by osmosensitive neurons in close proximity in the hypothalamus to osmoreceptors that mediate ADH secretion.<sup>12</sup> Thirst is sensed peripherally by oropharyngeal mechanoreceptors as dryness of the mouth. Thirst also may be stimulated by volume depletion through an incompletely understood mechanism. Experimental ponies drank when their plasma osmolalities increased by 3% after water deprivation, when plasma Na concentrations increased by approximately 5%, and after induction of a plasma volume deficit of 6%.<sup>14</sup>

## ☞ MECHANISM OF URINE CONCENTRATION

For the kidney to make concentrated urine, ADH must be produced, the renal collecting tubules must respond to ADH, and the renal medullary interstitium must be hypertonic. Generation of medullary hypertonicity is initiated in the thick ascending limb of the loop of Henle by active transport of NaCl out of the lumen. Because the thick ascending limb is impermeable to water, active resorption of NaCl results in hypotonicity of the fluid entering the distal tubule in the renal cortex (Figure 3-5, A). The distal tubules and cortical portions of the collecting ducts are permeable to water (see Figure 3-5, B), which is reabsorbed down its concentration gradient into

the interstitium. Reabsorbed water is transported rapidly out of the interstitium by the extensive cortical capillary network, and interstitial hypertonicity is preserved. Urea remains in the lumen of the distal tubule and cortical collecting duct and is concentrated further. Luminal fluid flows into the medullary collecting duct, which is permeable to water and urea when under the influence of ADH (see Figure 3-5, C). Water is reabsorbed down its progressively steeper concentration gradient as luminal fluid moves through the medullary collecting ducts. Some urea also is reabsorbed into the interstitium. Reabsorbed water is removed efficiently by the vasa recta in the renal medulla. Because these blood vessels also are arranged in a hairpin loop, minimal loss of medullary interstitial solute occurs with water removal. Some reabsorbed urea enters the loop of Henle (see Figure 3-5, D) and thus is recycled, helping to maintain medullary hypertonicity. In the absence of ADH the collecting ducts are relatively impermeable to water and urea, resulting in water and urea loss in urine and reduction of medullary solute. Prolonged diuresis of any cause may result in the loss of medullary hypertonicity (medullary washout) with subsequent impairment of renal concentrating ability. Water is reabsorbed down its concentration gradient from the thin descending limb of the loop of Henle (see Figure 3-5, E) as a consequence of medullary hypertonicity. This segment of the nephron is impermeable to NaCl and urea; thus the osmolality of luminal fluid in the most distal portion of the loop approaches that of the interstitium. The thin ascending limb of the loop of Henle is permeable to NaCl, which diffuses down its concentration gradient into the interstitium (see Figure 3-5, F). As previously mentioned, this segment is also permeable to urea, and some interstitial urea enters the tubule lumen by diffusion down its concentration gradient. Luminal fluid entering the thick ascending limb of the loop of Henle is thus hypotonic to the interstitium.

When luminal fluid reaches the thick ascending limb of the loop of Henle, approximately 80% of the glomerular

filtrate has been reabsorbed. Therefore only 20% of the glomerular filtrate is available for reabsorption via the action of ADH.<sup>15,16</sup>

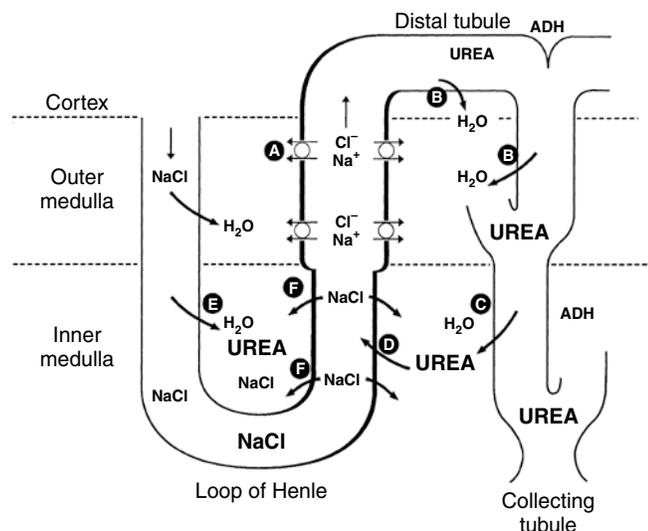

## ☞ PRIMARY POLYDIPSIA

Excessive water intake may result in water diuresis. Primary polydipsia has been described in horses residing in the southern United States during months when ambient temperature and humidity are high. Apparent psychogenic polydipsia may result from boredom, especially in stalled young horses.<sup>8</sup> Psychogenic polydipsia also has been reported anecdotally in horses with chronic liver disease and central nervous system signs that had been treated with intravenous fluids.<sup>17</sup> Primary disorders of thirst are poorly understood in horses.

## ☞ CAUSES OF POLYURIA WITH SECONDARY POLYDIPSIA

Increased urine flow may be induced by solute or water diuresis (Box 3-2). Solute diuresis results in increased urine flow because of excessive renal excretion of a nonreabsorbed solute such as glucose or sodium. During solute diuresis the urine osmolality is equal to or higher than the plasma osmolality. Primary renal insufficiency or failure (33% or fewer intact nephrons) result in solute diuresis, because each functional nephron must filter an increased amount of solute to maintain daily obligatory solute excretion. Fractional clearances of solutes such as Na, K, and Cl therefore appropriately increase. Solute diuresis caused by glucosuria occurs in hyperglycemic horses when the maximal renal reabsorptive capacity for glucose is exceeded (180 to 200 mg/dl).<sup>18</sup> Solute diuresis caused by glucosuria has been reported in horses with pituitary pars intermedia dysfunction (PPID pituitary adenoma) and in a hyperglycemic horse with bilateral granulosa cell tumors.<sup>19,20</sup> Primary diabetes mellitus, a common cause of hyperglycemia and glucosuria in other species, is uncommon in the horse, although type 2 diabetes mellitus was diagnosed in a 15-year-old Quarter Horse mare.<sup>21</sup> Primary renal tubular glucosuria caused by a defect in proximal tubular glucose reabsorption (as is seen in Basenji dogs with Fanconi-like syndrome)<sup>15</sup> has not been reported in horses. Psychogenic salt consumption also has been reported to cause solute diuresis in a horse.<sup>22</sup> Postobstructive solute diuresis is not diagnosed commonly in horses because nephrolithiasis and ureterolithiasis are uncommon; when they occur, the condition is often bilateral and associated with chronic renal failure, and treatment is usually unsuccessful.<sup>23,24</sup>

Decreased water resorption in the collecting tubules or inappropriately large voluntary water intake causes water diuresis. The osmolality of the urine during water diuresis is less than that of plasma. Water diuresis may be caused by insufficient ADH secretion, insensitivity of the receptors of the distal collecting duct and collecting tubules to the action of ADH, renal medullary solute washout, or apparent psychogenic polydipsia. Insufficient secretion of ADH (central diabetes insipidus) may be associated with PPID of horses but has never been documented<sup>25</sup> and with head trauma and potassium depletion in other species. A case of idiopathic central diabetes insipidus was reported in a Welsh pony.<sup>26</sup> Insensitivity of collecting duct receptors to ADH may occur during endotoxemia and hyperadrenocorticism (glucocorticoid excess associated with PPID). In other species potassium

PPID, pituitary pars intermedia dysfunction

\*Not reported in horses.

depletion, hypercalcemia, and the administration of certain drugs (e.g., gentamicin) have been reported to cause insensitivity of the collecting duct receptors to ADH.<sup>15</sup> Congenital diabetes insipidus also has been reported in other species.<sup>26</sup> True nephrogenic diabetes insipidus implies isolated dysfunction of response to ADH by collecting tubules that are not associated with other structural or metabolic lesions of the kidney. The occurrence of nephrogenic diabetes insipidus in two sibling Thoroughbred colts suggests that the condition might be heritable in some horses.<sup>27</sup> Renal medullary washout (loss of medullary Na, Cl, and urea) leading to water diuresis may result from chronic diuresis of any cause. Diuresis is associated with increased tubular flow rates and inability to

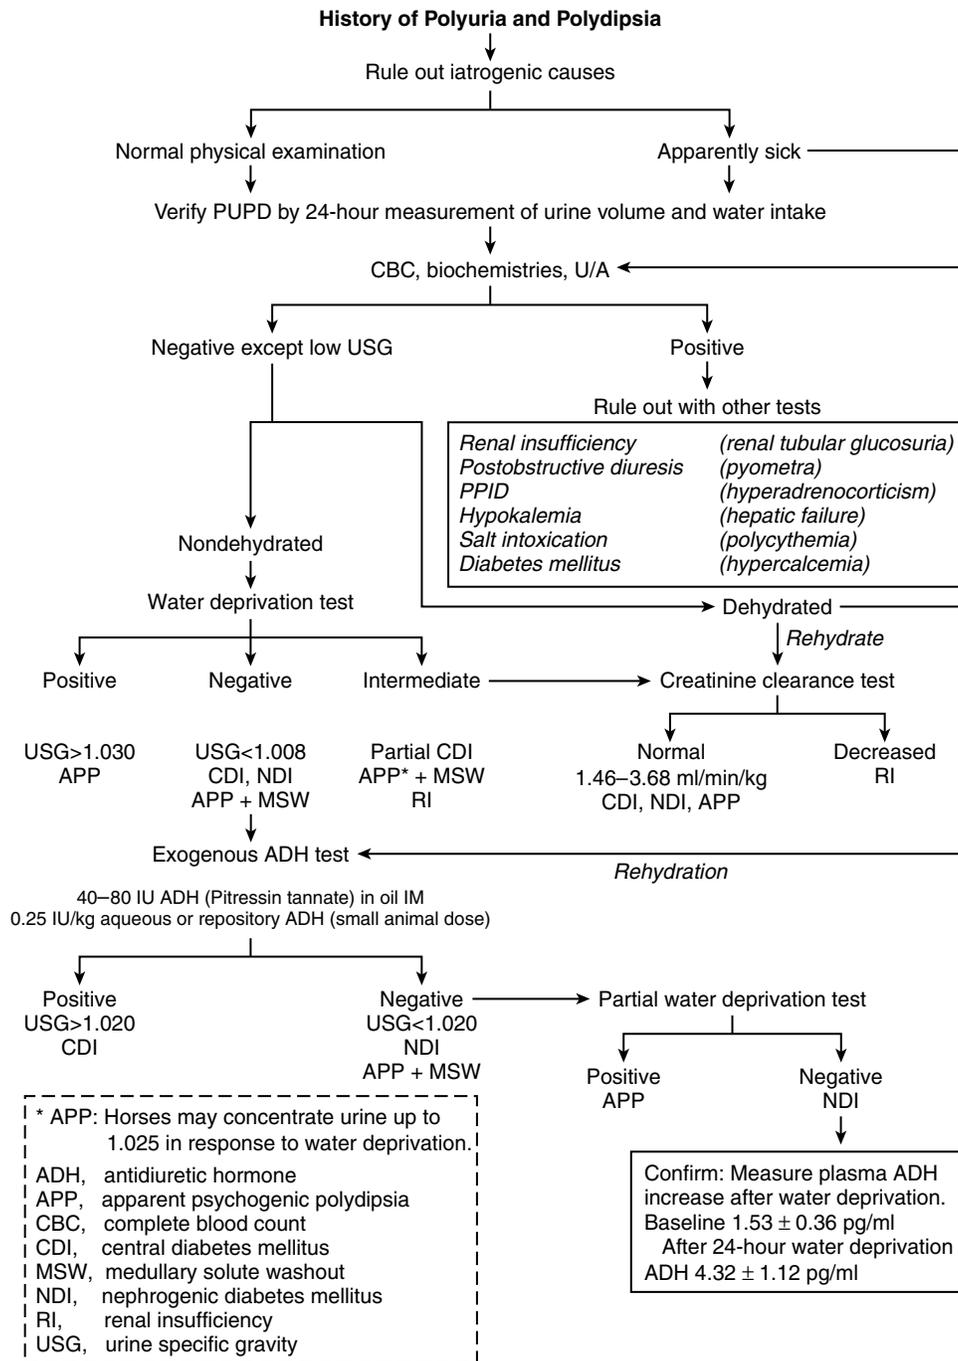

resorb sodium and urea adequately from the tubular lumen. Enhanced medullary blood flow may deplete medullary solute further. Water diuresis also has been reported in association with pyometra, hypoadrenocorticism (chronic renal sodium loss), chronic liver disease (increased aldosterone concentration promotes sodium retention, smaller daily load of urea for excretion caused by decreased conversion of ammonia to urea), primary polycythemia, hypercalcemia, and potassium depletion in other species.<sup>15</sup>

## ☞ APPROACH TO THE HORSE WITH POLYURIA AND POLYDIPSIA

Iatrogenic causes of polyuria and polydipsia (see Box 3-2) should be ruled out by careful assessment of the history and by documentation of return to normal urine volume and water intake after withdrawal of intravenous fluids, excess dietary salt, or drugs implicated in causing polyuria and polydipsia (Figure 3-6). Verification of 24-hour urine volume and water intake should be undertaken for horses suspected of having polyuria and polydipsia that do not display obvious polyuria (frequent large volume urination and wet stall) and polydipsia (water bucket always empty and overt thirst). Hemogram, serum biochemistries, and urinalysis should be assessed for all horses with polyuria and polydipsia. A hallmark finding in horses with polyuria and polydipsia is a decreased urine specific gravity (USG). Identification of other abnormalities on laboratory tests (e.g., increased blood urea nitrogen or creatinine concentrations, hyperglycemia, and hypokalemia) necessitates ruling out the presence of underlying diseases (e.g., renal insufficiency and PPID) using specialized laboratory tests.

The hydration status of horses then should be assessed carefully. Horses that are dehydrated should be rehydrated judiciously with intravenous fluids, with care taken not to overhydrate horses with renal insufficiency. After rehydration, when possible, creatinine clearance should be determined by using a urine collection apparatus to allow 24-hour volumetric urine collection. A creatinine clearance value below the reference range (1.46 to 3.68 ml/min/kg)<sup>28</sup> suggests that renal insufficiency with decreased glomerular filtration rate and solute diuresis are likely present. A creatinine clearance within the reference range indicates that central diabetes insipidus (CDI), nephrogenic diabetes insipidus (NDI), or apparent psychogenic polydipsia (APP) is present. To distinguish among these differential diagnoses, an exogenous ADH challenge test should be performed (see the subsequent discussion).

Horses with polyuria and polydipsia that are well hydrated and healthy according to physical examination and results of hemogram and serum biochemistry determinations should be subjected to a water deprivation test to assess renal ability to conserve water.<sup>2,29,30</sup> Water deprivation testing is contraindicated in a dehydrated horse with a low USG. Such horses have already undergone an endogenous water deprivation test (clinical dehydration is present) and have responded with an inappropriately low USG. The following guidelines for interpretation of water deprivation test results are based on practical experience and the limited data available. A positive response to water deprivation (USG >1.030) indicates that the horse has APP, whereas a negative response (USG <1.008) after 24 hours of water deprivation or greater than 5% weight loss<sup>31</sup> is consistent with a diagnosis of CDI, true NDI, insensitivity

the diagnosis of CDI. A negative response (USG > 1.020) implies that NDI or APP plus MSW is present.<sup>31</sup>

MSW may result in a decreased USG despite the presence of adequate ADH. A partial water deprivation test should result in an increase in USG in horses with APP plus MSW but should have no effect on horses with true NDI or insensitivity of collecting duct receptors to ADH. The horse is allowed to consume its normal diet and water ad libitum. Voluntary water consumption is monitored closely for 3 to 4 days to establish a baseline. Water available to the horse then is decreased by 5% to 10% of the baseline voluntary intake. Water should be offered in aliquots several times a day to prevent the horse from consuming most of the water in a short time. Water intake should never be restricted below maintenance requirements (about 40 ml/kg/day). During water restriction the horse is allowed to eat its regular diet. The horse should be weighed daily if possible and observed carefully for signs of dehydration (prolonged capillary refill time, increasing heart rate, prolonged skin tenting, and hypernatremia). Moderate water restriction in the face of continued intake of dietary solutes facilitates re-establishment of the corticomedullary osmotic gradient.<sup>15</sup> Results of partial water deprivation tests in horses have been reported infrequently.

The diagnosis of true NDI or insensitivity of collecting duct receptors to ADH may be confirmed by measuring plasma ADH concentrations before and after partial water deprivation. ADH concentrations have been reported to increase from baseline values of  $1.53 \pm 0.36$  pg/ml to  $4.32 \pm 1.12$  pg/ml after 24 hours of water deprivation in ponies.<sup>13</sup>

Because CDI, NDI, and APP are uncommon in horses, the presenting complaint of polyuria and polydipsia usually signifies other underlying disease. The most likely underlying disease is renal insufficiency. PPID should be considered in horses with compatible clinical signs (hirsutism, weight loss, and laminitis) and supporting laboratory data (hyperglycemia and failure of suppression of cortisol production by dexamethasone).<sup>33</sup> Medullary washout may be a more common complication of primary diseases and their therapy in horses than has been reported to date. Potential causes of diuresis compatible with the case history and clinical signs should be investigated, and a partial water deprivation test should be considered when horses exhibit polyuria and polydipsia.

## EDEMA

*Kenneth W. Hinchcliff*

*Edema* is defined as the excessive and abnormal accumulation of fluid in the interstitium. Interstitial fluid accumulates because of imbalances in the rates with which fluid enters and exits the interstitium. Factors that increase the rate of fluid flux from the capillary or impair lymph drainage sufficiently to overwhelm normal compensatory mechanisms result in accumulation of fluid and the development of edema.

## PHYSIOLOGY

The volume of interstitial fluid and lymph fluid in the normal horse is 8% to 10% of body mass,<sup>1</sup> or 36 to 45 L in a 450-kg horse. Interstitial fluid consists of water, protein, and

electrolytes. Compared with plasma, interstitial fluid has a slightly lower concentration of cationic electrolytes, a slightly higher concentration of chloride, and a much lower concentration of protein (1.2 versus 0.2 mOsm/L of water).<sup>2</sup> The amount and function of plasma proteins within the interstitial space are not inconsequential. A constant circulation of plasma proteins occurs between the vascular and interstitial spaces, with about half of the protein circulating every 24 hours in human beings. More than half of the plasma protein content of the body is contained within the interstitial space at any one time. Plasma proteins within the interstitial space are important in the transport of water-insoluble substances from the vascular space and in resistance to infection.<sup>3</sup>

Interstitial fluid is contained within the interstitium, the intercellular connective tissues that lie between the cellular elements of the vascular and cellular compartments of the body. The extracellular tissue of the interstitium, except in the case of bone, consists of a three-dimensional collagen fiber network embedded in a proteoglycan gel matrix.<sup>4</sup> Interstitial water exists as free water and as water within the proteoglycan gel. Normally, only a small proportion of interstitial fluid exists as free water, most of the water being contained in the interstitial gel. However, in edematous states, the proportion of fluid as free water within the interstitium increases.<sup>2</sup>

The source of interstitial fluid is the intravascular space. The volume of interstitial fluid is determined by the functional relationships of three major anatomic structures: the capillary, the interstitial space, and the lymphatics.<sup>5</sup> Functionally, the volume of fluid that accumulates in the interstitium is determined by the rate of ingress of fluid from the vascular space, the compliance of the interstitium, and the rate at which fluid is evacuated from the interstitium. The net rate of ingress of fluid from capillaries into the interstitium is determined by a number of factors acting across the capillary membrane, the effects of which are related by Starling's equation:

$$J = Kf[P_c - P_t] - \sigma(\pi_p - \pi_t)$$

in which  $J$  equals the volume flow across the capillary wall;  $Kf$  equals the filtration coefficient of the capillary wall (volume flow per unit time per 100 g of tissue per unit pressure);  $P_c$  equals capillary hydrostatic pressure;  $P_t$  equals interstitial fluid hydrostatic pressure;  $\sigma$  equals the osmotic reflection coefficient;  $\pi_p$  equals the colloid osmotic (oncotic) pressure of the plasma; and  $\pi_t$  equals the colloid osmotic (oncotic) pressure of the interstitial fluid.<sup>6</sup> Although all these factors act in concert to determine the rate of net fluid efflux from the capillary, considering them individually is conceptually easier.

## FILTRATION ( $K_f$ ) AND REFLECTION ( $\sigma$ ) COEFFICIENTS

Together the filtration and reflection coefficients describe the properties of the capillary membrane that determine the ease with which water, protein, and other plasma constituents move from the vascular space to the interstitium. The filtration coefficient, which is the product of the hydraulic permeability and surface area of the capillary, is a measure of the ease with which water crosses the capillary membrane. The reflection coefficient is an indicator of the degree to which the capillary membrane resists the passage of a substance, such as protein. A reflection coefficient can be defined for each substance; a reflection coefficient of 0 indicates that the molecule crosses the membrane as readily as does water, whereas a value of

1 indicates that the membrane is impermeable to the substance. The reflection coefficient for a substance may vary with the anatomic site of the capillary<sup>7,8</sup>: capillaries in the liver are permeable to albumin, whereas capillaries in muscle are much less permeable and cerebral capillaries are among the least permeable to albumin.

The movement of fluid and protein across the vascular membrane is assumed to be passive, with plasma water and protein exiting the vascular space through pores in the capillary membrane. However, the rate with which various plasma constituents cross the capillary membrane varies considerably depending on the constituent and the tissue. For example, muscle capillary pores are permeable to water molecules (reflection coefficient of 0) but much less permeable to albumin (reflection coefficient of approximately 0.9).<sup>2</sup> Movement of solutes across the endothelium is not understood fully, being complex, but is affected by the concentration of the solutes on either side of the membrane, solute charge and interaction with other solutes, and capillary pore configuration.<sup>9</sup>

Together the filtration and reflection coefficients partially determine the rate of fluid flux across the capillary wall and the composition of the fluid. For a given hydrostatic and oncotic pressure difference, tissues with higher filtration coefficients (whether because of a larger capillary surface area or more porous capillaries) will have a greater fluid flux. Conversely, under the same circumstance, increases in the reflection coefficient of the capillary wall reduce fluid flux. The differential permeability of the capillary membrane to water and protein has important consequences in the maintenance of the oncotic pressure difference between plasma and interstitial fluid.

Aquaporins are a diverse family of membrane proteins that are expressed predominantly in tissues in which edema and fluid imbalances are of major concern.<sup>10,11</sup> While water movement across cell membranes is driven by osmotic and hydrostatic forces, the speed of this process can be influenced by the presence of specific aquaporin channels. These channels are primarily water channels, although some are also permeable to small solutes. The pharmacologic modulation of the expression and activity of various aquaporins potentially could provide novel treatments for a variety of disorders, including brain edema.

## HYDROSTATIC AND COLLOID OSMOTIC PRESSURES

Transcapillary fluid flow results from an imbalance between the hydraulic forces favoring movement of water from the capillary into the interstitium and the forces favoring movement of water in the reverse direction. The forces contributing to fluid movement out of the capillary are the intracapillary hydrostatic pressure and the interstitial colloid osmotic pressure, whereas those forces favoring movement of fluid from the interstitium to the capillary are the interstitial hydrostatic pressure (if it is positive) and the plasma colloid osmotic pressure.<sup>12</sup>

The principal force favoring fluid efflux from the capillary is the hydrostatic pressure within the capillary. Capillary hydrostatic pressure varies among different tissues and decreases along the length of the capillary. Hydrostatic pressure within a capillary is determined by the arterial and venous pressures and by the precapillary and postcapillary resistances.<sup>13</sup> Specifically, capillary pressure is determined by the ratio of the

postcapillary resistance ( $R_a$ ) to the precapillary resistance ( $R_v$ ), and the arterial ( $P_a$ ) and venous ( $P_v$ ) pressures:

Thus a small increase in venous pressure has a much greater effect on capillary pressure than does an increase in arterial pressure. For this reason the hydrostatic pressure is greater in capillaries below the heart (e.g., legs) than in those above the heart (e.g., head).

The colloid osmotic pressure of the plasma is the principal force minimizing fluid efflux from the capillary. The colloid osmotic pressure is generated because the plasma and interstitial fluid are separated by a semipermeable membrane—the endothelium—and vary slightly, but significantly, in composition. As noted previously, the interstitial fluid has a lower protein concentration than does plasma but has an essentially identical electrolyte concentration. The difference in protein concentration across the semipermeable endothelium generates an osmotic force that tends to draw water from the interstitium into the plasma.

In addition to the capillary hydrostatic pressure, the colloid osmotic pressure and negative hydrostatic pressure of the interstitial fluid favor fluid movement out of the capillary. Fluid flux across the capillary results from the summation of these forces (Table 3-6). These figures should be recognized as representing the forces at the midpoint of an idealized capillary; the forces are dynamic, changing between tissues and even along the length of the capillary. In fact, a large net flux of fluid from the capillary occurs at its arteriolar end, where capillary hydrostatic forces are greatest and plasma oncotic forces are least, and a net flux of fluid into the capillary toward its venous end, where capillary hydrostatic forces are least and plasma oncotic pressure is greatest.

The small imbalance in filtration forces results in a net efflux of fluid from the capillary into the interstitial tissue. This fluid does not accumulate in the interstitium; it is removed by the lymphatics.

## LYMPHATICS

The lymphatics drain the interstitium of fluid and substances, notably proteins, that are not absorbed by the capillaries. The lymphatics represent the only means by which

TABLE 3-6

### Mean Forces (mm Hg) Influencing Fluid Movement into or out of the Capillary

Type of Pressure	Mean Force
<b>HYDROSTATIC PRESSURES</b>	
Mean capillary pressure	17.0
Interstitial pressure	-5.3
Total hydrostatic pressure favoring filtration	22.3
<b>COLLOID ONCOTIC PRESSURES</b>

interstitial protein is returned to the circulation. Interstitial fluid (and, with it, protein) moves down a pressure gradient into lymphatic capillaries through clefts between the lymphatic endothelial cells. Lymphatic endothelial cells are supported, and the lymphatic capillaries maintained patent, by anchoring filaments that attach the endothelial cells to surrounding connective tissue. Lymphatic fluid progresses centripetally through progressively larger vessels before draining into the great veins of the chest. Lymphatic valves prevent the retrograde flow of fluid from the lymphatics. Lymph is propelled by factors extrinsic to the lymphatics, including muscle activity, active and passive motion, posture, respiration, and blood vessel pulsation. Exercise causes a significant increase in lymph flow, at least in part because of the increase in tissue pressure that is associated with muscle contraction, although passive motion also increases lymph flow. Standing results in significant diminution or cessation of lymph flow from, and the prompt accumulation of interstitial fluid in, the lower extremities of human beings. In addition to the extrinsic factors affecting lymph flow, coordinated contractions of lymphatic vessels contribute substantially to the centripetal flow of lymph.<sup>4</sup>

## MECHANISMS OF EDEMA FORMATION

Simply stated, accumulation of excessive fluid in the interstitial spaces—edema—results from an imbalance of the rates of fluid filtration from the capillaries and drainage by the lymphatics. Perturbations of one or more of the forces that affect filtration across the capillary alter the rate at which fluid enters the interstitium. Increases in capillary hydrostatic pressure, decreases in plasma oncotic pressure, and increases in interstitial oncotic pressure all favor increased fluid filtration. Conversely, increased interstitial hydrostatic pressure and decreased interstitial oncotic pressure act to inhibit fluid filtration.

Box 3-3 lists the fundamental mechanisms by which excessive interstitial fluid accumulates. Increases in capillary hydrostatic pressure, which occur with venous obstruction or arteriolar dilation, such as that associated with inflammation, increase net fluid efflux. The edema that occurs with congestive heart failure likely has an increase in capillary hydrostatic pressure as one of its causes, although the mechanism is complex.<sup>4</sup> Posture also affects capillary hydrostatic pressure; capillaries below the level of the heart have higher hydrostatic pressures than do capillaries above the level of the heart.

A decrease in the oncotic gradient across the capillary endothelium, which occurs with a decreased plasma oncotic pressure or an increased interstitial oncotic pressure, results in an increase in efflux of fluid from the capillary. A decrease in plasma oncotic pressure decreases the oncotic gradient that favors movement of fluid into the capillary. Consequently, the capillary hydrostatic pressure, which favors filtration, predominates and fluid accumulates in the interstitium. Plasma oncotic pressure decreases when plasma protein concentration declines. Albumin is the plasma protein that exerts the preponderance of the oncotic force<sup>8</sup>; therefore clinically, edema often is associated with hypoalbuminemia. An increase in the permeability of the capillary membrane greatly increases fluid and protein transport into the interstitium and decreases the ability of the membrane to maintain a difference in oncotic pressure between the plasma and the interstitium.<sup>5</sup> Capillary

### BOX 3-3

#### PATHOGENESIS OF EDEMA

##### Increased Capillary Hydrostatic Pressure

- Venous obstruction
  - Thrombophlebitis
  - Compression (mass, tourniquet)
- Venous congestion
  - Posture (dependent limbs)
  - Congestive heart failure
- Arteriolar dilation
  - Inflammation
  - Increased body water

##### Decreased Plasma Oncotic Pressure

- Panhypoproteinemia
- Hypoalbuminemia

##### Increased Interstitial Oncotic Pressure

- Increased capillary permeability

##### Decreased Lymph Flow

- Lymphatic obstruction

permeability increases when the endothelium is damaged, such as by vasculitis or inflammatory reactions.

Lymphatic obstruction prevents the removal of interstitial fluid and protein. Filtration of fluid and passage of small amounts of protein into the interstitial space continues in the presence of lymphatic obstruction. The interstitial fluid is reabsorbed by the capillaries; however, the protein is not. Consequently, the protein content of the interstitial fluid gradually increases, with a resultant increase in interstitial oncotic pressure that favors filtration of fluid. The increased interstitial oncotic pressure causes fluid to accumulate in the interstitium, thus exacerbating the edema.<sup>2</sup>

Alterations in the magnitude of one or more of Starling's forces may be offset by compensatory changes in lymph flow and other of Starling's forces. In concert Starling's forces and lymph flow act as "edema safety factors" to prevent the excess accumulation of interstitial fluid and development of frank edema. For example, lymph flow increases with the increased filtration associated with increased capillary hydrostatic pressure. Thus a larger volume of fluid enters and is removed from the interstitial space. The interstitial protein concentration decreases as increased fluid flow washes protein out of the interstitial space. Reduced interstitial space protein concentration increases the oncotic gradient, inhibiting fluid efflux from the capillary, and decreases the rate of movement of fluid from the capillary to the interstitial space.<sup>6</sup>

## DIAGNOSTIC APPROACH TO THE PATIENT WITH EDEMA

Edema is not in itself a disease; rather, it is a sign of a disease process. Therefore the diagnostic approach to the patient with edema is based on an understanding of the pathogenesis of edema and knowledge of the diseases likely to be involved (Box 3-4). The diagnostic approach to an animal with edema should not be any different from that for any other sign of

disease. A clinical examination, including history and physical examination, permits the development of a list of potential diagnoses and dictates the appropriate subsequent steps in confirming the diagnosis. The reader is referred to those sections of the text that deal with specific diseases for a description of the appropriate diagnostic aids.

When taking the history of a horse that has edema, the veterinarian should focus on acquiring facts that have the greatest diagnostic use in differentiating among those diseases that have edema as a sign. The veterinarian should consider the following aspects:

- Housing, season, and geographic region
- Vaccine and parasiticide administration
- Exposure to other horses and diseases present within the herd
- The duration of the edema, its distribution, and the presence of any other clinical signs

The veterinarian should investigate the remainder of the history depending on the responses to initial questions.

The physical examination should begin with a visual evaluation of the attitude and physical condition of the horse. The temperature, pulse, and respiration should be recorded. Although the physical examination should be complete, particular attention should be paid to those body systems that the preliminary examination indicates may be involved in the disease process. The physical examination reveals the distribution and severity of edema. Edema that is localized to one extremity or is not bilaterally symmetric is more likely to be caused by local factors (e.g., lymphangitis, venous obstruction) than by systemic disease. Conversely, edema that involves several areas of the body and has a symmetric distribution is likely to be associated with systemic disease (e.g., the ventral edema of congestive heart failure).

After the initial clinical examination, the clinician will have developed an ordered list of potential diagnoses. Confirmation or elimination of these diagnoses depends on subsequent diagnostic procedures, including the response to therapy. Sections of this text deal with the specific disease processes for appropriate diagnostic procedures.

## SPINAL ATAXIA

Kathy K. Seino

The complaint of incoordination or ataxia is a commonly encountered clinical problem in the horse. Horses might exhibit obvious gait deficits such as weaving of the feet at the walk ("walking like a drunken sailor"), a broad-based stance when stopped from a trot, truncal sway, crossing over when turning, or pivoting on the inside limb when spun. More challenging may be the horse that exhibits poor performance in which the degree of ataxia may be a subtle manifestation appreciated only under saddle by the rider when a higher degree of coordination is required, such as in dressage or jumping.<sup>1</sup> Common complaints may be that the horse "is not bending as well," "refusing fences," "stumbling," or "switching leads." Spinal ataxia is the most commonly reported manifestation of neurologic disease in the horse, and there are numerous causes (Table 3-7).<sup>2,3</sup>

Spinal ataxia or sensory ataxia is distinguished from vestibular and cerebellar ataxia in that it occurs secondary to

Coggins test (agar gel immunodiffusion), ELISA

Aortic-iliac thrombosis

Rectal palpation

Cauda equina neuritis

Rule out other causes

Polyneuritis equi

Toxic agents

Stinging nettles

Ivermectin, moxidectin

Ionophores

Moldy corn

Locoism

Sorghum, Rye grass, Dallis grass

Heavy metals (lead, arsenic)

Crotalaria

Fluphenazine

Propylene glycol

IFAT, Indirect fluorescent antibody test; PCR, polymerase chain reaction; IgM, immunoglobulin M; ELISA, enzyme-linked immunosorbent assay; PRNT, plaque reduction neutralization test; MRI, magnetic resonance imaging; CT, computed tomography; CSF, cerebrospinal fluid; FA, fluorescent antibody; CBC, complete blood count.

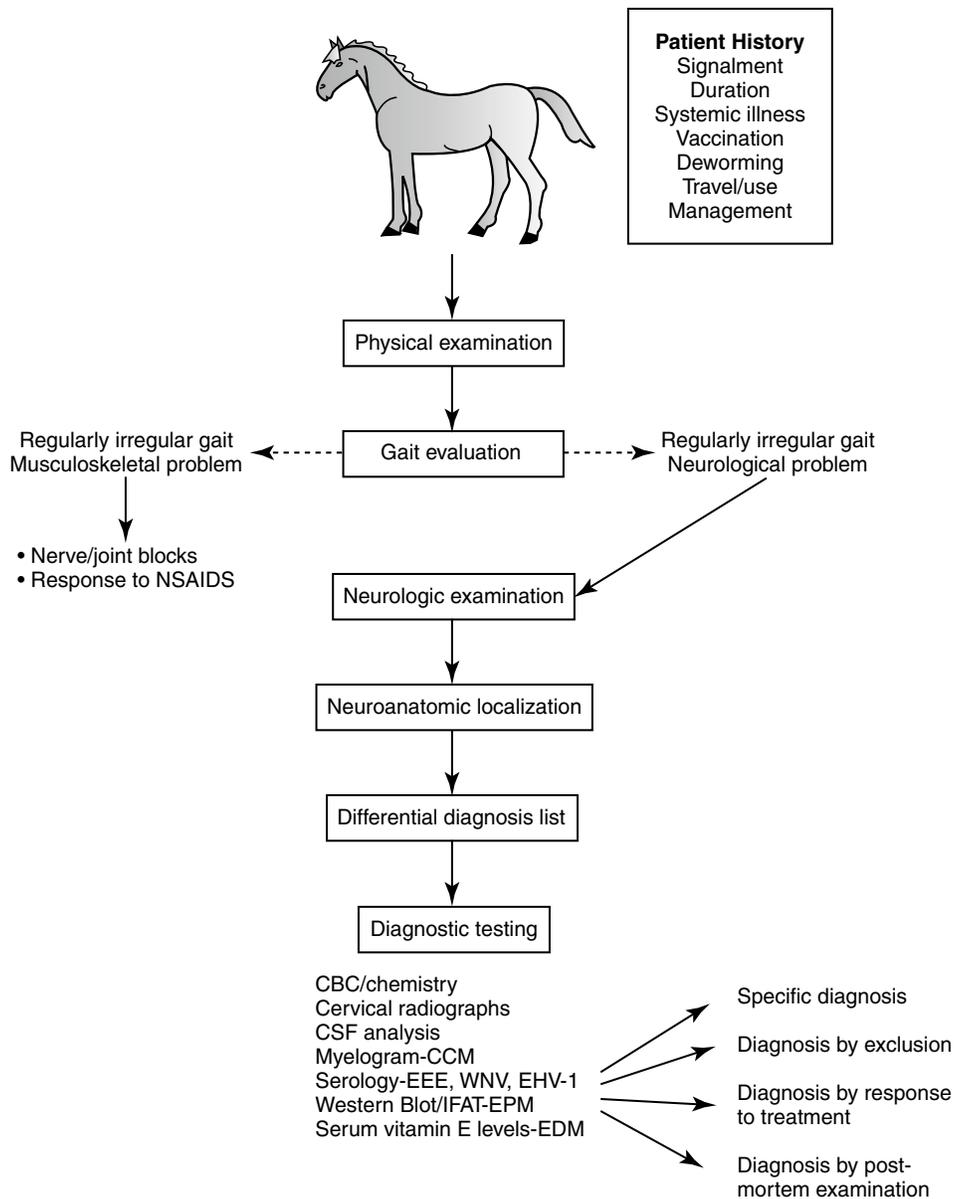

FIGURE 3-7 Diagnostic approach for a horse presenting with signs of spinal ataxia.

foramen magnum, mentation is normal. Spinal ataxia in the horse often manifests with a concomitant weakness or paresis as a result of simultaneous damage and involvement of the descending motor pathways.<sup>4,5</sup>

Accurate diagnosis of the cause of spinal ataxia in the horse requires a comprehensive evaluation of available historical information, a thorough physical examination, and a neurologic examination to localize the neuroanatomic lesion (Figure 3-7). These initial steps are critical in the development of a differential diagnosis list and the selection of appropriate ancillary tests to make a final diagnosis.

## 🌀 HISTORY AND SIGNALMENT

The signalment may offer important information for the clinician because breed, age, and gender predilections have been associated with certain causes of spinal ataxia in horses. For

instance, occipitoatlantoaxial malformations (OAAMs) occur most frequently in Arabian foals, in which it is an inherited disorder.<sup>6,7</sup> Neuroaxonal dystrophy has been reported in Morgan Horses.<sup>8</sup> In retrospective studies, although cervical compressive myelopathy (CCM) has been reported in most light and draft breeds, Thoroughbreds were more likely to develop CCM, with a predisposition for males more than females (3:1).<sup>2</sup> Warmblood breeds and Tennessee Walking Horses also seem to have a predisposition for development of CCM.<sup>5,9</sup> A breed predilection for equine degenerative myeloencephalopathy (EDM) has been associated with Appaloosas, Quarter Horses, and Peruvian Pasos.<sup>10,11</sup>

Consideration of age in the manifestation of spinal ataxia may also be beneficial. Congenital abnormalities are likely to manifest at an early age. Foals with occipitoatlantoaxial malformations typically develop neurologic deficits between birth and 6 months of age.<sup>7,12</sup>

Spinal ataxia caused by EDM typically manifests before the horse is 2 to 3 years of age, with most affected horses exhibiting symptoms before 6 months of age.<sup>13</sup> However, the condition can be recognized in horses at any age. During halter breaking and handling, weanlings are at more risk for cranial and cervical trauma.<sup>14</sup> Young horses of training age presenting for ataxia without cranial nerve signs should be assessed for cervical compressive myelopathy. In horses older than 10 years with spinal ataxia and cervical neck pain, CCM should also be considered as these horses may have developed osteoarthritis of the caudal cervical vertebrae (C6 to T1) sufficient to cause spinal cord compression.<sup>2</sup> Horses older than 5 years of age are more likely to have lumbar fractures and sacroiliac subluxations and fractures.<sup>15</sup>

The onset of clinical signs (acute or chronic) and progression is an important part of the evaluation of the horse with spinal ataxia. Acute onset of clinical signs may suggest a traumatic event as the cause. However, the clinician must consider whether an underlying proprioceptive deficit may have contributed to the traumatic event (e.g., falling, stumbling) or whether trauma may have worsened a preexisting condition (e.g., CCM). Horses affected with CCM are reported to have a waxing and waning of clinical signs.<sup>2</sup> Equine protozoal myeloencephalitis (EPM) may present as a slow and insidious course of disease or in some horses as an acute manifestation of neurologic disease.<sup>16</sup> Infectious causes of spinal ataxia such as equine herpesvirus-1 (EHV-1) myeloencephalopathy (EHM) and West Nile virus (WNV) encephalitis (WNE) typically manifest in a rapid progression of clinical signs over a few days that then stabilize.<sup>17,18</sup> Eastern equine encephalitis (EEE) is also rapidly progressive, and the disease is often fatal. In most affected horses cerebral signs predominate, especially as the disease progresses.<sup>19</sup> Rabies, which should be considered in any horse with acute neurologic disease, can initially present as ataxia. The disease is generally rapidly progressive and fatal.

By skillfully questioning the client, the clinician can elicit other important historical information, including previous systemic illnesses, vaccinations, deworming protocol, medications, travel history, and general management practices (e.g., feed, environment). Any history of systemic illnesses should be noted in a horse that exhibits signs of spinal ataxia. In foals neonatal septicemia could result in the hematogenous spread of bacteria (*E.coli*, *Salmonella* spp., *Streptococcus* spp., and *Actinobacillus* spp.) and subsequent vertebral osteomyelitis, with acute onset of neurologic signs caused by spinal cord compression even after the foal recovers from septicemia. A recent history of tail docking or injections may be linked with an ascending infection and subsequent hindlimb ataxia. Similarly, vertebral osteomyelitis may be iatrogenic from contaminated vaccines or drugs injected near the spinal column.<sup>20</sup> Various anthelmintics and tranquilizers have been reported to cause central nervous system (CNS) disease, and the history of recent medications should be noted (see Table 3-7).<sup>5</sup> Conversely, verminous meningoencephalomyelitis should not be ruled out as a differential in a horse with spinal ataxia that has a history of deworming with anthelmintics.<sup>20</sup> Type of feed and forage should also be evaluated because ataxia has been linked with grazing various types of grasses (see Table 3-7).<sup>21</sup> EDM has been linked in some cases to diets with a lack of green forage and commercially heated pellets.

The vaccination status of the horse for the arboviruses (EEE and Western equine encephalitis [WEE] viruses, WNV) as well

as for rabies and tetanus should be determined because these pathogens may cause neurologic disease. Specific information on the type of vaccine and when the vaccine was given is necessary to determine whether the horse was adequately protected. In particular, for the viral encephalomyelitides in endemic areas, the mosquito season may be prolonged; therefore it is recommended that horses receive multiple boosters when using a killed virus vaccine product.<sup>22</sup> Recent vaccination of a naïve horse should be noted because onset of protective immunity may not have been induced before the horse was infected, and recent vaccination history may also have a bearing on the interpretation of serologic tests.

Travel history may provide useful information to the clinician. Certain geographic distributions of several infectious CNS pathogens have been reported. EEE is endemic in the southeastern states, although it has been detected in all states east of the Mississippi River and a number of western states.<sup>20</sup> In areas of the geographic habitat of the definitive host *Didelphis virginiana* (opossum), approximately 50% of horses are exposed to *Sarcocystis neurona*, the causative agent for EPM, whereas in central Wyoming and Montana, the exposure rate in horses has been 6.5% and 0% respectively. A history of recent travel from a showing or racing venue, hospitalization in a veterinary facility, boarding at a riding school, and subsequent stress has been associated with horses that have developed EHM.<sup>18,23</sup>

Finally, whether the horse is seronegative for equine infectious anemia (EIA) virus (via Coggins test or one of the three other U.S. Department of Agriculture–approved ELISA tests) should be determined. Although rare, ataxia has been reported as the predominant clinical sign in horses with EIA.<sup>24</sup>

## ☞ PHYSICAL EXAMINATION

A thorough physical examination is an integral part of the evaluation of a horse with spinal ataxia for many reasons. Evidence of underlying systemic infection may help to narrow down the cause of neurologic disease. Infectious diseases such as arboviral encephalomyelitides and EHV-1 may cause generalized clinical signs of fever, depression, and inappetence that may precede neurologic signs. In light of the highly contagious nature of the recent outbreaks of the neurotropic equine herpesvirus-1 myeloencephalopathy, it is recommended that a horse with acute neurologic signs should be isolated and tested to rule out infection with EHV-1. High-level biosecurity measures should be instituted when the clinician is faced with multiple febrile horses, with one or more showing concomitant neurologic disease, because these horses may be viremic and shedding high levels of EHV-1.<sup>18,25</sup>

Underlying metabolic disturbances (i.e., electrolyte abnormalities, hypoglycemia in foals, hypocalcemia), circulatory shock, hyperammonia, and hepatoencephalopathy may manifest with neurologic signs and should be ruled out. Some horses may manifest severe abdominal pain with stumbling and trembling rather than the typical signs of colic. In horses with hindlimb gait deficits, a rectal examination with evaluation of the internal iliac artery pulses should be performed to rule out an aortic-iliac thrombosis. Palpation of large muscle masses for pain and firmness and palpation of the joints for distention should be done to help eliminate musculoskeletal problems. Assessment of digital pulses to rule out the possibility of laminitis as a non-neurologic cause of gait abnormality should be performed.

## ☞ NEUROLOGIC EXAMINATION AND NEUROANATOMIC LOCALIZATION

Neuroanatomic localization of the lesion based on the neurological examination is critical in the formation of the differential list for a horse with spinal ataxia. The neurologic examination should confirm that the horse is exhibiting neurologic deficits and the absence of musculoskeletal disease. This differentiation may be difficult, but it is important to establish because a normal response during a neurologic examination requires a sound musculoskeletal system. A horse with lameness resulting from a musculoskeletal problem will have a gait that is consistent or regularly irregular, whereas a gait in a neurologic horse is irregularly irregular and varies from step to step.<sup>5</sup> A horse with a neurologic gait deficit will have an abnormality that is apparent in all phases of the examination. Further assessment with nerve blocks, joint anesthesia, or response to NSAIDs may be beneficial in differentiating between musculoskeletal or neurologic disease.<sup>5</sup>

Once the presence of neurologic abnormalities has been established, it should then be determined whether the signs are central or peripheral; are from a single lesion, multifocal sites, or diffuse inflammation; and are symmetric or asymmetric because answers to these questions narrow down the differential diagnoses. EPM, for instance, is the most common cause of multifocal and diffuse lesions and should be considered in a horse with spinal ataxia and cranial nerve deficits as presenting symptoms. Other differentials include verminous meningoencephalomyelitis, WNE, EHM, and polyneuritis equi. Focal single lesions are likely to be caused by compressive lesions (CCM, intervertebral disc protrusion, fractures). Causes for spinal ataxia that manifest most often as symmetric lesions include CCM, EDM, cauda equina syndrome, and neuroaxonal dystrophy. A common presentation of horses affected with EPM is asymmetric muscle atrophy of the gluteal or quadriceps muscles and other muscles (e.g., infraspinatus, triceps) being reported.<sup>20</sup> Other conditions with asymmetric manifestation include verminous meningoencephalomyelitis and neoplasia.

A comprehensive review of neurologic examination of the horse and the means for neuroanatomic localization is provided elsewhere in this text. Briefly, for horses with ataxia, normal mentation, and no cranial deficits, the lesions are expected to be caudal to the foramen magnum. Cervical lesions (spinal cord C1-C6) result in proprioceptive deficits, weakness, and ataxia of all four limbs, with deficits typically one grade worse in the rear limbs than the front limbs. Lesions in the brachial intumescence (C7-T2) will result in worse deficits in the front limbs than the rear limbs. Lesions in the thoracolumbar region (T3-L3) will result in normal front limbs but deficits in the hindlimbs. Horses will manifest urinary incontinence, difficulty defecating, abnormal tail tone, and perineal hypalgesia with lesions in the sacral region (S3-S5). Poor tail tone with normal front and rear limbs indicates that the lesion is in the coccygeal region.<sup>5</sup> Certain conditions have been associated with a predilection for affecting specific regions. For instance, CCM can result from compression anywhere from C1 through C7, with most lesions occurring at C3-C4 in young horses and at C5-C6 or C6-C7 in older horses.<sup>21</sup> In horses with spinal ataxia, urinary incontinence, and difficulty defecating, EHM should be considered as a differential. In EDM neuronal fiber degeneration often occurs most prominently in the

midthoracic region, with horses manifesting more severe deficits in the rear limbs than the forelimbs.<sup>26</sup> Horses affected with cauda equina neuritis may manifest only anal and tail tone hyperalgesia or deficits with no gait abnormalities, and horses with true polyneuritis equi will often manifest cranial nerve abnormalities, head tilt, and gait abnormalities (ataxia and weakness) as well as sacral signs.<sup>27</sup>

## ☞ DIAGNOSTIC TESTS

A list of potential differential diagnoses for spinal ataxia is made by synthesis of the history, physical examination, and neuroanatomic localization of the lesion or lesions. The causes of spinal ataxia in the horse are listed in Table 3-7. CCM is the most common cause of spinal ataxia in the horse. Complete evaluation of a horse with spinal ataxia often includes a complete blood count, serum biochemistry profile, radiographs of the cervical spine, and cerebrospinal fluid (CSF) evaluation. Clinical pathologic findings may help identify an inflammatory leukogram (elevated leukocyte count with elevated fibrinogen) suggestive of an underlying systemic infection or abscess, leukopenia (which may be present with the viral CNS pathogens), underlying electrolyte abnormalities, and metabolic derangements. CSF findings may be surprisingly normal (even with trauma or spinal abscesses), or there may be evidence consistent with trauma and hemorrhage (xanthochromia and erythroid pleocytosis).<sup>21</sup> There also might be evidence of inflammation or infection. In horses with viral and other encephalitis, abnormal CSF findings may include elevated total protein levels with a moderate mononuclear pleocytosis, and, in the case of EHV-1, xanthochromia may be present. In acute infection EEE is unique in that it typically causes a marked neutrophilic pleocytosis.<sup>20</sup> Further selection of specific diagnostic tests depends on differential diagnoses determined during the evaluation (see Table 3-7) and are described in detail in the succeeding chapters of this book.

With some conditions a final diagnosis can be made only after excluding other differentials. For instance, antemortem diagnosis of EDM in horses is difficult. Low serum vitamin E levels are only supportive of EDM and are not often found in young horses exhibiting clinical signs of progressive spinal ataxia.<sup>13</sup> Because of the high prevalence of horses with antibody to *S. neurona* and limitations of the antemortem diagnostic tests for EPM, a response to antiprotozoal therapy is considered by some the diagnostic test of choice for EPM after exclusion of other differential diagnoses.<sup>20</sup> Diagnosis of verminous meningoencephalitis is often based on post-mortem findings, but this disorder should be considered as a differential diagnosis in a horse with cervical signs that has negative cervical radiographs and myelogram results, negative EPM test results, and negative response to antiprotozoal therapy.<sup>20</sup>

## SYNCOPE AND WEAKNESS

Mark V. Crisman

Syncope is a clinical syndrome consisting of a generalized weakness, sudden collapse, and a transient cessation of consciousness. Syncopal episodes are uncommon in horses, and

generally few or no premonitory warning or presyncopal (faintness) signs are evident to the rider or handler. The subsequent loss of consciousness and collapse may be potentially harmful or dangerous to the horse and the rider. Despite the infrequent reports of true syncopal episodes in horses, the clinical signs are sufficiently dramatic to cause great concern on the part of the owner. Syncope in horses has been virtually unstudied. Consequently, most of the following information has been drawn from studies of humans and other animal species.

Although presyncopal signs have been well described in human beings (i.e., dizziness, yawning, confusion, spots before the eyes), these signs are generally not evident in horses. Horses may stumble initially and go down or suddenly collapse. The depth and duration of unconsciousness may vary, but generally unconsciousness lasts a few minutes. Horses may be slightly unsteady or struggle during recovery. After a syncopal attack the horse will completely recover and appear normal.

## ☉ PATHOPHYSIOLOGY

Syncope results from a sudden reduction in cerebral blood flow and subsequent cerebral ischemia. Cerebral blood flow is maintained primarily by arterial blood pressure and cerebrovascular resistance. In response to falling or rising systemic blood pressure, the cerebral blood flow autoregulatory mechanism automatically regulates cerebral vessels to constrict or dilate. This control phenomenon maintains a constant cerebral blood flow despite fluctuations in arterial blood pressure, whether or not these fluctuations are physiologic or pathologic. If perfusion pressure in human beings falls below 60 mm Hg, the cerebral blood flow autoregulatory mechanism may fail. Mean resting arterial pressure measured at the carotid artery in horses has been reported to be  $97 \pm 12$  mm Hg at a heart rate of  $42 \pm 10$  beats/min.<sup>1</sup> Systolic pressure in horses experiencing syncope has not been determined.

Disturbances in oxygen supply to the brain generally result from three primary causes: hypoxemia, anemia, and ischemia. Although a variety of conditions or diseases may cause these disturbances, all three potentially deprive the brain of its critical oxygen supply.<sup>2</sup> *Hypoxemia* generally is defined as insufficient oxygen reaching the blood so that arterial oxygen content and tension are low. This insufficiency results from an inability of oxygen to cross the alveolar membrane (e.g., pulmonary disease) or low oxygen tension in the environment (e.g., high altitude). In situations of mild hypoxemia the cerebral blood flow autoregulatory mechanism maintains oxygen delivery to the brain. When the hypoxemia is severe or the compensatory mechanism fails, cerebral hypoxia occurs and syncope may result.

*Anemia* is defined functionally as a decreased oxygen-carrying capacity of the blood. This may be characterized by several mechanisms, including a reduction in the amount of hemoglobin available to bind and transport oxygen or changes in hemoglobin that interfere with oxygen binding (e.g., methemoglobin). If the anemia is severe, the oxygen concentration drops below the metabolic requirements of the brain despite increased cerebral blood flow.

Finally, cerebral ischemia results when cerebral blood flow is insufficient to supply cerebral tissue. Any disease that greatly reduces cardiac output, such as myocardial infarction or an arrhythmia, ultimately may result in cerebral ischemia.

If any of these aforementioned conditions occurs and cerebral blood flow is interrupted or stops with resultant cerebral underperfusion, consciousness is lost. If tissue oxygenation is restored immediately, consciousness generally returns quickly without sequelae.

Areas of the brain that maintain or control consciousness have been the subject of much debate and research. Generally, the level of activity of the brain (alertness) is maintained through sensory input to the ascending reticular activating system in the rostral brainstem, thalamus, and cerebral cortex. More specifically, the bulboreticular facilitatory area within the reticular substance of the middle and lateral pons and mesencephalon is considered to be the central driving component of the excitatory area of the brain. Recent studies have identified the role of the midbrain reticular formation and the thalamic intralaminar nuclei in maintaining consciousness and arousal in animals and human beings.<sup>3</sup> Syncope may result if regional cerebral blood flow to this area is disrupted for any reason.

In horses syncope may be cardiogenic or extracardiac (neurocardiogenic) in origin. The primary cause of syncope in horses is generally cardiovascular disease. Cardiogenic syncope may result from (1) myocardial disease, (2) cardiac dysrhythmias (i.e., atrial fibrillation and third-degree heart block), (3) congenital heart disease, (4) pulmonary hypertension or stenosis, and (5) pericardial disease. Although many of these conditions are uncommon in horses, atrial fibrillation has been associated with several reports of syncope.<sup>4</sup>

Cardiovascular disease, resulting in an inability to regulate heart rate or stroke volume, ultimately decreases cardiac output. Atrial fibrillation can lead to heart rates greater than 240 beats/min with submaximal exercise. The lack of effective atrial contraction prevents complete ventricular filling at the end of diastole, thus causing a great reduction in effective cardiac output. Complete heart block may be persistent or intermittent and also has been associated with syncopal episodes in horses. When the block is complete and the pacemaker below the block fails to function, syncope occurs. This situation has been reported in human beings and horses as Morgagni-Adams-Stokes syndrome. This syndrome is the most frequent arrhythmic cause of syncope in human beings.<sup>5</sup> Morgagni-Adams-Stokes attacks result from an advanced atrioventricular block and usually involve a momentary sense of weakness followed by an abrupt loss of consciousness. After cardiac standstill or prolonged periods of asystole, unconsciousness results from cerebral ischemia. These "cardiac faints" have been reported to occur several times a day in human beings. Additional, less common causes of cardiogenic syncope usually involve the distal conduction system (His-Purkinje system) and may be persistent or episodic. Heart block involving the atrioventricular node or proximal conduction system may be congenital or drug induced (e.g., digitalis). Sick sinus syndrome, a condition described in elderly human beings, involves impaired sinoatrial impulse formation or conduction and has been associated with cerebral anoxia. With any of these conditions, cardiac output does not increase sufficiently during skeletal muscle exercise to meet peripheral oxygen demands. Blood preferentially flows to exercising muscle, resulting in systemic arterial hypotension, which results in cerebral ischemia leading to weakness or syncope.

Extracardiac causes of syncope indirectly may involve the cardiovascular system and were referred to previously as *vasovagal* or *vasodepressor syncope*. The term *neurocardiogenic syncope* more accurately describes this phenomenon.

Neurocardiogenic syncope is the most common type of syncope reported in human beings and often is precipitated by stress or pain.<sup>6</sup> Although not specifically described in horses, a similar mechanism of collapse likely may exist. The critical cardiovascular features include hypotension and paradoxical sinus bradycardia, heart block, or sinus arrest after sympathetic excitation. Additionally, cardiac asystole may occur as an extreme manifestation of neurocardiogenic syncope. The mediating mechanisms of neurocardiogenic syncope are not well understood; however, several theories have been proposed. Hypercontractile states may cause excessive stimulation of the myocardial mechanoreceptors (C fibers) located in the left ventricle. The result is an exaggerated parasympathetic afferent signal carried by the vagus and glossopharyngeal nerves with a subsequent decrease in sympathetic tone. Inhibition of sympathetic vasoconstrictor activity results in vasodilation, which may be especially evident during periods of vigorous activity and increased heart rates and blood pressure. The excess vagal activity produces bradycardia and a decrease in cardiac output. This combination, along with a decrease in peripheral vascular resistance, ultimately leads to syncope.

Regardless of the specific cause, syncope results from a sudden fall in cerebral blood flow. The loss of consciousness is caused by a reduction of oxygenation to the parts of the brain that maintain consciousness. In horses syncope usually is caused by a fall in systemic blood pressure resulting from a decrease in cardiac output.

Additional, less common causes of syncope in horses may include neurologic disease from space-occupying lesions or increased intracranial pressure. Syncopal episodes have been reported in foals with severe respiratory or congenital heart disease.<sup>7</sup> After minimal exercise or restraint in these foals, hypoxemia and subsequently reduced cerebral blood flow may result in syncope. Certain drugs, specifically phenothiazine tranquilizers (acepromazine), have been reported to cause syncope in horses. These tranquilizers produce antiadrenergic effects primarily through  $\alpha_1$ -blockade with resultant vasodilation and hypotension. If phenothiazine tranquilizers are administered to severely hypovolemic horses or to horses that have hemorrhaged, severe hypotension and syncope may result.

Several disorders often are confused with syncope and should be differentiated carefully by an accurate history and thorough physical examination. These disorders include (1) epilepsy, (2) hypoglycemia, (3) narcolepsy and cataplexy, (4) sleep deprivation, (5) cerebrovascular disease, and (6) hyperkalemic periodic paralysis.

Epileptic seizures generally differ from syncope in that they have immediate onset and involve loss of consciousness, tonic and clonic convulsive activity with opisthotonos, and changes in visceral function (urination and defecation). Seizures commonly last for several minutes and often are followed by a postictal phase in which the horse may pace, appear blind, and not recognize its surroundings.

Metabolic disturbances such as hypoglycemia frequently are observed in neonatal foals and may be associated with weakness or syncopal-like episodes. Typically affected foals are premature or are subject to perinatal stress with subsequent increased glucose use following hypoxia or sepsis. Serum glucose determination is necessary to evaluate hypoglycemia.

Narcolepsy, an abnormal sleep tendency, and cataplexy occasionally may be difficult to distinguish from syncope as a cause of unconsciousness. Attacks of narcolepsy or cataplexy may be preceded by signs of weakness (buckling at the knees)

followed by total collapse and areflexia. Rapid eye movements may occur with an absence of spinal reflexes. No other neurologic abnormalities are observed between attacks, although animals may appear sleepy between episodes. Provocative testing with physostigmine (0.05 mg/kg) may induce narcoleptic attacks and might be helpful in differentiating syncope from narcolepsy or cataplexy. Recumbent sleep deprivation may also cause excessive drowsiness, often manifested by buckling and episodes of collapse.<sup>8</sup> Therefore potential physical and behavioral causes for a reluctance to lie down and sleep should be investigated.

Cerebrovascular disease associated with head trauma and subarachnoid hemorrhage may cause temporary unconsciousness in horses. Clinical signs resulting from brain trauma generally are associated with focal cerebral dysfunction and therefore are readily distinguishable from syncope.

Hyperkalemic periodic paralysis causes weakness and collapse without alterations in consciousness. This autosomal dominant disorder has been reported in certain lines of registered Quarter Horses, Paints, and Appaloosas. A reliable DNA-based test is available to diagnose hyperkalemic periodic paralysis in horses.

## ☞ EVALUATION OF SYNCOPE

A thorough evaluation of syncope in the horse consists of the following:

1. *History:* Emphasis should be placed on obtaining a detailed history. The onset and the duration of the problem, along with performance history and possible reasons for recumbent sleep deprivation, should be determined.
2. *Physical examination:* After a thorough physical examination and determination of vital signs, a detailed cardiovascular and neurologic examination should be performed. In addition to heart rate at rest and pulse characteristics, a thorough cardiac auscultation should be performed in a quiet room to identify any murmurs or cardiac dysrhythmias. An electrocardiogram (ECG) and echocardiogram also provide valuable information. Because some arrhythmias may be paroxysmal, continuous ECG monitoring may be useful. A neurologic examination should evaluate reflexes and sensory and motor function carefully to identify any central or peripheral neuropathies.
3. *Complete blood count and biochemical profile:* To rule out other potential causes of syncope-like episodes (e.g., hypoglycemia and sepsis), a complete blood count and biochemical profile should be performed. Additionally, serum lactate dehydrogenase (isoenzymes 1 and 2), creatine kinase (CK-2), and cardiac troponin I concentration determinations may be helpful in identifying cardiac dysfunction.<sup>9</sup>
4. *Exercise/stress test:* A thorough cardiac evaluation should be performed following strenuous exercise, including auscultation and an electrocardiogram. If available, a high-speed treadmill may be helpful in this phase of the evaluation. If any cardiac abnormalities are detected on physical examination, exercise testing on a treadmill will allow a more thorough evaluation of the cardiovascular system, although care must be taken to ensure that such testing does not exacerbate the condition of the horse.

Diagnosis of the cause of syncope in horses is not always easy because the cause should be considered a sign complex rather than a primary disease. In addition to the infrequent reports of syncope, the history is often vague, and the

neurologic and cardiovascular examinations may not lead to a specific cause. Even in the absence of apparently overt cardiovascular disease (e.g., atrial fibrillation), cardiac dysrhythmias cannot be excluded as the possible cause of syncope.

## ☉ TREATMENT OF SYNCOPE

Options for treating syncope in horses are limited. The frequency of the syncopal attacks and the underlying cause (i.e., cardiogenic or neurocardiogenic) may determine if a course of treatment should be undertaken. Generally, treatment of syncope should be directed toward preventing or correcting the cause of the decreased cerebral perfusion. An accurate pathophysiologic diagnosis is essential for treating cardiogenic syncope. A few reports in the literature indicate successful treatment of syncope associated with atrial fibrillation in horses.<sup>4</sup> A horse with a complete heart block returned to work after implantation of a transvenous cardiac pacing system.<sup>10</sup>

# PHARMACOLOGIC PRINCIPLES

## CHAPTER

## 4

### INTRODUCTION TO CLINICAL PHARMACOLOGY

*Patricia M. Dowling*

Drug administration is a daily and income-generating activity in equine practice. Before a drug is administered, the veterinarian must select a safe and efficacious dosage regimen based on the individual horse's physiology and the nature and formulation of the drug. If the ultimate goal of drug therapy is to improve or cure a disease, then it is the veterinarian's responsibility to ensure that the selected drug is efficacious with minimal toxicity or adverse reactions in the patient. Individual animals of various ages and species vary widely in their handling of an administered drug. Given that most veterinary practitioners deal with a number of animal species and frequently administer more than one drug at a time, it becomes obvious that there is a great potential for therapeutic error and adverse drug interactions. A basic understanding of pharmacokinetics and the effects of pathophysiology on drug disposition enables the clinician to optimize therapy while minimizing the risk of adverse drug effects.

### ☞ PHARMACOKINETICS

Pharmacokinetics is the mathematics of drug dosage determination. It involves mathematical evaluation of the rates of drug absorption and distribution throughout the body, along with metabolism and ultimate excretion from the body. Basic pharmacokinetic studies are usually performed in healthy animals. Unfortunately, however, veterinarians do not often administer drugs to normal, healthy animals. Dosage regimens derived from studies in healthy animals may not be accurate for diseased animals. Clinical pharmacokinetics is the study of the effects of disease states or other variables (age, sex, pregnancy) on the pharmacokinetics of drugs. Clinical pharmacokinetics guides veterinarians in adjusting dosage regimens determined in healthy animals to optimize treatment of diseased animals.

### ☞ PLASMA DRUG CONCENTRATIONS AS THERAPEUTIC GUIDELINES

Most pharmacokinetic information is derived from plasma drug concentrations, even though pharmacologic action depends on drug concentration at a particular effector site,

which is often a specific drug receptor. In reality, measuring drug concentrations at the drug receptor site is not practical. Instead, plasma (or serum) drug concentrations are measured and assumed to represent drug concentrations in the target tissues. Most cells in the body are perfused with tissue fluids or plasma, and drug concentrations usually reach equilibrium between tissue fluids and the blood. Therefore for most drugs pharmacologic action correlates well with the plasma drug concentration.

### ☞ VARIATION BETWEEN DRUG DOSE AND PLASMA DRUG CONCENTRATION

Drug dosages needed for a therapeutic effect differ widely among individuals. The "usual" dose has no effect in some individuals, causes serious toxicity in others, and produces an optimal effect in a few. The relationship between the dosage of a drug and its concentration in plasma is affected by its bioavailability, the animal's body size and fluid composition, variability in drug distribution within the body, and variability in rates of metabolism and excretion. These factors are all influenced by genetic differences in metabolism and excretion, environmental factors, disease alterations in system function, and concurrent administration of other drugs. Therefore the plasma concentration of a drug is not a perfect index of pharmacologic response. However, pharmacologic response is more closely related to plasma drug concentration than to drug dose. But therapeutic decisions should never be made on the basis of the plasma drug concentration alone. Knowledge of plasma drug concentration should always be used with careful medical observation and judgment to determine optimal therapy.

### ☞ DEFINITIONS IN PHARMACOKINETICS

Pharmacokinetic information is used to determine drug dosage regimens in clinical patients. An understanding of the way in which drug dosage regimens are derived and how they can be adjusted for different disease states requires knowledge of some basic pharmacokinetic terms. Mathematical *models* provide equations to describe drug concentration as a function of time. With an *open model* the drug is eliminated from

the body. An open model describes the fate of most drugs. With a *closed model* the drug is recirculated within the body (e.g., a drug that undergoes enterohepatic recirculation). In pharmacokinetic models the body is represented by a series of *compartments* that communicate reversibly with one another. A *compartment* is a tissue or group of tissues with similar blood flow and drug affinity. A drug is assumed to be uniformly distributed within a compartment and can move dynamically in and out of compartments. Rate constants represent the entry and exit of drugs from each compartment. The *central compartment* is made up of the highly perfused tissues that equilibrate rapidly with the drug. Overall drug elimination occurs mainly from the central compartment, because the kidneys and liver are well-perfused tissues. The *peripheral compartment* is made up of less-perfused tissues such as muscle and connective tissues. The *deep compartment* consists of slowly perfused tissues or depot tissues such as fat and bone. The presence of a deep compartment for drug distribution is important for toxins and drug residues. Most drugs in clinical use are described by one or two compartment models. Models with more than three compartments are usually not physiologically relevant. Describing drug disposition with compartment models creates differential equations that describe drug concentration changes in each compartment and provides a visual representation of the rate processes among compartments.

## ⊗ RATES AND ORDERS OF REACTIONS

The drug absorption or elimination rate is the speed with which it occurs. If the amount of drug in the body is decreasing over time, then the elimination rate is expressed as follows:

$$\Delta C / \Delta t$$

The absorption and elimination rate of a drug is determined experimentally by measuring the plasma drug concentration at given time intervals. *Rate constants* relate the observed rate of a kinetic process to the drug concentration that controls the process. The elimination rate constant ( $K$ ) is equal to the rate of drug elimination divided by the amount of drug in the body. The absorption rate constant ( $K_a$ ) describes the rate of drug absorption into the central compartment. *Reaction order* refers to the way that drug concentration influences reaction rate.

With a *zero order reaction* the amount of drug changes at a constant time interval, regardless of the drug concentration. The rate of drug elimination is as follows:

$$\Delta C / \Delta t = -K_0$$

where  $K_0$  is the zero order rate constant in mg/ml min. A graph of drug concentration versus time on regular graph paper for a zero order reaction produces a straight line (Figure 4-1), described by the equation:

$$C = -K_0 t + C_0$$

where  $C$  is the drug concentration at any time  $t$ , and  $C_0$  is the drug concentration at time zero. For most drugs zero order elimination occurs only when elimination mechanisms become saturated. Renal tubular secretion and bile secretion of drugs are examples of potentially saturable processes. The most well-known zero order reaction is the oxidation of ethanol in humans. The alcohol dehydrogenase system becomes saturated with very small amounts of ethanol. To achieve mild intoxication (1 mg/ml) throughout a 75-kg person, an intake of about 56 ml of absolute alcohol (or 4 oz of whiskey, vodka,

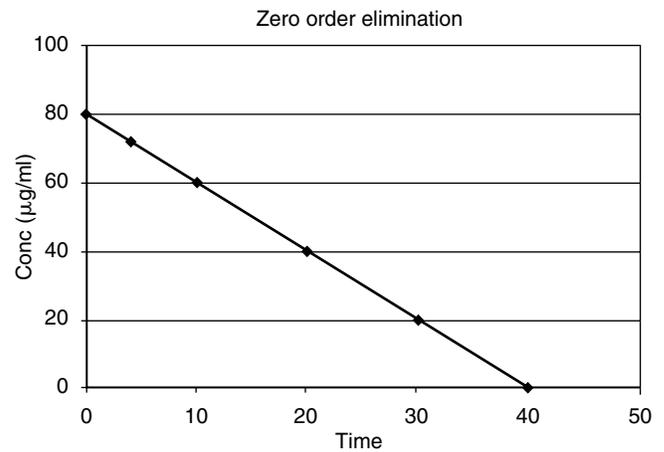

FIGURE 4-1 Drug concentration versus time for a zero order reaction produces a straight line on regular graph paper.

or gin) is required. The maximum amount of alcohol that can be eliminated is 10 ml per hour; therefore it takes 5 hours to totally eliminate the original 56 ml. Therefore to maintain a constant level of mild intoxication requires only 10 ml of ethanol or 25 ml of liquor per hour. In veterinary medicine, drugs with well-known zero order elimination include phenylbutazone in horses and deracoxibin dogs. Once elimination processes are saturated, increased dosages of such drugs result in wildly unpredictable plasma concentrations and easily result in toxicity.

With a first order reaction, the amount of drug changes at a rate proportional to the amount of drug remaining. The first order elimination rate is expressed as follows:

$$\Delta C / \Delta t = -KC$$

where  $K$  is the first order rate constant, is expressed in units of  $\text{time}^{-1}$  ( $\text{min}^{-1}$  or  $\text{hr}^{-1}$ ), and defines the fraction of drug eliminated from the body per unit time;  $C$  is the plasma drug concentration at any time  $t$ . Although  $K$  remains constant, the rate ( $>C/>t$ ) is always changing because  $C$  is always decreasing. A graph of drug concentration versus time for a first order reaction produces an exponential curve on regular graph paper but produces a straight line on semilogarithmic graph paper (Figure 4-2) and is described by the following equation:

$$C = C_0 e^{-Kt}$$

where  $C$  is drug concentration at any time  $t$ ,  $K$  is the first order rate constant in minutes or hours, and  $C_0$  is the drug concentration at time zero (the moment of injection). Most drugs are absorbed and eliminated by first order processes. Glomerular filtration by the kidney is a first order process.

## ⊗ CLINICAL APPLICATION OF COMPARTMENTAL MODELING, RATES, AND ORDERS OF REACTIONS

The aforementioned concepts can be combined to mathematically describe the changes in the drug concentration in the body over time. Drug disposition described by a one-compartment open model with intravenous (IV) injection and first order elimination (Figure 4-3) means that the body acts as one homogeneous compartment. A drug's concentration

in one part of the body is assumed to be proportional to its concentration in any other part. Many drugs administered by routes other than IV, such as oral, subcutaneous, intramuscular, or intradermal, are described by a one-compartment open model with first order absorption ( $K_a$ ) and elimination ( $K$ ) (Figure 4-4). With a two-compartment open model with IV injection and first order elimination, the model assumes the body acts as two compartments: the central compartment

(blood and highly vascularized tissues) and a peripheral compartment (less vascularized tissues). Most drugs administered in veterinary medicine are described by this model (Figure 4-5). Elimination is considered to occur only from the central compartment, because the liver and kidneys are highly vascularized tissues. The plasma concentration versus time graph does not produce a straight line on semilogarithmic paper but can be broken into two sections and described by the following biexponential equation:

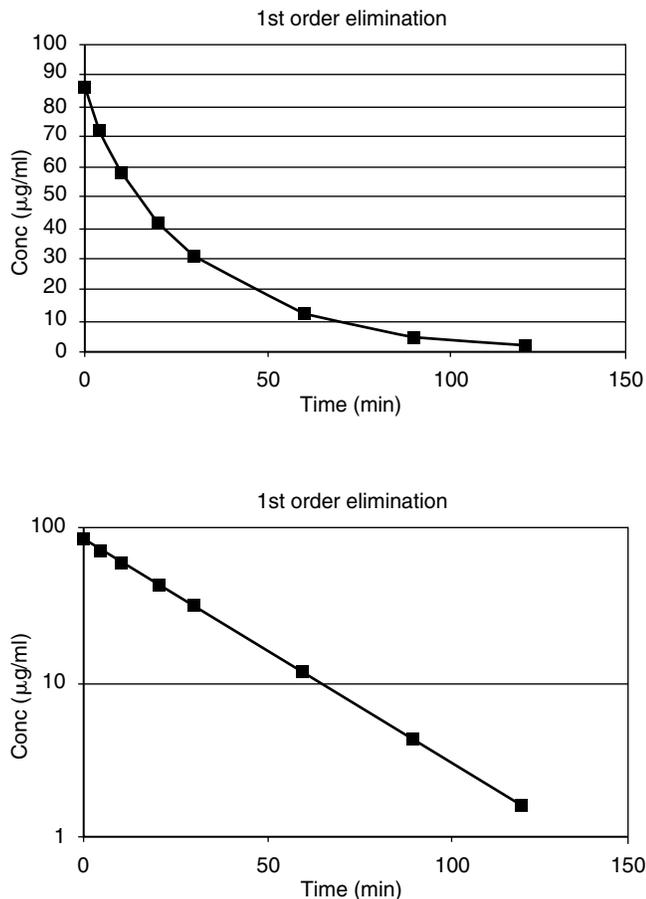

$$C = Ae^{-\alpha t} + Be^{-\beta t}$$

Where  $C$  is the concentration at any time  $t$ ,  $A$  is the y-intercept of the first portion of the curve extrapolated to zero, and  $\alpha$  is the slope of the line;  $B$  is the y-intercept of the latter portion of the curve extrapolated to zero, and  $\beta$  is its slope. The movement of drug between the central and peripheral compartments is described by the rate constants  $K_{12}$  and  $K_{21}$ .

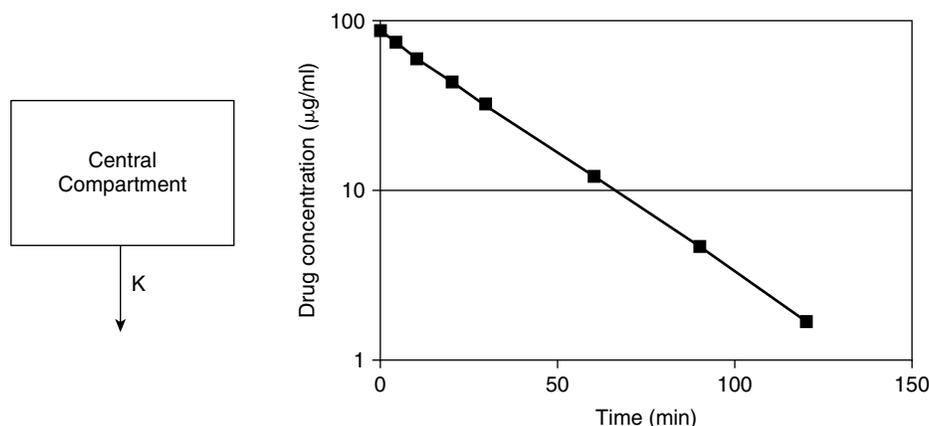

For some concentration versus time data, the line can be broken into three or more straight lines, and described mathematically with three or more exponential terms. Theoretically, drug distribution in the body can be described by as many compartments as there are different tissues, but for practical purposes more than three compartments models are not necessary. Drugs that are described by three compartment models usually have some tissue site where the drug is sequestered and slowly eliminated from the body, such as the aminoglycosides, which sequester in the renal tubular epithelial cells, and oxytetracycline, which sequesters in teeth and bone.

## ☞ DISTRIBUTION OF DRUGS IN THE BODY

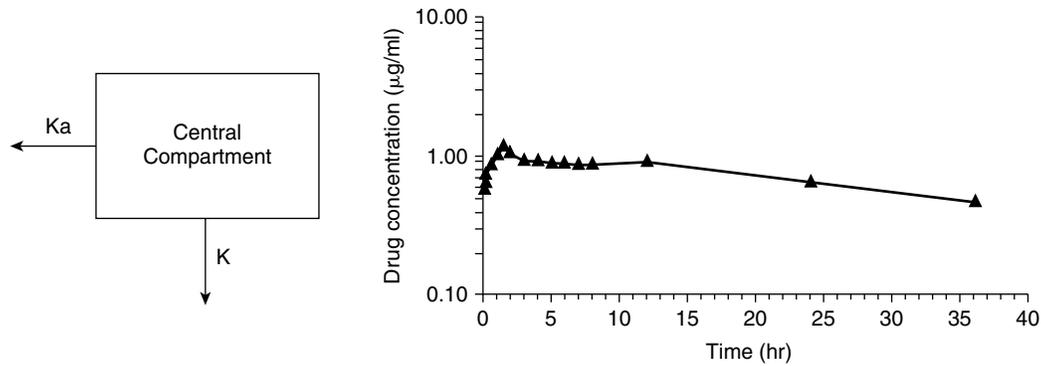

The volume of distribution ( $V_d$ ) of a drug is the mathematical term used to describe the apparent volume of the body in which a drug is dissolved.<sup>1</sup> The  $V_d$  is the parameter used to assess the amount of drug in the body from the measurement of a "snapshot" plasma concentration. The numerical value of  $V_d$  can give some indication of the distribution of the drug in the body. A drug's distribution is determined by its ability to cross biologic membranes and reach tissues outside

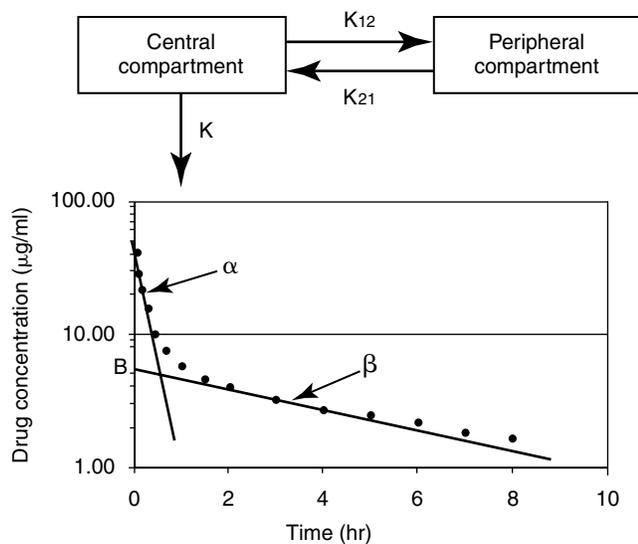

**FIGURE 4-2** Drug concentration versus time for a first order reaction produces an exponential curve on regular graph paper but produces a straight line on semilogarithmic graph paper.

**FIGURE 4-3** Graphic representation of a one-compartment open model with IV administration and first order elimination.

**FIGURE 4-4** Plasma concentration versus time graph after intramuscular administration of long-acting OTC to a horse, demonstrating a one-compartment open model with first order absorption and elimination.

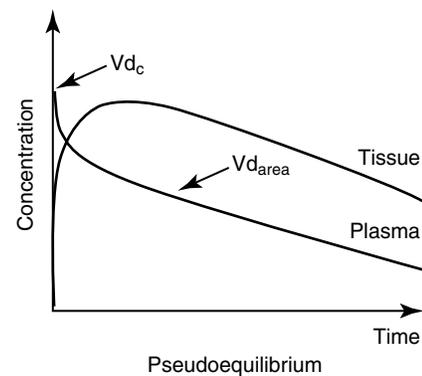

**FIGURE 4-5** Plasma concentration versus time graph after IV administration of gentamicin to a horse, demonstrating a two-compartment open model with first order elimination from the central compartment. The equation of the line is biexponential, where  $C = Ae^{-\alpha t} + Be^{-\beta t}$ .

the vascular system. The physical characteristics of the drug molecule, such as ionization, lipid solubility, molecular size, and degree of protein binding, determine its ability to cross biologic membranes.

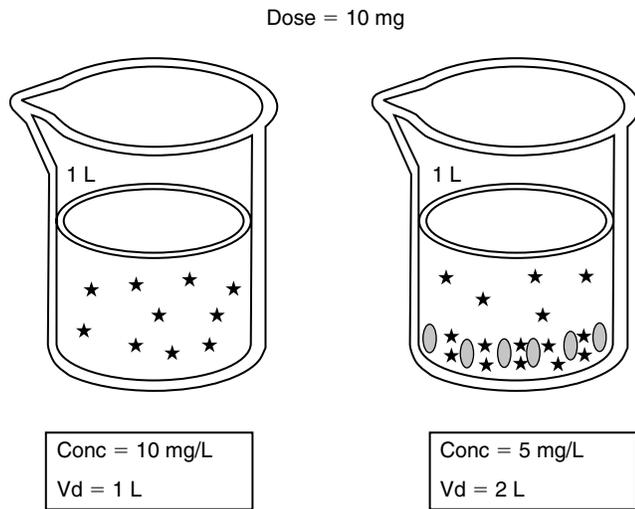

Three volumes of distribution ( $V_d$ ) are reported in the veterinary literature: the volume of the central compartment, the steady-state volume of distribution, and the volume of distribution calculated by the area method. Conceptually, the easiest demonstration of the volume of distribution is with the volume of the central compartment ( $V_{d_c}$ ). Just after an IV dose, plasma drug concentration is maximal (Figure 4-6). Assuming that the instant drug concentration ( $C_0$ ) results from the drug mixing in the blood, the  $V_{d_c}$  is the apparent volume from which drug elimination occurs, because the kidneys and liver belong to the central compartment, and is calculated from the following equation:

$$V_{d_c} = \text{dose} / C_0$$

**FIGURE 4-6** Graphical representation of the difference between the volume of the central compartment and the volume of distribution by area.

where  $C_0$  is the concentration at time zero, extrapolated from the plasma concentration versus time graph. To understand what the  $V_{d_c}$  for a drug represents, consider the body as a beaker filled with fluid (Figure 4-7). The fluid represents the plasma and other components of extracellular water. If a drug is administered intravenously, it rapidly distributes in the extracellular fluid. If the drug does not readily cross lipid membranes, it will be confined mainly to the extracellular fluid and a plasma sample therefore will have a high drug concentration. The higher the measured concentration in relation to the original dose, the lower the numerical value for  $V_{d_c}$ . Drugs such as the  $\beta$ -lactam and aminoglycoside antibiotics are poorly lipid soluble and therefore remain predominantly in the extracellular fluid and have low values for  $V_d$ . In contrast, some drugs readily cross lipid membranes and distribute into tissues. This is represented by the beaker on the right, where the stars at the bottom of the beaker represent drug molecules that have been taken up by tissues. A plasma sample will have a low drug concentration in proportion to the original dose and therefore will have a high numerical value for  $V_{d_c}$ . Given the limitations on measuring drug concentrations at “time zero” and using the aforementioned formula, the measured concentration of highly lipid-soluble drugs can be low enough to result in a value of  $V_{d_c}$  that is greater than 1 L/kg, so it is often referred to as an *apparent*

**FIGURE 4-7** The beaker on the left represents a low  $V_d$  drug that is mainly distributed to the extracellular fluid. A sample from the fluid will contain a high concentration of drug and therefore will have a low value for  $V_d$ . The beaker on the right represents a high  $V_d$  drug that readily crosses membranes and moves out of the extracellular fluid into tissues. A sample from the fluid will contain a low concentration of drug and therefore will have a high value for  $V_d$ .

*volume of distribution.* In the example on the right, the “apparent”  $V_d$  is 2 L/kg even though the beaker contains only 1 L of fluid.

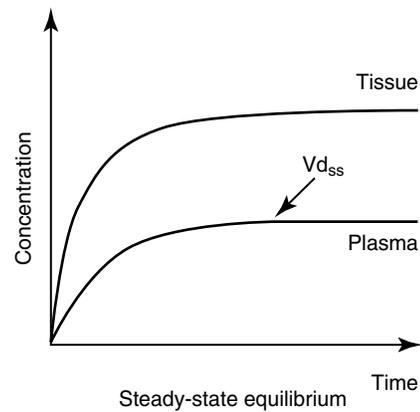

For most drugs after a single IV dose, the drug is distributed and begins to be eliminated simultaneously. When concentrations are measured and the data graphed, there is a distribution phase, wherein the plasma drug concentration that is due to elimination and not distribution increases until it reaches an asymptotic value at which pseudoequilibrium is achieved (see Figure 4-6). When pseudoequilibrium is reached, the movement of drug between the peripheral and central compartments reaches equilibrium, and decreasing plasma concentrations are now due only to irreversible elimination (described by the elimination rate constant,  $\beta$ ). The applicable  $V_d$  value in this situation is the volume of distribution by area ( $V_{d_{area}}$ ),

$$V_{d_{area}} = \text{Dose} \div \text{AUC}^{0-\infty} / \beta$$

where  $\text{AUC}^{0-\infty}$  is the area under the plasma concentration time curve from zero to infinity. To be calculated accurately, the amount of drug that enters the systemic circulation must be accurately known and the terminal phase must be a pure elimination phase. An inaccurate  $V_{d_{area}}$  is frequently published for “long-acting” intramuscular or subcutaneous administered drugs, where prolonged elimination is due to delayed absorption.

With an IV infusion or with a multiple dose regimen, the rate of drug entry into the body is equal to its elimination rate, and the body becomes a closed system with no clearance. In this situation the correct  $V_d$  to describe distribution is the  $V_d$  at steady-state ( $V_{d_{ss}}$ ; Figure 4-8):

$$V_{d_{ss}} = \frac{\text{Drug in body at steady-state}}{\text{Concentration in plasma}}$$

**FIGURE 4-8** Graphical representation of the volume of distribution when plasma concentrations are measured at steady-state conditions.

## CLINICAL USE OF THE DIFFERENT VOLUME OF DISTRIBUTION VALUES

The  $V_{d_c}$  is used to predict the initial plasma drug concentration after an IV bolus of a drug when a loading dose is needed to rapidly achieve a therapeutic drug concentration. The  $V_{d_{ss}}$  is used to calculate a loading dose when it is clinically necessary to rapidly reach steady-state concentrations. The  $V_{d_{area}}$  is used to predict the amount of drug remaining in the body. For all drugs the value of  $V_{d_{area}}$  is greater than  $V_{d_{ss}}$ , but generally the difference is small and the values are used interchangeably. However, with the IV administration of drugs that are rapidly eliminated into urine (e.g., aminoglycosides),  $V_{d_{area}}$  can be much larger than  $V_{d_{ss}}$  because a large fraction of the drug is eliminated before pseudoequilibrium is reached.

It is useful to compare a drug’s  $V_d$  to the distribution of water in the body in order to get an idea of its distribution. Drugs with a  $V_d$  value of less than 0.3 L/kg are predominantly confined to the ECF, whereas drugs with a  $V_d$  value of greater than 1 L/kg are highly lipid soluble and tend to distribute out of the extracellular fluid and into tissue compartments (Box 4-1). Although the value of  $V_d$  does not confirm penetration of a drug into specific tissues, in general the higher the value of the  $V_d$ , the more likely it is that the drug will reach sequestered sites such as the brain and cerebrospinal fluid, the prostate and other sex organs, the eye, and the mammary gland. Studies must be performed to confirm that therapeutic concentrations are achieved in such sites.

## CONDITIONS THAT AFFECT VOLUME OF DISTRIBUTION

The  $V_d$  is constant for any drug and will change only with physiologic or pathologic conditions that change the distribution of the drug. Drugs with high  $V_d$ s are usually very lipid soluble and typically are not significantly affected by changes in body water status and do not require dosage adjustment. However, there are many medical conditions that affect the disposition of low  $V_d$  drugs in a patient

## BOX 4-1

**VOLUME OF DISTRIBUTION (V<sub>d</sub>)  
OF VARIOUS DRUGS**
**Low V<sub>d</sub> Drugs (<0.3 L/kg)**

Penicillins  
Cephalosporins  
Aminoglycosides  
Nonsteroidal anti-inflammatory drugs  
Medium V<sub>d</sub> Drugs (> 0.3 - < 1 L/kg)  
Phenobarbital  
Sulfonamides  
Prednisolone  
Rifampin

**High V<sub>d</sub> Drugs (>1 L/kg)**

Macrolides  
Tetracyclines  
Fluoroquinolones  
Chloramphenicol  
Metronidazole  
Trimethoprim  
Dexamethasone  
Furosemide  
Ketamine  
Diazepam  
Firocoxib

(e.g., nonsteroidal anti-inflammatory drugs and aminoglycosides), and these drugs do require dosage adjustment because of their narrow therapeutic index. Many conditions in horses, such as colic, are characterized by volume contraction and dehydration and changes in acid-base balance, which affect the extracellular fluid volume. Neonatal foals have a higher percentage of body water than adult horses (80% versus 60% total body water), and the extra 20% is primarily confined to the extracellular fluid, so the V<sub>d</sub> of drugs such as gentamicin are higher in neonatal foals than older foals or adult horses.<sup>2</sup> Therefore to achieve equivalent therapeutic plasma concentrations of gentamicin in a neonatal foal, the dose must be higher than that administered to the older foal or adult horse.

## BIOAVAILABILITY

*Bioavailability* (F) is a measure of the systemic availability of a drug administered by a route other than IV.<sup>3</sup> Bioavailability is determined by comparing the area under the plasma drug concentration curve versus time (AUC) for the extravascular formulation to the AUC for the IV formulation. The AUC is calculated by computer or by the trapezoidal method, wherein the entire curve is divided into trapezoids, then the area of each trapezoid is calculated and summed to give the AUC. For an orally administered drug, use the following equation:

$$F = (AUC_{\text{oral}} \div AUC_{\text{iv}}) \times 100 = \% \text{ bioavailable}$$

If F is significantly less than 100%, the drug dose must be increased to achieve systemic drug concentrations similar to the IV formulation:

$$\text{Adjusted dose} = \text{dose}_{\text{iv}}/F$$

If the oral formulation of a drug has a mean bioavailability of 50%, the drug dose must be doubled to achieve the same concentrations in plasma as achieved using the IV formulation. However, the variability of the bioavailability in the population is more clinically significant than the mean. To make sure that the horse with the poorest absorption is dosed appropriately, the dose must be increased according to the lowest bioavailability, not the mean. For example, if a drug has a mean F of 50% with a range of 20% to 70%, then to achieve an exposure of 100% for all the treated horses, the dose must be multiplied by 5, not just 2. However, if this is done, the horses with an F of 70% will be overdosed by a factor of 3.5. For a drug with a narrow therapeutic window and a poor bioavailability, there may be no dose that is ideal for all horses in the population. Low bioavailability of antimicrobials and anthelmintics is a major cause of subtherapeutic dosages that promote drug resistance. Poor oral bioavailability is a major limitation of many drugs administered to horses.<sup>4</sup>

## LIPID SOLUBILITY AND DRUG IONIZATION (THE pH-PARTITION HYPOTHESIS)

The degree of lipid solubility determines how readily a drug will cross biologic membranes. Drugs are classified as lipid soluble (or nonpolar) versus water soluble (or polar). Highly lipophilic drugs diffuse easily across almost all tissue membranes. Most of the drugs used in equine practice exist as weak acids or weak bases. Their lipid solubility depends a great deal on their degree of ionization (charged state). An *ionized* drug is hydrophilic and poorly lipid soluble. A *nonionized* drug is lipophilic and can cross biologic membranes. The degree of ionization for a weak acid or weak base depends on the pKa of the drug and the pH of the surrounding fluid. At a given pH, there is an equilibrium between the ionized and nonionized proportions of drug. When the pH is equal to the pKa of the drug, then the drug will be 50% ionized and 50% nonionized (log 1 = 0). As the pH changes, the proportion of ionized to nonionized drug will change according to the *Henderson-Hasselbach* equations:

For a weak acid:

$$\text{pH} = \text{pKa} + \log (\text{ionized drug} / \text{nonionized drug})$$

For a weak base:

$$\text{pH} = \text{pKa} + \log (\text{ionized drug} / \text{nonionized drug})$$

Whereas the precise ratios of ionized versus nonionized drug can be calculated from the Henderson-Hasselbach equations, the relevance of the equations can be understood by simply remembering the sentence “like is nonionized in like.” For example, a weak acid will be most nonionized in an acidic environment, so aspirin is most nonionized in the stomach and is readily absorbed. The fluid of most sequestered sites in the body (cerebrospinal fluid, accessory sex gland fluid, milk, abscesses) has a pH more acidic than plasma. In cattle with mastitis weak acid antibiotics are typically administered by intramammary infusion, whereas weak bases are administered parenterally. This makes sense according to the pH-partition concept. Weak bases in the plasma are highly nonionized and

readily cross into the mammary gland. Then, as the equilibrium shifts, they become “ion-trapped” in the more acidic milk, but the fraction of nonionized drug in the mammary gland is available to cross the bacterial cell membrane for antimicrobial action. Weak acids such as penicillins and cephalosporins are highly ionized in plasma and therefore do not penetrate into the mammary gland very well, so these are most effective when administered by local infusion into the udder, where the extremely high local concentrations negate local pH effects.

Typically, drugs that are weak acids will have low Vd values and weak bases will have high values for Vd (Box 4-2). Amphoteric drugs such as the fluoroquinolones and tetracyclines have acidic and basic groups on their chemical structures. These drugs have a pH range where they are maximally nonionized. For example, enrofloxacin is most lipid soluble (nonionized) in the pH range of 6 to 8, so it is lipid soluble at most physiologic pHs. In acidic urine significant ionization occurs, which reduces enrofloxacin’s antibacterial activity. But this reduction in activity is offset by the extremely high concentrations of enrofloxacin achieved in urine, so it is of no clinical importance. Despite being weak bases, the aminoglycosides are very large, hydrophilic molecules and have high pKa values, so they are highly ionized at physiologic pHs. Therefore parenterally administered aminoglycosides do not cross lipid membranes well and do not achieve therapeutic concentrations in milk, accessory sex gland fluids, abscesses, or cerebrospinal fluid.

## DRUG PROTEIN BINDING

Protein binding can involve plasma proteins, extracellular tissue proteins, or intracellular tissue proteins. Many drugs in circulation are bound to plasma proteins, and because bound drug is too large to pass through biologic membranes, only free drug is available for delivery to the tissues and to produce the desired pharmacologic action. Therefore the degree of protein binding can greatly affect the pharmacokinetics of drugs. Acidic drugs such as nonsteroidal anti-inflammatory drugs tend to bind predominantly to albumin.<sup>5</sup> Albumin is the most abundant plasma protein, and it is critical to maintaining the

colloidal oncotic pressure in the vascular system. As a negative acute phase protein, albumin concentration decreases during inflammation. Hypoalbuminemia results from decreased production, seen with severe hepatic insufficiency, or by loss through increased rates of urinary excretion, such as in nephrotic syndrome or with mucosal damage, as with protein losing enteropathies. Basic drugs typically bind to  $\alpha$ -1 acid glycoprotein, which is an acute phase protein, whose hepatic production increases significantly with inflammatory conditions.<sup>6</sup> Other proteins, including corticosteroid binding globulin, are important for binding of some specific drugs but are less important in overall drug-protein binding.<sup>7</sup> There is equilibrium between free and bound drug, however, just like the relationship of ionized and nonionized drug molecules. Protein binding is most clinically significant for antimicrobial therapy, where a high degree of protein binding serves as a drug “depot,” allowing for increased duration of the time the drug concentration remains above the bacterial minimum inhibitory concentration, adding to antimicrobial efficacy.<sup>8</sup> For other drugs changes in plasma protein binding can influence individual pharmacokinetic parameters, but changes in plasma protein binding usually do not influence the clinical exposure of the patient to a drug. Changes in protein binding caused by drug interactions are assumed to instantaneously change free drug concentrations and have been frequently cited as a cause of adverse drug reactions. But the increase in free drug concentration is only transient, because drug distribution and drug elimination change to compensate. The often-cited example of the concurrent administration of phenylbutazone and warfarin leading to bleeding caused by increased free concentrations of warfarin is erroneous. The true interaction is from phenylbutazone-induced inhibition of the hepatic metabolism of warfarin, which results in increased plasma concentrations and increased anticoagulant effect.<sup>7</sup> Therefore adjustments in dosing regimens because of hypo-proteinemia or concurrent administration of highly bound drugs are not necessary except in the rare case of a drug with a high hepatic extraction ratio and narrow therapeutic index that is given parenterally (e.g., IV dosing of lidocaine).<sup>9</sup>

## ☞ DRUG ELIMINATION FROM THE BODY

*Drug elimination* refers to the irreversible removal of drug from the body by all routes of elimination. Elimination may be divided into two major components: excretion and biotransformation. Drug excretion is the removal of the intact drug. Most drugs are excreted by the kidney into the urine. Other pathways include the excretion of drug into bile, sweat, saliva, or milk. Biotransformation (drug metabolism) converts the drug in the body to a metabolite that is more readily excreted, usually by adding a chemical group to the molecule to make it more water soluble. Enzymes involved in biotransformation are mainly located in the liver. Other tissues, such as the kidney, lung, small intestine, and skin, contain biotransformation enzymes.

## ☞ ELIMINATION RATE CONSTANT AND ELIMINATION HALF-LIFE

The rate of elimination for most drugs is a first order process. The elimination rate constant (K) represents the sum of drug elimination by excretion and metabolism. Drug elimination

Tetracyclines

**FIGURE 4-9** For a drug with first order elimination, the plasma concentration decreases by 50% every hour, so the elimination half-life is 1 hour.

is considered always to occur from the central compartment, because the liver and kidney are well-perfused tissues. The elimination rate constant is used to calculate the drug's half-life ( $T_{1/2}$ ), or the time required for drug concentration to decrease by one half (Figure 4-9). For first order reactions,  $T_{1/2}$  is constant across the plasma concentration versus time curve and is calculated from:

$$T_{1/2} = 0.693 / K$$

where  $0.693 = \ln 2$  (the natural logarithm of 2). Mean residence time (MRT) is roughly the equivalent of  $T_{1/2}$  when pharmacokinetics are calculated using statistical moment theory. The MRT is the time it takes for drug concentration to decrease by 63.2%, so the MRT value is typically slightly greater than  $T_{1/2}$ . The  $T_{1/2}$  determines the drug dosage interval, how long a toxic or pharmacologic effect will persist, and drug withdrawal times for food animals or performance horses. Notice that it takes  $10 T_{1/2}$ s to decrease the plasma concentration by 99.9% (Table 4-1). Knowing a drug's plasma  $T_{1/2}$  can give the clinician some idea of the drug's withdrawal time for food or performance animals. However, for drugs that undergo hepatic metabolism (e.g., phenylbutazone) or drugs that sequester in specific tissues (e.g., aminoglycosides, isoxuprine), simply multiplying the  $T_{1/2}$  by a factor of 10 for a withdrawal time may not be sufficient to prevent violative residues. Also note that doubling a drug dose does not double the withdrawal time; it merely adds one half-life to the time it takes to reach the acceptable threshold concentration (Figure 4-10).

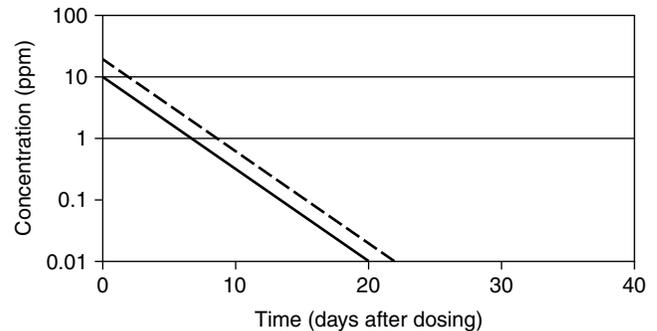

### FLIP-FLOP KINETICS

Long-acting drug formulations are often products whose carriers cause them to be slowly absorbed into the systemic circulation. Therefore the drug elimination rate is limited by the drug absorption rate. The value for  $K$  (the elimination rate constant) calculated from the plasma concentration versus time curve is actually the value for  $K_a$  (the absorption rate constant). The easiest way to identify "flip-flop" kinetics is to compare the plasma concentration versus time curve for the extravascular route of administration to the curve after the drug is given intravenously (Figure 4-11). If the elimination phases of the

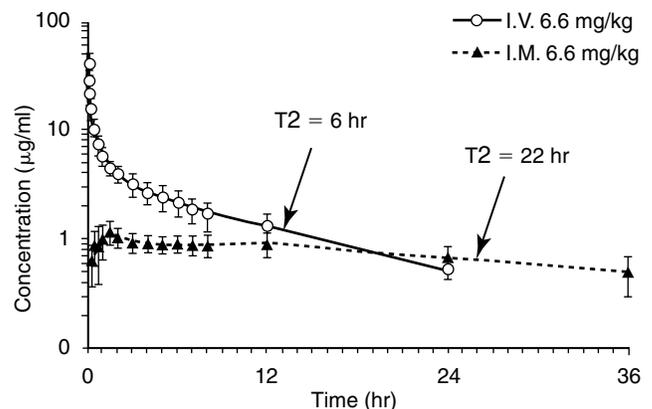

**TABLE 4-1**

#### Half-Life of Elimination of a Drug

Number of Half-Lives	Fraction of Drug Remaining (%)
0	100
1	50
2	25
3	12.5
4	6.25
5	3.125
6	1.56
7	0.78
8	0.39
9	0.195
10	0.0975

**FIGURE 4-10** Doubling a drug dose adds only one half-life to its withdrawal time. For this drug with an elimination half-life of 24 hours, if the dose is doubled to reach a plasma concentration of 20 µg/ml, then it will take 21 days instead of 20 days to reach an acceptable threshold of 0.01 µg/ml.

**FIGURE 4-11** Plasma concentration versus time graph for long-acting oxytetracycline in horses, demonstrating "flip-flop" kinetics. The delayed absorption from the intramuscular injection results in the slow elimination and triples the elimination half-life value.

curves are not parallel, then delayed absorption is prolonging elimination and the flip-flop phenomenon has occurred.

For a two-compartment model,  $\beta$  (from the equation  $C = Ae^{-\alpha t} + Be^{-\beta t}$ ) is the drug elimination rate constant from the entire body once the drug has reached equilibrium between the two compartments. Therefore  $\beta$  is used to calculate the elimination half-life:

$$T_{1/2} = 0.693/\beta$$

## CLEARANCE

*Clearance* is a measure of drug elimination from the body without reference to the mechanism of elimination. It is always reported in pharmacokinetic papers, but its significance is rarely explained in pharmacokinetic studies in horses. Clearance is the most important pharmacokinetic parameter because it is the only parameter that controls overall drug exposure and it is used to calculate the dosage required to maintain a specific average steady-state concentration.<sup>10</sup>

Clearance (Cl) is the total drug clearance and is the sum of renal clearance (Cl<sub>R</sub>), hepatic clearance (Cl<sub>H</sub>), and all other elimination mechanisms. By definition, Cl is the volume of fluid containing drug that is cleared of drug per unit of time (ml/kg/min). The most frequent technique for determining plasma Cl is to administer a single IV dose of a drug and then measure plasma concentrations over time. Then,

$$Cl = \text{Dose}/AUC$$

where *AUC* is the area under the plasma concentration time curve.

If the body is considered as the whole system clearing the drug, *Cl* can also be determined by the animal's cardiac output and the extraction ratio (*E*), where *E* is a numerical value between 0 and 1 that is the percentage of the drug that is cleared by a single pass through the clearing organ:

$$Cl = \text{Cardiac output} \times E$$

For a drug with an extraction ratio of 1 (100% removal by the liver and kidney on the first pass), then the expected value of *Cl* is about 50% of the cardiac output, because blood flow to the liver and the kidneys represents about half of the cardiac output.

In contrast to *Vd* values, *Cl* values have to be interpreted according to the value of cardiac output for the species involved. Given that most drugs are extracted primarily by renal and hepatic mechanisms, the extraction ratio is considered high if *E* is greater than 0.7, medium if *E* equals 0.3, and low if *E* is less than 0.1. Because the liver and kidneys receive about 50% of cardiac output, then the overall *E* is high if it is greater than 0.35, medium if it is about 0.15, and low if it is less than 0.05. From this and the cardiac output of the species, breakpoint values can be determined to classify drugs as

having high, medium, and low clearance. For the horse with a cardiac output of 55 ml/kg/min, a high *Cl* value is 19 ml/min/kg, medium *Cl* is 8.25 ml/min/kg, and low *Cl* is 3.6 ml/min/kg.

It is sometimes difficult to understand the difference between the elimination half-life and clearance. The relationship is as follows:

$$Cl = (Vd)(K) \text{ or} \\ Cl = (Vd)(0.693/T_{1/2})$$

Consider the values for clearance and *T*<sub>1/2</sub> values for four antimicrobial drugs (Table 4-2). Note that the plasma clearance values are similar, but the elimination half-lives are very different. Because the *T*<sub>1/2</sub> is influenced by the extent of drug distribution, the drugs have similar clearance, but oxytetracycline has the largest *Vd* and the longest *T*<sub>1/2</sub>. Because *T*<sub>1/2</sub> is derived from rate constants and does not have a physiologic basis, it is influenced by the sensitivity of the analytical method and by many pharmacokinetic parameters, and it is a poor parameter alone to evaluate physiologic (e.g., age, sex) or pathologic (e.g., renal failure) changes that effect drug disposition.

## RENAL CLEARANCE OF DRUGS

Renal excretion is the major route of elimination from the body for most drugs. Drug disposition by the kidneys includes glomerular filtration, active tubular secretion, and tubular reabsorption (Figure 4-12), such that renal drug clearance is defined by the following equation:

$$Cl_R = Cl_F + Cl_S - FR$$

where *Cl*<sub>R</sub> = total renal clearance

*Cl*<sub>F</sub> = clearance attributed to glomerular filtration

*Cl*<sub>S</sub> = clearance attributed to active tubular secretion

*FR* = fraction reabsorbed from the tubule back to circulation

Glomerular filtration (*Cl*<sub>F</sub>) occurs with small molecules (<300 molecular weight) of free drug (not bound to plasma proteins). Large molecules or protein-bound drugs do not get filtered at the glomerulus because of size and electrical hindrance. The kidneys receive approximately 25% of cardiac output, so the major driving force for glomerular filtration is the hydrostatic pressure within the glomerular capillaries. Glomerular filtration rate (GFR) is estimated by measuring a substance or drug that is eliminated only by glomerular filtration, such as creatinine or inulin.

If *Cl*<sub>R</sub> is greater than *Cl*<sub>F</sub>, then some tubular secretion is occurring. Active tubular secretion is a carrier-mediated transport system, located in the proximal renal tubule. It requires energy input because the drug is moved against a concentration gradient. Two active tubular secretion systems have been identified: anion secretion for acids and cation secretion for

TABLE 4-2

Comparison of Clearance to Elimination Half-life				
	Penicillin	Gentamicin	Oxytetracycline	Tylosin
Cl (ml/min/kg)	3.5	3.1	4.0	2.2
T <sub>2</sub> (min)	30	75	360	54

bases. Drugs with similar structures may compete with each other for the same transport system. For example, probenecid competes with penicillin or the fluoroquinolones for the same transport system, effectively decreasing  $Cl$  of these antimicrobials. In patients with reduced functional renal tissue, remaining transport systems become easily saturated and drug accumulation occurs.

If  $Cl_r$  is less than  $GFR$ , tubular reabsorption of drug is occurring. Tubular reabsorption is an active process for endogenous compounds (e.g., vitamins, electrolytes, glucose). It is a passive process for the majority of drugs. It occurs along the entire nephron but primarily in the distal renal tubule. Factors that affect reabsorption include the  $pK_a$  of the drug, urine pH, lipid solubility, drug size, and urine flow. Drug reabsorption is highly dependent on ionization, which is determined by the drug's  $pK_a$  and the pH of the urine. According to the Henderson-Hasselbach equation, a drug that is a weak base will be mainly nonionized in alkaline urine and a weak acid will be mainly ionized in alkaline urine. The nonionized form of the drug is more lipid soluble and has greater reabsorption (Table 4-3). The  $pK_a$  of a drug is constant, but urinary pH is highly variable in animals and varies with the diet, drug intake, time of day, and systemic acidosis/alkalosis. Species differences have a major influence on the renal excretion of ionized drugs. Carnivores, with a urine pH of 5.5 to 7.0, will have a greater renal excretion of basic drugs than herbivores, with a urine pH of 7.0 to 8.0.

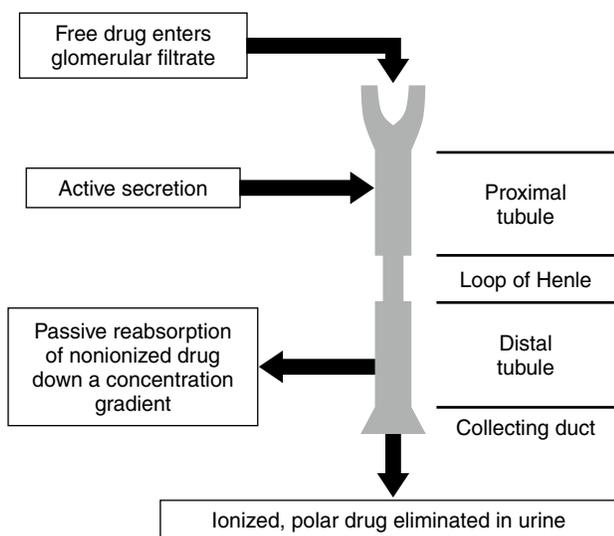

FIGURE 4-12 Movement of drugs in the renal tubule.

TABLE 4-3

Oxytetracycline	Base	10.4	1000	10	0.3

## HEPATIC CLEARANCE OF DRUGS

Nonrenal drug elimination is assumed to be due primarily to biotransformation (hepatic metabolism) and biliary excretion. Clearance of a drug by the liver is determined by hepatic blood flow ( $Q_H$ ) and the intrinsic ability of the liver to extract the drug (*extraction ratio*, or  $ER_H$ ):

$$Cl_H = (Q_H)(ER_H)$$

Drugs with a high extraction ratio (approaching 1) have  $Cl_H$  equal to the hepatic blood flow. These drugs are called *high clearance drugs*. Examples of drugs with high  $ER_H$  are lidocaine, propranolol, and isoproterenol. Clearance of drugs with high  $ER_H$  is highly influenced by changes in hepatic blood flow. Drugs that are administered orally and are absorbed across the intestinal mucosa must first pass through the liver via the portal circulation before being distributed to the rest of the body. Most of a drug with a high  $ER_H$  will be cleared in one pass through the liver; this is called the *first pass effect*, and it limits the oral administration of such drugs. Drugs that have a low hepatic extraction rate ( $ER_H \leq 0.2$ ) are not greatly affected by changes in hepatic blood flow. However, their clearance will be affected by changes in the hepatic microsomal enzyme systems and protein binding. A first pass effect does not interfere with the systemic availability of these drugs. Drugs with a low  $ER_H$  include chloramphenicol, phenylbutazone, phenobarbital, and digoxin.

## BIOTRANSFORMATION (HEPATIC METABOLISM) OF DRUGS

Metabolism is necessary for removal of lipophilic drugs from the body (Figure 4-13). Biotransformation depends on the chemical composition of the liver, activity of major drug metabolism enzymes, hepatic volume (perfusion rate), drug accessibility to and extraction by hepatic metabolic sites, and physicochemical properties of the drug. Biotransformation of a parent drug results in metabolites that may be active or inactive themselves. A *prodrug* is a drug administered in an inactive form that must be biotransformed to its active form, such as prednisone to prednisolone. Drug metabolic pathways are divided into *phase I* and *phase II* reactions. Phase I reactions (oxidation, reduction, hydrolysis, hydration, dethioacetylation, isomerization) typically

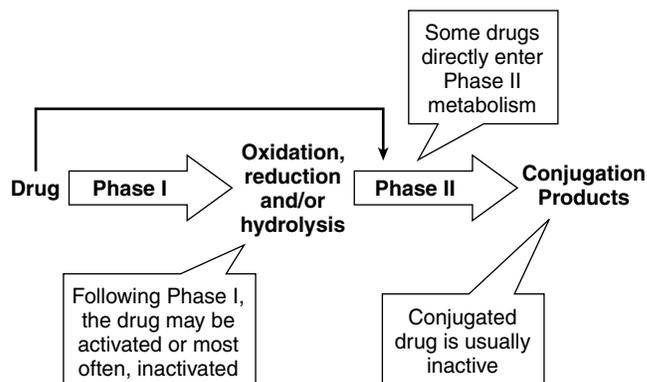

FIGURE 4-13 Hepatic metabolism increases the water solubility of drugs, facilitating excretion from the body.

add functional groups to the drug molecule necessary for phase II reactions. Phase II reactions (glucuronidation, glucosidation, sulfation, methylation, acetylation, amino acid conjugation, glutathione conjugation, and fatty acid conjugation) typically include conjugation reactions that increase the water solubility of the drug, facilitating excretion from the body.

Among the reactions catalyzed by drug metabolism enzymes, the cytochrome P450 mixed function oxidase system is the most intensively studied. This reaction catalyzes the hydroxylation of hundreds of structurally diverse drugs, whose only common characteristic is high lipid solubility. Species differences in drug metabolic rate are the primary source of variation in drug activity and toxicity. Cats have a poor ability to glucuronidate drugs, pigs are deficient in sulfate conjugation, and dogs are relatively poor acetylators.

## INDUCTION AND INHIBITION OF METABOLISM

Metabolism of drugs can be substantially affected by enzyme induction or inhibition by other drugs or chemicals (Box 4-3). In some cases the drug itself may alter its own metabolic fate by induction or inhibition. Many drugs are capable of inducing enzyme activity, thereby increasing the rate of metabolism and hepatic clearance of concurrently administered drugs, which typically results in a decreased pharmacologic effect. Enzyme induction typically occurs slowly, requiring several weeks to reach maximum effect. Induction is accompanied by increased hepatic ribonucleic acid (RNA) and protein synthesis and increased hepatic weight. Enzyme induction is important in the pathogenesis of hepatotoxicity and therapeutic failure of many drugs. Phenobarbital is a potent enzyme inducer known for hepatotoxicity and for inducing its own metabolism. Rifampin induces the metabolism of azole antifungals; concurrent administration with itraconazole results in subtherapeutic itraconazole concentrations.

### BOX 4-3

#### DRUGS THAT AFFECT ENZYME FUNCTION

##### Enzyme Inducers

Chlorinated hydrocarbons  
Griseofulvin  
Omeprazole  
Phenobarbital  
Phenytoin  
Rifampin

##### Enzyme Inhibitors

Chloramphenicol  
Cimetidine  
Dexamethasone  
Erythromycin  
Fluoroquinolones  
Ketoconazole  
Phenobarbital  
Phenylbutazone  
Prednisolone  
Quinidine

Drug-induced enzyme inhibition also occurs and typically results in prolonged clearance of a concurrently administered drug. The potential for toxicity or an exaggerated pharmacologic response is increased. In contrast to induction, inhibition occurs rapidly. Erythromycin and enrofloxacin are known inhibitors of the metabolism of theophylline; concurrent administration can cause central nervous system toxicity and seizures.<sup>11,12</sup>

## KINETICS OF DRUG METABOLISM

The enzymes that catalyze drug metabolism typically obey Michaelis-Menten kinetics as a *first order reaction*:

$$V = \frac{V_{\max}[C]}{K_m + [C]}$$

where  $V$  is the rate of drug metabolism,  $K_m$  is the Michaelis constant, and  $C$  is the drug concentration. In most clinical situations the drug concentration is much less than the Michaelis constant, so the equation reduces to the following:

$$V = \frac{V_{\max}[C]}{K_m}$$

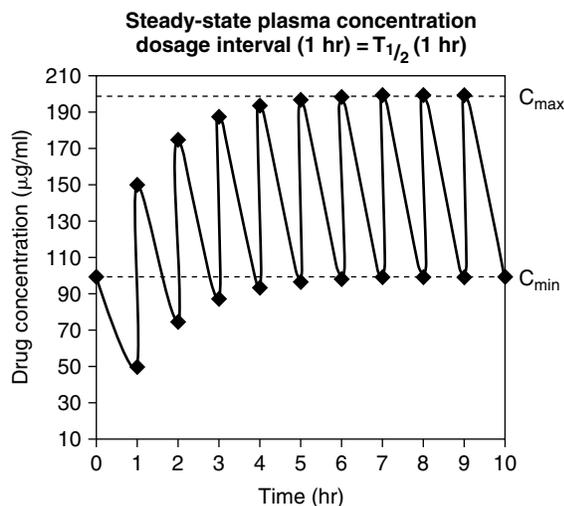

that is, the rate of drug metabolism is directly proportional to the concentration of free drug and first order kinetics are observed in that a constant fraction of drug is metabolized per unit of time. With a few drugs, such as phenylbutazone, ethanol, deracoxib, and phenytoin, or if very large doses of a drug are given, the drug concentrations achieved are much greater than  $K_m$  and the rate equation is as follows:

$$V = \frac{V_{\max}[C]}{[C]} = V_{\max}$$

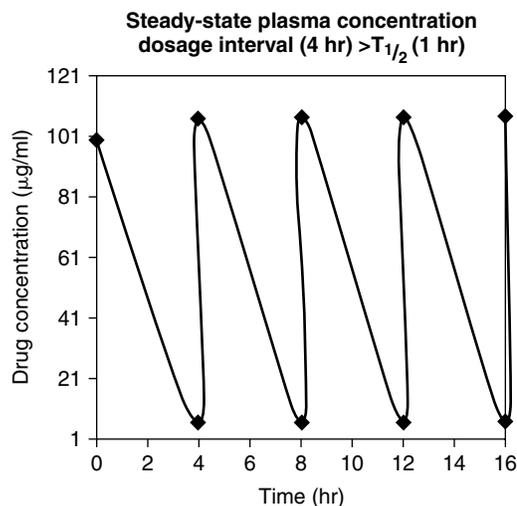

The enzymes are saturated by the high free drug concentrations, and the rate of metabolism remains constant over time. This is *zero-order kinetics* or *nonlinear kinetics*, and a constant amount of drug is metabolized per unit of time.

## DRUG ACCUMULATION

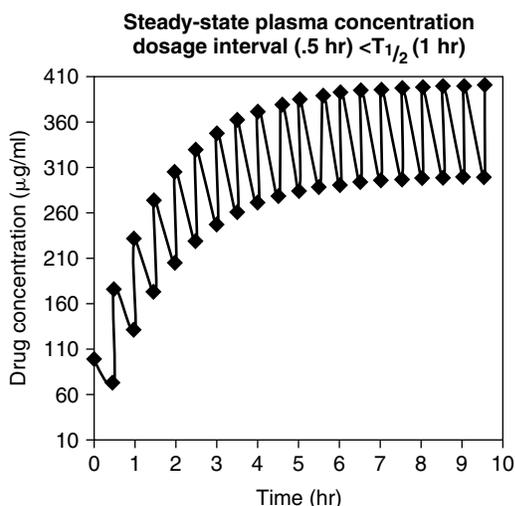

Drugs are often given in multiple-dosage regimens. To predict plasma drug concentrations, it is necessary to decide whether successive doses of a drug have any effect on the previous dose. The *principle of superposition* assumes that early doses of drug do not affect the pharmacokinetics of subsequent doses. For most drugs, as equal doses are given at a constant dosage interval, the plasma concentration-time curve plateaus and a *steady-state* is reached. At steady-state the plasma drug concentration fluctuates between a maximum concentration ( $C_{\max}$ , or peak) and minimum concentration ( $C_{\min}$ , or trough). Once steady-state is reached,  $C_{\max}$  and  $C_{\min}$  are constant and remain unchanged from dose to dose (Figure 4-14). The time to steady-state depends solely on the elimination half-life. It takes approximately six  $T_{1/2}$ s to reach 99% steady-state levels. The drug dose and dosage frequency influence the values of  $C_{\max}$  and  $C_{\min}$  at steady-state, while the dosage frequency and  $T_{1/2}$  influence the fluctuation between  $C_{\max}$  and  $C_{\min}$ .

**FIGURE 4-14** Plasma concentration versus time graph for an IV drug that produces a peak plasma concentration of 100 µg/ml after a single dose. After 6 hours (which equals 6 half-lives), the maximum and minimum drug concentrations become constant, further drug accumulation does not occur, and the drug is steady-state.

**FIGURE 4-16** Plasma concentration versus time graph for a drug with a dosage interval (4 hours) greater than the half-life (1 hour), resulting in no significant drug accumulation at steady-state.

**FIGURE 4-15** Plasma concentration versus time graph for a drug with a dosage interval (0.5 hour) less than the half-life (1 hour), demonstrating significant drug accumulation at steady-state.

### CLINICAL CONSEQUENCES OF DOSAGE INTERVALS LESS THAN THE HALF-LIFE

Drugs such as phenobarbital, potassium bromide, phenylbutazone, and digoxin are commonly given at dosage intervals much shorter than their  $T_{1/2}$ s (Figure 4-15). This results in a  $C_{max}$  at steady-state that is greater than the peak concentration after a single dose. There is minimal fluctuation between  $C_{max}$  and  $C_{min}$ , and missing a single dose will not affect plasma concentrations greatly. There is a lag time to reach the desired plasma concentrations at steady-state, and there will be a lag time for plasma concentrations to change in response to a dose change.

### CLINICAL CONSEQUENCES OF DOSAGE INTERVALS GREATER THAN THE HALF-LIFE

Drugs such as IV formulations of penicillin and cephalosporins are administered at dosage intervals that are greater than the  $T_{1/2}$  (Figure 4-16). As the dosage interval increases,  $C_{max}$  at steady-state is closer in value to the peak concentration after a single dose. If the dosage interval is greater than 10  $T_{1/2}$ s (the time required to eliminate 99.9% of the previous dose), drug accumulation essentially does not occur. There is marked fluctuation between  $C_{max}$  and  $C_{min}$  (peak and trough), and missing a dose will greatly affect plasma concentrations. However, there is minimal lag time to achieve the desired plasma concentration.

### DESIGNING DRUG DOSAGE REGIMENS

The success of drug therapy is highly dependent on the dosage regimen design. Not all drugs require rigid individualization of the dosage regimen. In the case of antimicrobials with a broad safety range, such as the penicillins and cephalosporins, the dosage is not titrated precisely but rather determined on the basis of clinical judgment to maintain an effective plasma concentration above the minimum inhibitory concentration of the bacterial pathogen. For drugs with a narrow therapeutic margin, such as digoxin, the aminoglycosides, and theophylline, the individualization of the dosage regimen is very important. The objective of the dosage regimen for these drugs is to produce a safe plasma drug concentration that does not exceed the minimum toxic concentration or fall below a critical minimum concentration below which the drug is not effective. Factors that influence the concentration of drug attained at the drug's site of action include the dose administered, the route of administration, release and absorption of drug from dosage form, the extent of drug distribution, and the rate of drug elimination.

The horse's age may have a profound effect on drug disposition (Table 4-4).<sup>13</sup> The definition of *geriatric* varies between

TABLE 4-4

Age-Related Changes in Geriatric and Pediatric Patients		
Body Part/Function Affected	Geriatric	Pediatric
Organ blood flow	Decreased	Increased
Total body water	Decreased	Greatly increased
Body fat	Increased	Decreased
Serum proteins	Decreased albumin	Decreased albumin
	Increased globulins	
Hepatic metabolism	Decreased	Greatly decreased

species, and in small animals it varies between breeds. Body composition and regional blood flow change in geriatric horses. Cardiac output decreases, so regional and organ blood flow also decrease. These changes have an impact on drug absorption, distribution, and elimination. Blood flow is preferably redistributed to the brain and heart, so there is an increase in risk of drug toxicity in these organs. Gastrointestinal motility and absorptive capacity are reduced. Hepatocyte number and function decrease along with hepatic and splanchnic blood flow. As renal blood flow decreases, GFR and active secretory capacity of the nephron decreases, resulting in decreased renal clearance of drugs. Lean body mass decreases while fatty tissues increase. The plasma concentrations of water-soluble (low volume of distribution) drugs tend to increase, whereas the plasma concentrations of lipid-soluble (high volume of distribution) drugs tend to decrease. Serum albumin decreases while gamma globulins increase, so total plasma protein concentrations essentially remain the same.

The definition of *neonate* also varies with species and age, but all the determinants of drug disposition are altered as the foal matures.<sup>14</sup> Blood flow to the heart and brain is greater and faster, making the foal more susceptible to drug-induced cardiotoxicity and neurotoxicity. Gastrointestinal absorption tends to be decreased as a result of decreased gastric emptying and decreased intestinal peristalsis. Absorption from intramuscular and subcutaneous sites changes as muscle mass and blood flow change. Neonates have less fat and greater total body water (primarily extracellular fluid) than adults. Therefore low Vd drugs (e.g., gentamicin, ketoprofen) distribute into a larger volume, making it necessary to increase the dose to avoid therapeutic failure. Because of low body fat stores, lipid-soluble drugs will have higher plasma concentrations in foals. For example, moxidectin is much more lipid soluble than ivermectin, so it is more easily overdosed in foals.<sup>15</sup> Drug elimination by both hepatic metabolism and renal excretion is limited in neonates, so drug dosing intervals need to be increased for many drugs, such as aminoglycosides and non-steroidal anti-inflammatory drugs.

In addition, the sick horse usually has impaired drug detoxifying ability. Hepatic damage reduces drug metabolism and may increase drug action, whereas renal damage

and impaired excretion decrease drug clearance. Alterations in gastrointestinal motility affect drug absorption, and are a concern in horses with postoperative ileus. Peripheral circulation is decreased in shock, resulting in decreased absorption of intramuscularly and subcutaneously administered drugs.

## PHARMACOKINETIC-BASED DOSAGE REGIMENS

A drug dose regimen is composed of a dose and a dosing frequency. Some drugs are given as single doses, so a specific plasma concentration will be targeted. When multiple doses of a drug are given, the dosage frequency and drug accumulation must be considered. There are simple calculations that can be used to design a patient-specific dose regimen.

### SINGLE DOSE REGIMEN

A single drug dose has its duration of action determined by the size of the dose, its elimination rate, and the volume of distribution. To calculate a single dose of a drug, or when assuming a once-a-day dosing, only the Vd and the desired plasma concentration are needed:

$$\text{Dose} = (V_d)(C_o)$$

For drugs administered other than intravenously, the dose must be corrected for bioavailability:

$$\text{Dose} = (V_d)(C_o)/(F)$$

### CONTINUOUS RATE INFUSION

When the desired response needs to be constant, the drug may be infused intravenously at a constant rate (R) following the initial IV dose:

$$R = (C)(V_d)(K)$$

The infusion rate is essentially the rate of drug loss from the body (mg/min or mg/hr). Therefore to maintain the established concentration of drug in the body, it is necessary to infuse drug at the rate equal to its loss (K = elimination rate). For example, the vasopressive drugs dopamine and dobutamine have extremely short elimination half-lives, so they must be administered by constant infusion.

### MULTIPLE DOSE REGIMEN

Continuous IV infusion offers the most precise control of drug levels in the body and is essential for precise control of drugs with a narrow safety margin or very rapid elimination. This method is not feasible for most drugs in veterinary medicine. It is possible to maintain an average desired plasma concentration by repeating doses at constant dosing intervals. Obviously, the highest plasma concentrations will occur soon after drug administration, and the lowest concentrations will be just before the next dose is administered. As long as the lowest concentration is acceptable for therapy and the highest concentration does not cause toxicity, these variations in plasma concentration are acceptable:

$$\text{Dose} = \frac{(C_{ave})(V_d)(\tau)}{(1.44)T_{1/2}}$$

where  $\tau$  = dosage interval and 1.44 is a constant to correct for log scale.

### LOADING DOSE FOLLOWED BY MAINTENANCE DOSE REGIMEN

Drugs that have long elimination half-lives, such as digoxin and the sulfonamides, have a long lag time to acceptable drug concentrations and therefore are usually given by a large loading dose ( $Dose_L$ ) followed by maintenance doses ( $Dose_M$ ).

$$Dose_L = \frac{Dose_M}{1 - e^{-K\tau}}$$

### ☞ THERAPEUTIC DRUG MONITORING

Monitoring plasma drug concentrations is valuable if there is a relationship between the plasma drug concentration and the desired clinical effect or an adverse effect. It is particularly helpful in horses with gastrointestinal, cardiovascular, hepatic, or renal disease. It is also useful when many drugs are being administered at the same time and may be altering one another's metabolic effects. Therapeutic drug monitoring (TDM) is often valuable for regulating the dosage of drugs used chronically or prophylactically. For those drugs in which plasma concentration and clinical effect are not related, other pharmacodynamic parameters may be monitored. For example, clotting times may be measured in patients on anticoagulant therapy.

The drugs for which TDM is commonly used are characterized by serious toxicity (e.g., digoxin, phenobarbital,

aminoglycosides); a steep dose-response curve, wherein a small increase in dose can cause a marked increase or decrease in response (e.g., theophylline); marked pharmacokinetic variability among individual patients, so dose is poorly predictive of plasma drug concentration (e.g., cyclosporine); easily saturated elimination mechanisms that lead to nonlinear kinetics; or when the cost of therapy justifies confirming a desired plasma drug concentration (Table 4-5).

### PERFORMING THERAPEUTIC DRUG MONITORING

Samples for TDM should not be submitted until plasma drug concentrations have reached steady-state in the patient (after approximately 6 elimination half-lives have passed). For conditions in which steady-state concentrations must be reached immediately, administer a loading dose. The risk of adverse drug reactions is obviously increased, so TDM can be used to proactively determine the proper maintenance dose. When a loading dose is being administered, TDM should be done after the loading dose to establish a baseline. The second TDM should be one drug half-life later to ensure that the maintenance dose is able to maintain the concentrations achieved by the loading dose. If the drug concentrations at the second sample do not match those of the first sample, the maintenance dose can be adjusted at this time rather than waiting for steady-state, with the risk of therapeutic failure or toxicity. The third time to do TDM is at steady-state to ensure an appropriate dosage regimen.

TABLE 4-5

Recommendations for Therapeutic Drug Monitoring					
Drug	Therapeutic Range	Vd (L/kg)	T <sub>1/2</sub>	Time to Steady-State	Sample Collection
Amikacin	25 µg/ml peak <5 µg/ml trough	0.25	1-2 h	1 day	Peak: 0.5-1 hour after administration  Trough: just before next dose or 8 hours after dosing if using once-daily administration; collect in plastic only
Bromide	Monotherapy: 2-3 µg/ml (20-30 mmol/L) W/phenobarb: 1-2 µg/ml (10-20 mmol/L)		24 d	4 months	Anytime
Digoxin	0.9-3.0 ng/ml	6.7	23 h	7 days	2-5 h post dose, collect in glass only
Gentamicin	10 µg/ml peak <2 µg/ml trough	0.3	1 h	1 day	Peak: 0.5-1 hour after administration  Trough: just before next dose or 8 hours after dosing if using once-daily administration; collect in plastic only
Phenobarbital	14-45 µg/ml (70-170 mmol/L)	0.96	24 hours	6 days	Anytime
Theophylline	10-20 µg/ml	.8	13 hours	3 days	1-2 hours postdose

## BOX 4-4

**INTERPRETING THE RESULTS OF THERAPEUTIC DRUG MONITORING****Plasma Concentrations Lower Than Anticipated**

Poor compliance with regimen  
 Error in dosage regimen  
 Wrong product (e.g., controlled release instead of immediate release)  
 Poor bioavailability  
 Rapid elimination  
 Increased apparent volume of distribution  
 Poor timing of blood sample

**Plasma Concentrations Higher Than Anticipated**

Poor compliance with regimen  
 Dose incorrect  
 Very rapid drug absorption  
 Decreased apparent volume of distribution  
 Slow elimination

**Plasma Concentration Correct, but Poor Patient Response to Therapy**

Diagnosis incorrect  
 Altered tissue receptor sensitivity (tolerance)  
 Drug interaction at receptor site

The number of samples collected for TDM depends on the drug, its  $T_{1/2}$ , and the reason for monitoring. To determine optimal aminoglycoside therapy, peak and trough samples are needed. To allow for the distribution phase, blood sampling for the peak concentration is done 0.5 to 1 hour after administration, and the trough sample is usually taken before the next dose. With very long elimination half-lives and twice-daily dosing, there are no statistically significant differences between  $C_{max}$  and  $C_{min}$  values for phenobarbital or potassium bromide. Therefore a single sample can be collected for TDM at any time during the dosing interval. However,  $C_{max}$  and  $C_{min}$  samples should be collected in any horse that is not responding as expected to therapy in order to determine if the horse has a shorter- or longer-than-normal elimination time for the drug (Box 4-4).

**ADJUSTMENT OF DOSAGE REGIMENS**

Adjustment of the dosage regimen is frequently required when drugs are administered to diseased horses, whereas the dosage regimens have been established in relatively healthy, normal horses. Adjustment is indicated when drug elimination or the drug's distribution is significantly altered in the animal. In general, the following rules are true:

- If the volume of distribution changes, change the drug dose.
- If the elimination of the drug changes, change the dosing interval.

For drug dosage regimens determined by TDM, modifications are made on a percentage basis:

$$\text{New Dose} = \text{Old Dose} \times (\text{Target} + \text{Concentration} \div \text{Measured Concentration})$$

**☞ DOSAGE ADJUSTMENTS IN RENAL FAILURE**

The ultimate route for drug elimination from the body is the kidney. Therefore it is not surprising that renal disease has a profound impact on the disposition of drugs administered to animals in renal failure. With reduced renal clearance, the parent drug, its metabolites, or both may accumulate in the patient and cause toxicity. Loss of proteins and electrolytes in urine and the alterations in acid-base balance associated with renal failure affect the pharmacokinetics and pharmacodynamics of drugs. Enhanced drug activity or toxicity can occur as a result of synergy with uremic complications. Altogether, these effects make it difficult to determine safe and effective drug dosages for veterinary patients in renal failure.

The goal of dosage adjustment is to provide a drug concentration-time profile in the horse with renal failure that is as similar as possible to that of a normal horse. The best approach to modifying drug therapy in horses with renal failure would be to carry out therapeutic drug monitoring and adjust the dosage for each patient. This is possible with some drugs, such as gentamicin and amikacin, but it is impractical and cost prohibitive for most drugs used in veterinary practice. The best approach for most drugs is to estimate a corrected dose from available renal function tests and then to monitor the patient closely for evidence of efficacy or toxicity. For drugs that are eliminated primarily by renal mechanisms, creatinine (Cr) clearance correlates well with drug clearance. Cr is an endogenous product of creatinine phosphate metabolism in muscle. It is removed by glomerular filtration, and serum concentrations are relatively constant in healthy people and animals. The elimination half-life of a drug that is eliminated in urine remains stable until Cr clearance is reduced to 30% to 40% of normal, which is why drug dosage regimens are typically not adjusted until two thirds of renal function has been lost.<sup>16</sup> In human patients Cr clearance is quantified by determining urinary Cr excretion over a 24-hour period. The measured Cr clearance is then used in formulas to make drug dosage adjustments. Unlike in human medicine, values for Cr clearance are not usually available for veterinary patients. When Cr clearance is not available, a single value of the patient's serum creatinine can be substituted in the formulas. However, the relationship between serum creatinine is not linear once serum creatinine is above 4 mg/dl, so the adjustment formulas are even less accurate for predicting an ideal dose adjustment.<sup>16</sup> These formulas do not account for changes in the volume of distribution, degree of protein binding, and non-renal clearance mechanisms of the drug that may be caused by the renal dysfunction. Therefore these dosage adjustments must be regarded as preliminary estimations to be followed by adjustments based on observed clinical response.

**DOSE-REDUCTION METHOD**

With the dose-reduction method the normal dosage regimen is adjusted by reducing the drug dose and maintaining the drug dosing interval.

$$\text{Adjusted dose} = \text{Normal Dose} \times (\text{Patient's Cr clearance} \div \text{Normal Cr clearance})$$

or

$$\text{Adjusted dose} = \text{Normal Dose} \times (\text{Normal Cr} / \text{Patient's Cr})$$

## INTERVAL-EXTENSION METHOD

With the interval-extension method the drug dose is maintained and the drug dosing interval is extended.

$$\text{Adjusted Interval} = \text{Normal Interval} \left[ \frac{1}{\text{Patient's Cr clearance/Normal Cr clearance}} \right]$$

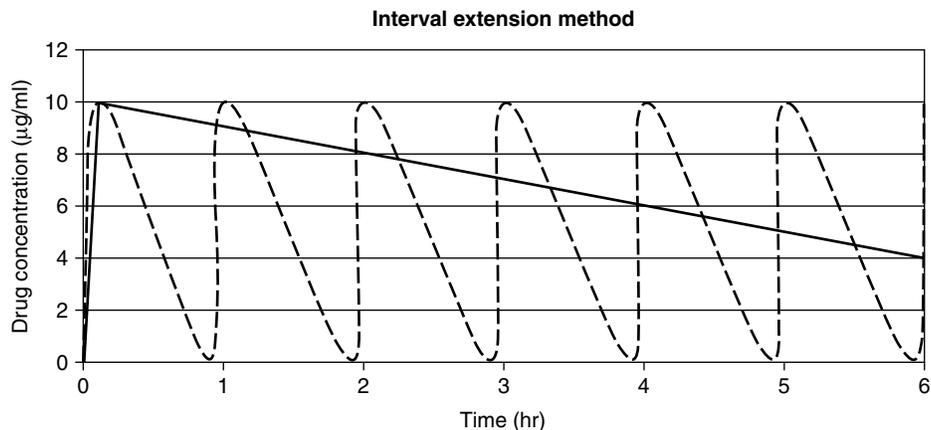

or

$$\text{Adjusted Interval} = \text{Normal Interval} \left[ \frac{1}{\text{Normal Serum Cr/Patient's Serum Cr}} \right]$$

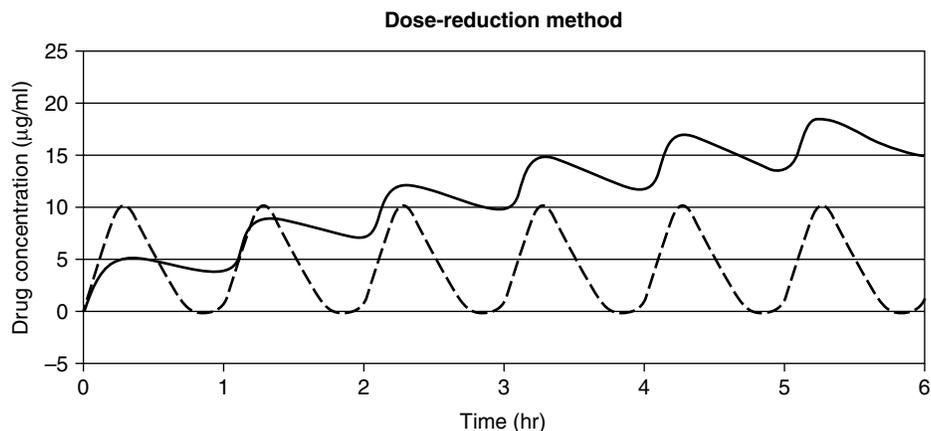

Both methods attempt to keep the average plasma drug concentrations constant. The interval-extension method produces  $C_{\max}$  and  $C_{\min}$  values similar to those seen in healthy patients (Figure 4-17), but it does produce substantial periods of time during which drug concentrations may be subtherapeutic. This is the preferred method with aminoglycosides, which have a long postantibiotic effect and in which a low trough concentration is desirable to reduce the risk of nephrotoxicity. Depending on the relationship of the elimination half-life to the dosage interval, significant drug accumulation may occur

with the dose-reduction method (Figure 4-18), but at steady-state there are no periods of time during which concentrations are subtherapeutic. This is the preferred method for the penicillin and cephalosporin antibiotics, wherein maintaining the plasma concentration above the pathogen's minimum inhibitory concentration (MIC) correlates with efficacy and the drugs are relatively nontoxic even if accumulation occurs. To decide which method to use, the practitioner should determine if drug efficacy and toxicity are related to peak, trough, or average plasma concentrations and then select the method that best balances efficacy against potential toxicity. The interval-extension method is more convenient for the client because the normal recommended dose is simply administered less frequently. In addition, if the drugs are available only in fixed dosage forms (e.g., capsules, unbreakable tablets), it is easier to adjust the dosage interval.

Because the elimination half-life is prolonged in patients with renal disease and it always takes six elimination half-lives to reach 99% of steady-state concentrations, there is a delay in reaching steady-state in horses with renal failure compared with horses with normal renal function. Therefore it may be necessary to administer a loading dose to rapidly achieve therapeutic drug concentrations. If the dose-reduction method

**FIGURE 4-17** Comparison of an interval-extension dosage regimen (*solid line*) in a renal failure patient with a normal dosage regimen in a healthy patient (*dotted line*). Normal elimination half-life was 15 minutes; in the patient with renal failure, it increased to 8 hours.

**FIGURE 4-18** Comparison of a dose-reduction dosage regimen in a renal failure patient (*solid line*) compared with a normal dosage regimen in a healthy patient (*dotted line*). Normal elimination half-life was 15 minutes; in the renal failure patient, it increased to 8 hours.

is used, this is achieved by giving the usual dose initially, followed by the reduced dose at the next time. If the interval-extension method is used, this is accomplished by giving a double dose initially.

For renal failure patients in general, the practitioner must consider the following:

1. Avoid using any drugs at all, unless there are definite therapeutic indications. If a drug is absolutely necessary, try to select one that is hepatically metabolized and excreted in bile rather than eliminated by the kidneys (e.g., doxycycline).
2. If therapeutic drug monitoring is available, tailor the drug dosage regimen to that specific patient.
3. If therapeutic drug monitoring is unavailable, determine if there are clinically proven, adjusted dosage regimens for specific drugs. The package insert that accompanies pharmaceuticals intended for human use often gives guidelines for adjusting dosages.
4. If the drug has not been sufficiently studied to have dosage adjustment recommendations, determine if there is sufficient information about its kinetics to estimate the proper drug dose in renal failure.
5. Carefully monitor treated patients for signs of efficacy and toxicity.

## ANTIMICROBIAL THERAPY

Patricia M. Dowling, Jennifer L. Davis

Successful antimicrobial therapy relies on administering sufficient doses so that pathogens at the site of infection are killed or suppressed to the extent that they can be eliminated by the host's immune system. There are complex pharmacokinetic (PK) and pharmacodynamic (PD) relationships among the host, the bacteria, and the antimicrobial. Pharmacokinetics is what the body does to a drug; the processes of absorption, distribution to the various organs and tissues, metabolism of lipid-soluble drugs into water-soluble metabolites, and finally renal excretion. Pharmacodynamics is what the antimicrobial does to the bacteria. It describes the drug action and responses of the bacteria. Pharmacokinetics and pharmacodynamics are interrelated in that PK effects determine the amount of drug that reaches the site of action, and the intensity of a PD effect is associated with the drug concentration at the site of action. New information on the PK/PD relationships of veterinary pathogens and antimicrobials is rapidly emerging and changing the way in which the dosage of antimicrobials is determined in equine practice.

## ☞ RATIONAL USE OF ANTIMICROBIAL AGENTS

The following questions must be considered when developing an antimicrobial regimen:

1. *Does the diagnosis warrant antimicrobial therapy?* Using antimicrobials to treat minor infections or purely viral or inflammatory diseases is irrational, expensive, and potentially hazardous to the patient; it also encourages antimicrobial resistance. Clients have come to expect antimicrobials for trivial infections or in the event that an infection may develop. Equine practitioners must resist client pressure to use or prescribe unnecessary drugs.

2. *What organism(s) are likely to be involved?* For many infections the likely organism can be successfully predicted on the basis of the history and clinical signs.
3. *What is the *in vitro* antimicrobial susceptibility of the organism?* For many pathogens the *in vitro* susceptibility can be reliably predicted. For example, *Streptococcus* species are typically susceptible to penicillin. However, many gram negative bacteria have unpredictable susceptibilities, and susceptibility testing is essential for determining appropriate drug therapy.
4. *In what part of the body or tissue is the infection located? Will the antimicrobial penetrate to the infection?* Consideration of the pathophysiology of the infection will help the practitioner select an effective therapy. Treatment of sequestered infections such as mastitis or meningitis requires antimicrobials that readily cross membrane barriers. Antimicrobials characterized by low values for volume of distribution (Vd) are unlikely to reach therapeutic concentrations in such sites.
5. *Will the antimicrobial be effective in the local environment of the organism?* The local infection environment reduces the efficacy of some antimicrobials. Sulfonamides are ineffective in purulent debris because para-amino benzoic acid (PABA) released from decaying neutrophils serves as a PABA source for bacteria and reduces the competitive effect of the sulfonamide. Aminoglycosides are ineffective in an abscess because of the acidic, anaerobic environment along with the presence of nucleic acid material from decaying cells, which inactivates the aminoglycosides.
6. *What drug formulation and dose regimen will maintain the appropriate antimicrobial concentration for the proper duration of time?* Label doses apply only to label pathogens. For off-label uses the dosage regimen must be adjusted depending on the antimicrobial susceptibility of the specific pathogen.
7. *What adverse drug reactions or toxicities might be expected? Do the benefits outweigh the risks?* The risks of adverse reactions from antimicrobials are often underappreciated. A serious adverse reaction may complicate treatment of the original problem and even be fatal. Failure to communicate the risks of adverse drug reactions to clients is a common cause of litigation.
8. *Can you choose an approved product? If using an antimicrobial in an off-label manner, can you determine appropriate withdrawal times for food animals? Can you determine appropriate withdrawal times for performance horses?* The antimicrobials used in horses are not approved for horses intended for food, and information on appropriate withdrawal times is lacking. Also, competitive horses are subject to the rules of the sport's governing association regarding drugs, which vary according to the organization, state or province, and country. Understanding the principles of drug elimination allows the practitioner to determine appropriate withdrawal times for competitive or slaughter horses.

## DOCUMENTING THE INFECTION

A diagnosis must be established before any therapy can be administered. It is not always necessary to culture samples from all patients with infectious diseases to identify the organism involved. Often the practitioner can base a diagnosis on

clinical experience from similar cases. The signs of some infectious diseases are so obvious that the need for microbiological identification is minimal; however, for those infectious diseases of unknown cause or for those attributable to organisms with irregular antimicrobial susceptibility, there is no substitute for isolation and identification of the causative agent. For these organisms initial therapy while waiting for culture results must include an antimicrobial with a broad spectrum of activity. However, broad spectrum drugs are usually more toxic and more expensive than narrow spectrum drugs. The use of broad spectrum antimicrobials for relatively trivial infections encourages development of antimicrobial-resistant organisms. Without evidence of a susceptible pathogen, such use is irrational and exposes the patient to unnecessary risks.

Whenever possible, the veterinarian should obtain a representative sample of material from a clinical patient. Beware of sampling grossly contaminated sites such as purulent nasal discharges. An immediate Gram stain can be performed from a direct smear and will direct initial therapy. Samples are submitted for appropriate culture and identification. If the identified organism has unpredictable susceptibility patterns, the practitioner should request a susceptibility test, such as Kirby-Bauer, E test, or MIC method.

In some clinical cases identification of the pathogen may be made by serologic demonstration of antibodies (e.g., anaplasmosis, leptospirosis, brucellosis).

### ANTIMICROBIAL DOSAGE REGIMEN DESIGN

Successful antimicrobial therapy relies on administering sufficient doses so that pathogens at the site of infection are killed or suppressed to the extent that they can be eliminated by the host's immune system. The relationship among the host, the bacteria, and the drug may be very complex. High plasma antimicrobial concentrations are *assumed* to be advantageous in that a large concentration of drug will diffuse into various tissues and body fluids. Drug concentration at the infection site is assumed to be of major importance in determining drug efficacy. Drug movement from the plasma to extravascular tissues depends on molecular size, lipid solubility, drug pKa, local pH, specific cellular transport mechanisms, and degree of

protein binding. The relationship between bacteria and drug in the laboratory is described by the following:

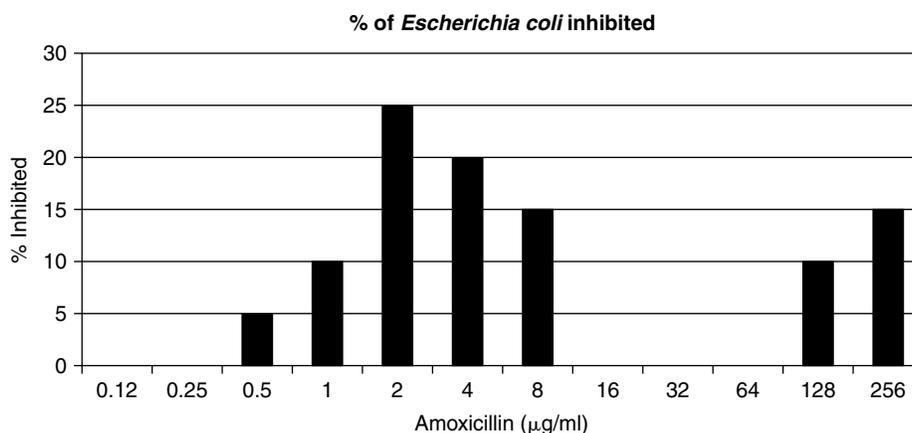

**MIC:** The lowest drug concentration that inhibits bacterial growth.

**Minimum bactericidal concentration (MBC):** The lowest drug concentration that kills 99.9% of bacteria.

The MICs are used to determine the drug dose, in an attempt to achieve blood and tissue concentrations that exceed the in vitro MIC for the pathogen.

### INTERPRETING MINIMUM INHIBITORY CONCENTRATIONS

According to the Clinical Laboratory Standards Institute (CLSI, formerly known as NCCLS) definition, the MIC values are derived as serially doubled concentrations (in  $\mu\text{g/ml}$ ). Susceptible (S), intermediate (I), and resistant (R) designations are derived from *breakpoints* assigned by laboratory-based PK and PD data, pathogen population MIC distribution, and clinical trial results.<sup>1</sup> A CLSI-approved breakpoint is specific for the animal species, disease, pathogen, antimicrobial, and dosage regimen. When a pathogen is reported as *susceptible*, it means that the recommended dosage of the antimicrobial will reach plasma or tissue concentrations that will inhibit bacterial growth in vivo. When a pathogen is reported as *resistant*, inhibitory antimicrobial concentrations are not safely attainable in the patient. If the pathogen is reported as *intermediate*, then administering the antimicrobial at higher-than-recommended doses may result in effective therapy.<sup>2</sup> Susceptibility testing results predict which bacteria have intrinsic or acquired resistance mechanisms to a particular antimicrobial. In vitro tests do this because bacterial susceptibility usually clusters around a small range of MICs. In Figure 4-19 the bacterial inhibition of *E. coli* by amoxicillin has a bimodal distribution. The large cluster of *Escherichia coli* inhibited by amoxicillin concentrations of 0.5 to 16  $\mu\text{g/ml}$  are considered the *normal range* and 16  $\mu\text{g/ml}$  is considered the breakpoint of susceptibility. *E. coli* requiring an amoxicillin concentration of 16  $\mu\text{g/ml}$  to be inhibited are likely to have intrinsic or acquired resistance mechanisms, and amoxicillin is unlikely to be a successful treatment for patients infected with these isolates. In vitro susceptibility tests predict treatment outcome

**FIGURE 4-19** The percentage of *Escherichia coli* inhibited by increasing concentrations of amoxicillin has a bimodal distribution. *E. coli* requiring more than 16  $\mu\text{g/ml}$  of amoxicillin to be inhibited are likely to have intrinsic or acquired resistance mechanisms. Amoxicillin therapy in patients with this pathogen is unlikely to be effective.

fairly well, considering that many variables in the host-pathogen relationship are not taken into account.<sup>1</sup> Antimicrobial susceptibility data may not account for the following:

1. *Host defenses*: The interaction between the host and the pathogen is complex and not predicted by *in vitro* tests. Antimicrobial drug action takes place in concert with host defenses such as humoral and cell-mediated immunity; complement components; and nonspecific antibacterial factors such as lactoferrin, lactoperoxidase, and lysozyme.<sup>3</sup>
2. *Drug distribution in the body*: The *S*, *I*, and *R* designations assigned by the microbiology laboratory are typically based on safely achievable plasma concentrations. This does not necessarily take into account extremely high concentrations of antimicrobials achieved in organs and fluids of excretion (kidney, urine, bile) or with local administration of high drug concentrations (e.g., ophthalmic ointments). Macrolide antimicrobials are characterized by negligible plasma concentrations despite very high lung concentrations.<sup>4</sup> Pathophysiology may alter drug distribution, and some antimicrobials, such as the tetracyclines, accumulate in pneumonic lung tissues.<sup>5</sup>
3. *Growth rates and size of inoculum*: The incubator of the microbiology laboratory is an ideal setting for bacterial growth. Conditions are managed to promote rapid growth, and rapidly dividing bacteria are more susceptible to antimicrobial drugs. Replication rates may be much slower at the infection site, and MICs are generally unreliable for slow-growing bacteria. Standardized inoculums used in the laboratory may over- or under-represent pathogen numbers in infected tissues.<sup>3</sup>
4. *Mixed infections*: Separate susceptibility testing of pathogens in a mixed infection does not account for the pathologic synergism between bacteria. The by-products of one bacterium may facilitate the establishment and growth of another.<sup>6</sup>
5. *Infection environment*: Many antimicrobials are inactive in purulent exudate, which is typically anaerobic, acidic, and hyperosmolar. Some antimicrobials have different activity in body fluids (e.g., plasma, milk, bile) than in nutrient-rich laboratory media. Deposition of fibrin may alter tissue penetration of antimicrobials. Many bacteria are capable of producing a polysaccharide slime capsule to protect them from host factors. Mastitis pathogens typically increase their replication rate when incubated in mastitic milk.<sup>3</sup>
7. *Topically administered antimicrobials are not tested*: Veterinary microbiology laboratories may not routinely do susceptibility testing for antimicrobials that are used only topically. Polymixin B is one of the most effective antimicrobials for superficial *Pseudomonas* infections,<sup>7</sup> but because it causes neurotoxicity and nephrotoxicity if administered systemically, it is rarely included in susceptibility testing. Bacitracin and mupirocin are other examples of topical antimicrobials rarely tested by diagnostic laboratories.
8. *In vivo synergism may occur with antimicrobial combinations*: Despite predictions of resistance from susceptibility testing, therapy may be successful because of synergistic combinations of antimicrobials. Synergism between penicillins and aminoglycosides has been recognized for streptococcal, enterococcal, and staphylococcal infections.<sup>8</sup> The synergism is attributed to increased cellular uptake of the aminoglycoside after cell wall damage from the penicillin.

9. *The CLSI breakpoints may be inappropriate*: The CLSI breakpoints were originally established with bacterial isolates from humans, using human PK data and clinical trials. A veterinary subcommittee was established in 1993 and has proposed veterinary-specific guidelines for susceptibility tests for a limited number of antimicrobials.<sup>9</sup> Currently, only ceftiofur, ampicillin, and gentamicin have CLSI-approved breakpoints for equine pathogens. Diagnostic laboratories use human-derived breakpoints for other bacteria-drug combinations.

Therefore the true relevance of any *in vitro* MIC in predicting the *in vivo* results of drug therapy is questionable. The MIC results are not a positive order to use a particular antimicrobial. Selection of the optimal antimicrobial must take into consideration other factors, such as the site of infection, pharmacokinetics of the drugs, and effect of underlying diseases. Considering all of these factors, most veterinarians determine a drug dosage regimen that uses a target plasma drug concentration based on a multiple of the *in vitro* MIC (usually 2 to 10).

## BACTERICIDAL VERSUS BACTERIOSTATIC ANTIMICROBIALS

It is common to classify antimicrobials as *bactericidal* or *bacteriostatic* (Box 4-5). If the ratio of the MBC to MIC is small (<4 to 6), a drug is considered bactericidal, and it is possible to obtain drug concentrations that will kill 99.9% of the organisms exposed. If the ratio of MBC to MIC is large, it may not be possible to safely administer dosages of the drug to kill 99.9% of the bacteria, and the drug is considered bacteriostatic.

For many drugs the distinction between bactericidal and bacteriostatic is not exact and depends on the drug concentration attained in the target tissue and the pathogen involved. Specific situations in which a bactericidal drug is preferred over a bacteriostatic drug include immunocompromised patients such as neonates, life-threatening infections such as bacterial endocarditis and meningitis, and surgical prophylaxis.

## POSTANTIBIOTIC EFFECT

For some bacteria-antimicrobial interactions, bacterial growth remains suppressed for a period after drug concentration has decreased below the MIC.<sup>10</sup> This postantibiotic effect (PAE) may be the reason that dosage regimens that fail to maintain

drug concentration above the MIC are still efficacious. The PAE depends on the antimicrobial and the bacterial pathogen (Table 4-6).

### PHARMACOKINETIC-PHARMACODYNAMIC RELATIONSHIPS

The PK-PD relationship between an antimicrobial and a pathogen determines the way that the dosage regimen is calculated.<sup>11</sup> The PK parameters used in drug dosage design are the area under the plasma concentration versus time curve (AUC) from 0 to 24 hours, the maximum plasma concentration (C<sub>max</sub>), and the time the antimicrobial concentration exceeds a defined PD threshold (T). The most commonly used PD parameter is the MIC. In relating the PK and PD parameters to clinical efficacy, antimicrobial drug action is classified as either concentration dependent or time dependent (Box 4-6; Figures 4-20 and 4-21). For antimicrobials whose efficacy is concentration dependent, high plasma concentrations relative to the MIC of the pathogen (C<sub>max</sub>:MIC) and the area under the plasma concentration-time curve that is above the bacterial MIC during the dosage interval (area under the inhibitory curve, AUC<sub>0-24</sub>:MIC) are the major determinants of clinical efficacy. These drugs also have prolonged PAEs, thereby allowing once-a-day dosing while maintaining maximum clinical efficacy. For fluoroquinolones (e.g., enrofloxacin, orbifloxacin, difloxacin, marbofloxacin), clinical efficacy is associated with achieving either an AUC<sub>0-24</sub>:MIC greater than 125 or a C<sub>max</sub>:MIC greater than 10. For aminoglycosides (e.g., gentamicin, amikacin), achieving a C<sub>max</sub>:MIC greater than 10 is considered optimal for efficacy. Other antimicrobials that appear to have concentration-dependent activity include metronidazole (C<sub>max</sub>:MIC>10-25) and azithromycin (AUC<sub>0-24</sub>:MIC):MIC>25). For some pathogens with very high MIC values, such as *Pseudomonas aeruginosa*, achieving the optimum PK/PD ratios may be impossible with label or even higher-than-label dosages. In such cases underdosing is ineffective and merely contributes to antimicrobial resistance.

For antimicrobials whose efficacy is time dependent, the time during which the antimicrobial concentration exceeds the MIC of the pathogen determines clinical efficacy (T>MIC). How much above the MIC and for what percentage of the dosing interval concentrations should be above the MIC are still

#### BOX 4-6

being debated and are likely specific for individual bacteria-drug combinations. Typically, exceeding the MIC by 1 to 5 multiples for between 40% and 100% of the dosage interval is appropriate for time-dependent killers. The T>MIC should be closer to 100% for bacteriostatic antimicrobials and for patients that are immunosuppressed. These drugs typically require frequent dosing or constant rate infusions for appropriate therapy. In sequestered infections penetration of the antimicrobial to the site of infection may require high plasma concentrations to achieve a sufficient concentration gradient. In such cases the AUC<sub>0-24</sub> hr:MIC and/or C<sub>max</sub>:MIC may also be important in determining efficacy of otherwise time-dependent antimicrobials.

### DESIGNING THE DRUG DOSAGE REGIMEN

When designing specific antimicrobial dosage regimens, the practitioner targets a specific plasma drug concentration. High plasma antimicrobial concentrations are *assumed* to be advantageous in that a large concentration of drug will diffuse into various tissues and body fluids. In light of the previous information, antimicrobial dosage regimens are designed in one of two ways: either to maximize plasma concentration or to

**FIGURE 4-20** For time-dependent antimicrobials the time during which the antimicrobial concentration exceeds the minimum inhibitory concentration of the pathogen determines clinical efficacy.

**FIGURE 4-21** For concentration-dependent antimicrobials, the inhibitory quotient (*IQ*) and the area under the inhibitory curve are the major determinants of clinical efficacy.

provide a plasma concentration above the bacterial MIC for some percentage of the dosage interval.

For *concentration-dependent killers* with a prolonged PAE whose PK-PD relationship is to have an ideal  $C_{max}:MIC$ , and if the volume of distribution ( $V_d$ ) of the antimicrobial is known, a precise drug dosage regimen for the pathogen can be calculated from the following equation:

$$\text{Dose} = (V_d) (\text{desired plasma concentration})$$

where the desired plasma concentration is some multiple of the MIC (usually 8-10) and once-daily dosing is assumed.

For *concentration-dependent killers* whose PK-PD relationship is to have an ideal  $AUC_{0-24}:MIC$ , the following equation can be used to calculate a daily dose:

$$\text{Dose} = (AUC_{0-24}:MIC) (MIC) (Cl) \\ (F) (24 \text{ hr})$$

where  $AUC_{0-24}:MIC$  is  $\geq 100$ ,  $Cl$  is clearance (volume of blood cleared of drug per day in ml/kg/day), and  $F$  is bioavailability.

For *time-dependent killers* the objective is to keep the average plasma drug concentration above the pathogen's MIC for the duration of the dosage interval. Again, by using  $V_d$  and

elimination half-life information, the practitioner can precisely calculate a dosing regimen:

$$\text{Dose} = (\text{desired avg plasma conc}) (V_d)(\text{dosage interval}) \\ 1.44(t_{1/2})$$

## CONCURRENT USE OF ADDITIONAL ANTIMICROBIALS

Combination antimicrobial therapy is commonplace in veterinary medicine, but combination therapy has rarely been demonstrated as superior to single drug therapy through clinical trials. Use of multiple antimicrobial drugs should be limited to the following cases:

1. Known synergism against specific organisms<sup>8</sup>
2. Prevention of rapid development of bacterial resistance<sup>12</sup>
3. To extend antimicrobial spectrum of initial therapy of life-threatening conditions<sup>13</sup>
4. To treat known mixed bacterial infections<sup>14</sup>

Multiple antimicrobial therapy is implicated as a cause of diarrhea in horses, likely from the additive antibacterial

effects against normal gastrointestinal flora.<sup>15</sup> Antagonistic combinations such as penicillin and tetracyclines should be avoided; penicillins require actively dividing bacteria to exert their bactericidal effects on the bacterial cell wall, and the bacteriostatic action of tetracyclines suppress cell wall formation.<sup>2</sup>

## ☉ PROPHYLACTIC USE OF ANTIMICROBIALS

There are few reports examining the efficacy of prophylactic antimicrobials in veterinary medicine in general and in horses specifically.<sup>16</sup> Because of the lack of controlled veterinary studies, information on prophylaxis is largely extrapolated from human studies. The relative risk of infection must warrant the use of prophylactic antimicrobials. The risks of adverse effects from the prophylactic drug must be less than the risk of development of disease and its consequences. In veterinary medicine most of the risk of infection depends on the skill of the surgeon and handling practices in the hospital.<sup>17</sup> The organism or organisms that are likely to cause the infection and their antimicrobial susceptibility should be known or accurately predicted. The antimicrobial should be bactericidal and must be administered and distributed to the site of potential infection before the onset of infection. The veterinarian should consider drugs that can be given intravenously and have a high volume of distribution. Drugs used prophylactically should not be those that would be used therapeutically. The duration of antimicrobial prophylaxis should be as abbreviated as possible. Most of the time a single preoperative dose is sufficient and cost effective.<sup>18</sup>

## ☉ β-LACTAMS: PENICILLINS AND CEPHALOSPORINS

The β-lactam antibiotics are among the most commonly used antibiotics. Their use and popularity are due to their safety, efficacy, flexibility in dosage forms, and relatively low expense. Both penicillins and cephalosporins have a four-member β-lactam ring. The β-lactam ring is unstable and is a major target for bacterial resistance mechanisms.

### MECHANISM OF ACTION

β-lactam antibiotics act on enzymes called *penicillin-binding proteins (PBPs)* responsible for building the bacterial cell wall.<sup>2</sup> Therefore they are active only against rapidly multiplying organisms in which the binding of penicillin within the cell wall interferes with production of cell wall peptidoglycans and results in cell lysis in a hypo- or iso-osmotic environment. There may be anywhere between two to eight PBPs in a bacteria. When β-lactam antibiotics bind covalently and irreversibly to the PBPs, the bacterial cell wall is disrupted and lysis occurs. Differences in the spectrum and action of β-lactam antibiotics are due to their relative affinity for different PBPs. To bind to the PBPs, the β-lactam antibiotic must first diffuse through the bacterial cell wall. Gram negative organisms have an additional lipopolysaccharide layer that decreases antibiotic penetration. Therefore gram positive bacteria are usually more susceptible to the action of β-lactams than gram negative bacteria. Because the penicillins poorly penetrate mammalian cells, they are ineffective in the treatment of intracellular pathogens.

## RESISTANCE MECHANISMS

Resistance mechanisms to the β-lactams include failure of the antibiotic to penetrate the outer bacterial cell layers and alteration of PBPs that decrease the affinity of the PBP for the antibiotic.<sup>19–21</sup> Alterations of the PBPs occur with methicillin-resistant staphylococci.<sup>22</sup> A third mechanism of resistance is from production of β-lactamase enzymes.<sup>23,24</sup> There may be as many as 50 β-lactamase enzymes (penicillinases, cephalosporinases) produced by bacteria. These enzymes hydrolyze the cyclic amide bond of the β-lactam ring and inactivate the antibiotic. Staphylococcal β-lactamases are produced by coagulase positive *Staphylococcus* spp. The synthesis of these enzymes is plasmid encoded, and the enzymes are exocellular. These enzymes typically do not inactivate cephalosporins and antistaphylococcal penicillins. Most of these β-lactamases can be inactivated by inhibitors such as clavulanic acid and sulbactam. The Gram negative β-lactamases are a diverse group of enzymes that can be chromosomal coded, plasmid coded, or both. *E. coli* lactamase is coded by plasmids and hydrolyzes both cephalosporins and penicillins. Chromosomal-mediated lactamases hydrolyze penicillin, cephalosporins, or both.

## ☉ BENZYL PENICILLIN (PENICILLIN G)

Penicillin G was the first antibiotic developed and remains one of the most effective antibiotics available. It is still the initial drug of choice for many bacterial infections.

### SPECTRUM OF ACTIVITY

Aerobic bacteria susceptible to penicillin G include most β-hemolytic streptococci, β-lactamase-negative staphylococci, *Actinomyces* spp., some *Bacillus anthracis*, *Corynebacterium* spp., and *Erysipelothrix rhusiopathiae*.<sup>25</sup> Most species of anaerobes are susceptible, excluding β-lactamase-producing *Bacteroides* spp.<sup>26</sup> Penicillin G is easily inactivated by β-lactamases and has little efficacy against organisms that can produce these enzymes. In addition, penicillin G is ineffective against those bacteria that are resistant by other mechanisms, such as having a relatively impermeable cell wall. Therefore penicillin G has little activity against many staphylococci and most gram negative bacteria.<sup>23</sup>

## PHARMACOKINETICS

### ABSORPTION

Because penicillin is a weak acid with a pKa of 2.7, it is highly ionized in plasma. Gastric absorption of penicillin G is poor because it is rapidly hydrolyzed in the acid environment of the stomach. Phenoxymethyl penicillin (penicillin V) can be given orally to horses and has a half-life of absorption of 0.2 hours.<sup>27</sup> The sodium and potassium salts of penicillin G are the only dosage forms that are suitable for IV administration and are quickly absorbed from intramuscular or subcutaneous sites of administration.<sup>28</sup> Procaine penicillin G is more slowly absorbed from intramuscular administration than are the sodium or potassium salts and so produces lower but more sustained plasma concentrations. Benzathine penicillin G is the least soluble of the dosage forms; it is very slowly absorbed, producing sustained but subtherapeutic plasma concentrations of penicillin G.<sup>28</sup> The rate of absorption from intramuscular injections of procaine penicillin G varies depending on the

injection site, with injections into the neck muscle producing more rapid absorption and higher plasma concentrations than with injections into the hindquarters.<sup>29</sup>

### DISTRIBUTION

The Vd of sodium penicillin G is 0.7 L/kg,<sup>30</sup> and there is a moderate degree of protein binding (52%-54%).<sup>31</sup> After absorption penicillin is distributed mainly in extracellular fluid and may not reach therapeutic concentrations in sequestered infections.<sup>32</sup>

### ELIMINATION

Elimination of penicillin is primarily renal, as unchanged drug by glomerular filtration and active renal tubular secretion. The elimination half-life of penicillin G is 1 hour,<sup>31,32</sup> and total clearance is  $8.5 \pm 1.33$  mL/min/kg.<sup>30</sup> Oral penicillin V has an elimination half-life of 3.7 hours.<sup>27</sup>

## ADVERSE EFFECTS AND DRUG INTERACTIONS

### IMMUNE-MEDIATED REACTIONS

Penicillin is associated with immune-mediated hemolytic anemia (Type II hypersensitivity),<sup>33,34</sup> and anaphylaxis (Type I hypersensitivity) in horses.<sup>35</sup> The immune-mediated anemia usually resolves with discontinuation of penicillin therapy. Anaphylaxis usually occurs after previous exposure to penicillin and can be fatal. IV epinephrine and oxygen administration and respiratory support are indicated. Although it is widely assumed that penicillin and cephalosporins are cross-reactive in sensitive individuals, the actual incidence in humans is extremely low.<sup>36</sup>

### PROCAINE REACTIONS AND USE IN PERFORMANCE HORSES

When procaine penicillin G products are accidentally administered intravascularly, they cause extreme central nervous system stimulation.<sup>37,38</sup> Most horses will survive unless they fatally traumatize themselves during the reaction. Diazepam will attenuate the reaction if given before procaine administration but has no effect if given afterwards.<sup>37</sup> Veterinary formulations contain higher concentrations of procaine than human formulations, and high temperatures increase the solubility of procaine. Therefore penicillin procaine G should be kept refrigerated and administered by careful intramuscular injection. Even with careful intramuscular injection, adverse reactions are still reported in horses. Repeated injections increase the chance of intravascular administration and may increase the sensitivity to procaine as a result of neuronal sensitization (kindling). Once absorbed into the circulation, procaine is hydrolyzed by plasma esterases to the nontoxic metabolites PABA and diethylaminoethanol.<sup>39</sup> Horses that have had documented adverse reactions to intramuscular procaine penicillin G injections had significantly lower procaine hydrolyzing capacity compared with horses that did not have a history of adverse reactions.<sup>40</sup> Procaine is slowly eliminated in urine, is easily detectable by regulatory laboratories, and commonly causes violative residues in racehorses and performance horses given penicillin procaine G.<sup>41</sup>

### ELECTROLYTE IMBALANCES

The sodium or potassium content of IV formulations can contribute to electrolyte imbalances associated with congestive heart failure and renal function impairment.

A million units of potassium penicillin contain 1.7 mEq of potassium, so it should be administered by slow IV injection.

### PHENYLBUTAZONE

Concurrent administration with phenylbutazone in horses increases plasma concentrations of penicillin G but lowers tissue concentrations. The effect is likely due to a lower peripheral distribution.<sup>30</sup>

## FORMULATIONS

Na<sup>+</sup> and K<sup>+</sup> penicillin (also called *crystalline penicillin*) are water-soluble formulations and may be injected intravenously, intramuscularly, or subcutaneously. They achieve rapid plasma concentrations but have very short elimination half-lives and therefore must be administered frequently or by continuous rate infusion. Potassium penicillin is usually less expensive than sodium penicillin but must be administered more carefully because rapid IV administration can cause cardiac arrhythmias. Procaine penicillin G is a poorly soluble salt that is slowly absorbed after intramuscular injection. It is the most commonly used formulation of penicillin in horses. Benzathine penicillin G is a very insoluble salt that is used in long-acting penicillin preparations, which contain a 50:50 mixture of procaine penicillin G and benzathine penicillin G. Because the benzathine fraction is poorly absorbed and plasma concentrations are below the MICs of most pathogens, use of these products is not recommended in horses.<sup>32</sup>

## CLINICAL USE

Penicillin is still the antimicrobial of choice for many diseases in horses, such as streptococcal and anaerobic infections. Traumatic wounds are frequently infected with *Streptococcus zooepidemicus*, which is routinely susceptible to penicillin.<sup>13</sup> However, iatrogenic wounds are frequently infected with penicillinase-producing *Staphylococcus aureus* or other staphylococci, so culture and susceptibility testing is necessary before initiating penicillin therapy.<sup>13,42</sup>

The IV formulations are used when high doses are necessary for adequate concentrations at the site of infection in life-threatening situations. The dosage of penicillin G varies greatly depending on the formulation, species, and disease being treated.

## AMINOPENICILLINS

### SPECTRUM OF ACTIVITY

The aminopenicillins are able to penetrate the outer layer of gram negative bacteria better than penicillin G; therefore they have activity against many of the gram negative bacteria (*E. coli*, *Salmonella*, *Pasteurella* spp.) as well as gram positive bacteria.<sup>2</sup> However, resistance to the aminopenicillins is easily acquired by gram negative bacteria, so they are not usually effective against *Klebsiella*, *Proteus*, *Pseudomonas*, and *S. aureus*. Most anaerobes are sensitive, except  $\beta$ -lactamase producing strains of *Bacteroides*.<sup>26</sup> Amoxicillin penetrates the gram negative cell more easily than does ampicillin; therefore it has greater activity against gram negative bacteria.<sup>25</sup>

## PHARMACOKINETICS

### ABSORPTION

In horses ampicillin sodium is well absorbed after intramuscular or subcutaneous administration; however, oral dosage forms are poorly absorbed by adult horses.<sup>43</sup> The intramuscular administration of ampicillin trihydrate produces lower ampicillin blood concentrations that extend over a longer period of time than does intramuscular ampicillin sodium.<sup>43</sup> Oral absorption of amoxicillin is between 5.3% and 10.4% in adult horses<sup>44,45</sup> but between 36% and 42% in foals.<sup>46</sup> The ampicillin prodrugs are converted to ampicillin as they are absorbed from the gastrointestinal tract. Compared with the bioavailability of oral ampicillin (2%), the ampicillin esters have improved oral bioavailabilities in adult horses: pivampicillin (31%), bacampicillin (39%), and talampicillin (23%).<sup>47</sup> The low oral bioavailability of ampicillin esters is due to chemical hydrolysis in the high pH of equine ileal contents.

### DISTRIBUTION

The aminopenicillins are rapidly and widely distributed into most body fluids; distribution into cerebrospinal fluid is low unless the meninges are inflamed. The Vd of amoxicillin in adult horses is 0.19<sup>48</sup> and 0.27 L/kg in neonatal foals.<sup>46</sup> The Vd of ampicillin in horses ranges between 0.18 to 0.7 L/kg.<sup>49,50</sup> Peak serum concentrations of ampicillin are 6.2 to 9.7 µg/ml 16 minutes after an intramuscular dose of 10 mg/kg of ampicillin sodium.<sup>43</sup> Penetration into synovial fluid is high,<sup>43,51</sup> and concentrations are increased and persist in infected joints.<sup>52</sup> In a subcutaneous tissue chamber model in ponies, concentrations of IV ampicillin sodium, oral pivampicillin, and intramuscular procaine penicillin G remained above the MIC of *Streptococcus zooepidemicus* for 8, 12, and 24 hours, respectively.<sup>53</sup> The protein binding of amoxicillin is moderate (37%-38%),<sup>54</sup> whereas it is low for ampicillin (6%-8%).<sup>31</sup>

### ELIMINATION

Amoxicillin and ampicillin are primarily excreted unchanged in the urine. The elimination half-life of amoxicillin is approximately 1 hour in horses and foals.<sup>45,46,52,54</sup> The elimination half-life of ampicillin ranges between 0.5 hour to 2.3 hours.<sup>43,49,50,55,56</sup>

## ADVERSE EFFECTS AND DRUG

### INTERACTIONS

Amoxicillin and ampicillin have the same adverse effects as penicillin G. Their spectrum of action is greatly enhanced when combined with β-lactamase inhibitors such as clavulanic acid and sulbactam.

## FORMULATIONS

Sodium ampicillin is available as a human aqueous formulation for IV, intramuscular, and subcutaneous injection. The reconstituted aqueous formulations are unstable after more than a few hours. Ampicillin trihydrate is a poorly soluble, slow-release aqueous suspension approved for use in large animals. Absorption is erratic, and it produces prolonged but low plasma concentrations.

## CLINICAL USE

Indications for ampicillin or amoxicillin are few insofar as they offer little advantage over benzyl penicillins because of acquired resistance in gram negative bacteria. Based on a tissue cage inflammation model, an intramuscular dosage of 15 mg/kg of ampicillin sodium given every 6 hours would be required to treat ampicillin-susceptible bacteria.<sup>50</sup> Sodium ampicillin may be substituted for sodium or potassium penicillin as a choice for surgical prophylaxis.

## ☞ ANTIPSEUDOMONAL PENICILLINS

Because of its strong antipseudomonal activity, ticarcillin is used to treat endometritis in mares.

## SPECTRUM OF ACTIVITY

Carbenicillin, ticarcillin, and piperacillin are the antipseudomonal penicillins.<sup>2</sup> This group of penicillins can penetrate the outer cell wall of *Pseudomonas* sp. and other gram negative bacteria. They are susceptible to β-lactamase inactivation by *Klebsiella* spp. This group has activity against gram negative bacteria at the expense of activity against gram positive bacteria. They retain activity against anaerobic bacteria and are synergistic when administered with aminoglycosides.

## PHARMACOKINETICS

Absorption of intramuscular ticarcillin is 65%, and the elimination half-life is less than 1 hour in horses.<sup>57,58</sup> Peak endometrial concentrations after IV administration were 12.9 µg/g but were greater than 150 µg/g when 6 grams of ticarcillin were diluted in 250 ml of saline and infused into the uterus.<sup>57</sup>

## ☞ β-LACTAMASE INHIBITORS

## SPECTRUM OF ACTIVITY

The β-lactamase inhibitors are a specific class of drugs that inhibit bacterial β-lactamase, so they are administered in combination with β-lactam antibiotics.<sup>59</sup> These drugs combine with β-lactamase enzymes produced by gram negative and some gram positive bacteria. An inactive enzyme complex is formed, and the co-administered antibiotic is then able to exert its effect. New evidence suggests that β-lactamase inhibitors, once thought to have little antimicrobial activity of their own, bind to different PBPs, affecting autolysis and contributing to the activity of the concomitantly administered β-lactam antibiotic.<sup>60</sup> The primary drugs of this class are clavulanic acid and sulbactam. They extend the spectrum of amoxicillin and ampicillin to include β-lactamase-producing *E coli*, *Klebsiella*, *Proteus*, and *Staphylococcus* spp.<sup>24</sup> Most anaerobes, including *Bacteroides fragilis*, are susceptible.<sup>26</sup>

## PHARMACOKINETICS

### ABSORPTION

Absorption of ticarcillin and clavulanic acid in foals is age dependent; neonatal foals have a higher systemic bioavailability after IM administration than older foals (100% and 88% versus 100% and 27%, respectively).<sup>61</sup> When administered intramuscularly in combination with clavulanic acid,

ticarcillin demonstrates “flip-flop” kinetics, wherein the elimination half-life is longer after intramuscular than IV injection as a result of slow absorption from the injection site.<sup>62</sup> Systemic absorption of both ticarcillin and clavulanic acid is poor after intrauterine administration.<sup>63</sup>

### DISTRIBUTION

The Vd of ticarcillin in older foals was 0.24 L/kg, and the Vd of clavulanic acid was 0.48 L/kg. In neonatal foals the Vd of ticarcillin was higher at 0.69 L/kg, as would be expected for a low-Vd drug in a neonate, with its increased extracellular fluid volume.<sup>61</sup> In mares the Vd of ticarcillin was 0.13 L/kg, and the Vd of clavulanic acid was 0.18 L/kg.<sup>63</sup>

### ELIMINATION

Ticarcillin demonstrates age-dependent elimination in foals. In neonatal foals the Vd and clearance of ticarcillin were approximately double those reported for older foals and mares.<sup>61</sup> The renal elimination mechanism of ticarcillin appears immature in a 3-day-old foal but near normal adult function by 28 days of age. In mares the elimination half-life of clavulanic acid is 0.4 hour.<sup>63</sup>

### ADVERSE EFFECTS AND DRUG INTERACTIONS

When ticarcillin is administered intramuscularly into the hindquarters at a concentration of 400 mg/ml with 13.2 mg/ml clavulanic acid, foals showed signs of significant local discomfort.<sup>61</sup> A lower concentration of drug did not cause signs of discomfort in neonatal foals. The penicillin  $\beta$ -lactam inhibitor drugs can be used in combination with aminoglycosides for a synergistic effect against the pathogens commonly encountered in septicemic foals.<sup>64</sup>

### FORMULATIONS

Amoxicillin-clavulanic acid is available only as oral tablets or suspension for humans and small animals. Ampicillin-sulbactam was available as a trihydrate formulation labeled for cattle and used in Canada, but it is no longer marketed. Sodium ampicillin-sulbactam and ticarcillin disodium-clavulanic acid formulations are available for human use.

### CLINICAL USE

IV ampicillin-sulbactam or ticarcillin-clavulanic acid are treatment options for gram negative bacterial infections in valuable foals. Clavulanic acid concentrations were too low when the combination was administered to mares through IV or intrauterine routes to be of value over straight ticarcillin in the treatment of endometritis.<sup>63</sup>

## ☞ CEPHALOSPORINS

### SPECTRUM OF ACTIVITY

The widespread emergence of penicillin-resistant staphylococci in the 1950s provided the impetus for the development of the cephalosporin antibiotics. In human medicine cephalosporins are widely used; however, it is said that cephalosporins are drugs in search of diseases to treat—meaning that precise therapeutic indications for these drugs are difficult to define, and there is a tendency to use these drugs when older,

cheaper drugs would suffice.<sup>65</sup> Their use in equine medicine is not widespread because of their relative expense and because equine clinical experience includes only a few specific agents. They were initially grouped into three “generations” primarily on the basis of their antibacterial activity, but some of the newer cephalosporins did not easily fit into this scheme, so an expanded classification was developed (Table 4-7).<sup>2</sup> By convention, cephalosporins discovered before 1975 are spelled with a *ph* and after 1975 with an *f*.

Cephalosporins are broad spectrum antibiotics with a wide range of antimicrobial activity.<sup>2,66</sup> They are usually active against  $\beta$ -hemolytic streptococci and against  $\beta$ -lactamase-producing staphylococci but not against methicillin- (oxacillin-) resistant *Staphylococcus aureus* (MRSA) or mycobacteria. Most enterococci are resistant. In the absence of acquired resistance, *E. coli* and *Salmonella* are usually susceptible, as are some *Proteus* and *Klebsiella* spp. Group 7 cephalosporins are effective against Enterobacteriaceae and other gram negative bacteria that are resistant to earlier generations of cephalosporins because of acquired  $\beta$ -lactamase resistance. Common gram negative aerobic respiratory pathogens such as *Haemophilus* and *Pasteurella*, including  $\beta$ -lactamase producers, are usually susceptible to cephalosporins. Although most corynebacteria are susceptible, *Rhodococcus equi* is usually resistant. Only antipseudomonal (group 6) and group 7 cephalosporins are effective against *Pseudomonas aeruginosa*. Activity against non-spore-forming anaerobic bacteria is variable and similar to that of the aminopenicillins. Cefoxitin is notably resistant to  $\beta$ -lactamase-producing anaerobes, including *Bacteroides fragilis*. Ceftiofur is active against respiratory pathogens such as streptococci, *Pasteurella* spp., and *Histophilus* spp. and most anaerobes but has less activity against *S. aureus* and Enterobacteriaceae than other group 4 drugs. *Bacteroides* spp. and *Pseudomonas* spp. are resistant to ceftiofur. When administered, ceftiofur is rapidly metabolized to the active metabolite desfuroylceftiofur. Desfuroylceftiofur is less active than ceftiofur against *S. aureus* and *Proteus* spp.<sup>67</sup> Diagnostic laboratories use a ceftiofur disc for susceptibility testing because of the instability of desfuroylceftiofur, so susceptibility testing results for staphylococci and *Proteus* spp. may not reliably predict the efficacy of ceftiofur therapy.

The broad spectrum antibacterial activity of the cephalosporins may cause overgrowth (“superinfection”) by inherently resistant bacteria, including *Clostridium difficile*, which no longer have to compete with the normal microbial flora. Nosocomial infection with vancomycin-resistant enterococci (VRE) has become a serious problem in human hospitals. One of the highest risk factors for contracting a VRE infection in a human hospital is treatment with a cephalosporin.<sup>68</sup>

### PHARMACOKINETICS

#### ABSORPTION, DISTRIBUTION, AND ELIMINATION

See Table 4-7 for the PK parameters for the cephalosporins in horses. Intramuscular and subcutaneous administration of cephalosporins results in rapid drug absorption, but the extent varies with the drug and the species. Oral bioavailability is acceptable in neonates but rapidly becomes too low to be practical for older foals or adults.<sup>69,70</sup> The values for Vd in horses for the cephalosporins are typically low (< 0.3 L/kg), indicating distribution primarily to extracellular

TABLE 4-7

Pharmacokinetics of Cephalosporins in Horses		
CLASSIFICATION OF CEPHALOSPORINS		
Group	Characteristics	Examples
1 (First generation)	Parenteral; resistant to staphylococcal $\beta$ -lactamase; sensitive to enterobacterial $\beta$ -lactamase	Cephacetrile, cephaloridine, cephalothin, cephapirin, cephalozin
2 (First generation)	Oral; resistant to staphylococcal $\beta$ -lactamase; moderately resistant to some enterobacterial $\beta$ -lactamase	Cefadroxil, cephadrine, cephalixin
3 (Second generation)	Parenteral and oral; resistant to many $\beta$ -lactamases	Cefaclor, cefotetan, cefoxitin, cefuroxime, cefamandole
4 (Third generation)	Parenteral; resistant to many $\beta$ -lactamases	Cefotaxime, ceftizoxime, ceftriaxone, ceftiofur, cevofecin, latamoxef
5 (Third generation)	Oral; resistant to many $\beta$ -lactamases	Cefetamet, cefixime, cefpodoxime
6 (Third generation)	Parenteral; resistant to many $\beta$ -lactamases; active against <i>Pseudomonas aeruginosa</i>	Cefoperazone, cefsulodin, ceftazidime
7 (Fourth generation); included with group 6 in some classifications	Parenteral; resistant to staphylococcal, enterobacterial and pseudomonal $\beta$ -lactamases	Cefepime, cefquinome, cefpirome

fluid. However, they have good distribution into the extracellular fluid of most tissues, including pleural, pericardial, and synovial fluid. Penetration into cortical and cancellous bone is usually adequate.<sup>71</sup> Cephalosporins penetrate poorly into the ocular humour and, except for some third-generation drugs, do not achieve therapeutic concentrations in the central nervous system.<sup>2</sup> In general the group 4-6 cephalosporins have an increased ability to penetrate the central nervous system.<sup>72</sup> Higher Vd values for foals reflect the increased extracellular fluid compartment of the neonate.<sup>69,73</sup> Most cephalosporins are rapidly eliminated as the unchanged drug in the urine. Cephalothin, cephapirin, cefotaxime, and ceftiofur are deacetylated by the liver, and their metabolites have significant antibacterial activity. For ceftiofur most of the antibacterial activity is attributed to its metabolite, desfuroyl-ceftiofur.<sup>74</sup> Renal excretion of cephalosporins occurs through a combination of glomerular filtration and active tubular secretion. Therefore it may be necessary to modify the dosage regimen of most cephalosporins for patients in renal failure. For the cephalosporins that undergo hepatic metabolism, hepatic insufficiency may decrease metabolism and increase drug accumulation. Dose-dependent kinetics occurred in foals administered cefadroxil, as demonstrated by increasing mean residence time, which suggests saturation of immature renal tubular secretion at high doses.<sup>69</sup> For some cephalosporins delayed absorption from the intramuscular injection site results in flip-flop kinetics.<sup>75</sup>

#### ADVERSE EFFECTS AND DRUG INTERACTIONS

The adverse effects of the cephalosporins are similar to those reported for the penicillins. In general cephalosporins have a high therapeutic index. Bleeding disorders have been reported in humans but not in animals.<sup>76</sup> The reaction appears to be related to vitamin K antagonism. Ceftriaxone and cefepime cause gastrointestinal disturbances after administration to foals and horses.<sup>77-79</sup> Ceftiofur is associated with injection site inflammation and diarrhea caused by altered gastrointestinal

flora in horses.<sup>80,81</sup> The currently available cephalosporins are considered to be potentially nephrotoxic by way of deposition of immune complexes in the glomerular basement membrane or from a direct toxic effect leading to acute tubular necrosis.<sup>82</sup> Like the penicillins, cephalosporins can be synergistic with aminoglycosides against many pathogens.<sup>83</sup> In human medicine it is recommended that cephalosporins not be used in conjunction with aminoglycosides; however, animal studies demonstrate a protective effect of the cephalosporins against nephrotoxicity.<sup>84</sup>

#### FORMULATIONS

Cefadroxil is available as veterinary formulated tablets or suspension for small animals. Cephalexin is available as human tablets and suspensions for oral administration. The parenteral formulations of cephalosporins are usually sodium salts (e.g., cefazolin, cefoxitin, ceftiofur). Cefepime (human) and ceftiofur (food animal "ready to use") are available as hydrochloride formulations. Cephapirin is available in the United States only in bovine mastitis and intrauterine formulations.

#### CLINICAL USE

Of the group 1 to 3 cephalosporins, cefazolin,<sup>85,86</sup> cephalothin,<sup>87</sup> cephapirin,<sup>88-90</sup> cefadroxil,<sup>69,70</sup> cephradine,<sup>91</sup> and cefoxitin<sup>92</sup> have been used in horses. In addition to ceftiofur, ceftriaxone<sup>77</sup> and cefotaxime<sup>78,93</sup> are group 4 drugs that have been used in horses and septic foals. Cefpodoxime is a group 5 drug that has been investigated for oral use in foals.<sup>94</sup> Cefoperazone,<sup>75</sup> a group 6 drug, and cefepime,<sup>98,110</sup> a group 7 drug, have been studied for use in horses and neonatal foals. Both drugs have strong resistance to  $\beta$ -lactamases, including those produced by *Pseudomonas*.

Ceftiofur is the only cephalosporin approved for equine use and the only one routinely used in equine practice,

where it is a good alternative to penicillin or trimethoprim/sulfonamides for the treatment of streptococcal infections.<sup>13,96-98</sup> Other than ceftiofur, clinical use of group 3 to 7 cephalosporins is usually restricted to septic foals with bacterial infections caused by strains with multiple drug resistance. Ceftiofur or any of the parenteral cephalosporins are effectively used for local treatment of musculoskeletal infections.<sup>99-101</sup>

## AMINOGLYCOSIDES

The aminoglycoside antibiotics include streptomycin, neomycin, gentamicin, amikacin, tobramycin, and kanamycin. They have a chemical structure of amino sugars joined by a glycoside linkage. The importance of this group in veterinary medicine is to treat serious infections caused by aerobic gram negative bacteria and staphylococci. Amikacin and tobramycin have excellent activity against *Pseudomonas aeruginosa*. However, the use of aminoglycosides has been eclipsed by the fluoroquinolones, which have stronger safety profiles and better distribution kinetics.<sup>2</sup> Nevertheless, the aminoglycosides remain important drugs in the treatment of severe gram negative sepsis, although their highly cationic, polar nature means that distribution across membranes is limited. Single daily dosing is now recommended for most dosage regimens because it maximizes efficacy and reduces toxicity.

### MECHANISM OF ACTION

The aminoglycosides are large molecules with numerous amino acid groups, making them basic polycations that are highly ionized at physiologic pHs. Aminoglycosides must penetrate the bacteria to assert their effect. Susceptible, aerobic gram negative bacteria actively pump the aminoglycoside into the cell. This is initiated by an oxygen-dependent interaction between the antibiotic cations and the negatively charged ions of the bacterial membrane lipopolysaccharides. This interaction displaces divalent cations ( $\text{Ca}^{++}$ ,  $\text{Mg}^{++}$ ), which affects membrane permeability.<sup>102</sup> Once inside the bacterial cell, aminoglycosides bind to the 30S ribosomal subunit and cause a misreading of the genetic code, interrupting normal bacterial protein synthesis. This changes the cell membrane permeability, resulting in additional antibiotic uptake, further cell disruption, and ultimately cell death.

Aminoglycoside action is bactericidal and concentration dependent. For example, concentrations of gentamicin in the range of 0.5 to 5.0  $\mu\text{g}/\text{ml}$  are bactericidal for gram positive and some gram negative bacteria. At 10 to 15  $\mu\text{g}/\text{ml}$ , gentamicin is effective against the more resistant bacteria such as *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*, and *Proteus mirabilis*.<sup>103</sup> The clinical implication is that high initial doses of aminoglycosides increase ionic bonding, enhancing the initial concentration-dependent phase of rapid antibiotic internalization, which leads to greater immediate bactericidal activity. Human clinical studies demonstrate that proper initial therapeutic doses of aminoglycosides are critical in reducing mortality from gram negative septicemia. For antimicrobials whose efficacy is concentration dependent, high plasma concentration levels relative to the MIC of the pathogen (Cmax:MIC ratio, also known as the *inhibitory quotient*, or IQ) and the area under the plasma concentration-time curve

that is above the bacterial MIC during the dosage interval (area under the inhibitory curve, AUC = AUC/MIC) are the major determinants of clinical efficacy. For the aminoglycosides a Cmax:MIC ratio of 10 is suggested to achieve optimal efficacy.<sup>11</sup>

The aminoglycosides have a significant PAE, the period of time during which antimicrobial concentrations are below the bacterial MIC but the antimicrobial-damaged bacteria are more susceptible to host defenses. The duration of the PAE tends to increase as the initial aminoglycoside concentration increases.<sup>104</sup>

Antimicrobial activity of aminoglycosides is enhanced in an alkaline environment (pH of 6-8). They bind to and are inactivated by the nucleic acid material released by decaying white blood cells. Therefore they are usually ineffective in the acidic, hyperosmolar, anaerobic environment of abscesses.

### SPECTRUM OF ACTIVITY

The aminoglycosides are effective against most aerobic gram negative bacteria, including *Pseudomonas*.<sup>2</sup> They are somewhat effective against staphylococci, although resistance can occur. They are often effective against enterococci, but therapy against streptococci is more effective when combined with a  $\beta$ -lactam antibiotic. *Salmonella* and *Brucella* spp. are intracellular pathogens and are often resistant. Some mycobacteria, spirochetes, and mycoplasma are susceptible. Aminoglycosides are ineffective against anaerobic bacteria because aminoglycoside penetration into the bacteria requires an oxygen-dependent transport mechanism. Amikacin was developed from kanamycin and has the broadest spectrum of activity of the aminoglycosides. It is effective against strains not susceptible to other aminoglycosides because it is more resistant to bacterial enzymatic inactivation and is considered the least nephrotoxic. However, it is poorly active against *Streptococcus zooepidemicus* compared with gentamicin, so amikacin should be reserved for pathogens known to be resistant to gentamicin.<sup>13</sup>

### RESISTANCE MECHANISMS

Aminoglycoside resistance is primarily due to enzymes encoded by genes located on bacterial plasmids. These phosphotransferases, acetyltransferases, and adenylyltransferases act internally to alter the aminoglycoside and prevent it from binding to ribosomes.<sup>2</sup> Amikacin is least susceptible to enzyme inactivation. Plasmid-mediated resistance to the aminoglycosides is transferable between bacteria. A single type of plasmid may confer cross-resistance to multiple aminoglycosides and to other unrelated antimicrobials. A single bacterial isolate may have any one of a variety of combinations of resistance to different antibiotics conferred by the particular plasmid it carries. As an example, an *E. coli* strain may be resistant to ampicillin, apramycin, chloramphenicol, gentamicin, kanamycin, sulfonamide, streptomycin, tetracycline, and trimethoprim.<sup>105</sup> The nature of resistance in organisms such as *E. coli* and *Salmonella* species has been a focus of international research because of concerns about potential transference of antimicrobial resistance from animal to human pathogens. Bacteria may also utilize other methods that reduce the efficacy of aminoglycosides. Some strains of bacteria are less permeable to aminoglycosides, requiring much higher concentrations of aminoglycosides to kill

them, and therefore can be selected for during treatment. Resistance resulting from chromosomal resistance is minimal and develops slowly for most of the aminoglycosides, with the exception of streptomycin or dihydrostreptomycin; resistance to streptomycin can occur from a single-step mutation.

### FIRST EXPOSURE ADAPTIVE RESISTANCE

Both subinhibitory and inhibitory aminoglycoside concentrations produce resistance in bacterial cells surviving the initial ionic binding.<sup>106</sup> This adaptive resistance is due to decreased aminoglycoside transport into the bacteria. Exposure to one dose of an aminoglycoside is sufficient to produce resistant variants of an organism with altered metabolism and impaired aminoglycoside uptake. In vitro animal and clinical studies show that the resistance occurs within 1 or 2 hours of the first dose. The duration of adaptive resistance relates directly to the elimination half-life of the aminoglycoside. With normal aminoglycoside pharmacokinetics, the resistance may be maximal for up to 16 hours after a single dose of aminoglycoside, followed by partial return of bacterial susceptibility at 24 hours and complete recovery at approximately 40 hours.<sup>107</sup> If the aminoglycoside is dosed multiple times a day or the drug concentration remains constant, as with a continuous infusion, adaptive resistance persists and increases. Adaptive resistance is likely to persist in peripheral compartments, which are often the site of infection because of the persistence of aminoglycosides at these sites. Dose administration at 24-hour intervals, or longer, may increase efficacy by allowing time for adaptive resistance to reverse.<sup>106,108,109</sup> Some clinicians have expressed reservations about once-daily dosing when intestinal damage allows continued exposure to bacteria that may replicate during the prolonged periods of subtherapeutic aminoglycoside concentrations, but this has not been documented clinically.

### PHARMACOKINETICS

**Absorption** See Table 4-8 for the pharmacokinetics of gentamicin and amikacin in horses. Amikacin and gentamicin are rapidly and well absorbed from intramuscular and subcutaneous routes of administration but are not absorbed orally.<sup>102</sup>

**Distribution** The aminoglycosides are polar antibiotics; therefore distribution is limited to the extracellular fluid space. The Vd in most species ranges between 0.15 to 0.3 L/kg but is higher in neonates.<sup>110,111</sup> After parenteral administration, effective concentrations are obtained in synovial, perilymph, pleural, peritoneal, and pericardial fluid.<sup>112</sup> Therapeutic concentrations are not achieved in bile, cerebrospinal fluid, respiratory secretions, and prostatic and ocular fluids.<sup>102,113</sup> Gentamicin does not cross the placenta of late-term mares.<sup>114</sup> The predominant site of drug accumulation is the renal cortex in most species. The following general relative gentamicin concentrations are reached over time with repeated doses, from highest to lowest concentrations: renal cortex > renal medulla > liver/lung/spleen > skeletal muscle.<sup>102</sup> Gentamicin distributes into jejunal and colonic tissue, with a peak gentamicin concentration of 4.13 µg/ml in the large colon and 2.26 µg/ml in the jejunum.<sup>115</sup>

In endotoxemia gentamicin concentrations increase in serum as a result of a fever-induced decrease in the volume of the extracellular fluid compartment.<sup>116</sup> The administration of

therapeutic fluids, similar to those that are used in the treatment of colic, does not significantly change the pharmacokinetics of concurrently administered gentamicin.<sup>117</sup> The pharmacokinetics of gentamicin are unchanged in horses undergoing colic surgery.<sup>118</sup> Peritoneal lavage had no effect on pharmacokinetics of gentamicin in healthy horses after abdominal surgery, in which localized nonseptic peritonitis was induced.<sup>119</sup>

Endometrial tissue concentrations of gentamicin were higher than plasma concentrations after 7 days of intramuscular therapy with a dose of 5 mg/kg every 8 hours.<sup>120</sup> Intrauterine administration of 2 grams of amikacin produced a peak of more than 40 µg/gram of endometrial tissue within 1 hour after infusion. Between 2 and 4 µg of amikacin per gram of endometrial tissue were still present 24 hours after infusion.<sup>121</sup> Intrauterine administration of 2.5 grams of gentamicin once daily for 5 days resulted in endometrial tissue concentrations of 41.65 µg/gram 24 hours after the last dose.<sup>122</sup>

Gentamicin distributed into synovial fluid in normal horses and reached a peak of 6.4 µg/ml at 2 hours with a single 4.4 mg/kg IV dose.<sup>123</sup> However, local inflammation may increase drug concentrations in the joint, and concentrations may also increase with repeated doses. Intra-articular administration of 150 mg of gentamicin resulted in a peak synovial concentration of 1828 µg/ml 15 minutes after injection, and synovial concentrations remain greater than 10 µg/ml for at least 24 hours.<sup>124</sup> Regional perfusion techniques are excellent methods to deliver aminoglycosides locally and prevent the adverse effects of systemic therapy.<sup>125-130</sup> When intraosseous perfusion was compared with IV perfusion, each technique produced mean peak concentrations of amikacin ranging between 5 to 50 times that of recommended peak serum concentrations for therapeutic efficacy.<sup>131</sup> Gentamicin-impregnated polymethylmethacrylate beads or collagen sponges may also be used to achieve extremely high local concentrations of drug, while avoiding systemic toxicity.<sup>99,132-135</sup>

### ELIMINATION

The aminoglycosides are almost exclusively eliminated in urine by glomerular filtration.<sup>102</sup> The plasma elimination half-lives range between 1 to 3 hours in adult animals but are increased in neonates or animals with renal dysfunction.<sup>111</sup> Renal accumulation results in extended withdrawal times for food animals.

## ADVERSE EFFECTS AND DRUG INTERACTIONS

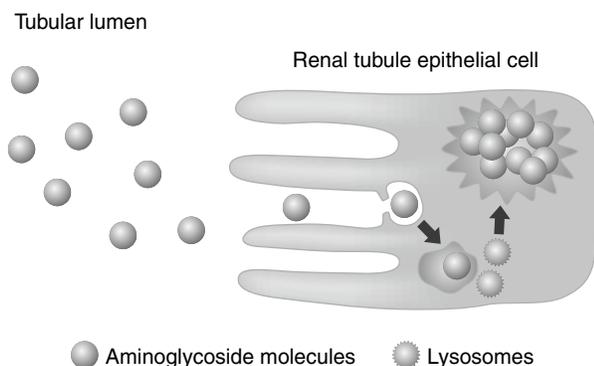

### NEPHROTOXICITY

The aminoglycosides enter the renal tubule after filtration through the glomerulus (Figure 4-22). From the luminal fluid the cationic aminoglycoside molecules bind to anionic phospholipids on the proximal tubular cells.<sup>136</sup> The aminoglycoside is taken into the cell by way of carrier-mediated pinocytosis and translocated into cytoplasmic vacuoles, which fuse with lysosomes.<sup>137</sup> The drug is sequestered unchanged in the lysosomes. With additional pinocytosis drug continues to accumulate within the lysosomes. The accumulated aminoglycoside interferes with normal lysosomal function, and eventually the overloaded lysosomes swell and rupture. Lysosomal enzymes, phospholipids, and the aminoglycoside are released into the cytosol of the proximal tubular cell, disrupting other organelles and causing cell death.<sup>138</sup>

TABLE 4-8

MRT, Mean residence time; IV, intravenous; IM, intramuscular.

**FIGURE 4-22** Nephrotoxicity occurs from ionic binding of aminoglycoside molecules to polysaccharide cations on the proximal tubular epithelium, followed by pinocytosis and accumulation within lysosomes.

The risk factors for aminoglycoside toxicity include: prolonged therapy (>7 to 10 days), acidosis and electrolyte disturbances (hypokalemia, hyponatremia), volume depletion (shock, endotoxemia), concurrent nephrotoxic drug therapy, preexisting renal disease, and elevated plasma trough concentrations.<sup>139-144</sup> Calcium supplementation can reduce the risk of nephrotoxicity.<sup>145</sup> Administration of antioxidants such as silymarin and vitamin E may decrease aminoglycoside nephrotoxicity.<sup>146</sup> The risk of nephrotoxicity can also be decreased by feeding the patient a diet high in protein and calcium, such as alfalfa hay, because protein and calcium cations compete with aminoglycoside cations for binding to renal tubular epithelial cells.<sup>147</sup> High dietary protein also

increases GFR and renal blood flow, reducing aminoglycoside accumulation.<sup>148</sup>

Uptake and accumulation of aminoglycosides into renal tubular epithelium demonstrates saturable kinetics. Because nephrotoxicity is related to aminoglycoside accumulation in the renal proximal tubular cells, it is logical that peak concentrations are not related to toxicity and that longer dose intervals results in less total drug exposure to the renal brush border membrane. High-dose, once-daily dosing of aminoglycosides has now become common in human and veterinary medicine; it takes advantage of the concentration-dependent killing and long PAE of these drugs and prevents first exposure adaptive resistance and toxicity.<sup>113,118,149-151</sup>

#### OTOTOXICITY

Aminoglycoside ototoxicity occurs from the same accumulation mechanisms as nephrotoxicity. In the inner ear aminoglycosides appear to generate free radicals that subsequently do permanent damage to sensory cells and neurons.<sup>152-154</sup> Gentamicin damages the cochlear division of the eighth cranial nerve, resulting in vertigo, and amikacin damages the auditory division of the eighth cranial nerve, resulting in permanent deafness. This drug-specific toxicity may be due to the distribution characteristics of each drug and concentration achieved in each sensory organ.<sup>155,156</sup>

#### THERAPEUTIC DRUG MONITORING

Individual horses can differ widely in the serum concentrations produced by the same aminoglycoside dosage regimen. When this relative unpredictability is combined with the often small difference between therapeutic and toxic serum concentrations, determining serum concentrations in a particular patient becomes very valuable. There is a tendency

to underdose neonatal patients, especially those that are receiving aggressive fluid therapy.<sup>157</sup> To maximize efficacy and minimize toxicity, therapeutic drug monitoring of gentamicin or amikacin is recommended. Peak concentrations are targeted to achieve a peak plasma concentration:MIC ratio of 10.<sup>11,102,107</sup> Because the trough concentration is associated with nephrotoxicity, it is recommended that trough concentrations be less than 2 µg/ml for gentamicin and less than 5 µg/ml for amikacin before the next dose is administered.<sup>102,107</sup> To allow for the distribution phase, blood sampling for the peak concentration is performed 0.5 to 1 hour after IV administration, and the trough sample is usually taken before the next dose. The peak and trough concentrations can then be used to estimate the elimination half-life for the individual patient. An increase in the elimination half-life during therapy is a very sensitive indicator of early tubular insult.<sup>158</sup> If a once-daily regimen is used, a blood sample just before the next dose will be well below the recommended trough concentrations and may even be below the limit of detection of the assay. For these patients an 8-hour postdose sample will provide a more accurate estimate of the elimination half-life.

If therapeutic drug monitoring is unavailable, then once-daily high-dose therapy is recommended; the development of nephrotoxicity is detected by an increase in urine gamma glutamyl transferase (UGGT) enzyme and an increase in the urine GGT:urine creatinine (UCr) ratio. The UGGT:UCr may increase to two to three times baseline within 3 days of a nephrotoxic dose.<sup>139,158,159</sup> If these tests are not available, the development of proteinuria is the next best indicator of nephrotoxicity and is easily determined in a practice setting.<sup>158,159</sup> Elevations in serum urea nitrogen and Cr confirm nephrotoxicity but are not seen for 7 days after significant renal damage has occurred.<sup>111</sup> Elimination half-lives of 24 to 45 hours have been reported in horses with renal toxicity, further prolonging the toxic exposure to the drug.<sup>142</sup> While peritoneal dialysis is useful in lowering creatinine and serum urea nitrates, it may not be effective in significantly increasing the elimination of the accumulating aminoglycoside.<sup>142</sup> The horse's ability to recover most likely depends on the type of medication exposure and the amount of healthy renal tissue remaining to compensate.

### NEUROMUSCULAR BLOCKADE

Neuromuscular blockade is a rare effect, related to blockade of acetylcholine at the nicotinic cholinergic receptor.<sup>160</sup> It is most often seen when anesthetic agents are administered concurrently with aminoglycosides.<sup>161</sup> Affected patients should be treated promptly with parenteral calcium chloride at 10 to 20 mg/kg intravenously or calcium gluconate at 30 to 60 mg/kg intravenously to reverse dyspnea from muscle response depression. IV edrophonium at 0.5 mg/kg will also reverse neuromuscular blocking effects.<sup>160</sup>

### DRUG INTERACTIONS

Aminoglycosides are inactivated if combined in vitro with other drugs because of pH incompatibilities. The aminoglycosides are synergistic against streptococci, *Pseudomonas*, and other gram negative bacteria if combined with β-lactam antibiotics as a result of the bacterial cell wall being disrupted by the β-lactam antibiotic. Halothane anesthesia causes significant changes in the pharmacokinetics of gentamicin;

total body clearance and volume of distribution decrease, and half-life of elimination increases.<sup>162</sup> A longer gentamicin dosing interval after anesthesia may help correct for the changes, but the practitioner should seriously consider selecting another antimicrobial. Neuromuscular blocking agents or drugs with neuromuscular blocking activity should not be used concurrently with aminoglycosides because they can increase the risk of neuromuscular blockade, particularly during anesthesia.<sup>161</sup> Other nephrotoxic drugs should be avoided when possible during aminoglycoside therapy. Concurrent administration of phenylbutazone with gentamicin decreases the elimination half-life of gentamicin by 23% and decreases the Vd by 26%; the pharmacokinetics of phenylbutazone are not affected.<sup>163</sup> Flunixin has no effect on the pharmacokinetics of gentamicin when administered concurrently to adult horses.<sup>118</sup>

### FORMULATIONS

Gentamicin and amikacin are available as brand name and generic solutions for intrauterine infusion in mares. Although not labeled for other routes of administration, they are commonly administered by IV, intramuscular, subcutaneous, intra-articular, and intraosseous routes to horses. Gentamicin is also available in ophthalmic formulations for the treatment of gram negative keratitis.

### CLINICAL USE

Gentamicin and amikacin are commonly used to treat serious gram negative infection in horses and septicemia in foals. Amikacin is used when antimicrobial resistance to gentamicin has developed in gram negative pathogens, but gentamicin has greater activity against streptococci than amikacin.<sup>13</sup> The aminoglycosides are usually administered concurrently with β-lactam antimicrobials for a possible synergistic effect. The use of aminoglycosides in horses has been limited because of toxicity concerns, but high-dose once-daily dosing greatly reduces the risks. Use of the aminoglycosides is also limited by their poor penetration of cellular membranes and inactivation in purulent environments.

### ☞ CHLORAMPHENICOL AND FLORFENICOL

Chloramphenicol (CHPC) was isolated in 1947 from a soil actinomycete from Venezuela. Florfenicol (FLF) is a fluorinated derivative of CHPC.

### MECHANISM OF ACTION

Both CHPC and FLF are bacteriostatic antibiotics that inhibit protein synthesis by binding to ribosomal subunits of susceptible bacteria, leading to the inhibition of peptidyl transferase and thereby preventing the transfer of amino acids to growing peptide chains and subsequent protein formation.<sup>164</sup> These antibiotics have a very wide spectrum of activity, including streptococci, staphylococci, anaerobes, *Haemophilus*, *Salmonella*, *Pasteurella*, *Mycoplasma*, and *Brucella* spp. FLF has activity against CHPC-resistant strains of *E. coli*, *Klebsiella*, *Proteus*, *Salmonella*, and *S. aureus*. Both are also active against rickettsia, chlamydia, and hemobartonella.<sup>2</sup>

## MECHANISMS OF RESISTANCE

Bacterial resistance to CHPC results from plasmid-mediated bacterial production of acetylase enzymes. Acetylation of hydroxyl groups prevents drug binding to the 50-S ribosomal subunit. FLF has a fluorine atom instead of the hydroxyl group located at C-3 in the structure of CHPC and thiamphenicol. Initially FLF was less susceptible to deactivation by bacteria with plasmid-transmissible resistance to CHPC. Recently, new resistances to CHPC and FLF have been identified in cattle pathogens.<sup>165,166</sup>

## PHARMACOKINETICS

### ABSORPTION

CHPC and FLF are rapidly absorbed after oral administration. The oral bioavailability of CHPC in foals is 83%,<sup>167</sup> but only 40% after a single administration in mares and bioavailability declines to 20% after five doses.<sup>168</sup> The oral bioavailability of FLF in horses is 81%.<sup>169</sup> The commercially available formulation of FLF is a long-acting injectable product for cattle and is characterized by delayed absorption and low plasma concentrations.<sup>170</sup>

### DISTRIBUTION

Because of high lipid solubility and low protein binding, CHPC and FLF are widely distributed throughout the body. Highest drug levels are attained in the liver and kidney, but therapeutic drug concentrations are attained in most tissues and fluids, including ocular humor and synovial fluid.<sup>2</sup> CHPC may achieve cerebrospinal fluid concentrations of up to 50% of plasma concentrations when the meninges are normal, and more if inflammation is present.<sup>171</sup> FLF does not penetrate the blood-brain barrier as readily as CHPC.<sup>172</sup> The Vd of CHPC is 2.83 L/kg in horses<sup>173</sup> and 1.6 L/kg in neonatal foals.<sup>167</sup> The Vd of FLF is 0.72 L/kg in horses.<sup>184</sup> The degree of protein binding of CHPC in horses is 30%,<sup>174</sup> whereas FLF has a low degree of protein binding in cattle.<sup>175</sup>

### ELIMINATION

In most species these drugs are eliminated by renal excretion of parent drug and by hepatic glucuronide conjugation and elimination in feces. The elimination half-life of CHPC in foals older than 7 days and adult horses is less than 1 hour.<sup>167,173,174,176,177</sup> In 1-day-old foals the elimination half-life is 5.3 hours, indicating the immaturity of the foal's hepatic metabolism capacity.<sup>176</sup> FLF has an elimination half-life of 1.8 hours in horses after IV administration.<sup>169</sup> The long-acting formulation for cattle is slowly eliminated on account of the prolonged absorption from the intramuscular injection site (flip-flop kinetics).<sup>170</sup>

## ADVERSE EFFECTS AND DRUG INTERACTIONS

Insofar as these drugs are protein synthesis inhibitors, dose-related anemia and pancytopenia are associated with chronic therapy (>14 days), causing a decrease in protein synthesis in the bone marrow. FLF is more likely than CHPC to cause reversible bone marrow suppression with chronic dosing<sup>172</sup> or overdose.<sup>178</sup> In humans an idiosyncratic aplastic anemia occurs with exposure to CHPC.<sup>179</sup> The reaction is rare (1 in 30,000), and not dose related. Toxic effects are related to the presence of the para-nitro group on the CHPC molecule. This reaction does not occur with FLF, insofar as it lacks the para-nitro group. CHPC is a hepatic microsomal enzyme inhibitor. It decreases the clearance of other drugs metabolized by the

same cytochrome P450 enzymes, including phenytoin, phenobarbital, pentobarbital, phenylbutazone, xylazine, and cyclophosphamide.<sup>180,181</sup> Whether FLF affects the metabolism of other drugs is unknown.

Although CHPC is well-tolerated by horses, FLF alters fecal consistency with single doses administered intravenously, orally, or intramuscularly.<sup>169</sup> In a chronic dosing study with the cattle intramuscular formulation, all horses remained clinically normal but had dramatic alterations in enteric flora. *Salmonella* spp., *E. coli*, and *Clostridium perfringens* in these horses rapidly developed resistance to FLF.<sup>170</sup>

In general, CHPC or FLF should not be administered concurrently with penicillins, macrolides, aminoglycosides, or fluoroquinolones. CHPC or FLF may antagonize the activity of penicillins or aminoglycosides, and they act on the same ribosomal site as the macrolides.<sup>182,183</sup> Inhibition of protein synthesis by CHPC or FLF interferes with the production of autolysins necessary for cell lysis after fluoroquinolones interfere with DNA supercoiling.<sup>184</sup>

## FORMULATIONS

CHPC sodium succinate is a water-soluble formulation for IV use and is hydrolyzed to CHPC in the liver. CHPC free base and CHPC-palmitate are available for oral administration. The CHPC-palmitate is hydrolyzed in the gastrointestinal tract to CHPC. Ophthalmic formulations of CHPC are also available. FLF is available only as a cattle product in three carriers (2-pyrrolidone, propylene glycol, and polyethylene glycol) to give it a long-acting effect.

## CLINICAL USE

CHPC is banned for use in any type of food animal because it can lead to idiosyncratic aplastic anaemia in humans. It is used in small animals and horses for a variety of bacterial infections, especially when penetration into the central nervous system is desired, but appropriate precautions should be taken in handling the product to prevent human exposure. FLF should not be routinely used in horses because of its effects on gastrointestinal flora and the clinical limitations of the long-acting cattle formulation.

## ☞ POTENTIATED SULFONAMIDES

The sulfonamides are a group of organic compounds with chemotherapeutic activity (hence they are antimicrobials, not antibiotics). They have a common chemical nucleus that is closely related to *p*-aminobenzoic acid, an essential component in the folic acid pathway of nucleic acid synthesis. Sulfonamides are combined with diaminopyrimidines such as trimethoprim (TMP) and pyrimethamine (PYM), which inhibit an essential step further along the folate pathway. Because the potentiated sulfonamides are remarkably synergistic and nontoxic, they are commonly used in equine medicine. Their use is complicated by differences in pharmacokinetics among TMP and PYM and the various sulfonamides used in the combinations.

## MECHANISM OF ACTION

The sulfonamides inhibit the bacterial enzyme dihydropteroate synthetase (DPS) in the folic acid pathway, thereby blocking bacterial nucleic acid synthesis. Sulfonamides substitute

for PABA, preventing its conversion to dihydrofolic acid. Alone, this action is considered bacteriostatic. Because the activity is by competitive substitution, the sulfonamide tissue concentration must be kept high enough to prevent bacterial access to PABA. Therefore the sulfonamides are ineffective in pus and necrotic tissue, which provide additional sources of PABA to the bacteria. The sulfonamides are nontoxic to mammalian cells because they use dietary folate for synthesis of dihydrofolic acid and do not require PABA. The addition of TMP or PYM to a sulfonamide creates a bactericidal combination. TMP inhibits bacterial folic acid synthesis at the next step in the folic acid sequence, inhibiting the conversion of dihydrofolic acid to tetrahydrofolic acid by inhibiting dihydrofolate reductase. This enzyme is present in both bacteria and mammalian cells, but the bacterial enzyme is inhibited at much lower concentrations than necessary to inhibit the mammalian enzyme.<sup>185</sup> The MICs against specific susceptible bacteria for each drug are generally lowered when the antimicrobials are administered in the potentiated sulfonamide combination. The resistance developed to the potentiated sulfonamides is lower than that to each individual drug; this is an important benefit because resistance to sulfonamides is very common and resistance develops rapidly to diaminopyrimidines when used alone.<sup>186</sup>

The potentiated sulfonamides have a broad spectrum of activity. The following bacteria are usually susceptible: *Streptococcus*, *Proteus*, *E. coli*, *Pasteurella*, *Haemophilus*, and *Salmonella* spp. Staphylococci, anaerobes, *Nocardia*, *Corynebacterium*, *Klebsiella*, and *Enterobacter* are susceptible but may become resistant. *Pseudomonas* spp., *Bacterioides* spp., and enterococci are usually resistant.<sup>13,42,187</sup> Other significant organisms that are susceptible to potentiated sulfonamides include protozoa (*Toxoplasma gondii*, *Sarcocystis neurona*) and coccidia. PYM is more effective than TMP against protozoa.<sup>186</sup> The potentiated sulfonamides are formulated at a fixed ratio of 1:5 of TMP to sulfonamide. The optimum concentration for bactericidal action is 1:20.<sup>185</sup> When and where this optimum concentration is achieved are difficult to predict in vivo, but a 1:20 ratio is used in susceptibility testing.<sup>188</sup>

## MECHANISMS OF RESISTANCE

Bacterial resistance to the sulfonamides is common and may be from chromosomal mutations or mediated by plasmids. Chromosomal mutations can lead to bacterial hyperproduction of PABA, which overcomes the competitive substitution of the sulfonamides. Plasmid-encoded resistance results in a by-pass of the drug-sensitive step by production of altered forms of the DPS enzyme with a lower affinity for sulphonamides. Resistance to TMP usually occurs by plasmid-encoded production of TMP-resistant dihydrofolate reductase. Other resistance mechanisms include excessive bacterial production of dihydrofolate reductase (DHFR) and reduction in the ability of the drug to penetrate the bacterial cell wall. Cross-resistance among sulfonamides is considered complete and often occurs with pyrimidines.<sup>185</sup> Resistance to the TMP-sulfonamide combinations develops slowly but is now common among equine bacterial isolates.<sup>13,189</sup>

## PHARMACOKINETICS

Pharmacokinetics of the potentiated sulfonamides are complicated by the distinct differences between disposition of TMP and PYM and the various sulfonamides. When sulfonamides

and diaminopyrimidines are administered concurrently to horses, the pharmacokinetics of each drug appears to be unaffected by the presence of the other. Table 4-9 outlines the pharmacokinetics of specific potentiated sulfonamide combinations in horses. Although the potentiated sulfonamides are frequently used interchangeably, pharmacokinetics studies show that they are not bioequivalent in horses.

## ABSORPTION

In general, potentiated sulfonamides are readily absorbed from the gastrointestinal tract of horses but may be affected by feeding.<sup>190-192</sup> For TMP and sulphachlorpyridazine, peak plasma concentrations and bioavailabilities are significantly reduced when the drug is mixed with concentrate compared with nasogastric administration.<sup>193</sup> Both drugs also demonstrate a biphasic absorption pattern, and it appears that this is due to a portion of the TMP and sulphachlorpyridazine dose binding to feed, with a second absorption phase occurring in the large intestine.<sup>194</sup> Bioavailability following intrauterine administration was 23% to 43% for TMP and 29% to 34% for sulfadoxine, and both were detected in the milk of lactating mares.<sup>195</sup> The oral bioavailability of PYM is 56% in horses.<sup>196</sup>

## DISTRIBUTION

Because the sulfonamides are weak acids and relatively hydrophilic, they distribute well in extracellular and interstitial fluids and typically have values for Vd of 0.3 to 0.7 L/kg. Concentrations of sulfonamides in tissues are generally lower than those in plasma. The diaminopyrimidines are lipophilic weak bases and penetrate intracellularly better than sulfonamides, resulting in values for Vd of 1.5 to 2.7 L/kg and higher tissue concentrations than plasma concentrations.<sup>185</sup> Distribution of potentiated sulfonamides has been broadly investigated in the horse. Sulfadiazine and TMP and sulfamethoxazole and TMP are all well distributed into peritoneal fluid, cerebrospinal fluid, synovial fluid, and urine.<sup>197-199</sup> Inflammation in the meninges or synovium does not significantly affect distribution into the respective fluids. After repeated doses sulfamethoxazole, unlike TMP, accumulates in the cerebrospinal fluid.<sup>197</sup> Cerebrospinal fluid concentrations of PYR reach 25% to 50% of serum concentrations but do not appear to accumulate in horses with daily dosing.<sup>200</sup>

Sulfonamides can be highly bound to plasma proteins, but the extent of binding depends on species, drug, and concentration. In the horse the degree of protein binding varies between 33% for sulfaphenazole to 93% for sulfamethoxine.<sup>185</sup> Approximately 50% of TMP is protein bound, and binding is independent of plasma concentration.<sup>201</sup> Although only free drug is available for antimicrobial action, protein-bound drug serves as a reservoir and extends the duration of action of these drugs.

## METABOLISM

Diaminopyrimidines and sulfonamides are metabolized by the liver, usually by acetylation, aromatic hydroxylation, and glucuronidation.<sup>185</sup> The acetylated, hydroxylated, and conjugated forms of the sulfonamides are significantly less microbiologically active than their parent compounds. The precise metabolic pathways for TMP or PYR have not been elucidated. Metabolites may compete with the parent drug for involvement in folic acid synthesis. They have little detrimental effect on bacteria, so their presence can decrease the activity of the remaining parent drug.<sup>202,203</sup>

TABLE 4-9

## Pharmacokinetics of Trimethoprim, Pyrimethamine, and Sulfonamides in Horses

Drug	Volume of Distribution (L/kg)	Half-life or MRT (hour)	Protein Binding (%)	Clearance (ml/min/kg)	Dose† (mg/kg)
Trimethoprim	—	2.4	—	—	PO: 5
Sulfadiazine <sup>191</sup>	—	7.4	—	—	PO: 25
Trimethoprim	2.0	2.8	35	8.8	IV: 2.5
Sulfadiazine <sup>213</sup>	0.5	4.6	20	1.5	IV: 12.5
Trimethoprim	1.5	3	50	—	IV: 8
Sulfadoxine <sup>201</sup>	0.39	14	14-72	—	IV: 40
Trimethoprim	2.8	3.4	—	11	IV: 7.5
Sulfamethoxazole <sup>222</sup>	0.5	4.8	—	1.4	IV: 36.5
Trimethoprim	1.6	1.9	—	13	IV: 2.5
Sulfamethoxazole <sup>197</sup>	0.33	3.5	—	1.3	IV: 12.5
Trimethoprim	1.5	2.6	—	7.7	IV: 5
Sulfachlorpyridazine <sup>193</sup>	0.26	3.8	—	2.6	IV: 25
Pyrimethamine <sup>196</sup>	1.5	12	—	1.6	IV, PO: 1
Sulfadiazine <sup>202</sup>	0.4	3.8	43	2.3	IV: 20
Sulfamerazine <sup>202</sup>	0.49	3.2	44	1.8	IV: 20
Sulfamethazine <sup>192</sup>	0.63	11.4	—	0.8	IV: 160
Sulfamethazine <sup>202</sup>	0.33	5.4	69	0.9	IV: 20

MRT, Mean residence time; PO, oral; IV, intravenous.

## ELIMINATION

Sulfonamides are primarily excreted in urine, but excretion in feces, bile, milk, sweat, and tears also occurs. Renal excretion of unchanged drug and metabolites occurs by glomerular filtration and active tubular secretion.<sup>185</sup> Reabsorption occurs in the distal tubule by passive diffusion. Because most sulfonamides are weak acids, alkaline urine increases their ionization and elimination. Renal excretion of TMP occurs by glomerular filtration, active tubular secretion, and reabsorption. In horses it appears that a large percentage of TMP is metabolized before elimination in urine (46%) and feces (52%). The clearance of the diaminopyrimidines is affected by urine pH, plasma concentration, and extent of diuresis. In contrast to the sulfonamides, alkaline urine increases the reabsorption of the basic TMP.<sup>201</sup>

## ADVERSE EFFECTS AND DRUG INTERACTIONS

The potentiated sulfonamides are noted for their widely varying adverse effects. Crystalluria, hematuria, and renal tubular obstruction can result from poorly soluble sulfonamides, especially in dehydrated patients with acidic urine.<sup>185</sup> However, the lower doses of sulfonamide used in the potentiated sulfonamide combinations make crystallization less likely than with sulfonamides administered alone. Local infusion of potentiated sulfonamides into the uterus of mares caused irritation of the endometrium and a decreased pregnancy rate.<sup>195</sup> Intramuscular administration is not recommended because of tissue irritation from the organic solvents, high concentration, and high pH of the formulations. IV administration must be done

by slow and careful injection. Rapid administration is associated with thrombophlebitis and anaphylaxis.<sup>185,204</sup> The concurrent use of IV potentiated sulfonamides with detomidine is contraindicated because it appears that the potentiated sulfonamide sensitizes the myocardium and results in cardiac dysrhythmias and hypotension that may be fatal.<sup>205,206</sup> The procaine in procaine penicillin G is a PABA analog and may reduce efficacy if used concurrently with potentiated sulfonamides.<sup>2</sup>

## FOLATE ANTAGONISM EFFECTS

The nonregenerative anemias seen in response to long-term administration of potentiated sulfonamides are believed to be related to folate reduction with long-term, high-dose administration, such as in the treatment of equine protozoal myeloencephalitis (EPM). Concurrent therapy with TMP and PYR does not increase the efficacy against protozoa and is suspected to increase the incidence of adverse effects caused by folate reduction. Supplementation with oral folic acid is often recommended for horses on long-term potentiated sulfonamide therapy.<sup>207</sup> The administration of oral folic acid to pregnant mares being treated for EPM may not protect the fetus from the effects of folate deficiency. Mares have delivered foals with congenital defects after oral administration of potentiated sulfonamides.<sup>208</sup> These mares had also been supplemented with oral folic acid and vitamin E during the period of antibiotic treatment. Each of three mares on this dosage regimen produced a foal with renal hypoplasia or nephrosis and bone marrow aplasia or hypoplasia. In both mares and foals, serum folate

concentrations were below the laboratory reference range, and in two foals folate was less than 30% of the minimum reference range. The risk of congenital defects should be considered when treating pregnant mares with PYM and sulfonamide. Treatment with TMP-sulfamethoxazole and PYM does not affect semen quality, testicular volume, sperm production efficiency, erection, or libido of healthy stallions. However, treatment may induce changes in copulatory form and agility and alter the pattern and strength of ejaculation.<sup>209</sup> Stallions that develop neurologic signs during treatment should be bred with caution. TMP/sulfamethoxazole has been associated with immune-mediated hemolytic anemia in a horse.<sup>210</sup>

### EFFECTS ON GASTROINTESTINAL FLORA

The effects of potentiated sulfonamides on normal gastrointestinal flora are controversial. In some studies potentiated sulfonamides alone or with concurrent penicillin therapy are associated with diarrhea in horses.<sup>211,212</sup> Other studies show little effect on fecal flora.<sup>213,214</sup> The likelihood of any antimicrobial therapy causing diarrhea in a horse depends on several factors, including the antibacterial spectrum of the drug and the drug concentrations achieved in the gastrointestinal tract. The presence or absence of potential pathogens in the composition of the individual horse's microflora and the presence of antimicrobial-resistant pathogens in the hospital or clinic environment are also important factors in the incidence of gastrointestinal disturbances.

### FORMULATIONS

TMP/sulfadiazine is available as a 48% injectable solution for IV administration in horses. It is also available as oral paste and powder formulations for horses. Generic tablets of TMP/sulfamethoxazole available for human use are commonly administered to horses. A commercially available PYR/sulfadiazine formulation is marketed for the treatment of equine protozoal myelitis in horses.

### CLINICAL USE

It is very difficult to apply pharmacokinetic principles to determine drug dosage regimens for the potentiated sulfonamides. Different pathogens have varying MIC values, and the optimal ratio of TMP or PYM to sulfonamide also varies among bacteria and protozoa. The most important component of the formulation for efficacy appears to be the diaminopyrimidine, and the choice of sulfonamide may not be nearly as important. Therefore there is considerable controversy regarding the dosage regimen of these combinations. The veterinary products are labeled for once-daily administration, but studies indicate that twice-daily dosing is better for attaining therapeutic plasma concentrations.<sup>213,215</sup> Despite frequent clinical use for equine streptococcal infections, even prophylactic administration failed to prevent abscessation caused by *Streptococcus equi* subsp. *zooepidemicus*.<sup>216</sup>

## ☞ TETRACYCLINES

*Tetracycline* was discovered after a team of workers examined 100,000 soil samples from around the world. Tetracycline derivatives include *oxytetracycline*, *chlortetracycline*, *doxycycline*, and *minocycline*. Oxytetracycline (OTC) and doxycycline (DXC) are used in horses.

### MECHANISM OF ACTION

The tetracyclines bind to the 30-S ribosomal subunit and interfere with bacterial protein synthesis. They are bacteriostatic at usual therapeutic concentrations but bactericidal at high concentrations. Drug entry into the bacteria is by an energy-dependent mechanism. Mammalian cells do not possess the tetracycline transport mechanism. Tetracyclines are most active at an acidic pH. The tetracyclines are broad-spectrum in activity; they are effective against gram positive and gram negative bacteria, as well as *Chlamydia*, *Mycoplasma*, and *Rickettsia* spp. and some protozoa (*Haemobartonella*, *Anaplasma* spp.). Their activity against staphylococci is limited, and they are not active against group D streptococci (enterococci). *Pseudomonas*, *E. coli*, *Klebsiella*, and *Proteus* are usually resistant. Most anaerobes are susceptible to DXC.<sup>2</sup> In vitro concentrations of OTC above 0.01 µg/ml effectively suppress growth of *Neorickettsia risticii*.<sup>217</sup> Tetracyclines are also effective against intracellular pathogens of foals, such as *Lawsonia intracellularis* and *Rhodococcus equi*.<sup>218</sup> Multiple other actions have been attributed to DXC, including anticollagenolytic activity through inhibition of matrix metalloproteinases (MMPs), anti-inflammatory activity, and ability to enhance corneal repair.<sup>219</sup>

### MECHANISMS OF RESISTANCE

Widespread acquired resistance in many pathogens limits the clinical usefulness of the tetracyclines. Resistance occurs from plasmid-mediated failure in the active transport of the drug into the bacterial cell and increased efflux from the cell. Another major mechanism of resistance involves cytoplasmic production of a protein that protects the ribosome from tetracycline action.<sup>2</sup>

### PHARMACOKINETICS

#### ABSORPTION

Oral absorption of OTC is erratic, and oral administration is not recommended in horses because its adverse effects on gastrointestinal flora.<sup>214</sup> At an oral dose of 10 mg/kg in fed horses, DXC produced serum, synovial fluid, peritoneal fluid, and endometrial tissue concentrations above 0.25 µg/ml, suggesting effective therapy for gram positive infections.<sup>220</sup> At an oral dose of 20 mg/kg in fasted horses DXC produced mean maximum plasma concentration of 0.91 µg/ml following a single dose and 1.74 µg/ml after multiple doses using a 12-hour dosing interval.<sup>221</sup> A precise bioavailability cannot be determined because IV administration of DXC causes cardiac toxicity.<sup>222</sup> However, using allometric scaling, the estimated systemic absorption for DXC after oral administration in horses is only 2.7%.<sup>221</sup> Oral absorption of DXC in foals is higher, with a single oral dose of 10 mg/kg producing mean maximum plasma concentrations of 2.54 µg/ml and 4.05 µg/ml after multiple doses using a 12-hour dosing interval.<sup>223</sup> The long-acting formulation of OTC in polyethylene glycol has a bioavailability of 83% after intramuscular injection in horses.<sup>224</sup>

#### DISTRIBUTION

The tetracyclines are well distributed to most tissues, except the central nervous system. Therapeutic levels may be achieved, however, when the meninges are inflamed. Tetracyclines readily diffuse into milk.<sup>2</sup> OTC reaches 50% of plasma

concentrations in synovial fluid and peritoneal fluid. Urine OTC concentrations are relatively high, with peak concentrations above 1500 µg/ml.<sup>225</sup> The Vd of OTC in neonatal foals is 2 L/kg<sup>226</sup> and 0.34 to 0.95 L/kg in adult horses.<sup>224,227</sup> The apparent Vd of DXC in horses after oral absorption is 25 L/kg, indicating the high lipid solubility and tissue penetration of DXC. Synovial and peritoneal fluids achieve the same DXC concentrations as plasma, and endometrial tissue concentrations are more than twice plasma concentrations. DXC is not detectable in cerebrospinal fluid after oral administration.<sup>220</sup> DXC concentrates intracellularly, with mean maximum concentrations in polymorphonuclear cells approximately 17 times higher than concentrations found in plasma.<sup>221</sup> In foals peritoneal fluid, synovial fluid, and bronchoalveolar lavage cell activity of DXC were similar to plasma concentrations; however, activity in the cerebrospinal fluid was significantly lower, and activity in pulmonary epithelial lining fluid and urine was significantly higher.<sup>223</sup>

Ocular penetration of systemic DXC has been studied. Vitreal drug concentrations were 0.17 µg/mL after multiple doses of 10 mg/kg.<sup>228</sup> Aqueous humor concentrations were approximately 0.11 µg/mL after multiple doses of 20 mg/kg, which represented 7.5% of corresponding plasma concentrations.<sup>221</sup> DXC was also detectable in the precocular tear film of horses without ocular disease after once-daily administration of 20 mg/kg.<sup>219</sup>

OTC is 50% protein bound in horses.<sup>229</sup> Plasma protein binding of DXC is high (82%), which is similar to that of other species.<sup>221</sup> This impairs distribution of DXC into the extracellular fluid.

## ELIMINATION

The tetracyclines are not known to be biotransformed to any significant extent before elimination. OTC is eliminated in urine unchanged primarily by glomerular filtration. Unmetabolized drug is also eliminated with bile into the gastrointestinal tract and may undergo enterohepatic recirculation, prolonging its effects.<sup>2</sup> DXC is primarily excreted into the feces by way of nonbiliary routes in an inactive form. Therefore DXC does not accumulate in patients with renal insufficiency.<sup>230</sup> The clearance of OTC in foals is 3.3 ml/min/kg<sup>226</sup> and 2.2 ml/min/kg in adult horses.<sup>224</sup> When administered intravenously, the elimination half-life is 7 hours in foals<sup>226</sup> and 6 hours in horses.<sup>224</sup> Because of flip-flop kinetics, the elimination half-life is 22 hours after intramuscular administration of OTC in polyethylene glycol.<sup>224</sup> DXC clearance cannot be accurately determined from oral dosing.<sup>221</sup>

## ADVERSE EFFECTS AND DRUG INTERACTIONS

### GASTROINTESTINAL EFFECTS AND INTERACTIONS

Calcium-containing products (e.g., milk, antacids) or other divalent cations will chelate with tetracyclines and interfere with gastrointestinal absorption.<sup>2</sup> Because DXC is less likely than the older tetracyclines to form chelation complexes with divalent and trivalent metals, there is less interference with oral absorption by calcium or other substances.<sup>230</sup>

The clinical use of OTC in horses is controversial because of reports of adverse gastrointestinal effects. However, adverse effects were also associated with excessive dosage,<sup>231</sup> concomitant use of other antimicrobials, and stressors such as surgery and transport.<sup>232-235</sup> Anecdotally, OTC therapy has been used successfully in equine practice, and recognition of the equine

rickettsial diseases has increased OTC use in horses.<sup>236-238</sup> In a chronic dosing study using a long-acting formulation of OTC, no deleterious effects on fecal flora were detected and treated horses remained clinically normal.<sup>239</sup> DXC is less likely to cause adverse gastrointestinal effects because it is bound in an inactive form in the intestines; however, at higher doses the risk of adverse effects may be increased. One study reported that doses of 20 mg/kg orally twice daily produced signs of abdominal discomfort in one horse and a severe enterocolitis in another. The other four horses in that study were unaffected.<sup>221</sup> DXC administered to foals at 10 mg/kg orally twice daily for 8 to 17 days for treatment of *Lawsonia intracellularis* infection did not produce any adverse effects.<sup>218</sup>

### RENAL EFFECTS

Renal tubular necrosis caused by OTC is associated with high doses, outdated parenteral products, endotoxemia, dehydration and hypovolemia, and concurrent pigment nephropathy.<sup>2,240</sup> In normal foals high-dose IV OTC administration for the correction of flexural deformities does not cause renal toxicity.<sup>241</sup> Oliguric renal failure developed in a foal that had concurrent neonatal isoerythrolysis given 70 mg/kg of IV OTC for a flexural deformity.<sup>240</sup>

### CARDIOVASCULAR EFFECTS

Rapid IV administration of OTC results in hypotension and collapse. This is attributed to intravascular chelation of calcium, decreased blood pressure from the drug vehicle (propylene glycol), or both. Pretreatment with IV calcium borogluconate prevents collapse.<sup>242,243</sup> Rapid IV administration of DXC to horses causes tachycardia, systemic arterial hypertension, collapse, and death.<sup>222,244</sup> It is suggested that this reaction is due to chelation of intracellular calcium, resulting in neuromuscular blockade of the myocardium. Plasma total and ionized calcium concentrations are not affected by IV DXC administration.

### MUSCULOSKELETAL EFFECTS

Intramuscular injection of long-acting OTC formulations causes localized pain and swelling at the injection site.<sup>2,239</sup> OTC causes flexor tendon relaxation; this effect has been used to treat foals with flexural deformities.<sup>245,246</sup> OTC induces a dose-dependent inhibition of collagen gel contraction by equine myofibroblasts. Inhibition of normal collagen organization may provide the mechanistic explanation for the results seen after the pharmacologic treatment of flexural deformities by OTC administration.<sup>247</sup> Because of the neuromuscular blocking effects, tetracyclines are not recommended for the treatment of diseases affecting the neuromuscular junction, such as botulism.

## FORMULATIONS

Injectable OTC products are formulated as short- or long-acting products. The short-acting solutions are in propylene glycol and have concentrations of 50 or 100 mg/ml. The long-acting solutions are in 2-pyrrolidone or polyethylene glycol and have a concentration of 200 mg/ml. The polyethylene glycol formulation is less irritating than the 2-pyrrolidone formulation. The long-acting formulations may be administered by slow IV injection, but the long-acting effect is lost.<sup>194</sup> DXC tablets are available in multiple generic and proprietary formulations.

## CLINICAL USE

OTC is the drug of choice for treatment of Potomac horse fever (*Neorickettsia risticii*) and equine anaplasmosis (*Anaplasma phagocytophilum*). It is also used to treat contracted flexor tendons in foals and calves. Its use for other microbial infections in horses is controversial because of concerns related to adverse gastrointestinal effects and widespread antimicrobial resistance. DXC is also indicated for rickettsial diseases in horses and may be a suitable oral alternative to OTC. Tetracyclines are commonly used for treatment of proliferative enteropathy caused by *Lawsonia intracellularis*. DXC is also used for the treatment of keratomalacic diseases in horses because it may decrease corneal proteinases such as MMP-2 and MMP-9.<sup>219</sup>

## MACROLIDES AND AZALIDES

The macrolide antibiotics include *erythromycin*, *clarithromycin*, *tylosin*, *tilmicosin*, and *tiamulin*. *Azalides*, such as *azithromycin*, have a similar mechanism of action but have a methylated nitrogen in the macrocyclic ring. Triamides, such as *tulathromycin*, are semisynthetic macrolides prepared by fermentation followed by organic synthesis. Because of their adverse gastrointestinal effects, these drugs are typically contraindicated in adult horses; however, *erythromycin*, *clarithromycin*, and *azithromycin* are commonly used in foals.

## MECHANISM OF ACTION

The macrolides and their derivatives bind to the 50-S ribosomal subunit in a manner similar to that of CHPC and FLF, and they interfere with protein synthesis. They are usually considered bacteriostatic but may be bactericidal at high concentrations. Macrolides are not effective against gram negative bacteria, except some strains of *Pasteurella* and *Haemophilus* in cattle.<sup>2</sup> *Azithromycin* is more active than the macrolides against gram negative bacteria and anaerobes.<sup>217,248</sup> Susceptible bacteria include staphylococci, streptococci, *Campylobacter jejunii*, *Clostridium* spp., *Rhodococcus equi*, *Lawsonia intracellularis*, *Mycoplasma* spp., and *Chlamydia* spp.<sup>249</sup> Antimicrobial activity of these weak bases is optimum at an alkaline pH; therefore they have reduced activity in acidic environments (e.g., pus, abscesses) but may be clinically effective because of high concentrations due to ion-trapping. *Erythromycin* has nonantimicrobial effects on host cell metabolism, inflammatory mediators, and gastrointestinal motility.<sup>250,251</sup>

## MECHANISMS OF RESISTANCE

The routine use of the macrolides is limited because bacterial resistance develops quickly after repeated exposure.<sup>252</sup> Mechanisms of resistance include decreased drug entry into bacteria, inability to bind to the bacterial 50-S ribosomal subunit, and plasmid-mediated production of esterases.<sup>2</sup> Resistance to *erythromycin* has been reported in 13% of *R. equi* isolates.<sup>253</sup> Extensive cross-resistance occurs among the macrolides.<sup>2</sup>

## PHARMACOKINETICS

### ABSORPTION

*Erythromycin* is available for oral administration as enteric-coated *erythromycin* base, *erythromycin* esters (ethylsuccinate or estolate), and *erythromycin* salts (phosphate or

stearate). Because of expense, many practitioners administer the drug as crushed enteric-coated tablets of *erythromycin* base. However, *erythromycin* base is degraded in the stomach by gastric acid. The esterified formulations are absorbed intact and must be hydrolyzed to the active *erythromycin* A. The *erythromycin* salts are absorbed unchanged.<sup>250</sup> The oral bioavailability of *erythromycin* base is 17% in fasted foals, with most of the drug being degraded and absorbed as the microbiologically inactive anhydro*erythromycin* A.<sup>254</sup> Microencapsulation of the base improves the oral bioavailability of *erythromycin* base to 26% in fasted foals, but it remains only 7.7% in fed foals.<sup>255</sup> The oral bioavailability of *erythromycin* estolate in fasted foals is 36% but only 16% for *erythromycin* phosphate.<sup>256</sup> The estolate formulation appears to have the best pharmacokinetic profile in foals. Because of injection site irritation, intramuscular administration of *erythromycin* is not recommended in horses. The reported oral bioavailability of *azithromycin* in foals ranges between 39% to 56%.<sup>257,258</sup> The oral bioavailability of *clarithromycin* in foals is similar (57%).<sup>259</sup> The bioavailability of *tulathromycin* has not been determined; however, after intramuscular administration the drug is rapidly detected in the plasma of foals, with maximum concentrations of 0.41 µg/ml 4 hours after administration.<sup>260</sup>

### DISTRIBUTION

The macrolides are well distributed into most tissues. *Erythromycin*, *clarithromycin*, and *azithromycin* concentrate in leukocytes, making them very effective against intracellular pathogens such as *Rhodococcus equi*.<sup>261</sup> Concentrations of *azithromycin* and *clarithromycin* in bronchoalveolar lavage cells were significantly higher than *erythromycin*, and *azithromycin* had a significantly longer elimination half-life from the cells.<sup>262</sup> Bronchoalveolar cell and pulmonary epithelial lining fluid concentrations of *azithromycin* are 15- to 170-fold and 1- to 16-fold higher than concurrent serum concentrations, respectively, and did not decrease for up to 48 hours after administration.<sup>257</sup> *Clarithromycin* concentrations in bronchoalveolar cell and pulmonary epithelial lining fluid are 91- to 105-fold and 324- to 585-fold higher than concurrent serum concentrations, respectively; however, in contrast to *azithromycin*, *clarithromycin* concentrations significantly decreased within 12 hours of administration.<sup>259</sup> *Tulathromycin* concentrates in bronchoalveolar cells, and concentrations are detectable for at least 8 days after a single administration. Concentrations are higher 192 hours after administration than at 24 hours after administration, indicating ongoing accumulation within these cells.<sup>260</sup>

Because they are weak bases, macrolides are ion trapped in milk, cerebrospinal fluid, and gastric fluids. The Vd for *erythromycin* is 2.7 L/kg in foals.<sup>254</sup> *Azithromycin* is known for its high degree of lipid solubility, and the Vd of *azithromycin* in foals is 11.6 to 18.6 L/kg.<sup>257,258</sup> *Clarithromycin* also exhibits a large volume of distribution, with reported values of 10.4 L/kg.<sup>259</sup> Peritoneal and synovial fluid concentrations of *azithromycin* and *clarithromycin* parallel serum concentrations.<sup>259</sup> The apparent Vd for *tulathromycin* after intramuscular administration is 15.2 L/kg.<sup>260</sup>

### ELIMINATION

*Erythromycin* is extensively metabolized, with much of the parent drug and active metabolite excreted into the bile, resulting in an elimination half-life of 1 to 2 hours.<sup>254-256,263</sup> *Erythromycin* inhibits the metabolism of a number of other drugs by interfering with cytochrome P450 enzymes.<sup>2</sup> In addition, the degradation

product anhydroerythromycin A is a potent inhibitor of cytochrome P450-mediated metabolism.<sup>264</sup> Erythromycin undergoes enterohepatic cycling.<sup>2</sup> Azithromycin is not highly metabolized and is primarily eliminated in bile. The elimination half-life is 16 to 20.3 hours in foals.<sup>257,258</sup> Clarithromycin is extensively metabolized in humans, and the active metabolite, 14-hydroxy-clarithromycin, is produced in foals, although the pharmacokinetics have not been quantitated.<sup>259</sup> The elimination half-life of clarithromycin in foals is intermediate between erythromycin and azithromycin at 5.4 hours.<sup>259</sup> Tulathromycin has the longest elimination half-life, reported at 117 hours in foals.<sup>260</sup>

## ADVERSE EFFECTS AND DRUG INTERACTIONS

The use of erythromycin in horses is associated with a number of adverse effects. Since erythromycin came into clinical use in the 1950s, it was apparent that therapy was frequently accompanied by adverse gastrointestinal effects. Macrolide antibiotics, including erythromycin and clarithromycin, are motilin receptor agonists. They also appear to stimulate motility via cholinergic and noncholinergic neuronal pathways. At microbially ineffective doses they stimulate migrating motility complexes and antegrade peristalsis in the gastrointestinal tract.<sup>251,263,265,266</sup> When used at antimicrobial doses, erythromycin is associated with potentially fatal colitis from *Clostridium* spp.<sup>267-269</sup>

Erythromycin is also associated with acute respiratory distress syndrome, hyperthermia, gastroenteritis, and hepatotoxicity in foals.<sup>264,270,271</sup> The mechanism of hyperthermia in erythromycin-treated foals has not been elucidated but likely results from derangement of the hypothalamic temperature set-point.<sup>270</sup> Extreme care should be taken when administering erythromycin to foals with respiratory disease during periods of hot weather. Foals should not be left outside on hot, sunny days while on erythromycin therapy. Erythromycin also interferes with host cell metabolism and decreases inflammatory responses in airways, but the clinical significance of this has not been determined.<sup>264</sup>

Erythromycin is commonly administered in conjunction with rifampin to take advantage of antimicrobial synergism and reduce the chance of resistance development.<sup>12</sup> Erythromycin may interact with other drugs metabolized by the same cytochrome P450 enzyme system. Concurrent administration of erythromycin with theophylline results in a doubling of plasma theophylline concentrations and can result in seizures in foals.<sup>2</sup>

Azithromycin is associated with fewer adverse effects than erythromycin in human beings. No adverse reactions were detected during or after repeated intragastric administration of azithromycin or clarithromycin in foals.<sup>257,259</sup> Azithromycin has been used successfully in adult horses without adverse effects; however, there are anecdotal reports of antimicrobial-associated colitis in older weanlings.

In a study that evaluated the use of tulathromycin in foals with evidence of pulmonary abscessation, self-limiting diarrhea, fever, and injection site reactions were the only adverse effects noted. In one foal in that study, the injection site reaction was severe and resulted in temporary lameness and severe swelling.<sup>272</sup>

## FORMULATIONS

Because the base of erythromycin is unstable in gastric acid, it is formulated as enteric-coated erythromycin tablets. Erythromycin stearate and erythromycin phosphate are insoluble

salt formulations that disassociate in the intestine, allowing absorption of the free erythromycin base. Erythromycin ethylsuccinate and erythromycin estolate are ester formulations that are absorbed intact from the intestine, and then plasma esterases release active drug. Erythromycin is available in an intramuscular formulation approved for cattle. Because of its highly irritating nature, this formulation is not recommended for intramuscular use in horses and it can be fatal if injected intravenously. A human-labeled formulation of erythromycin lactobionate is available for IV use. Tablet formulations are available for azithromycin in 250-, 500-, and 600-mg strengths. Clarithromycin is available as an immediate and extended release tablet. The extended release formulations have not been studied in horses. Tulathromycin is available as a 100-mg/ml injectable solution for cattle and swine.

## CLINICAL USE

On account of its association with potentially fatal adverse effects, erythromycin is usually limited to treatment of *Rhodococcus equi* infections in foals. It also has been shown to be an effective therapy for Potomac horse fever<sup>273</sup> and equine proliferative enteropathy caused by *Lawsonia intracellularis*.<sup>274</sup> Its motilin-like activity is exploited for use as a treatment for adynamic ileus in horses.<sup>251</sup> Azithromycin has become an attractive alternative to erythromycin for the treatment of *R. equi* infections in foals because of its pharmacokinetic profile, which allows once-daily or every-other-day dosing and an apparent reduced incidence of adverse effects.<sup>275</sup> However, in a retrospective study of 81 foals treated for naturally occurring *R. equi* infection, the combination of clarithromycin and rifampin was shown to be superior to combinations of azithromycin and rifampin and erythromycin and rifampin.<sup>261</sup> Tulathromycin may be an acceptable treatment for pulmonary abscesses in foals. Pharmacokinetic and efficacy studies suggest that a once-weekly dosing regimen at 2.5 mg/kg, administered intramuscularly, may be effective.<sup>260,272</sup> This provides a more affordable treatment alternative, although injection site reactions may limit the use of this drug in horses.

## FLUOROQUINOLONES

The quinolones are a group of synthetic antimicrobials. The first was *nalidixic acid*, which was introduced in 1964. It had good activity against gram negative bacteria but had a low Vd and numerous adverse effects and was limited to treatment of urinary tract infections. Further chemical manipulation resulted in development of the fluorinated quinolones, which had extended antimicrobial activity with improved safety. Included in this group are *ciprofloxacin*, *enrofloxacin*, *danofloxacin*, *difloxacin*, *orbifloxacin*, *marbofloxacin*, *floxacin*, *moxifloxacin*, and *levofloxacin*. No fluoroquinolones are approved for use in horses, but because of their pharmacokinetics and antimicrobial activity, they are commonly used for serious gram negative infections.

## MECHANISM OF ACTION

The fluoroquinolones have a unique mechanism of action for bacterial killing. The fluoroquinolones inhibit bacterial deoxyribonucleic acid (DNA) gyrase (also known as *topoisomerase II*).

Bacteria have a single chromosome consisting of double-stranded DNA. Within the bacterial cell the chromosome is folded around an RNA core, and each fold is supercoiled. DNA gyrase, which has been found in every organism examined, is responsible for supercoiling the strand of bacterial DNA. The DNA gyrase structure has four subunits: two A monomers and two B monomers. The enzyme forms a heart-shaped molecule, with the A monomers forming the atria and the B monomers forming the ventricles. The bacterial DNA binds to the gyrase in the cleft between the A and B subunits. The DNA gyrase nicks double-stranded DNA, introduces negative supercoils, and seals the nicked DNA. The fluoroquinolones bind to the DNA-DNA gyrase complex and inhibit the DNA resealing, resulting in abnormal spatial DNA configuration, which leads to DNA degradation by exonucleases.<sup>276</sup>

Fluoroquinolone activity is concentration dependent, and clinical efficacy is most associated with achieving either a  $AUC_{0-24}:MIC$  greater than 125 or a  $C_{max}:MIC$  greater than 10. These PK/PD relationships are related, insofar as increasing the dose to increase the peak plasma concentration will also increase the AUC value.<sup>2</sup>

All of the fluoroquinolones are bactericidal, although these drugs have an optimum concentration for bacterial killing. Higher or lower drug concentrations result in reduced bactericidal activity. It is thought that the DNA-DNA gyrase complex has two binding sites for fluoroquinolones. At low drug concentrations only one binding site is occupied, resulting in single-stranded nicks in the DNA. Reduced killing at high concentrations is thought to be due to dose-dependent inhibition of RNA or protein synthesis. RNA and protein synthesis are required for production of bacterial autolysins, which are responsible for the fluoroquinolone-induced cell lysis.<sup>2,276</sup>

The fluoroquinolones are broad spectrum in activity, with activity against most gram negative bacteria; some gram positive bacteria; and *Mycoplasma*, *Chlamydia*, and *Rickettsia* spp. They are particularly effective against the enteric gram negative pathogens, including some strains resistant to aminoglycosides and cephalosporins. Reported MICs are very low, and MBCs are one to two times the MIC for most pathogens. They are usually active against staphylococci but have variable activity against streptococci and enterococci. Most diagnostic laboratories use ciprofloxacin or enrofloxacin to determine pathogen susceptibility; however, MIC values vary among the fluoroquinolones. Ciprofloxacin has the greatest activity against *Pseudomonas* spp. Orbifloxacin has lower MIC values than enrofloxacin for the gram negative bacteria *Actinobacillus equuli*, *E. coli*, *Pasteurella* spp., and *Salmonella* spp. Enrofloxacin has lower MIC values for the gram positive bacteria and *Pseudomonas* spp.<sup>2</sup>

Most fluoroquinolones are not active against anaerobic bacteria.<sup>277</sup> This susceptibility pattern may be a therapeutic advantage in the treatment of enteric infections in horses, because gastrointestinal anaerobes rarely cause disease and usually are protective by competitively inhibiting colonization by pathogenic aerobic organisms.

The fluoroquinolones concentrate within phagocytic cells. Uptake occurs by simple diffusion, and intracellular concentrations may be several times greater than plasma concentrations. Intracellular drug is microbiologically active against intracellular pathogens such as *Brucella* spp., *Mycoplasma* spp., and *Mycobacterium* spp.<sup>2</sup> Exposure of gram negative bacteria to fluoroquinolones at concentrations several times the MIC

for 1 to 2 hours results in a PAE with a recovery period of 1 to 6 hours. This effect suggests that fluoroquinolone dosage regimens can tolerate plasma concentrations below the pathogen's MIC for extended periods of time without a reduction in efficacy.<sup>278</sup>

## MECHANISMS OF RESISTANCE

Microbial resistance to the fluoroquinolones is primarily due to chromosomal mutations that alter bacterial DNA gyrase, decrease cell wall permeability, or increase fluoroquinolone efflux from the cell. Plasmid-mediated resistance has only recently been documented for the fluoroquinolones. Fluoroquinolone-resistance plasmids can be transmitted horizontally and provide low-level resistance that facilitates the emergence of higher-level resistance at therapeutic levels.<sup>279</sup> The fluoroquinolones must penetrate bacteria to reach the target DNA gyrase. The fluoroquinolones diffuse through porin channels in the outer membrane of gram negative bacteria. *Pseudomonas* spp. resistance is associated with alterations in a wide range of outer-membrane proteins. From these mutations the increase in the MICs of the fluoroquinolones is relatively low (2- to 32-fold). However, there is cross-resistance with unrelated antibiotics, most frequently TMP, tetracycline, CHPC, and cefoxitin.<sup>280</sup>

Since the fluoroquinolones have been used intensively in human medicine in the last 2 decades, high-level resistance has emerged in some pathogens. Chronic fluoroquinolone use encourages the development of chromosomally mediated resistance. In high-level resistant bacterial strains, one resistance mechanism alone is usually not responsible; rather, two or three mechanisms of resistance operate in conjunction. In resistant *S. aureus* increased efflux is often coupled with a gyrase mutation.<sup>281</sup> In resistant *E. coli* gyrase mutations are usually associated with changes in the outer membrane proteins.<sup>282</sup>

## PHARMACOKINETICS

### ABSORPTION

The fluoroquinolones are rapidly and well absorbed from the gastrointestinal tract of monogastrics and preruminant calves. Enrofloxacin is more lipid soluble than ciprofloxacin and has a higher oral bioavailability than ciprofloxacin in horses and small animals. The oral bioavailability of ciprofloxacin is only 6.8% in adult ponies.<sup>283</sup> The oral bioavailability of enrofloxacin is approximately 60% in adult horses and 42% in foals.<sup>284-286</sup> The moderate oral absorption of enrofloxacin has been determined to be due to hepatic first pass effect.<sup>287</sup> Oral absorption of enrofloxacin is not affected by feeding.<sup>288</sup> Antacids containing divalent cations (calcium, magnesium) chelate fluoroquinolones and reduce oral bioavailability.<sup>2</sup> Bioavailability from parenteral injection is nearly 100% for all fluoroquinolones, but intramuscular injections of enrofloxacin are irritating to tissues.<sup>289</sup> For economic reasons and client convenience, practitioners have attempted to administer the bovine injectable solution of enrofloxacin orally to horses. This results in a bioavailability of approximately 65% in horses when administered intragastrically.<sup>290</sup> Unfortunately, the injectable formulation is highly irritating to the oral mucosa and may cause ulceration with repeated use. A methylcellulose gel formulation has better oral absorption but may also cause oral ulceration.<sup>291</sup>

## DISTRIBUTION

The fluoroquinolones are extremely lipid soluble and well distributed to most tissues. Tissue concentrations typically exceed plasma concentrations during therapy. Extremely high concentrations are achieved in the kidney, urine, liver, and bile. Therapeutic concentrations for gram negative bacteria may be achieved in cerebrospinal and ocular fluids.<sup>283,285,292,293</sup> Aqueous humor concentrations of enrofloxacin after IV administration of 3 daily doses of 7.5 mg/kg were 0.32 µg/ml.<sup>294</sup> Plasma protein binding of fluoroquinolones is low to moderate in most species. Protein binding data are available only for orbifloxacin and levofloxacin in the horse, which are reported to be 21%<sup>295</sup> and 28%,<sup>296</sup> respectively.

## ELIMINATION

The fluoroquinolones are predominantly excreted in the urine by glomerular filtration and active tubular secretion.<sup>2</sup> For marbofloxacin approximately 40% is excreted unchanged in the urine, whereas with enrofloxacin only 3.4% is excreted unchanged in the urine.<sup>287</sup> Ciprofloxacin undergoes some self-oxidation, and its metabolites also have antimicrobial activity. Enrofloxacin is metabolized (de-ethylated) to ciprofloxacin in horses, with serum ciprofloxacin concentrations reaching 20% to 35% of enrofloxacin concentrations.<sup>289</sup> Metabolism of enrofloxacin to ciprofloxacin is negligible in foals, and ciprofloxacin was not detected in the plasma of foals in which IV or oral enrofloxacin was administered.<sup>284</sup> The elimination half-life of ciprofloxacin in ponies is 2.5 hours and 5 hours in horses.<sup>283</sup> Enrofloxacin has an elimination half-life of 4.4 hours after IV administration and 10 hours after intramuscular administration, indicating flip-flop kinetics.<sup>289</sup> With oral administration the elimination half-life of enrofloxacin is 8 hours.<sup>293</sup>

## ADVERSE EFFECTS AND DRUG INTERACTIONS

Toxicity of fluoroquinolones is mild in most species, and gastrointestinal irritation is the most common side effect.<sup>2</sup> The only fluoroquinolone reported to cause gastrointestinal effects in experimental horses is moxifloxacin.<sup>297</sup> The effects of most clinical concern are arthropathies. Transient arthropathies occur when fluoroquinolones are used in the therapy of *Pseudomonas* pneumonia in children with cystic fibrosis, but their benefits are considered to outweigh the risks of use.<sup>298</sup> Chronic high-dose fluoroquinolone therapy causes articular cartilage lesions in juvenile dogs, particularly in weight-bearing joints.<sup>299</sup> No documented arthropathies have been reported for calves, swine, or poultry. An in vitro study using equine cartilage explants did not demonstrate cartilage damage from enrofloxacin, although proteoglycan synthesis was reduced at high doses.<sup>300</sup> Arthropathies have been documented in 2-week-old foals after receiving 10 mg/kg of enrofloxacin orally.<sup>301</sup> Damage was characterized by synovial joint effusion and lameness and erosion and cleft formation in articular cartilage. Arthropathies were not seen in adult horses that were given up to 25 mg/kg of IV enrofloxacin daily for 3 weeks or 15 mg/kg orally every 12 hours for 3 weeks.<sup>292,302</sup> Although they are not recommended for use in pregnant humans or animals, the fluoroquinolones appear to have little effect on the developing fetus.<sup>303</sup> Enrofloxacin was successfully used to treat chronic pleuritis in a pregnant mare with no apparent detrimental effects on the foal.<sup>304</sup>

Ciprofloxacin and enrofloxacin interfere with the cytochrome P450 system metabolism of methylxanthines such as theophylline. Serum theophylline concentrations may double and result in central nervous system and cardiac toxicity, so concentrations must be monitored during therapy.<sup>305</sup>

The fluoroquinolones may cause adverse central nervous system effects in humans and animals as a result of a  $\gamma$ -aminobutyric acid (GABA) receptor antagonism. This has been associated with an increase in the incidence of seizures in human beings and dogs. Administration of enrofloxacin to human beings results in hallucinations.<sup>2</sup> Rapid IV administration of high doses of enrofloxacin to horses causes transient neurologic signs, including excitability and seizurelike activity.<sup>302</sup> This can be prevented by slow injection or dilution of the dose. Dilution of the dose should be performed in sterile saline solution, because the cations found in other fluids, such as lactated Ringer's solution, may chelate and inactivate the drug. Photosensitivity reactions and Achilles tendon rupture have been associated with fluoroquinolone use in humans but have not been reported in animals.<sup>276</sup>

The fluoroquinolones have been used in combination with other antimicrobial agents to expand the therapeutic spectrum, suppress emergence of drug-resistant bacterial populations, or exploit inhibitory or bactericidal synergism against drug-resistant populations. Minimal synergy occurs between fluoroquinolones and  $\beta$ -lactams or aminoglycosides against gram negative enteric bacteria because of the already high susceptibility of these organisms. Combinations with aminoglycosides,  $\beta$ -lactams, or vancomycin are additive or indifferent against staphylococci. Antagonism between fluoroquinolones and CHPC or rifampin appears to be due to the inhibition of bacterial autolysin synthesis from concurrent administration of bacterial protein synthesis inhibitors.<sup>2</sup>

## FORMULATIONS

Ciprofloxacin is available as human-labeled tablets, a diluted solution for IV administration, and a solution for ophthalmic use. Enrofloxacin is available as oral tablets and a 50 mg/ml injectable solution for intramuscular injection in dogs and as a 100 mg/ml injectable solution for the subcutaneous treatment of cattle. Both injectable solutions can be administered intravenously to horses. Orbifloxacin, marbofloxacin, and danofloxacin are available as oral tablets for small animals.

## CLINICAL USE

The use of fluoroquinolones in horses has been limited because of the risk of arthropathies; however, enrofloxacin has been successfully used in clinical cases, and fluoroquinolones may be the only viable option for treating some infections.<sup>304,306-308</sup> Informed consent from the client should always be obtained before using fluoroquinolones in young horses. Because the fluoroquinolones are concentration-dependent killers with a long PAE, the ideal dosage regimen is once-daily high-dose therapy.

## ☞ RIFAMPIN

### MECHANISM OF ACTION

The rifamycins are antibiotics produced from *Streptomyces mediterranei*. Rifampin inhibits DNA-dependent RNA polymerase in susceptible organisms, suppressing RNA synthesis.

It has no effect on the mammalian enzyme. Its action is bacteriostatic or bactericidal depending on the susceptibility of the bacteria and the concentration of the drug. Rifampin is effective against a variety of mycobacterium species and *S. aureus*, *Haemophilus*, and *Rhodococcus equi*. Rifampin is considered especially active in the treatment of staphylococcal and rhodococcal infections and in the eradication of pathogens located in difficult-to-reach target areas, such as inside phagocytic cells. It is active at an acid pH, making it a rational choice for the treatment of septic foci and granulomatous infections. It has moderate activity against *Actinobacillus suis*, *Actinobacillus equuli*, *Bordetella bronchiseptica*, and *Pasteurella* spp. Equine isolates of *Pseudomonas aeruginosa*, *E. coli*, *Enterobacter cloacae*, *Klebsiella pneumoniae*, *Proteus* spp., and *Salmonella* spp. are resistant. The ability of rifampin to reach intracellular bacteria can make it difficult to predict in vivo therapy results on the basis of in vitro sensitivity tests.<sup>309</sup> Because bacterial resistance to rifampin develops rapidly, it is usually administered with another antimicrobial.<sup>310</sup> Although it is commonly combined with erythromycin for the treatment of *R. equi*,<sup>12</sup> resistance to the combination has been reported.<sup>252,311</sup> The combination is also effective for treatment of equine monocytic ehrlichiosis (Potomac horse fever).<sup>273</sup> Rifampin is also commonly administered with newer macrolide and macrolide derivative drugs, such as clarithromycin and azithromycin.<sup>261</sup>

## PHARMACOKINETICS

### ABSORPTION

The oral bioavailability of rifampin varies between 70% in fasted horses to 26% when administered with feed.<sup>29,309,312</sup> Because rifampin is usually administered with feed, recommended dosages compensate for the decreased bioavailability. Bioavailability after intramuscular injection is 60%.<sup>313</sup>

### DISTRIBUTION

Rifampin is highly lipophilic and penetrates most tissues as well as milk, bone, abscesses, and the central nervous system. Feces, saliva, sweat, tears, and urine may be discolored red-orange by rifampin and its metabolites.<sup>314</sup> The Vd of rifampin in horses is 0.6 to 0.9 L/kg.<sup>312,313</sup> Rifampin is 78% bound to plasma proteins.<sup>312</sup>

### ELIMINATION

In other species rifampin is deacetylated in the liver to a metabolite that also has antibacterial activity. Desacetylrifampin was not detected in equine serum samples after an IV dose of 10 mg/kg or oral doses of 10 mg/kg every 12 hours for seven doses.<sup>312</sup> Desacetylrifampin was measured in urine, but rifampin was much more predominant. However, only 6.82% of the total dose was recovered in the urine as either rifampin or desacetylrifampin. The elimination half-life of rifampin is 6 to 8 hours after IV administration and 12 to 13 hours after oral administration.<sup>309,312</sup> Because of immature hepatic metabolism, elimination of rifampin is delayed in very young foals.<sup>315,316</sup> Plasma clearance ranges between 1.14 to 1.34 ml/min/kg.<sup>312,313</sup> As a hepatic enzyme inducer, rifampin induces its own metabolism so that multiple oral dosing significantly decreases the elimination half-life. Enzyme induction is typically not seen with fewer than 5 days of therapy, but once it occurs, the increase in enzyme activity may last for more than 2 weeks after discontinuation of treatment.<sup>317</sup>

## ADVERSE EFFECTS AND DRUG INTERACTIONS

Rifampin stains everything it touches red, and treated animals may produce red urine, tears, sweat, and saliva. There are no harmful consequences from this effect. Most horses object to the taste of rifampin, so care must be taken to deposit a dose quite far back on the tongue and rinse the horse's mouth afterward. Microsomal enzyme induction from rifampin may shorten the elimination half-life and decrease plasma drug concentrations of CHPC, corticosteroids, theophylline, itraconazole, ketoconazole, warfarin, and barbiturates.<sup>314</sup>

## FORMULATIONS

Rifampin is available as human-labeled capsules or suspension for oral administration or as a diluted solution for IV use.

## CLINICAL USE

Rifampin is primarily used in the treatment of pulmonary abscess caused by *R. equi* and *L. intracellularis* proliferative enteropathy in foals in combination with a macrolide or a macrolide derivative.

## ☞ METRONIDAZOLE

### MECHANISM OF ACTION

Metronidazole is rapidly taken up by bacteria, where it is metabolized by a reduction process to cytotoxic derivatives (short-lived free radical compounds). These cytotoxic compounds damage DNA and other critical intracellular macromolecules. Aerobic bacteria lack the reductive pathway necessary to produce the radical compounds.<sup>318</sup> Metronidazole is highly effective against anaerobic bacteria, including *Bacteroides fragilis* (penicillin resistant), *Fusobacterium*, and *Clostridium* spp. Metronidazole-resistant *Clostridium difficile* may cause diarrhea in foals.<sup>319</sup> Metronidazole has good activity against protozoa, including *Giardia* and *Trichomonas* spp.<sup>320</sup> Metronidazole has anti-inflammatory effects in human beings, particularly in the gastrointestinal tract, and has been used in them for the treatment of chronic inflammatory bowel diseases.<sup>321</sup>

## PHARMACOKINETICS

### ABSORPTION

Metronidazole is rapidly and well absorbed after oral administration in horses, with an oral bioavailability of 75% to 85%.<sup>320,322</sup> In horses with gastrointestinal ileus, metronidazole may be administered rectally and is rapidly absorbed; however, the bioavailability is only 30%.<sup>323</sup>

### DISTRIBUTION

Metronidazole is lipophilic and widely distributed in tissues. It penetrates bone, abscesses, and the central nervous system. The Vd in mares is 0.7 to 1.7L/kg.<sup>320,322</sup>

### ELIMINATION

Metronidazole is primarily metabolized in the liver. Both metabolites and unchanged drug are eliminated in urine and feces. Plasma clearance is 2.8 ml/min/kg, and elimination half-life is 3 to 4 hours in horses.<sup>320,322-324</sup>

## ADVERSE EFFECTS AND DRUG INTERACTIONS

With clinical use in horses, anorexia is the only adverse effect associated with the oral use of metronidazole.<sup>325</sup> Metronidazole produces mutations in bacteria, and carcinogenicity occurs in laboratory mice with prolonged exposure. Therefore metronidazole is banned from use in food animals. Because it has been implicated as a teratogen in laboratory animals, use in pregnant animals is not recommended.<sup>2</sup>

Because of its limited antimicrobial spectrum, metronidazole is merely additive to aminoglycosides and  $\beta$ -lactams in the treatment of polymicrobial infections.<sup>2</sup>

## FORMULATIONS

Metronidazole is available only as human-labeled formulations. It is most commonly administered orally as tablets and capsules. Because it is poorly soluble, the IV formulation must be diluted in a large volume for administration, and it is cost prohibitive in adult horses.

## CLINICAL USE

Metronidazole is used to treat anaerobic infections, especially pleuropneumonia and lung abscesses caused by penicillin-resistant *Bacteroides fragilis* and clostridial enterocolitis.<sup>14,325-327</sup> Although rectal absorption is inferior to oral absorption, it is a viable option for treatment when oral administration is not feasible. Metronidazole has also been used for the treatment of infiltrative bowel diseases in the horse.<sup>328</sup>

### NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

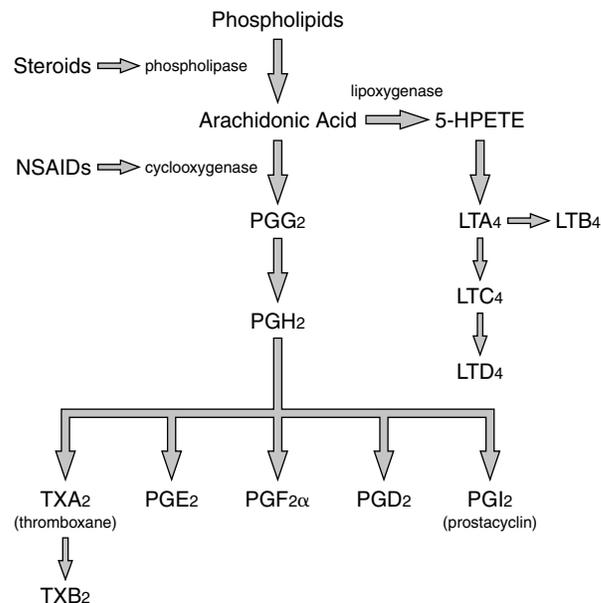

Patricia M. Dowling

The most commonly used drugs for treatment of pain and inflammation in horses are the nonsteroidal anti-inflammatory drugs (NSAIDs). The NSAIDs inhibit the enzyme cyclooxygenase (COX), which converts arachidonic acid to the prostaglandins thromboxane and prostacyclin (Figure 4-23). Blocking these eicosanoids results in anti-inflammatory, analgesic, antipyretic, antiendotoxic, and antithrombotic effects.<sup>1</sup>

## MECHANISM OF ACTION

### CYCLOOXYGENASE INHIBITION

Two different, distinct forms of COX have been identified. The constitutively expressed form was considered normal for homeostasis and is referred to as COX-1, whereas the inducible form produced in response to injury was considered detrimental and is referred to as COX-2.<sup>2</sup> COX-1 is found in platelets, the kidneys, and the gastrointestinal tract; COX-2 is identified in fibroblasts, chondrocytes, endothelial cells, macrophages, and mesangial cells. COX-2 is induced by exposure to various cytokines, mitogens, and endotoxin and is upregulated at sites of inflammation.<sup>3</sup> Unfortunately, this classification of “good” versus “bad” COX proved too simplistic to explain the roles of the different forms of COX.<sup>4</sup> COX-2 is produced constitutively in the brain, spinal cord, kidney, ovary, uterus,

**FIGURE 4-23** In the arachidonic acid cascade, cyclooxygenase works on arachidonic acid to produce prostaglandins (PG), thromboxanes (TX), and prostacyclin, whereas lipoxygenase works on arachidonic acid to produce leukotrienes (LT). NSAIDs, Nonsteroidal anti-inflammatory drugs; HPETE, hydroperoxyeicosatetraenic acid.

placenta, thymus, bone, cartilage, synovia, endothelia, prostate, and lung. COX-2 is involved in cellular processes such as gene expression, differentiation, mitogenesis, apoptosis, bone modeling, wound healing, and neoplasia<sup>5</sup> but can also be induced by hormones, nitric oxide, cytokines, and lipoxygenase products.

The prostaglandins produced in the gastrointestinal tract and kidney that maintain mucosal integrity in the upper gastrointestinal tract and renal perfusion, respectively, originally appeared to be derived only from COX-1. It was suggested that COX-2-selective NSAIDs would suppress prostaglandin synthesis at sites of inflammation but would spare constitutive prostaglandin synthesis in the gastrointestinal tract and kidney.<sup>6</sup> Most of the currently available NSAIDs vary in their potency as inhibitors of COX-1, but are far more potent inhibitors of COX-2 than COX-1. The pharmaceutical companies raced to develop COX-2-selective NSAIDs, but this now appears to be an imperfect solution.<sup>5</sup> If COX-2 is primarily responsible for the prostaglandins that mediate pain, inflammation, and fever, then COX-2-selective drugs are not necessarily more therapeutically effective, because the nonselective NSAIDs are already very effective inhibitors of COX-2.<sup>7</sup> Moreover, COX-1-derived prostaglandins contribute to pain, inflammation and fever, so COX-2-selective NSAIDs may actually be less effective.<sup>8</sup> Studies are now published showing that some COX-2 “selective” drugs are therapeutically effective only at doses high enough to inhibit COX-1.<sup>7</sup> Because COX-2 also produces beneficial prostaglandins, the highly selective COX-2 inhibitors produced adverse reactions not seen with traditional NSAIDs.<sup>9</sup> Also, gastrointestinal ulceration is associated with significant mucosal inflammation and expression of COX-2, yet COX-2-derived prostaglandins are responsible for promoting healing.<sup>10</sup> It is now widely accepted

that both COX-1 and COX-2 are involved in mucosal defense in the gastrointestinal tract.<sup>11</sup> Likewise, both COX-1 and COX-2 are involved in normal renal function, insofar as prostaglandins affect renal circulation through vasodilation, renin secretion, and sodium and water excretion. As in the gastrointestinal tract, it was thought that COX-1–derived prostaglandins were involved in regulating homeostatic functions and COX-2–derived prostaglandins were involved only in inflammation or tissue damage. However, constitutive expression has been demonstrated for both isoforms in the kidney. Traditional NSAIDs and COX-2–selective NSAIDs both reduce sodium excretion and may cause acute renal failure when maintenance of adequate renal perfusion is prostaglandin dependent.<sup>12</sup>

### ANTI-INFLAMMATORY EFFECTS

The NSAIDs are primarily anti-inflammatory as a result of their inhibition of prostaglandin production. Therefore NSAIDs do not resolve inflammation but prevent its ongoing occurrence. Whereas prostaglandin production will rapidly diminish, any previously present prostaglandin must be removed before inflammation will subside. From tissue cage work, it has been shown that phenylbutazone, ketoprofen, and carprofen have delayed peak concentrations at the site of inflammation and persist in inflammatory exudates for long periods of time after plasma concentrations are negligible.<sup>13-15</sup> This explains the delayed onset and prolonged duration of anti-inflammatory action that does not correlate with plasma pharmacokinetics of the NSAIDs.

The NSAIDs are commonly used in horses to attenuate the prostaglandin-mediated effects of endotoxin.<sup>16-18</sup> Low-dose flunixin has anti-endotoxin effects without obscuring the signs of colic pain, but because it does not alter endotoxin-induced leukopenia, there is little benefit in using the low dose over the recommended dose.<sup>19-25</sup> Flunixin and phenylbutazone significantly inhibit movement of polymorphonuclear and mononuclear cells and antagonize the effects of endotoxin on bowel motility.<sup>16,26</sup>

### OTHER ANTI-INFLAMMATORY EFFECTS

COX inhibition does not explain all of the anti-inflammatory activity of NSAIDs. NSAIDs are more lipophilic at a low pH, such as is found in inflamed tissues. Some anti-inflammatory action appears to be related to their ability to insert into the lipid bilayer of cells and disrupt normal signals and protein-protein interactions in cell membranes. In the cell membrane of neutrophils, NSAIDs inhibit neutrophil aggregation, decrease enzyme release and superoxide generation, and inhibit lipoygenase.<sup>27,28</sup>

### ANALGESIC EFFECTS

The NSAIDs act as analgesics by inhibiting COX and preventing the production of prostaglandins that sensitize the afferent nociceptors at peripheral sites of inflammation. However, increasing evidence suggests that some NSAIDs have a central mechanism of action at the level of the spinal cord for analgesia unrelated to COX inhibition.<sup>29</sup> This action is synergistic with opioids and  $\beta_2$ -receptor--adrenergic drugs.<sup>29,30</sup> Work with the specific enantiomers of some NSAIDs has shown the S enantiomers to have good COX-inhibitory effects, whereas

R forms can have weak activity against COX yet still produce analgesia.<sup>31,32</sup>

### CLINICAL IMPLICATIONS FOR TREATING PAIN AND INFLAMMATION

For managing pain and inflammation in horses, NSAIDs are more effective as analgesics when inflammation is a part of the pain process and when they are given before the onset of the inflammatory process or insult. The time to onset and duration of analgesia of NSAIDs does not correlate well with their anti-inflammatory properties. Because the analgesic effect has a more rapid onset and shorter duration of action than the anti-inflammatory action, dosage regimens for effective analgesia may need to be different than those for anti-inflammatory effects.

### ☞ CHIRALITY

Many of the NSAIDs are *stereoisomers*. Stereoisomers consist of enantiomers with the same molecular formula, but because of asymmetrically oriented chemical groups on a central carbon, they form three-dimensional, nonsuperimposable mirror images and are known as *chiral* compounds.<sup>33</sup> This means that they are like one's hands: superimposable palm to palm but not palm to back. For the NSAIDs it is common to use the *S* (*sinister*) and *R* (*rectus*) designations for each of a pair of enantiomers.<sup>34</sup> Although each member of a pair of enantiomers differs in three-dimensional orientation, their physical properties (e.g., melting and boiling points, refractive index, solubility) are identical. Biologic systems are highly chiral environments, and the pharmacokinetics and pharmacodynamic effects of each of a pair of enantiomers may be very different. Stereospecificity may occur in the pharmacokinetic processes of absorption, distribution, metabolism, and excretion, especially if the process involves a carrier protein.<sup>35</sup> If the fit of a drug molecule into the binding site on a protein, enzyme, or receptor involves the chiral center, then the affinity for attachment will be different for each of a pair of enantiomers. Therapeutic efficacy, toxicity, or both may be related specifically to one enantiomer. For the chiral NSAIDs the *S* enantiomer typically is associated with COX inhibition and the *R* enantiomer is associated with analgesic effects.<sup>33</sup> Most chiral drugs are formulated as racemic mixtures, containing equal amounts of each enantiomer, because pure enantiomeric compounds are difficult and expensive to manufacture. All of the propionic acid NSAIDs (i.e., ketoprofen, carprofen, vedoprofen, naproxen) are chiral compounds, and, except for naproxen, they are formulated as racemic mixtures. After administration some enantiomers undergo *chiral inversion*, as hepatic enzymes convert one form of the enantiomer to the other form. When chiral inversion of the propionic acid derivatives occurs, it is almost invariably unidirectional, from *R* to *S*.<sup>33</sup> The degree of chiral inversion varies among species and cannot be predicted from one species to another, making extrapolating dosages for NSAIDs extremely hazardous.

### ☞ PHYSICAL PROPERTIES

Almost all NSAIDs are weak acids and highly bound to plasma proteins such as albumin.<sup>1</sup> Therefore they are well absorbed from the stomach, and most of the drug in the plasma is protein bound. Because of protein binding, they

are predominantly distributed in the extracellular fluid and only low concentrations of NSAIDs are found in normal tissues and joint fluid. In damaged tissues and joints, however, NSAID concentrations increase to therapeutic levels because of increased blood flow, vascular permeability, and acute phase protein penetration into sites of inflammation. Most NSAIDs undergo hepatic metabolism either through oxidation or glucuronide conjugation before being eliminated in the urine.<sup>1</sup>

## ☉ DRUG INTERACTIONS

The occurrence and potential hazards of drug interactions must be considered before initiating therapeutic use of the NSAIDs. In general, any two NSAIDs administered together will be additive in their effect.<sup>36-39</sup> Because most NSAIDs act by similar mechanisms of COX inhibition, a higher dose of a single NSAID should produce the same response. Antacids, mucoprotective agents, and adsorbent antidiarrheal drugs can interfere with the absorption of NSAIDs.<sup>36</sup> Concurrent use of corticosteroids is generally contraindicated because corticosteroids increase the secretion of gastric acid, pepsin, and trypsin; alter the structure of gastric mucin; and decrease mucosal cell proliferation. This action is synergistic with NSAID-induced gastrointestinal mucosal damage, but the specific risks of concurrent NSAID and steroid administration are unknown.<sup>40</sup> CHPC decreases the elimination rate, and rifampin significantly increases the elimination rate of phenylbutazone.<sup>41</sup> Concurrent administration of phenylbutazone and procaine penicillin G results in higher serum concentrations of penicillin because of decreased tissue distribution.<sup>42</sup> Concurrent administration of gentamicin and phenylbutazone results in increased distribution and delayed elimination of gentamicin.<sup>43</sup> Phenylbutazone decreases urinary excretion of furosemide and attenuates furosemide-induced increases in urinary excretion of sodium and chloride.<sup>44,45</sup>

## ☉ ADVERSE EFFECTS OF NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

The adverse effects of the NSAIDs are primarily related to COX inhibition in tissues where prostaglandins are beneficial and protective. NSAIDs classically inhibit platelet aggregation by preventing thromboxane production via the COX-1 pathway.<sup>1</sup> Recovery of platelet function is dependent on the pharmacokinetics of the NSAID and the mechanism of COX inhibition.<sup>46-50</sup> Aspirin permanently modifies COX, so platelet function is restored only by the production of new platelets.<sup>46,50</sup> Renal papillary necrosis (medullary crest necrosis), oral and gastrointestinal ulceration, and right dorsal colitis have been associated with NSAID use in the horse.<sup>51-59</sup> The NSAIDs have a higher incidence of toxicity in neonates because kidney and liver function is not fully developed.<sup>58,60-62</sup> When indicated in neonates, NSAIDs should be administered at the lowest possible doses and at extended dosing intervals. NSAIDs should be administered very cautiously to dehydrated animals.<sup>53,55</sup> Because they mostly distribute in extracellular water, plasma concentrations will be greater than normal in the dehydrated animal and more likely to cause toxicity.

Treatment of NSAID-induced gastrointestinal toxicity is intensive and mainly symptomatic.<sup>51</sup> The hypoproteinemia that results from loss of plasma proteins into the ulcerated

gastrointestinal tract can be corrected with IV infusions of plasma. The fluid and electrolyte losses that accompany the diarrhea are managed with commercially available IV fluids. Broad-spectrum antimicrobials are indicated when bacterial septicemia appears to exist. Pain must be managed with opioid analgesics. Anti-ulcer medications may be beneficial and speed recovery. Surgical removal of damaged sections of stomach or colon may be necessary in some cases.<sup>51</sup> Recovery is usually slow, and in severe cases the prognosis is always guarded.

The renal toxicity of NSAIDs is a major concern, particularly in the perioperative period. NSAIDs typically have little effect on renal function in normal adult animals.<sup>63</sup> However, they decrease renal blood flow and GFR in patients with congestive heart failure, that are hypotensive or hypovolemic (especially during anesthesia and surgery), or that have chronic renal disease.<sup>12</sup> A more severe dose-dependent toxicity associated most commonly with phenylbutazone is renal papillary necrosis.<sup>53,58,59</sup> Although attributed to impaired renal blood flow, other mechanisms, such as direct nephrotoxicity of the drug or its metabolites, also may be involved.

The effects of NSAIDs on proteoglycan synthesis should be considered in their clinical use for equine joint disease. Many NSAIDs affect cartilage anabolism in addition to their anti-inflammatory actions.<sup>64,65</sup> A few NSAIDs, such as carprofen, increase proteoglycan synthesis.<sup>64,66</sup> Phenylbutazone does not affect proteoglycan synthesis or chondrocyte viability, but it is protective against chondrocyte-mediated catabolism.<sup>65</sup> The effects of NSAIDs on bone healing are currently controversial, with some laboratory animal studies showing detrimental effects and others showing little or no effect on bone healing.<sup>67</sup> Currently the only NSAID that has shown negative bone healing effects in horses is phenylbutazone.<sup>68</sup> Clinicians should consider the clear benefits of analgesia in equine patients against the potential adverse effects.

## ☉ ASPIRIN

Aspirin (sodium salicylate) is available only in oral forms. Because it is a weak acid, it is best absorbed in the acidic environment of the upper gastrointestinal tract. During absorption aspirin is partially hydrolyzed to salicylic acid and distributed throughout the body. Highest concentrations are attained in the liver, heart, lungs, renal cortex, and plasma. Extent of protein binding is moderate (about 60%) and depends on species and drug and albumin concentrations.<sup>1</sup> Aspirin is hepatically metabolized by glycine and glucuronide conjugation. Salicylates and their metabolites are rapidly excreted in urine by way of glomerular filtration and active tubular excretion, with an elimination half-life in the horse of approximately 1 hour.<sup>69</sup> In the horse salicylic acid is the primary salicyl compound found in urine.<sup>70</sup> Significant tubular reabsorption occurs, which depends greatly on pH.<sup>1</sup>

Aspirin is the most effective NSAID for antiplatelet therapy.<sup>46,71,72</sup> Aspirin irreversibly acetylates the COX present in platelets, which inhibits the formation of thromboxane A<sub>2</sub>, which is responsible for vasoconstriction and platelet aggregation.<sup>46,71,72</sup> Antiplatelet therapy may be beneficial in the management of equine laminitis, disseminated intravascular coagulation, and equine verminous arteritis. A precise antiplatelet dose has not been established, but a dose of 12 mg/kg prolongs bleeding time for 48 hours.<sup>46</sup>

## ☞ CARPROFEN

Carprofen is a propionic acid derivative formulated as a racemic mixture. Currently available for use in horses in Europe, approval is being sought for North America. The  $V_d$  is 0.1 L/kg for the R enantiomer and 0.29 L/kg for the S enantiomer.<sup>13</sup> At the recommended dose of 0.7 mg/kg, carprofen has a longer elimination half-life in horses than most other NSAIDs. After IV administration, the plasma elimination half-life is 21 hours for the R enantiomer and 17 hours for the S enantiomer. The R enantiomer predominates in plasma and exudates because of the hepatic stereospecificity for glucuronidation of the S enantiomer, leading to its more rapid clearance.<sup>73</sup> Chiral inversion of carprofen does not occur in the horse.<sup>73</sup> Like other NSAIDs, carprofen accumulates in inflammatory exudate but produces only modest reductions in the concentrations of eicosanoids compared with flunixin or phenylbutazone.<sup>31,74</sup> Despite this, carprofen produces significant analgesia, probably owing to the central actions of the R enantiomer.<sup>74</sup>

## ☞ DICLOFENAC

Diclofenac is available as a 1% liposomal suspension cream for topical application in horses. It is used to control pain and inflammation associated with osteoarthritis in the tarsal, carpal, metacarpophalangeal, metatarsophalangeal, and proximal interphalangeal joints in horses. A 5-inch ribbon of diclofenac topical cream is applied twice daily over the affected joint for up to 10 days. Owners should wear rubber gloves to prevent absorption into the hands. A single topical application of diclofenac cream produced measurable concentrations of diclofenac in transudate within 6 hours and significantly attenuated carrageenan-induced local production of prostaglandin  $E_2$ .<sup>75</sup> However, in an amphoterin B acute synovitis model, there was no overall difference between the diclofenac treated group and the control group.<sup>76</sup> In a controlled field study in horses with osteoarthritis of the tarsal, carpal, metacarpophalangeal, metatarsophalangeal, and proximal interphalangeal joints, average lameness scores showed statistically significant improvement after treatment with diclofenac topical cream.<sup>77</sup> The limited systemic absorption of diclofenac makes it useful in the treatment of acute lameness in competitive horses.<sup>78</sup> However, as a result of central sensitization and windup, locally administered diclofenac will be less effective than systemically administered NSAIDs for therapy of chronic pain.

## ☞ FIROCOXIB

Firocoxib is a COX-2-selective NSAID in an oral paste formulation for treatment of musculoskeletal pain in horses. Firocoxib is dosed at 0.1 mg/kg for up to 14 days. In horses firocoxib is well absorbed, with an oral bioavailability of 79%, and  $V_d$  values are approximately 2 L/kg. Firocoxib is slowly eliminated, with reported elimination half-lives as long as 2 days.<sup>79,80</sup> In horses renal clearance of firocoxib is less than total body clearance, which indicates that hepatic clearance through metabolism of firocoxib is the main pathway for elimination in horses.<sup>80</sup> In clinical trials of horses with naturally occurring osteoarthritis, overall clinical efficacy of firocoxib was comparable to that of a paste formulation of phenylbutazone.<sup>81</sup>

## ☞ FLUNIXIN MEGLUMINE

Flunixin meglumine is a very potent inhibitor of COX that is approved for use in horses and is available in injectable and oral formulations. Flunixin is rapidly absorbed after oral administration, with a bioavailability of 86% and peak serum levels within 30 minutes.<sup>82</sup> Absorption is delayed by feeding.<sup>83</sup> The  $V_d$  is 0.1 to 0.3 L/kg in horses, and the plasma elimination half-life is 1 to 2 hours.<sup>82-84</sup> In newborn foals the elimination half-life is prolonged at 13.4 hours. The  $V_d$  is also increased in the newborn foal, as is expected with a low  $V_d$  drug in the neonate.<sup>85</sup> It is highly protein bound (86%) but appears to readily partition into tissues, hence the relatively high volume of distribution.<sup>86,87</sup> The elimination half-life in inflammatory exudate is 16 hours.<sup>88</sup> The onset of anti-inflammatory action is within 2 hours, peak response occurs between 12 and 16 hours, and duration of action is 36 hours. Analgesic effects have a more rapid onset and shorter duration. Only 14% of a dose is excreted in urine, but otherwise little is known about the metabolism of flunixin.<sup>1</sup>

Flunixin is used in horses for a variety of inflammatory and painful conditions, including colic, colitis, exertional rhabdomyolysis, endotoxic shock, respiratory disease, ocular disease, general surgery, and laminitis.<sup>1</sup> Flunixin is more effective than phenylbutazone in preventing the clinical signs of endotoxemia but appears equivalent to ketoprofen.<sup>89</sup> Flunixin may prevent abortion in endotoxic mares.<sup>90</sup> Flunixin is dosed at 1.1 mg/kg every 24 hours for musculoskeletal pain but may be administered more frequently (every 8 to 12 hours) for colic pain. Low-dose therapy at 0.25 mg/kg every 8 hours is used for anti-endotoxic effects but will not provide much analgesia at this dose. Extremely high doses of flunixin may mask signs of surgical colic pain and interfere with treatment decisions.

Flunixin has a good safety profile, but high doses or chronic dosing can cause anorexia, depression, and gastrointestinal ulcers.<sup>56,91</sup> In normal foals the label dose of flunixin administered for 5 days did not produce adverse effects, but 6 times the label dose resulted in gastrointestinal ulcers.<sup>62</sup> In another study foals were administered flunixin at the label dose for 30 days, and all treated foals developed gastric ulcers.<sup>60</sup> Intramuscular injections of flunixin are highly irritating to muscle and have been incriminated in cases of clostridial myonecrosis in horses; they should therefore be avoided when possible, despite the label directions.<sup>92,93</sup> If not treated promptly and aggressively, clostridial myonecrosis causes severe tissue damage and may be rapidly fatal. Flunixin treatment of horses with ischemic gastrointestinal disease may cause prolonged permeability defects in recovering mucosa.<sup>94-96</sup>

## ☞ KETOPROFEN

Ketoprofen is a chiral propionic acid derivative approved for horses as a racemic solution for IV or intramuscular injection. Oral and rectal bioavailability is too poor for these routes to be used clinically.<sup>15,97,98</sup> Ketoprofen is 92.8% protein bound in horses.<sup>99</sup> Ketoprofen has a moderate  $V_d$  for both enantiomers of approximately 0.5 L/kg and short plasma elimination half-lives of 1 to 1.5 hours.<sup>15,32,88,99,100</sup> Ketoprofen is hepatically metabolized by conjugation reactions, with only 25% of a dose eliminated as unchanged drug in urine.<sup>99</sup> The S enantiomer is associated with antiprostaglandin activity and toxicity, whereas the R enantiomer is associated with analgesia and does not produce gastrointestinal ulceration.<sup>15,101</sup> Because of

chiral inversion, the S enantiomer predominates in horses.<sup>15</sup> Ketoprofen accumulates in inflammatory exudates in the horse, where the elimination half-life of the S enantiomer is 23 hours and the R enantiomer is 20 hours. The maximum anti-inflammatory effects of ketoprofen occur at 4 hours after a dose and last for 24 hours, illustrating that the anti-inflammatory effects are not related to plasma concentrations.<sup>88</sup>

In studies of noninfectious arthritis, endotoxemia, and colic, ketoprofen is clinically similar to flunixin meglumine in efficacy.<sup>88,89,101</sup> In an experimentally induced synovitis model, phenylbutazone was more effective in reducing lameness and synovial fluid prostaglandin concentrations.<sup>102</sup> In horses with chronic laminitis, ketoprofen was more effective than phenylbutazone at relieving pain but only at a higher-than-label dose.<sup>103</sup> In a comparative toxicity study, ketoprofen at the label dose had less potential for toxicity than flunixin meglumine or phenylbutazone.<sup>56</sup> In drug tolerance studies using 25 times the label dose for 5 days, horses developed depression, icterus, nephritis, hepatitis, and hemorrhagic necrosis of the adrenal glands.<sup>104</sup>

## PHENYLBUTAZONE

Phenylbutazone is the most widely used NSAID in the horse and is available in many generic IV and oral formulations. After oral administration, phenylbutazone is well absorbed, but time to peak concentration may be delayed by feeding.<sup>105-107</sup> The Vd is 0.15 L/kg, with highest concentrations in the liver, heart, kidney, lungs, and plasma.<sup>108</sup> The elimination half-life is 3.5 to 7 hours.<sup>109</sup> In neonatal foals the Vd is higher (0.27 L/kg) and the elimination half-life is longer (6.4 to 22.1 hours) than in adult horses.<sup>110</sup> Plasma protein binding in horses is greater than 99%.<sup>109</sup> Phenylbutazone is metabolized in the liver to oxyphenbutazone, an active metabolite that is eliminated more slowly from the body than phenylbutazone. Oxyphenbutazone inhibits the metabolism of phenylbutazone. Phenylbutazone and its metabolite cross the placenta and are excreted in milk. Less than 2% is excreted in the urine as unchanged drug. The capacity of the liver to metabolize phenylbutazone becomes overwhelmed at relatively low drug doses, resulting in dose-dependent kinetics.<sup>111</sup> The elimination half-life increases with increasing dose rates and increasing age.<sup>111-113</sup> The elimination half-life from exudate is 24 hours.<sup>14</sup> Therapeutic efficacy lasts for more than 24 hours as a result of the irreversible binding of phenylbutazone to COX, slow elimination from inflamed tissues, and long elimination half-life of oxyphenbutazone.<sup>109</sup> Therefore high or frequent doses of phenylbutazone result in disproportionately increasing plasma concentrations, which easily result in toxicity.

Phenylbutazone is used extensively in horses for a variety of musculoskeletal disorders. Although phenylbutazone also antagonizes the disruptive effects of endotoxin on bowel motility, flunixin meglumine is generally preferred for treatment of colic in horses.<sup>16</sup> Phenylbutazone appears to inhibit prostaglandin synthesis at low plasma concentrations in the horse (5-15 µg/ml), whereas much higher drug concentrations are needed in human beings (50-150 µg/ml).<sup>109</sup> This discrepancy is probably due to a species difference in the structure of COX. An initial dose of 4.4 mg/kg every 12 hours on the first day of therapy is followed by a decreased dose and increased dosing interval for subsequent therapy. Because of the accumulation from the long elimination half-life of phenylbutazone and oxyphenbutazone, chronic therapy should be every other day or only as needed to control pain.

Phenylbutazone has a narrow safety margin, especially in foals and ponies and dehydrated horses.<sup>53,62</sup> Phenylbutazone toxicity most commonly results in adverse gastrointestinal effects, including oral, esophageal, gastric, cecal, and right dorsal colonic ulcerations, and accompanying protein-losing enteropathy, hypoproteinemia, leukopenia, and anemia.<sup>51-55,114</sup> Renal papillary necrosis (renal medullary crest necrosis) results from inhibition of prostaglandins that maintain renal blood flow and direct toxicity of phenylbutazone and metabolites.<sup>59</sup> Because phenylbutazone can mask symptoms of lameness in horses for several days after therapy, it may be used to disguise lameness during soundness examinations or for competitive purposes.<sup>109</sup> Extravascular administration results in severe tissue necrosis. Phenylbutazone may have a negative effect on bone healing in horses.<sup>68</sup> Phenylbutazone significantly suppresses total T4 and free T4 concentrations in horses for 10 days.<sup>115</sup>

## VEDAPROFEN

Vedaprofen is structurally related to ketoprofen and carprofen and also is formulated as a racemic mixture of S and R enantiomers. It is available in some countries as an IV injectable solution and as a palatable gel for oral administration with a loading dose of 2 mg/kg followed by 1 mg/kg every 12 hours. Oral bioavailability is approximately 100%, and it is highly protein bound (99%). Within 2 hours after IV administration, the mean R:S plasma concentration ratio is 95:5. This is due to marked distribution and elimination differences between the enantiomers, and not chiral inversion. The R enantiomer has an elimination half-life of 2.2 hours and a volume of distribution of 0.23 L/kg, and the S enantiomer has an elimination half-life of 0.76 hours and a volume of distribution of 0.5 L/kg.<sup>116</sup> Both enantiomers accumulate in inflammatory exudate and are more slowly cleared from exudate than from plasma. In an equine acute nonimmune inflammation model, vedaprofen produced significant inhibition of inflammatory swelling and partially inhibited leukocyte migration into the exudate. Inhibition of leukocyte migration was not seen in this model with other NSAIDs.<sup>116</sup>

# ASPECTS OF CLINICAL NUTRITION

## CHAPTER 5

Raymond J. Geor\*

Veterinarians are a primary source of nutritional information and advice for horse owners. Therefore it is reasonable to expect equine practitioners to have some expertise in the clinical assessment of nutritional status and feeding programs so that they may assist horse owners in the selection of rations for an individual horse or group of horses. Additionally, because diet composition can contribute to the pathophysiology and clinical manifestations of certain chronic diseases (e.g., some forms of chronic exertional rhabdomyolysis), the veterinarian is often consulted to make recommendations for special diets. Special dietary considerations are also required for sick neonatal foals or adult horses. This chapter provides an overview of the principles of clinical assessment of nutritional status and feeding programs, reviews carbohydrate nutrition for horses (including the types of carbohydrates in horse feeds, terminology and methods for analysis of carbohydrates in feeds, and strategies for mitigation of gastrointestinal disturbances associated with carbohydrate nutrition), and summarizes current recommendations for the nutritional support of neonatal or adult horses with acute illness. Other topics are feeding management of thin and starved horses and dietary recommendations for the management of obesity, which is becoming a significant problem in equine medicine. The reader is referred to the most recent edition of the National Research Council's *Nutrient Requirements of Horses* for a complete discussion of equine nutrition.<sup>1</sup>

### ☞ EVALUATION OF NUTRITIONAL STATUS AND FEEDING PROGRAMS

Clinical assessment of a feeding program for an individual or group of horses involves three basic elements: assessment of general health and dietary history, clinical examination, and evaluation of current diet and feeding method (i.e., types and amounts of feeds and how they are fed). The physiologic state and intended use of the horse (e.g., pregnant, lactating, in athletic work) affect its nutritional requirements and therefore are vital with respect to the evaluation of the feeding program and the making of any necessary adjustments. It also is useful to inspect housing and feeding facilities, including feed bins, hay

storage, and the watering system. Commercial software programs are available to assist with ration evaluation in relation to nutrient requirements.<sup>2</sup> Figure 5-1 shows an example of a simple form that can be used to collect clinical data, including signalment, body weight and condition, and details regarding the horse's current and recommended ration. Box 5-1 provides explanations for a number of nutritional terms used to describe feed nutrients and fractions, the knowledge of which is relevant to the interpretation of feed analysis data.

### CLINICAL EXAMINATION

*Body condition scoring* (BCS) and measurement of body weight are the cornerstones of the clinical assessment of nutritional status. In some situations laboratory analysis of blood or other tissue samples may be indicated as part of the nutritional evaluation (e.g., measurement of whole blood selenium concentration). It must be recognized that no single laboratory value is a reliable indicator of nutritional status in an individual animal. Nonetheless, blood or tissue measurements may be valuable for evaluation of herd problems, wherein samples should be obtained from a representative number of animals.

Body weight and BCS, which assesses subcutaneous fat deposition, are indicators of long-term energy balance: energy (calorie) intake relative to the horse's needs. In general, horses that receive inadequate dietary energy will lose body weight and condition, whereas weight gain and the development of overconditioning (high BCS) signify energy intake in excess of requirements. Although a number of systems have been used to determine BCS, the most widely applied method is that developed by Henneke.<sup>3</sup> The Henneke system uses a 1- to 9-point scale and requires the assessment of subcutaneous fat deposition in six areas: over the crest of the neck, withers, behind the shoulder, over the ribs, along the back, and around the tail-head. Considerable variation may exist in the pattern of fat deposition among horses; for example, some horses have little fat deposited over the ribs even when other areas of the body are well covered. In addition, fat deposits are sometimes asymmetrically distributed. Therefore it is important to evaluate all six areas of the body on both sides. A score between 1 and 9 is assigned, wherein 1 indicates severe emaciation and 9 indicates extreme fatness (Table 5-1). Body condition scores of 4 to 6 are regarded as ideal depending on use of the horse. Studies of weight gain and loss in moderately conditioned

\*The editors acknowledge and appreciate the contribution of Debra K. Rooney, a former author of this chapter. Her original work has been incorporated into this edition.

(+1, +2, -1, -2, etc.)

**Current Horse Weight** \_\_\_\_\_**Target Horse Weight** \_\_\_\_\_

*Guide:* For an 1100- to 1200-lb horse, change in 1 BCS unit = 45 to 70 lb, but greater weight change may be necessary to alter BCS in very thin or very obese horses. Also, note that altering feed intake can have a rapid effect on body weight by increasing or decreasing gut fill. Thus, a change in gut fill can affect body weight by 10 to 20 lb, without a concomitant change in body condition score.

**Recommended Energy Intake for Target Weight** \_\_\_\_\_ **Mcal/d**  
(see Box 2)

Suggested Adjustments for Weight Change (estimates)

Increase BCS 1 unit in 60 days (add 6 to 7 Mcal/d)

Increase BCS 2 units in 90 days (add 9 to 10 Mcal/d)

Decrease BCS 1 unit in 60 days (subtract 6 to 7 Mcal/d)

Decrease BCS 2 units in 120 days (subtract 6 to 7 Mcal/d)

FIGURE 5-1, cont'd

BOX 5-1

**NUTRITIONAL TERMINOLOGY RELEVANT TO THE INTERPRETATION OF FEED COMPOSITION DATA**

**Moisture:** % of feed that is water

**Dry matter:** 100% minus the water in feed

Most hays and concentrates are approximately 90% water.

Fresh pasture can contain 60%-80% water.

Feed compositions are usually compared on a *dry matter basis* (100% dry matter), but feeds with similar concentrations of dry matter can be compared on an *as-fed basis*.

**Crude protein (CP):** Also called *total protein*; this value is calculated by measuring total nitrogen.

**Acid detergent fiber (ADF):** A chemically determined fraction that contains cellulose and lignin. ADF is inversely related to digestibility and is used to estimate the digestible energy content of horse feeds.

**Neutral detergent fiber (NDF):** A chemically determined fraction that contains cellulose, lignin, and hemicellulose. NDF contains most of the structural carbohydrates in plants; as plants mature, they contain more stem (more structure), and therefore DF increases with maturity. The NDF fraction includes the ADF fraction. There is a general inverse relationship between NDF in forages and voluntary forage intake by horses—in other words, when two hays of similar variety are compared, the forage with lower NDF will be consumed in higher amounts by horses.

**Nonfiber carbohydrates (NFCs):** Not a measured fraction. NFC is determined by calculating the difference between total DM and the sum of NDF, crude fat, ash, and crude protein. Types of carbohydrates that are included in the NFC fraction are true nonfiber carbohydrates such as monosaccharides and starch, but it also includes some carbohydrates that are resistant to mammalian enzymatic digestion such as pectin (found in beet pulp and alfalfa hay) and fructan (found in some grasses).

**Ethanol soluble carbohydrates (ESCs):** Part of the nonstructural carbohydrate fraction. The ESC fraction contains mostly simple sugars, disaccharides. Some laboratories categorize this fraction as *sugars*.

**Starch:** Contains amylose and amylopectin. The starch analysis does not separate easily digested starch and starch resistant to small intestinal digestion.

**Nonstructural carbohydrate (NSC):** Previously, the NSC fraction included all carbohydrates not included in NDF, but today it is commonly defined as starch plus ESC. Therefore the NSC in a feed represents the carbohydrates that are expected to be digested and absorbed from the small intestine as glucose or other simple sugars.

**Water-soluble carbohydrates (WSCs):** This fraction includes the simple carbohydrates that appear in the ESC fraction as well as *some* longer chain carbohydrates, including fructans. Fructans are storage carbohydrates synthesized by some plants, especially cool season grasses. Some nutritionists calculate fructan as the difference between WSC and ESC, but this estimate has not been validated.

**Digestible energy (DE):** Not a measured value. DE is calculated from other analyzed fractions, including ADF and crude protein. The amount of fat in the feed affects the true DE value of a feed, but if crude fat was not a requested item on the feed analysis, the DE might be calculated using an average value for crude fat. For common forages (e.g., hay and pasture), the DE value calculated by a laboratory is a relatively accurate assessment of the true DE value. For concentrate feeds the calculated DE value may not represent the true DE value.

Adjusted Crude Protein, %TDN, NEL, NEM, NEG, relative feed value: Not relevant to horse diet analyses.

TABLE 5-1

Description of Body Condition Scores in Horses							
Condition Score	General Condition	Neck	Shoulder	Withers	Ribs	Loin	Tailhead
1	Very Poor	Individual bone structure visible; feels very bony	Bone structure very visible and sharp to touch	Bones easily visible; no fat; razorlike	Ribs very visible and skin furrows between ribs	Spine bones visible; ends feel pointed	Tailhead and hips very visible
Animal extremely emaciated; no fatty tissue can be felt							
2	Very Thin	Bones just visible; animal emaciated	Possible to outline bone structure	Withers obvious, very minimal fat covering	Ribs prominent, slight depression between ribs	Slight fat covering other vertical and flat spin projections; ends feel rounded	Tailhead and hipbones obvious to the eye
3	Thin	Thin, flat muscle covering, no raised muscle or fat	Shoulder accentuated; some fat cover but thinner than is desirable	Withers thin and accentuated with some, although little, fat cover	Slight fat cover over ribs. Rib outline obvious to the eye	Fat buildup halfway on vertical spines, but easily visible; flat spinal bones not felt	Tailhead prominent; hip bones rounded but easily visible; pin bones covered
4	Moderately Thin	Neck with some fat; horse not obviously thin	Shoulder not obviously thin with some fat cover	Withers not obviously thin, smooth edges but prominent	Faint outline visible to the eye	Slight outward ridge along back	Fat palpable
5	Moderate	Neck blends smoothly into body with some fat cover	Shoulder blends smoothly into body	Withers smoothly rounded over top	Ribs cannot be seen but can be easily felt	Back level	Fat around tailhead beginning to feel spongy
6	Moderately Fleishy	Fat easily palpable	Fat layer palpable	Fat palpable	Fat over ribs feels spongy	May have slight inward crease	Fat around tailhead soft and palpable
7	Fleishy	Visible fat deposits or lumps along neck	Fat buildup behind shoulder	Fat covering withers is firm	Individual ribs still palpable	May have slight inward crease down back	Fat around tailhead soft and rounded off
8	Fat	Noticeable thickening of neck	Area behind shoulder filled in flush with body	Area along withers filled with fat	Difficult to feel ribs	Crease down back evident	Tailhead fat very soft and flabby
Fat deposited along inner buttocks							
9	Extremely Fat	Bulging fat	Bulging fat	Bulging fat	Patchy fat over ribs	Obvious deep crease down back	Building fat around tailhead
Fat along inner buttocks may rub together; flank filled in flush							

(BCS = 4-7) Thoroughbred, Quarter Horse, and Arabian horses indicate that one BCS unit represents approximately 25 to 35 kg of body weight.<sup>4,5</sup> The body weight associated with each unit of body condition may be higher in fat or thin horses.

The Henneke BCS system, originally developed for use in Quarter Horse broodmares,<sup>3</sup> is most appropriate for use in light breeds such as Thoroughbreds, Arabians, and Standardbreds. This system may not be suitable for ponies and larger-breed horses (e.g., drafts) that have a different pattern of fat distribution. A 9-point BCS system for Warmblood horses was developed to account for differences in conformation

and patterns of fat deposition in this breed when compared with Quarter Horses.<sup>6</sup> For example, fat begins to cover the hip bones of Quarter Horses at a BCS of 4, whereas the hip bones of Warmblood horses remain prominent at a BCS of 6 (using the system developed for Warmbloods).

It also should be noted that the BCS system does not register differences in regional adiposity that may signify increased risk of disease. In humans visceral (abdominal) adiposity is more closely linked than generalized obesity to the risk for diabetes and cardiovascular disease, and measurement of waist circumference is a better indicator of abdominal fat

accumulation than is body mass index.<sup>7</sup> In horses and ponies there may be a similar association between regional adiposity and disease risk. In studies of horses and ponies with a predisposition to pasture-associated laminitis, some affected animals are not obese on the basis of BCS (i.e., BCS <7) and have no external evidence of regional adiposity, but others have enlarged fat deposits on the neck (“cresty neck”) and thoracic and tailhead regions; these fat deposits are sometimes asymmetrically distributed.<sup>8,9</sup> Neck crest adiposity, assessed by the ratio of mean neck circumference to height at the withers (NCHR), is negatively associated with insulin sensitivity in horses and ponies.<sup>9,10</sup> Although cutoff values for NCHR in relation to obesity and disease risk have not been defined, repeated measurement of mean neck circumference is useful for monitoring the effectiveness of a weight loss program.

Knowledge of a horse's body weight is needed for accurate calculation of nutrient and feed requirements. It is important to note that the body weight of an individual horse can vary between 5% to 15% depending on hydration and feeding status and on gastrointestinal fill. Accordingly, it is important to standardize the time of feeding relative to measurement of body weight. Body weight may be measured directly by use of a platform scale or, in mature horses, estimated from body measurements such as heart girth circumference and body length.<sup>11,12</sup> Heart girth is measured immediately behind the elbows, and body length is measured from the point of the shoulder to the tuber ischii:

$$\text{Body weight (kg)} = [\text{Heart girth (cm)}^2 \times \text{length (cm)}] / 11,800$$

Body weight also can be estimated from measurement of heart girth circumference by use of a weight tape calibrated for horses. Measurements should be taken in a consistent manner, with the horse standing on a flat surface, and care must be taken not to pull the tape too tightly. Clinicians are advised to take the average of several (e.g., 3 or 4) measurements. Accuracy of these measurements is affected by a number of factors, including breed, conformation, level of fitness, thickness of hair coat, gastrointestinal fill, and pregnancy status.<sup>12</sup> Body weight based on heart girth is most accurate when this method is applied to mature horses with an average BCS (i.e., 5-7). Underestimation or overestimation of body weight may occur when weight tapes are used to estimate the body weight of horses with low or high condition scores.

## DIET AND RATION EVALUATION

It is useful to first examine the physical characteristics of feeds (i.e., visual appearance [color, presence of foreign material such as mold and dust] and odor). Preserved forages (e.g., hay) should be evaluated for type (grass versus legume), leaf-to-stem ratio, and presence of seed heads. Hays with good nutritional value are characterized by a large proportion of leaf; when compared with stems, leaves have higher nonstructural carbohydrates (starches, sugars, fructans), lower structural carbohydrates (hemicellulose, cellulose, lignin), and higher protein.<sup>1</sup> Therefore second- and third-cutting hays, which often have a higher stem-to-leaf ratio, tend to provide higher nutritional value than first-cutting hay. The latter is usually harvested at a more mature stage. The presence of seed heads and a stemmy, coarse appearance are also indications of advanced maturity at cutting. Some studies have reported an inverse relationship between the neutral detergent fiber (NDF, the fraction that

contains cellulose, hemicellulose, and lignin) and voluntary hay intake (i.e., the voluntary intake of stemmy hays with high NDF content will be lower compared with that of hays with high leaf-to-stem ratio).<sup>1,13</sup>

The next step in the evaluation is to estimate daily feed intake. Owners or stable managers should be questioned to determine the amounts of hay, concentrates, and supplements provided (and whether the horse regularly refuses any of these feedstuffs). All feeds, including several flakes or biscuits of hay, should be weighed to estimate the actual amounts of feed provided to the horse. Significant errors may occur when volume (e.g., “a coffee can full”) rather than weight is used to estimate feed provision because grains, concentrates, and hays vary markedly in weight per unit volume. A handheld fish scale or similar scale works well for this task. It is difficult to measure actual feed intake, particularly when forage is fed on the ground, where wastage can be as high as 25%, or fed to groups of horses. The other challenge is estimation of pasture forage intake, which is generally taken as the difference between the mean intake of digestible energy (DE) for horses, with consideration given to their weight, age, and physiologic condition, minus actual daily intakes of hay and grains. As previously mentioned, regular assessment of body weight and BCS over time will provide the best guide to the adequacy of energy intake. Reported values for daily dry matter intake (DMI) by horses, ponies, and donkeys range between 0.8% to 5.2% of body weight.<sup>1</sup> Young and mature horses appear to have a maximal daily DMI of 3% to 3.2% of body weight, but intakes in the range of 2.0% to 2.5% of body weight are more typical (this includes horses maintained on an all-hay diet). Some evidence suggests that ponies may have higher daily DMI than horses.<sup>1</sup>

The clinician also should evaluate feeding management, particularly when a problem under investigation may be due to poor feeding practices (e.g., weight loss, colic). For example, what are the relative proportions of forage and grain/concentrate? Does the ration contain adequate high-quality forage? How many times a day is the horse fed? How frequently is the diet changed, and are these changes made gradually (ideally over 7 to 10 days) or suddenly? Several epidemiologic studies have reported that changes in diet (grain/concentrate or hay, even when switching to hay of the same type) significantly increase the risk of colic.<sup>14-16</sup> The risk of gastrointestinal problems also increases when horses are fed large quantities of starch-rich grain and concentrate feeds or inadequate long-stem roughage.<sup>14,16</sup> As a general guide, all horses should receive a *minimum* of 1.0% of body weight per day as hay or the equivalent; forage at 1.5% of body weight per day is preferred. For a 450- to 500-kg horse, grain or concentrate meals should be no more than 2.5 kg (approximately 5 lb) to reduce risk of hindgut disturbances associated with the cecal delivery of undigested starch. If the daily ration includes more than 5.0 kg of grain or concentrate, it should be provided in more than two feedings per day (see the section on carbohydrates in equine nutrition).<sup>16</sup>

Information on the nutrient content of the diet is needed to determine the adequacy of the ration. Several approaches can be used to estimate the nutrient contents of feeds. The feed tags on commercial feeds provide some nutritional information, including a list of ingredients and data on some nutrients. However, feed manufacturers are required to guarantee only that minimums were met and maximums were not exceeded; in other words, the actual content of listed nutrients is not provided. An alternative source of data on the nutrient content of feeds is published databases (e.g., National

Research Council [NRC] publications, feed company Web sites). Although the nutrient profiles available from these databases provide a useful guide, these data may not correspond exactly to the feedstuff provided to the horse under evaluation because of differences in geography, growing and harvesting conditions, and other factors. The ideal, although not always practical, approach is to submit samples of feed and forages (core hay samples, pasture clippings) for laboratory analysis of nutrient content. At least two samples (approximately 250 g each) of each grain or concentrate should be taken; these should be mixed thoroughly with the composite sample submitted for analysis. Approximately 10% of the hay store should be sampled by use of a hay probe. Again, these samples should be well mixed, with the composite sample shipped to the laboratory in a sealable plastic bag. Garden shears can be used to obtain pasture clippings, which should be sampled in a Z pattern and cut to grazing height. It may be necessary to sample clippings taken from several pastures to determine the range of nutrients on the farm. The basic nutrient profile from analysis includes dry matter (DM), DE, crude protein (CP), acid detergent fiber (ADF), NDF, fat (EE, ether extract), ash, calcium, magnesium, phosphorus, sodium, and potassium (see Box 5-1). Trace element and vitamin analyses are available depending on need and expense. Some laboratories will perform additional analyses and calculations to provide estimates of some of the carbohydrate fractions. For example, Equi-Analytical Inc. (Ithaca, NY; [www.equi-analytical.com](http://www.equi-analytical.com)) analyzes starch and ethanol-soluble carbohydrates (which are mostly simple sugars). More information on dietary carbohydrates is presented later in this chapter.

With data on feed composition (and estimated intake of feeds), it is possible to formally evaluate the ration against published feeding standards (e.g., NRC 2007<sup>1</sup>). The NRC developed a simple Web-based program that calculates nutrient requirements derived from the 2007 *Nutrient Requirements of Horses* (<http://nrc88.nas.edu/nrh/>); this program can also be downloaded to a personal computer. The user is first required to enter basic information such as age, body weight, and physiologic state (e.g., stallion, lactating mare, working horse) and then data on the horse's ration—specifically, the amount and nutrient profile of each feed and supplement fed to the horse. The program uses these data to calculate nutrient requirements, dietary supply, and the difference between the two amounts. Unfortunately, only a limited number of nutrients are evaluated: DE, CP, lysine, Ca, P, Na, Cl, and K. The NRC recommendations are also based on minimum nutrient requirements, whereas many nutritionists favor feeding standards based on optimal ranges. Several nutrition companies have developed more comprehensive computer software programs. For example, Microsteed, developed by Kentucky Equine Research (KER), Inc., can evaluate the ration against both the NRC minimums and a set of optimums recommended by company nutritionists.<sup>17</sup>

The process outlined in the preceding paragraphs will facilitate decisions regarding the adequacy of the current ration. If gross deficiencies or excesses are identified, adjustments can be recommended and implemented. Another important aspect is the need for follow-up monitoring, particularly if a goal has been set for weight loss or gain. Figure 5-1 outlines a simple way to estimate energy needs and intake and calculate ration adjustments necessary to facilitate weight loss or gain. A more detailed discussion of dietary management of thin or obese horses is presented later in this chapter.

## ☞ CARBOHYDRATES IN EQUINE NUTRITION

Carbohydrates are the primary source of energy in the diet of horses. As nonruminant herbivores, horses evolved to utilize forages high in structural carbohydrates, with bacterial fermentation and production of volatile fatty acids (VFAs) in a highly developed large intestine. However, modern horses, particularly those in athletic training, are often fed cereal grains or other starch-rich feeds to meet energy requirements. For example, some survey studies indicate that racehorses weighing 450 to 550 kg typically receive 3 to 6 kg of feed per day, with some horses receiving more than 8 kg per day.<sup>18,19</sup> Such high grain intakes by horses (or a low forage-to-grain ratio such as 30:70) have been implicated in the development of gastrointestinal problems, particularly colic associated with disturbances to hindgut function<sup>20,21</sup> and gastric ulcer disease.<sup>22,23</sup> Additionally, diets rich in starch and sugar contribute to the clinical expression of chronic muscle diseases (polysaccharide storage myopathy and recurrent exertional rhabdomyolysis) in genetically susceptible horses<sup>24</sup> and likely exacerbate insulin resistance and susceptibility to laminitis in horses and ponies with the metabolic syndrome phenotype.<sup>25</sup> Therefore equine veterinarians should have working knowledge of carbohydrate digestion and metabolism and methods for assessment of the carbohydrate fractions in feeds. This information can be used in the formulation of diets and feeding programs that control intake of certain carbohydrates and potentially mitigate risk of these conditions.

### CLASSIFICATION AND NOMENCLATURE

Plant carbohydrates in equine feeds can be subdivided into the structural carbohydrates (SCs), which largely make up the fibrous portion of the diet and originate from the plant cell wall, and the nonstructural carbohydrates (NSCs), which originate from the cell content. Diets for horses, whether based on pasture, conserved forage, concentrates, or a combination of all three, contain both SCs and NSCs.<sup>26</sup>

All dietary carbohydrates contain similar amounts of gross energy. However, when utilized by the horse, they provide variable amounts of DE, metabolizable energy, and net energy.<sup>27</sup> Carbohydrates digested and absorbed as monosaccharides in the small intestine yield more energy than carbohydrates digested by microbial action (predominantly fermentation), and a glycemic response to the ingestion of such carbohydrates tends to occur.<sup>28</sup> The type of linkage between the monosaccharide residues in the carbohydrate also affects the site of digestion of these compounds and thus their nutritional value. Hydrolysis of the  $\alpha$ 1-6 and the  $\alpha$ 1-4 linkages of starch and maltose, for example, can occur in the equine small intestine, but horses do not produce the enzymes necessary to digest the  $\beta$ 1-4 linkages found in cellulose or the mixed linkages found in hemicellulose.<sup>28</sup> Therefore digestion of cellulose and hemicellulose must occur as a result of microbial fermentation, which does not result in a pronounced glycemic response. Stachyose, raffinose,  $\beta$ -glucans, fructooligosaccharides (or fructans), and pectin are also thought to be resistant to enzymatic hydrolysis. Thus an understanding of the various carbohydrate fractions in plants (including means of digestion) is needed to determine the potential for a feed to result in a glycemic-insulinemic response.

## SIMPLE SUGARS

This fraction comprises monosaccharides and disaccharides (i.e., glucose, fructose, and sucrose). The simple sugar content of these plants is low; the sugars produced by way of photosynthesis can be used immediately by the plant to supply energy for metabolism, protein synthesis, and growth, or they can be elaborated into more complex *oligosaccharides* (e.g., raffinose and stachyose) or the *structural polysaccharides* of the plant cell wall (e.g., cellulose, hemicellulose, and pectin). When sugar production exceeds the immediate requirements for metabolism, the excess sugars are polymerized to form “storage,” or “reserve,” carbohydrates. Storage carbohydrates mostly are in the form of starch or fructan. Starches, fructans, together with the simple sugars and the oligosaccharides, make up the NSC fraction of the diet.<sup>26</sup>

## OLIGOSACCHARIDES

The raffinose family of oligosaccharides are  $\alpha$ -galactosyl derivatives of sucrose. The most common are the trisaccharide, raffinose (composed of galactose, fructose, and glucose) and the tetrasaccharide, stachyose. These oligosaccharides are found in sugar beet molasses and whole grains. Soybean oligosaccharides make up approximately 5% of DM in whole beans and up to 8% of DM in soybean meal. Together raffinose and stachyose rank second only to sucrose in abundance as water-soluble carbohydrates. However, raffinose and stachyose cannot be directly digested by the horse because of the absence of the enzyme  $\alpha$ -galactosidase.

## STRUCTURAL POLYSACCHARIDES

This fraction includes dietary fiber that is composed of cellulose, pectin, and hemicelluloses, along with mannans, galactans, and xyloglucans.<sup>26</sup> Total nonstarch polysaccharides (NSPs) are the sum of the water-soluble and water-insoluble NSPs and include cellulosic and noncellulosic polysaccharides. Although some of the NSPs are water soluble, these are not digestible by mammalian enzymes, and digestion therefore can occur only through fermentation, which may occur proximal to the cecum.

## STARCH

Starch is the main storage polysaccharide in most higher plants, including the forage legumes (e.g., clover, alfalfa). Starch is stored in both the vegetative tissues (i.e., nonreproductive tissues such as leaves and stems) and the reproductive tissues (i.e., flowers, seeds). The starch content of grass seed ranges from approximately 300 to 400 g starch/kg seed DM, whereas oats, barley, and corn contain approximately 400, 550, and 700 g starch/kg DM, respectively.<sup>26</sup> The amount of starch stored in the leaves of legumes rarely exceeds 75 g starch/kg DM.

Starch consists of polymers of glucose, which occur in two forms: amylose and amylopectin. Amylose is a linear  $\alpha$ -(1-4) linked molecule, and amylopectin is a larger, highly branched molecule containing both  $\alpha$ -(1-4) and  $\alpha$ -(1-6) linkages. The ratio of amylose to amylopectin largely depends on the botanical origin of the starch. For example, in wheat flour amylose is around 30% of the total starch, whereas corn can contain up to 70% amylose. The extent to which starch is digested preceally depends on many factors, including the availability of the starch to mammalian enzymes (e.g., the extent to which any outer husk or hull has been broken down), the ratio of amylose to amylopectin within the starch granule, the effect

of processing (thermal treatment, for example, improves the digestibility of corn and barley starch), and intestinal passage rate.<sup>29</sup> Glucose availability in the small intestine tends to be higher for starches with high amylopectin content. As discussed in more detail later, the ingestion of excessive levels of starch may exceed the relatively limited amylolytic capacity of the equine foregut. Any undigested starch (including resistant starch) that has not been fermented in the stomach and small intestine by resident microbes will pass into the large intestine, where it will be fermented, yielding less net energy than when it is absorbed as glucose.<sup>29</sup>

## FRUCTAN

Fructan is the major storage carbohydrate of the vegetative tissues of temperate grasses. Depending on the number of fructose molecules, fructans can be described as oligosaccharides (<10 monosaccharide units) or polysaccharides (>10 units). High levels of fructan can accumulate in the vegetative tissues of pasture grasses, with implications for the development of pasture-associated laminitis.<sup>26</sup> In a 3-year northern European study of the water-soluble carbohydrate (WSC; sugar plus fructan) components in the vegetative structures of temperate grasses, fructan contents of up to 279 g/kg DM were recorded.<sup>26</sup> Fructan accumulation (unlike that for starch) can occur below the temperature threshold for plant growth (approximately 6° C).<sup>30</sup> Therefore cold, bright days that result in high rates of photosynthesis but minimal plant growth may lead to the production of large quantities of excess sucrose and, in turn, substantial fructan accumulation.

## EVALUATION OF THE CARBOHYDRATE CONTENT IN FEEDS

A number of analytical techniques and terms have been used to describe the carbohydrate fractions in feeds. It is important to understand what the different terms mean—and recognize the variation among laboratories with respect to analytical methods and definitions (see [Box 5-1](#)).

### WATER-SOLUBLE CARBOHYDRATES

The WSC fraction includes the simple (glucose, sucrose, fructose) and more complex (oligosaccharides and fructans) sugars. Although not all of these components can be digested by mammalian enzymes, most can be rapidly fermented by gram positive bacteria, resulting in the production of lactic acid. However, it is important to note that starch, which also can be fermented in this way, is not included in this category. Some commercial laboratories measure WSC (i.e., free sugars plus oligosaccharides and fructans) but report it simply as sugar, whereas others use the term *sugar* to describe the free sugar fraction only.

### ETHANOL SOLUBLE CARBOHYDRATES

The term *ethanol soluble carbohydrates* (ESCs) refers to the component of the WSC that is digestible by mammalian enzymes and elicits a glycemic response (i.e., simple sugars). The difference between the WSC and ESC fractions has been used to approximate the amount of fructan in a particular feedstuff, although the accuracy of this calculation has not been verified.

### NONSTRUCTURAL CARBOHYDRATES

The NSC fraction includes the monosaccharides and disaccharides, oligosaccharides (including fructan), fructan polysaccharides, and starch. Several methods have been used to

estimate the NSC content of feeds. The system developed by Van Soest<sup>31</sup> estimates NSC *by difference*, wherein the feed is partitioned into neutral detergent solubles and NDF. The NDF fraction contains cellulose, most of the hemicellulose, and lignin. Until recently, the NSC content of a feed was determined on the basis of feed analysis and the “by-difference method,” according to the following equation:

$$\text{NSC} = 100 - (\text{crude protein \%} + \text{NDF \%} + \text{moisture \%} + \text{fat \%} + \text{ash \%})$$

This estimate was taken to represent the combined sugar, starch, and fructan content of the feed. However, it also includes pectins, gums, and mucilages that, unlike starch, sugar, and fructan, are not subject to very rapid fermentation and therefore do not induce the marked changes in lactic acid concentrations and pH within the hindgut that can occur with excess intake of sugars, starch, or fructan. Therefore the NSC by-difference fraction is now referred to as *nonfiber carbohydrate*, or *NFC*. The quantitative difference between measured NSC and NFC is small for some feeds (e.g., cereal grains) but can be quite large for other feeds (e.g., feeds with substantial pectin, such as sugar beet pulp) (Table 5-2).

Most commercial feed analysis laboratories do not completely fractionate the carbohydrates that make up the NSC, but in most feeds the amount of NSC can be approximated by summing the amount of starch and WSC. The extent to which the sum of starch and WSC accounts for all NSC depends on the analytic procedures used to measure these fractions. This determination probably more accurately reflects the potential for a feed to be rapidly fermented to produce lactic acid.

## CARBOHYDRATE NUTRITION AND COLIC

Colic is caused by many conditions, each of which may be related to specific risk factors, such as changes in diet, feeding practices, exercise patterns, and housing or inappropriate parasite control programs. An association between feeding

practices and disturbances in gastrointestinal function has long been hypothesized,<sup>32,33</sup> but the mechanisms linking diet with the development of intestinal dysfunction are poorly understood. Indeed, the exact relationship between diet and colic is difficult to determine because of the variety of feeds and feeding practices used throughout the world as well as differences in study populations. Furthermore, it is often difficult to separate the effects of diet and feeding schedule from other management practices, which often depend on the horse's breed and use. Nonetheless, the results of recent epidemiologic studies support the proposition that diet composition and recent changes in diet are important risk factors for development of colic.<sup>34-39</sup> Tinker et al.<sup>37</sup> prospectively examined the risk for colic at 31 horse farms over a 1-year period. Both a change in concentrate feeding (odds ratio [OR] = 3.6 relative to no colic) and the feeding of high levels of concentrate (>2.5 kg/day dry matter, OR = 4.8, >5 kg/day dry matter, OR = 6.3, relative to feeding no concentrate) were identified as risk factors for colic. In addition, colic risk increased when processed feeds such as pellets were fed. Hudson et al.<sup>36</sup> reported that a recent (within 2 weeks) change in type of grain or concentrate fed (OR = 2.6), the feeding of more than 2.7 kg of oats per day (OR = 5.9), and a change in the batch of hay fed (OR = 4.9) were significant risk factors for an episode of colic. In another prospective case-control study, neither the amount nor type of concentrate fed was associated with the colic risk, although the researchers did conclude that horses at pasture may have a decreased risk of colic.<sup>38</sup> On the other hand, a recent (within 2 weeks) change in diet, in particular the type of hay fed (including hay from a different source or cutting of the same type of hay) was a significant risk factor for colic.<sup>38</sup> In this study feeding hay other than coastal/Bermuda or alfalfa significantly increased the colic risk, but this finding may have reflected hay quality and digestibility rather than type of hay per se. Changing to a poorer quality, less digestible hay or feeding wheat straw or cornstalks may predispose horses to large colon impaction.<sup>38</sup> In a practitioner-based colic study in the United Kingdom, a recent change in management was associated with at least 43% of the cases of spasmodic or mild undiagnosed colic. The most common management change was turnout onto lush pasture in the spring.<sup>39</sup> In reviewing the results of available epidemiologic studies, Cohen estimated that approximately one third of colic cases had a history of a recent change in diet.<sup>40</sup> The ingestion of high-concentrate and low-forage diets has also been implicated in the development of gastric ulcers, which in turn may result in signs of colic.<sup>23</sup>

These observations raise several questions regarding the effects of diet composition and dietary change on gastrointestinal function, including the capacity of the equine digestive tract for grain (starch) digestion, possible reasons for increased colic risk with high levels of grain feeding, and the effect of a sudden change in diet (grain or forage) on gastrointestinal function.

## CARBOHYDRATE DIGESTION AND HINDGUT FUNCTION

From a digestive viewpoint carbohydrates in horse feedstuffs can be divided into three main fractions: (1) hydrolyzable carbohydrates (CHO-H), which can be digested in the small intestine by mammalian enzymes (or they can be fermented, both in the foregut and hindgut); (2) rapidly fermented carbohydrates (CHO-F<sub>R</sub>), which cannot be broken down by mammalian

TABLE 5-2

### Neutral Detergent Fiber, Nonfiber Carbohydrate, and Nonstructural Carbohydrate Composition of Selected Feedstuffs on a Dry Matter Basis\*

Feedstuff	% NDF	% NFC†	% NSC‡
Alfalfa hay	43.1	22.0	12.5
Beet pulp	47.3	36.2	19.5
Corn gluten meal	7.0	17.3	12.0
Mixed, mostly grass hay	60.9	16.6	13.6
Soybean meal (48% CP)	9.6	34.4	17.2
Soyhulls	66.6	14.1	5.3

NDF, Neutral detergent fiber; NFC, nonfiber carbohydrate; NSC, nonstructural carbohydrate.

\*The values shown here may vary from those shown elsewhere in this chapter. The values are provided to illustrate differences among feeds and carbohydrate categories. Actual values for individual feeds may vary by stage of maturity, variety, and source.

†%NFC = (100% - %CP - %EE - %Ash - %NDF); CP = crude protein, EE = ether extract.

‡%NSC determined by direct measurement.

digestive enzymes but are readily available for microbial fermentation; and (3) slowly fermentable carbohydrates (CHO-F<sub>S</sub>). The hydrolyzable fraction includes hexoses, disaccharides, some oligosaccharides, and the nonresistant starches. Although some fermentation of these compounds may occur in the stomach, the primary products of digestion of these compounds are monosaccharides that can be absorbed in the small intestine, with a relatively high energy yield. The rapidly fermentable fraction included pectin, fructan, and some oligosaccharides not digested in the small intestine. Resistant starch and neutral detergent hemicellulose could also be included in the rapidly fermentable fraction. The slowly fermentable carbohydrate fraction includes cellulose, hemicellulose, and ligno-cellulose that result primarily in the production of acetate in the large intestine.

### FOREGUT DIGESTION

Carbohydrate digestion begins in the stomach, which in the horse is relatively small and inelastic (capacity 9-15 L for a 500-kg horse). Bacterial fermentation of ingested feed is initiated in the cranial (squamous) portion of the stomach, with conversion of some of the available simple sugars or starches to lactic acid.<sup>41</sup> This microbial activity and starch/sugar degradation slows when the gastric contents pass to the fundic gland region and are mixed with gastric secretions containing pepsinogen. Horse saliva contains minimal amylase activity, and little enzymatic carbohydrate digestion occurs in the stomach.

The small and large intestines are the primary sites of carbohydrate digestion. Starch digestion in the small intestine first involves degradation by  $\alpha$ -amylase into disaccharide (maltose), trisaccharide (maltotriose), and  $\alpha$ -dextrin units. Subsequently, there is hydrolysis of maltose, maltotriose, and  $\alpha$ -dextrin units by small intestine brush border glycanases, primarily amyloglucosidase (AMG), to form free glucose.<sup>42</sup> The disaccharidases sucrose, lactase, and maltase are expressed along the length of the small intestine.<sup>43</sup> D-glucose and D-galactose are transported across the equine intestinal brush border membrane by a Na<sup>+</sup>/glucose co-transporter type 1 isoform (SGLT1),<sup>43</sup> and fructose is absorbed by way of an equine-specific GLUT-5 transporter.<sup>15</sup> The activity of both transport proteins is highest in the duodenum and lowest in the ileum.<sup>15</sup> Sugars taken up by enterocytes are transported down concentration gradients into the circulation by way of the GLUT-2 transporter. Preliminary studies have demonstrated upregulation of small intestinal SGLT1 expression with an increase in dietary starch content.<sup>44</sup>

It has been proposed that starch digestion in the small intestine is limited by amyolytic activity (e.g., the availability and activity of  $\alpha$ -amylase). The activity of  $\alpha$ -amylase in pancreatic tissue of horses is low relative to that of other species,<sup>45</sup> although the activities of brush border glycanases appear to be comparable to those observed in humans, pigs, and dogs.<sup>46,47</sup> The activity of  $\alpha$ -amylase in pancreatic tissue of horses fed either hay or hay and concentrate for at least 8 weeks was unaffected by diet.<sup>46</sup> However, in a related study, the amylase activity of jejunal chyme was modestly higher in horses that received a diet with added corn, oats, or barley when compared with only hay.<sup>47</sup>

The extent of starch digestion in the small intestine is affected by the type and amount of starch digested (see the section on strategies for minimizing gastrointestinal disturbances).<sup>48</sup> At low levels of starch intake (<100 g/100 kg body weight from oats, barley, or corn as a single meal), approximately 80% of the starch was digested in the small intestine.

When starch feeding was doubled (250 to 270 g/100 kg body weight), prececal starch digestibility decreased to between 50% and 55%.<sup>49</sup> Therefore most nutritionists recommend that an individual grain or concentrate meal contain no more than 2 g starch per kg body weight. For example, if a grain concentrate is 50% starch, no more than 4 g/kg bodyweight (Bwt) or approximately 2 kg for a 500-kg horse should be fed. At higher intakes in a single meal, particularly when unprocessed corn or barley is fed, there is the risk of substantial starch overflow into the hindgut, where it will undergo rapid fermentation.

### HINDGUT DIGESTION

The equine large intestine (cecum and colon) is an enlarged fermentative chamber that contains an extremely abundant and highly complex community of microorganisms. Although some fermentation of feedstuffs occurs in the stomach and small intestine, most fermentation occurs in the hindgut. The microbial hydrolysis of dietary plant fiber within the large intestine leads to the release of soluble sugars that are subsequently fermented to the VFAs acetate, propionate, and butyrate, which are an important source of energy. In addition, the VFAs (particularly butyrate) regulate the expression of genes controlling proliferation, apoptosis, and differentiation of gut epithelial cells.<sup>50</sup>

The rate of fermentation and the microbial and biochemical contents of the large intestine are affected by diet composition and feeding pattern (i.e., continuous grazing, or small, frequent meals, versus large meals administered twice daily). A change from forage only to a forage and concentrate diet will result in an increased rate of fermentation and marked changes in the microbial population, luminal pH, and the contents of VFA and lactate.<sup>51</sup> The extent of these changes is likely dependent on the nature and abruptness of the dietary change. With a sudden increase in grain (i.e., starch) feeding, a portion of the ingested starch passes into the cecum undigested, where it undergoes rapid fermentation with increased production of lactate and gas and a decrease in cecal-colonic pH. Increasing proportions of grain result in decreased acetate and increased propionate and lactate contents of the cecum and colon.<sup>51</sup> Other biochemical changes with the rapid fermentation of starch (or other CHO-F<sub>R</sub>, such as fructan) in the hindgut may include an increase in the production of vasoactive monoamines (e.g., tyramine, tryptamine), endotoxins, and exotoxins, all of which have been implicated in the pathogenesis of laminitis.<sup>52</sup>

After an increase in starch feeding, the numbers of lactobacilli and total anaerobic bacteria increase, whereas the numbers of xylanolytic and pectinolytic bacteria decrease.<sup>53</sup> Overall, there is an increase in amyolytic, lactic acid-producing bacteria and decreases in the proportions of acid-utilizing (particularly lactate) and cellulolytic (i.e., fiber-degrading) bacteria. Reduced efficiency of fiber utilization and decreased energy yield may result from the decline in cellulolytic bacteria with high grain feeding. In horses fed forage only, pH within the cecum and colon is in the range of 6.7 to 7.0. The feeding of increasing amounts of corn or barley starch is associated with proportionate decreases in cecal pH, with values approaching 6.0 when 3 to 4 g/kg Bwt is fed as a single meal.<sup>51,54,55</sup> A similar dose of oat starch was not associated with a significant decrease in pH, consistent with other data demonstrating higher prececal digestibility of oat starch versus barley and corn starch.<sup>55</sup> Some nutritionists have suggested that a cecal pH of 6.0 represents subclinical acidosis and that the risk of clinically apparent intestinal dysfunction (e.g., increased permeability) is substantially

increased when hindgut pH is less than 6.0.<sup>2,55</sup> Similar disruptions to the hindgut environment probably occur with the delivery of other rapidly fermentable substrate, such as fructan, which can compose 5% to 40% of grass DM,<sup>26</sup> particularly temperate species such as perennial ryegrass and timothy. In vitro experiments have demonstrated that fructan induces a more rapid decrease in the pH of cecal contents compared with corn starch,<sup>56</sup> and one type of fructan (rafitlose) has been used to induce carbohydrate overload and laminitis.<sup>57</sup>

These disturbances to the hindgut environment put the horse at greater risk for digestive disturbances such as colic, osmotic diarrhea, and laminitis.<sup>32,33</sup> Scenarios favoring the presentation of large loads of rapidly fermentable substrate to the hindgut include (1) a sudden introduction to grain feeding or an abrupt increase in the amount of grain concentrate; (2) the feeding of large grain meals that, even in horses adapted to such feeds, overwhelm the hydrolytic or absorptive capacity of the small intestine; and (3) the grazing of lush pasture or forage with high contents of rapidly fermentable substrate such as fructan and simple sugars. It is therefore apparent that feeding strategies designed to minimize hindgut disturbances must focus on reducing the flow of rapidly fermented substrate to the cecum and large colon.

## RECOMMENDATIONS FOR MINIMIZING DIGESTIVE DISTURBANCES

### FEEDING FREQUENCY

Ideally, feeding strategies for horses kept under intensive conditions would mimic the pattern of a grazing animal—that is, an almost continuous feeding pattern that minimizes fluctuations in the rate of delivery of substrate to the large intestine and, when forage makes up the bulk of the diet, ensures some stability of the hindgut ecosystem. A more continuous feeding pattern also may minimize fluctuations in gastric acidity and therefore be of benefit in horses at risk for squamous mucosal ulcer disease. For stabled horses fed two large meals daily, foraging behavior should be encouraged by increasing the availability of hay (or even a variety of different forages) and pasture or dry lot turnout (with forage available). Provision of more frequent (e.g., thrice daily rather than twice daily), smaller concentrate meals throughout the day is also recommended to minimize delivery of undigested hydrolyzable carbohydrate to the hindgut. Extending eating time by diluting the energy density of the meal (e.g., chopped hay mixed with concentrates) or feeding forage before grain or concentrate may be helpful. For some greedy eaters placement of several large stones in the feeder trough may slow the rate of intake.

### ADEQUATE FORAGE AND FIBER

For hard-working horses with high DE requirements, the provision of roughage is often restricted in favor of grain concentrates to ensure adequate DE intake within limits of typical dry matter consumption. However, there is considerable circumstantial evidence associating low-roughage diets with digestive disturbances (e.g., hindgut acidosis, colic, gastric ulcers) and behavioral problems. There also is evidence that the adverse effects of high starch intake on hindgut function are mitigated when the ration is at least 50% NDF.<sup>58</sup> Accordingly, there is rationale for feeding programs that promote higher roughage intake. An absolute fiber requirement has not been defined, but a minimum of 1.0 kg long-stem forage

per 100 kg Bwt (i.e., 5.0 kg for a 500-kg horse, as fed basis) has been recommended. Some nutritionists have suggested that a rate of 1.5 kg per 100 kg Bwt is preferable. Alternatively, fiber intake can be increased by feeding other sources such as sugar beet pulp or soya hulls, both of which are highly digestible (i.e., the DE yield is higher compared with that of hay) and are now commonly added to energy supplements for horses. This approach also facilitates a decrease in reliance on grain or sweet feed for energy, thereby decreasing the risk of digestive disturbances associated with high starch intake.

Forage quality is another important consideration. The feeding of highly lignified fiber sources (e.g., straw), which are poorly degraded in the large intestine, may increase the risk of impaction colic. High intake of straw is possible when it is used for bedding, particularly when an inadequate amount of hay (or roughage with low palatability) is offered. An increase in the provision of palatable forage or a change in bedding can be helpful in these situations. Moldy forage should not be fed to equids.

## LIMITING DELIVERY OF RAPIDLY FERMENTED SUBSTRATE TO THE HINDGUT

**Size of Grain-concentrate Meals** The feeding of large meals rich in starch and sugar can overwhelm the digestive capacity of the small intestine and destabilize the hindgut because of rapid fermentation of these substrates. No more than 2 g starch/kg Bwt should be fed in a single meal. For a grain or sweet feed mix that is 40% to 50% starch, this upper limit equates to approximately 2.0 kg per meal for a 500-kg horse.

**Feed Starch Sources with High Prececal Digestibility** Prececal starch digestibility varies with the type of grain and the nature of any mechanical or thermal processing. Whereas oat starch has a prececal digestibility of around 80% to 90%, approximately 35% of equivalent doses of barley or corn starch (from unprocessed grains) reaches the cecum undigested. The higher prececal digestibility of oat starch may relate to the small size of the starch granules when compared with other grains, providing a large surface area for exposure to intestinal amylase. Milling, grinding, and various heat treatments (e.g., steam flaking, micronization, extrusion) improves the prececal starch digestibility of oats, barley, and corn. In one study the pre-ileal digestibility of ground oats was 97% when compared with 83% for whole oats. Rolling or breaking did not improve the pre-ileal digestibility of oats. For corn and barley pre-ileal starch digestibility is substantially increased after heat (e.g., steam-flaked corn, micronized barley) but not mechanical treatment. Overall, oats appear to be the safest source of starch for horses, although barley and corn are acceptable *if* they are subjected to some form of heat treatment.

**Use Alternative Sources of Energy** The energy demands of growth, lactation, and performance can be readily met by provision of alternative energy sources such as vegetable oil (fat) and nonstarch carbohydrates (e.g., sugar beet pulp, soya hulls). Commercial concentrates made with these ingredients contain varying amounts of starch and sugar, but in general amounts are substantially lower compared with straight cereals or sweet feed mixes. Compared with more traditional fiber sources such as hay, soya hulls and beet pulp contain lower indigestible material (e.g., lignin) and higher amounts of nonstarch polysaccharides, pectins, and gums, which can be digested to a large extent within the time period that they remain within the gastrointestinal tract. This translates to a higher energy yield. A variety of vegetable oils (e.g., corn, soy,

safflower, or flaxseed) and other sources of fat (e.g., stabilized rice bran; approximately 20% fat) are suitable for inclusion in equine diets. Corn oil tends to be the most palatable oil, but most types have acceptable palatability provided that they are fresh and not rancid. One recommendation is to feed up to 100 g oil/100 kg body weight daily. For reference purposes, 450 ml of oil (approximately 420 g) provides about 3.4 megacalories (Mcal) of DE. This daily amount should be divided into two or three meals and introduced gradually (e.g., starting at 50 ml/day). Vitamin E (100 to 200 IU/100 ml of oil) should be added to the ration if supplemental vegetable oil is provided.

**Pasture Grazing** An unresolved problem is management of the intake of rapidly fermentable substrate (e.g., fructan) by horses at pasture, particularly animals with a history of pasture-associated laminitis or those with recognized risk factors for this disease (i.e., obesity, insulin resistance). The most obvious avoidance strategy is to prevent access to pasture and feed preserved forage with low NSC content (e.g., <10% NSC). Alternative approaches are to restrict access to pasture at certain times of the day, avoiding peaks in forage NSC content that may increase risk of laminitis, or to apply a grazing muzzle that limits forage intake (but allows water intake). Several factors affect the accumulation of fructans and other forms of NSC in pasture plants, including plant growth rate, temperature, and light intensity. There also is marked diurnal variation, with peak concentrations in the afternoon and a nadir during the night and early morning, and it has been suggested that horses grazing in the afternoon may ingest twofold to fourfold quantities of NSC when compared with that ingested during night or early morning grazing. These observations are the basis for the recommendation to restrict grazing to late night and early morning, with removal of the horse or pony from pasture by midmorning.

### GRADUAL DIETARY CHANGES

The increased risk of colic in the 2-week period after a change in hay or grain feeding suggests that all changes in diet and pattern of feeding should be gradual. Horses should receive a blend of old and new hays during the transition between hay batches (e.g., over a 7- to 10-day period, with a gradual increase in the proportion of the new forage) and a conservative introduction to concentrate feeding or changes in type of grain or concentrate. One suggestion is to start at about 0.5 kg/day (split into two feedings) for a 450- to 500-kg horse, with increasing increments of no more than 0.5 kg per day until attainment of the target feeding rate.

### EFFICACY OF PROBIOTIC SUPPLEMENTS AND FEED ADDITIVES PURPORTED TO STABILIZE THE HINDGUT ENVIRONMENT

There is considerable interest in the use of feed additives such as live yeast culture, probiotics (bacterial species), and buffers (e.g., sodium bicarbonate) as a strategy to minimize the negative effects of cereal-based diets. Yeast cultures might be beneficial for stabilization of the hindgut environment in the face of high cereal feeding. In horses fed high starch meals (3.4 g/kg Bwt/meal, as barley), daily supplementation with 10 g of a live yeast (*Saccharomyces cerevisiae*) culture preparation attenuated postfeeding decreases in cecal and colonic pH and alterations in hindgut microbial populations.<sup>59</sup> Thus supplementation with live yeast culture may be beneficial in horses fed a high grain ration, but from a practical standpoint it may be more important to ensure adequate fiber in the diet,

decrease the quantity of grain, and emphasize use of non-starch energy sources that do not adversely affect the hindgut environment.

Probiotics have been defined as live microorganisms that, when ingested or administered orally, provide a beneficial effect beyond that of their nutritional value.<sup>60</sup> Many probiotics are marketed for use in horses, the primary rationale being the treatment or prevention of gastrointestinal diseases (e.g., as an adjunct therapy in the management of acute or chronic diarrhea) or prophylactic administration for prevention of colic associated with disturbances to gut microflora (e.g., for horses fed a high cereal ration). Anecdotal data suggest that the use of probiotics in horses is widespread; however, as with many nutritional supplements, there is a dearth of scientific data regarding safety and efficacy. An effective probiotic organism must be resistant to destruction by gastric acid, pancreatic secretions, and bile salts and be able to colonize the intestinal tract. Weese and Rousseau have screened equine intestinal microflora for organisms meeting these criteria and initially identified *Lactobacillus pentosus* (WE7) as a potential equine probiotic. However, in a randomized controlled clinical trial of 153 neonatal foals (24-48 hours old), the administration of freeze-dried *L. pentosus* WE7 for 7 days was significantly associated with the development of signs of depression, anorexia, and colic and more days with diarrhea compared with the placebo treatment.<sup>60</sup> On the other hand, supplementation with *Saccharomyces boulardii* reduced significantly the duration of diarrhea in horses with enterocolitides.<sup>61</sup>

The feeding of a protected sodium bicarbonate product has been reported to moderate the decrease in fecal pH associated with grain feeding in horses,<sup>62</sup> perhaps as a result of the buffering of lactic acid produced in the cecum and colon. This approach may be useful for mitigation of hindgut disturbances associated with grain feeding or the grazing of lush pasture.

## ☞ NUTRITIONAL SUPPORT OF SICK HORSES

There are little data on the effects of different feeding practices on short- and long-term outcomes of sick horses, and many recommendations regarding nutritional management are based on anecdotal evidence or clinician experience rather than the results of controlled studies. In human medicine nutritional status is an independent determinant of morbidity in hospital patients.<sup>63,64</sup> Nutrient deprivation is associated with immunosuppression and alterations in gastrointestinal function, including decreased motility, villus atrophy, and a decrease in gut barrier function resulting from an increase in intestinal permeability, particularly in patients with preexisting malnutrition.<sup>65</sup> Consequently, nutritional support is standard practice in the care of sick people.

Healthy adult horses can tolerate 2 to 3 days of feed withdrawal without ill effect. Starvation invokes neuroendocrine responses that lower metabolic rate, conserve lean tissues (i.e., skeletal muscle), and promote use of fat stores to meet energy demands.<sup>66</sup> This strategy prolongs life in the face of nutrient deprivation. The metabolic response to critical illness (e.g., sepsis) contrasts with that of simple starvation. Increased sympathetic nervous system activity, inflammatory cytokines (e.g., interleukin-1 [IL-1], IL-2, IL-6, tumor necrosis factor  $\alpha$  [TNF- $\alpha$ ]), and catabolic hormones (catecholamines, cortisol, and glucagon) combine to increase metabolic rate and induce a state of hypercatabolism.<sup>67</sup> Stimulation of proteolytic pathways in

skeletal muscle provides amino acids for hepatic gluconeogenesis and synthesis of acute phase proteins. Amino acids (from catabolism of lean tissues) rather than fatty acids are the primary source of energy substrate. There also is disruption of glucose regulation with development of marked insulin resistance. Unabated, this hypercatabolic state results in large nitrogen losses, severe muscle wasting, and compromise of immune function and tissue healing.<sup>66-68</sup>

Severe hyperlipidemia has been described in horses with colic, colitis, or both that had clinical and laboratory evidence of systemic inflammatory response syndrome (SIRS).<sup>69</sup> The increase in circulating lipids likely reflects both an increase in the mobilization of fat reserves (lipolysis) and a decrease in lipid clearance from blood, with both processes potentially modulated by SIRS, endotoxemia, or both. Studies in other species have demonstrated that the activity of endothelial lipoprotein lipase, the enzyme responsible for tissue uptake of circulating lipids, is decreased by TNF- $\alpha$ , whereas the activity of hormone-sensitive lipase is increased during endotoxemia.<sup>68,70,71</sup> In horses with severe hypertriglyceridemia, treatment with intravenous dextrose solution or partial parenteral nutrition resulted in a decrease in serum triglyceride concentrations to reference limits, and appetite improved coincident with the decrease in circulating lipids.<sup>69</sup>

## CANDIDATES FOR NUTRITIONAL SUPPORT

Several factors affect the decision to provide nutritional support to a sick horse, including the duration of inappetence or anorexia, the nutritional state before illness (e.g., poor versus good body condition), physiologic state (e.g., growing animals, last trimester of pregnancy, lactation), and the presence of clinical indicators of a hypercatabolic state (e.g., hyperlipidemia or lipemia).<sup>72,73</sup> As a general guide, horses that have not eaten for 48 to 72 hours are candidates for nutritional support. However, earlier intervention should be considered when there is evidence of compromised nutritional status, such as horses in thin body condition (BCS <3); those with a history of weight loss, poor feed intake, or both for more than 48 hours before examination; and those with evidence of sepsis, SIRS, or severe hyperlipidemia (e.g., triglycerides >500 mg/dl). Aggressive nutritional support also is indicated for obese (BCS >7) animals, particularly pony breeds, miniature horses, donkeys, and lactating mares, all of which are at high risk for development of hyperlipemia and hepatic lipidosis during periods of negative energy balance. Old horses or those with evidence of endocrine (pituitary pars intermedia dysfunction [PPID], equine Cushing's disease) and metabolic disease (equine metabolic syndrome) also are candidates for early nutritional intervention.

## ESTIMATING NUTRIENT AND FEED REQUIREMENTS

The nutritional requirements of sick horses have not been determined, so recommendations are largely based on data from healthy horses, with some extrapolation from data in other species. As for healthy animals, however, the first consideration is energy (calories). As discussed, negative energy balance caused by starvation or underfeeding can compromise immune function, delay wound healing, and result in a marked decrease in lean mass (e.g., skeletal muscle), the latter resulting from the breakdown of endogenous protein

for use in energy-requiring processes. On the other hand, studies in humans and other species have shown that an oversupply of energy (*hyperalimentation*) is also detrimental, with complications such as hyperglycemia, hyperinsulinemia, hypertriglyceridemia, insulin resistance, and increased risk of septic complications.<sup>74</sup> A proposed mechanism of increased complications induced by hyperalimentation is an increase in the expression of TNF receptors associated with an increase in nuclear factor  $\kappa$ B binding to the nucleus.<sup>75</sup> Furthermore, in septic animals high caloric intake results in an increase in mortality.<sup>76,77</sup> For these reasons, the current thinking in human medicine is to underfeed nonprotein calories (15 to 25 kilocalories [kcal]/kg daily or no more than 66% of calculated energy requirements) to minimize risk of septic complications.<sup>74</sup>

The sixth edition of *Nutrient Requirements of Horses*<sup>1</sup> reported that the DE needs of mature horses at maintenance ranges between 30.3 to 36.3 kcal/kg body weight daily. The lower end of this range is suitable for minimally active animals with a tendency to gain weight ("easy keepers"), and the high value should be applied to animals with a nervous temperament ("hard keepers"). For healthy horses confined to a stall, daily energy requirements are probably 25% to 40% lower than in horses kept at pasture or in similar circumstances that require it to engage in some voluntary activity. Pagan and Hintz<sup>78</sup> reported that the DE requirement of healthy horses kept in stalls was approximately 22 to 23 kcal/kg Bwt per day, or 30% lower than the DE required by horses kept at pasture. This *stall maintenance* caloric requirement can be estimated by the following equation:  $RER = [21 \text{ kcal} \times \text{Bwt (kg)}] + 975 \text{ kcal}$ , where RER is resting energy requirement. Energy requirements are also affected by the level of feed intake. Thermogenesis associated with the digestion, fermentation, and metabolism of feed can account for 15% to 25% of daily energy expenditure. Because horses recovering from illness generally consume less feed, some reduction in the energy losses associated with digestion and nutrient processing is to be expected.

Another consideration in the estimation of energy requirements is the effect of disease or surgical intervention on metabolic rate. There is conflicting evidence from human studies regarding the effects of surgery, injury, or illness (e.g., sepsis) on metabolic rate and energy requirements. Some studies have demonstrated that abdominal surgery increases energy needs by as much as 30%, whereas others have reported minimal change in energy requirements after gastrointestinal surgery, perhaps a reflection of the decrease in physical activity during hospitalization.<sup>79,80</sup> On balance, it appears that energy needs are minimally altered by surgery or injury unless there are major complications such as generalized burns or sepsis, in which case energy requirements may increase by 40% to 100%.<sup>80</sup> The potential effects of underlying disease (e.g., endotoxemia or SIRS) on the energy requirements of horses are unknown. However, in sick neonatal foals resting metabolic rate and energy requirements were considerably lower compared with those of healthy foals of the same age,<sup>81,82</sup> and horses that underwent resection of the small intestine gained weight when fed at true maintenance (i.e., 32 to 33 kcal/kg/day) during the postoperative period.<sup>83</sup> This author recommends that the caloric requirements of sick horses initially be based on the RER or stall maintenance equation (i.e., 22 to 23 kcal/kg/day). Thereafter there should be a gradual increase in the ration, although true maintenance DE may not be required until the horse returns to normal management (e.g., field turnout). Practitioners should keep in mind that regular

measurement of body weight or assessment of BCS should be undertaken during convalescence to judge the adequacy of energy provision and provide a basis for adjustments in feeding.

Protein serves an important role in tissue maintenance, immune function, wound healing, and the slowing of endogenous protein catabolism. Protein requirements must be considered in light of caloric intake and underlying disease process. When energy supply from carbohydrate and fat is limited, endogenous protein will be used for energy, contributing to a loss of lean body mass. Therefore the practitioner should, when developing a nutritional plan, first ensure that minimal energy needs are met and then calculate protein requirements. For humans suggested protein requirements range between 1.2 and 2.0 g protein/kg/day, with the higher end of this range recommended for patients undergoing major intestinal surgery.<sup>84</sup> The crude protein (CP) requirement of healthy adult horses at maintenance is approximately 1.25 g CP/kg body weight/day and this value is an appropriate starting point in the development of a nutritional plan for sick horses: As the efficiency of digestion for most dietary proteins in horse feeds is about 70%, this level of CP will provide approximately 0.9 g available protein/kg body weight. For parenteral feeding a slight lowering of protein feeding is reasonable given the higher metabolic availability of amino acids administered by the intravenous route. In recent reports of parenteral feeding of horses, 0.6 to 0.8 g protein/kg/day (1 g per 40 to 50 kcal) was administered (as a balanced amino acid solution).<sup>83,85</sup> There may be justification for higher levels of dietary protein (e.g., 2 g CP/kg/day), particularly for horses in poor body condition (BCS <3) or those with SIRS, hypoproteinemia, or hypoalbuminemia.

## MODES OF NUTRITIONAL THERAPY

The mode of nutritional therapy will depend on the underlying disease, the horse's appetite, and complications that arise during convalescence. The popular phrase in human clinical nutrition "if the gut works, use it" is used when discussing the pros and cons of enteral nutrition (EN) versus parenteral nutritional (PN) support. Historically, PN has been associated with several complications, including intestinal atrophy, failure of gut barrier function, bacterial translocation, increased incidence of sepsis, and hyperglycemia. In rodent models intestinal villous atrophy develops within a few days of the start of PN, and withdrawal of enteral feeding has been associated with bacterial translocation, systemic inflammation, and sepsis.<sup>86-88</sup> Early human studies also suggested that complication rates (particularly sepsis) and mortality were higher in patients receiving PN compared with those who received EN. However, critical review of human studies has indicated that PN (i.e., complete bowel rest) is not associated with intestinal atrophy, whereas the incidence of bacterial translocation is the same in patients receiving PN and those receiving EN.<sup>74</sup> Although EN is preferable when the gastrointestinal tract is functional, the weight of evidence from human studies indicates that PN is an important alternative to EN when a risk of malnutrition is present and EN is not tolerated or not possible because of poor gastrointestinal function. These same principles can be applied when developing a plan for the nutritional management of sick horses. Parenteral nutrition should be considered for horses with ileus and other intestinal conditions that prevent voluntary or enteral feeding,

particularly when the withholding of oral feeding is expected to exceed 48 hours.

## ASSISTED ENTERAL FEEDING

Assisted enteral feeding (AEF) is accomplished by the infusion of a liquid diet through a nasogastric tube. Diet options for AEF include human-marketed enteral products, commercial pelleted horse feeds, and homemade recipes.<sup>89,90</sup> Formulations marketed for humans that have been administered to adult horses include Vital HN and Osmolyte HN (Ross Laboratories, Columbus, Ohio). Both formulations are devoid of fiber, which is an advantage because it facilitates administration through a small diameter nasogastric tube but also a disadvantage insofar as it may lead to the development of diarrhea when these products are fed to horses. There also have been anecdotal reports of laminitis in horses fed these diets. Risk of these complications may be mitigated by gradually introducing the liquid diet over a 3- to 4-day period, but diarrhea remains common, perhaps indicating the importance of dietary fiber for maintenance of normal hindgut function. It also should be recognized that the mix of energy substrates in these fiber-free enteral formulas for human use differs from that in typical equine rations. Osmolyte contains approximately 29% of calories from lipid and 54% of calories from hydrolyzable carbohydrate (mostly sugars), and Vital HN provides about 10% calories from lipid and 74% from carbohydrate. The high lipid content of Osmolyte may contribute to digestive disturbances in horses not adapted to fat-supplemented rations, and use of a high carbohydrate diet such as Vital HN may be contraindicated for horses with abnormal glucose metabolism (insulin resistance). Collectively, these considerations argue against the use in horses of fiber-free enteral products intended for human use. Diets containing a moderate amount of fiber (10% to 20% crude fiber [CF], DM basis) appear to be a more suitable choice for AEF in horses.

A simple approach is to use a commercially available pelleted feed that contains a source of fiber, such as Equine Senior (Land O' Lakes-Purina Feed, St. Louis, Mo.) or similar "complete feeds" that contain added fiber and can be fed without hay. These products contain about 14% to 25% CF and provide 2.6 to 3.1 Mcal DE/kg diet (as fed). Therefore 3.5 to 4.0 kg of diet would be needed to meet the stall energy requirements of a 500-kg horse. Vegetable oils (75 to 375 ml per day) can be added to increase the caloric density of the diet (Table 5-3). One standard cup (approximately 225 ml or 210 g) of oil provides about 1.7 Mcal of DE. Vitamin E (100 to 200 IU per 100 ml of oil) should be added to the ration if supplemental vegetable oil is provided. When providing supplemental fat to a sick horse (450 to 500 kg Bwt), 75 to 125 ml per day (¼ to ½ cup) should be given initially and then gradually increased if no adverse response is seen (e.g., diarrhea, steatorrhea, lipemia). Feeding vegetable oil may be contraindicated in horses and ponies with hypertriglyceridemia (triglyceride concentration >40 to 500 mg/dl) or hepatic lipidosis.

Variations on the alfalfa/dextrose/casein enteral formulation first described by Naylor et al.<sup>90</sup> also can be used for AEF (Table 5-4). The recipe designed by Naylor et al.<sup>90</sup> provides about 3 Mcal DE/kg diet and is 33% CP and 12% CF. The higher protein content, compared with that of typical equine diets, may be beneficial for debilitated or hypoproteinemic horses. In healthy horses this diet reportedly maintained body weight and serum biochemical parameters within reference limits. However, diarrhea and laminitis were occasional complications.

\*These allowances should be divided and administered into three or four feedings daily. Stall maintenance requirements for a 500-kg horse are 12 Mcal DE/day.

<sup>†</sup>Composition of electrolyte mixture: sodium chloride (NaCl) 10 g; sodium bicarbonate (NaHCO<sub>3</sub>) 15 g; potassium chloride (KCl) 75 g; potassium phosphate (dibasic anhydrous, K<sub>2</sub>HPO<sub>4</sub>) 60 g; calcium chloride (CaCl<sub>2</sub>·2H<sub>2</sub>O) 45 g; magnesium oxide (MgO) 25 g.

Suggested feeding protocols for a complete pelleted feed with supplemental vegetable oil and for the alfalfa/dextrose/casein formulation are presented in Tables 5-3 and 5-4, respectively. The rate of diet administration should be gradually increased over a 3- to 5-day period. A suggested rate of introduction is to administer ¼ of the final target volume of feed on day 1, ½ total volume on day 2, ¾ total volume on day 3, and the total volume on day 4 or 5. Clinical signs of intolerance to enteral feeding will dictate a slower rate of introduction. In hospital settings the enteral diet should be administered in a minimum of four and preferably six feedings per day, with no more than 6 to 8 L per feeding for a 450- to 500-kg horse (including volume of water used to flush the tube). This volume should be administered over a 10- to 15-minute period. In field settings a more practical approach is to administer two treatments daily, although it will not be possible to meet stall maintenance nutritional requirements with this treatment regimen.

Pelleted feeds should be soaked in warm water to soften before mixing in a blender (ratio of 1 kg pelleted feed to 6 liters of water). A fresh batch of diet should be made before each feeding. A tube with a ½-inch (12-mm) inner diameter is suitable for most enteral diets that contain fiber. The end of

the tube should be open ended, rather than fenestrated, to prevent the tube from becoming clogged. Intermittent nasogastric intubation or placement of an indwelling nasogastric tube can be used to facilitate feeding. In hospitalized horses feeding tubes can be left in place for up to 8 days, although nasopharyngeal irritation and mucoid nasal discharge are expected outcomes (when longer-term AEF is anticipated, placement of the tube through cervical esophagostomy is recommended). Softer silicon tubes are less irritating compared with tubes made of polyvinylchloride, do not tend to harden when left in place, and are generally recommended for horses requiring AEF for a number of days. Before placing the tube, the clinician should establish that the diet solution flows adequately through the tube. It may be necessary to add more water or to mix the feed in a blender a second time. The tube should be positioned in the stomach rather than the distal esophagus to minimize risk of reflux of feed around the tube. The tube should be secured to the halter; between feedings application of a muzzle may be necessary to prevent the horse from dislodging the tube. A marine bilge pump is recommended for infusion of fiber-containing diets. After administration of the diet, the tube should be flushed with approximately 1 L of water followed by a small volume of air to ensure that no feed

material remains in the tube. The end of the tube should be capped with a syringe case between feedings.

Close clinical monitoring, particularly of gastrointestinal function, is imperative for horses receiving AEF. Repeated ultrasonographic examinations can be useful for evaluation of gastric distention and intestinal motility. The presence of residual gastric fluid should be assessed (i.e., by siphoning) before each feeding. Substantial gastric reflux (>1 to 2 L) is an indication to withhold enteral feeding for at least 1 to 2 hours, with re-evaluation before recommencement of diet administration. Persistent gastric reflux indicates intolerance to enteral feeding and the need for parenteral feeding. Similarly, signs of colic, ileus, abdominal distention, and increased digital pulses suggest an intolerance to enteral feeding and are an indication to discontinue therapy or decrease the volume and frequency of feedings. The passage of loose feces is not uncommon in horses receiving AEF and of minimal concern if not accompanied by clinical signs of depression, dehydration, ileus, or colic. It is important to measure the total volume of water administered through the nasogastric tube. Daily water requirements (approximately 50 ml/kg/day) can generally be met during AEF if the horse is fed four to five times daily. Frequent measurements of hematocrit and plasma total protein concentration also are useful for monitoring hydration status and the adequacy of water administration. Hypokalemia, ionized hypomagnesemia, and ionized hypocalcemia can occur in horses with gastrointestinal disease. Accordingly, frequent measurements of serum electrolytes and ionized calcium and magnesium are recommended during AEF in these patients. Supplementation with potassium, calcium, magnesium, or both may be necessary. Horses also should be monitored for development of complications associated with repeated or indwelling nasogastric intubation, including rhinitis, pharyngitis, and esophageal ulceration. Body weight should be measured daily to assess the adequacy of nutritional support, although changes in body weight may reflect alterations in fluid balance rather than the effect of feeding.

### PARENTERAL NUTRITIONAL SUPPORT

Parenteral nutrition is indicated for horses with gastrointestinal tract dysfunction (e.g., ileus, gastric reflux) or conditions that mandate complete bowel rest (e.g., small intestinal resection, duodenitis-proximal jejunitis). Durham et al.<sup>83,85</sup> examined the effects of postoperative PN in 15 horses (versus 15 control horses) recovering from resection and anastomosis of strangulated small intestine and reported no beneficial effect of PN on time to first oral feeding, duration of hospitalization, costs of treatment, or short-term survival (up until 5 months after discharge), although the PN protocol did confer improved nutritional status, as reflected by lower serum concentrations of triglycerides and total bilirubin and higher concentrations of glucose. However, the duration and volume of postoperative gastric reflux were longer in the PN group than in the control horses, perhaps as a result of alterations in gastric or small intestinal motility, and there was an insignificant trend for catheter-site complications in the PN group.<sup>83</sup> The authors concluded that further study of a larger number of horses is necessary to determine the clinical benefits and possible harmful side effects of PN in horses recovering from small intestinal surgery. Studies of the effects of PN in human patients also have yielded equivocal findings. Several studies have demonstrated that perioperative PN is associated with reduced morbidity and mortality in malnourished patients.<sup>91-93</sup> In contrast, perioperative

PN in well-nourished human patients has been associated with increased morbidity, particularly septic complications.<sup>94,95</sup> Nonetheless, as previously discussed, the current consensus in human clinical nutrition is that PN is an important component of overall case management, particularly in patients with evidence of malnourishment, gut failure, and increased nutritional requirements (e.g., pregnancy, lactation, growth).

The following paragraphs provide a brief overview of the composition of PN solutions, methods for delivery, and potential complications. As with EN support, the goal of PN is to administer calories and amino acids such that loss of body protein (and lean body mass) is minimized.<sup>73</sup> Carbohydrates, in the form of a 50% dextrose solution (3.4 kcal/g or 1.7 kcal/ml; osmolarity 2525 mOsm/L), and lipid, as a 10% to 20% emulsion (20% emulsion: 9 kcal/g or 2 kcal/ml; osmolarity 260 mOsm/L), are the primary sources of energy used in PN solutions, whereas an amino acid solution (e.g., Travasol 8.5% or 10%; Baxter Health Care Corporation) is used to meet protein requirements (e.g., protein synthesis, immune function). Commercial lipid emulsions (e.g., Intralipid 20%; Baxter Health Care Corporation, Deerfield, IL) consist of soybean oil, egg yolk phospholipid, and glycerin. These emulsions provide mainly unsaturated fatty acids (linoleic, 44% to 62%; oleic, 19% to 30%; linolenic, 4% to 11%; palmitic, 7% to 14%). PN solutions with and without lipid can be used (i.e., dextrose/amino acid or dextrose/lipid/amino acid mixtures). The addition of lipids to the PN formula results in a solution with lower osmolarity compared with a dextrose/amino acid mixture of similar caloric density. Hence the lipid-containing solution should be less irritating to peripheral veins. Lipid solutions must be included in the formula if target calorie provision approaches true maintenance (32 to 33 kcal/kg/day) because this level of calorie delivery from a dextrose/amino acid PN solution often results in marked hyperglycemia and glucosuria. However, when the target daily energy provision is 20 to 22 kcal/kg/day, dextrose/amino acid mixtures can be used. In human medicine this approach is referred to as a *partial parenteral nutrition* and is often employed in postoperative patients who require only a few days of intravenous nutritional support;<sup>74</sup> similarly, partial PN is recommended for horses requiring short-term (3 to 7 days) intravenous feeding. Lipid administration is not recommended for patients at high risk for severe hypertriglyceridemia or hyperlipemia (e.g., ponies, miniature horses, donkeys). Serum triglyceride concentrations should be monitored on a regular basis if lipid solutions are administered to these patients. As discussed previously, provision of amino acids (protein) at a rate of 0.6 to 0.8 g/kg body weight daily is one guideline for meeting protein requirements in adult horses, although some authors have recommended 1 to 1.5 g/kg/day, and provision of amino acids at 0.6 to 2 g/kg/day has been used in sick horses without apparent complications.

A suggested PN formula (Table 5-5) comprises 1 L of 50% dextrose (0.5 g/ml dextrose  $\times$  3.4 kcal/g  $\times$  1000 ml = 1700 kcal), 1 L of a 10% amino acid solution (0.1g/ml of amino acids  $\times$  4 kcal/g  $\times$  1000 ml = 400 kcal), and 500 ml of 20% lipid emulsion (0.2 g/ml lipid  $\times$  9 kcal/g  $\times$  500 ml = 900 kcal). These components are diluted with 4 L of isotonic fluid, yielding a final volume of 6.5 liters and a caloric density of approximately 0.45 kcal/ml. A multivitamin supplement may be added to this mixture. This solution can be prepared up to 24 hours before administration, with storage at 4° C until use. Administration of PN solutions should be through a dedicated intravenous catheter (i.e., do not administer other medications with

\*For parenteral nutrition, daily energy needs are estimated at 23 kcal/kg/day (11.5 Mcal per day for a 500-kg horse).

this catheter), preferably one inserted into a large vein such as the jugular to minimize the risk of complications associated with the infusion of hyperosmotic solutions. Alternatively, a double-lumen catheter can be used, allowing the PN solution to be given through one port and medications and other fluids through the other port. To minimize the risk of thrombophlebitis, nontrombogenic catheters such as those made from polyurethane are recommended. Meticulous attention to sterile technique is needed during catheter placement to further minimize the risk of thrombophlebitis and other septic complications. The fluid lines used for delivery of the PN solution should be changed every 24 hours. An infusion pump is required to ensure accurate delivery of the PN solution. The bag containing the PN solution should be covered with a brown bag during administration to protect it from light, which can degrade the amino acids within the solution.

Table 5-5 provides a recommended rate of parenteral feeding for a 500-kg horse. The initial rate of PN solution administration should be approximately 35% of target calorie provision, increasing to 60% to 65% after 12 hours and 100% (23 kcal/kg/day) at 24 hours, provided that there are no complications, such as the development of marked hyperglycemia, glucosuria, or hyperlipemia. Hyperglycemia and hyperlipemia were the most common complications of postoperative PN in horses after intestinal surgery. In one report hyperglycemia was observed in 52 of 79 horses receiving PN,<sup>96</sup> perhaps because of insulin resistance, an excessive rate of administration, or both. Blood glucose concentrations should be measured every 4 to 8 hours in horses receiving PN, and the rate of dextrose administration should be decreased if glucose concentrations exceed renal threshold (approximately 180 to 200 mg/dl). A constant-rate insulin infusion (e.g., regular insulin at a starting dose of 0.05 to 0.1 IU/kg/hr) can be instituted if the reduction in dextrose administration rate fails to correct the

hyperglycemia. Blood glucose concentrations must be closely monitored (e.g., every 2 to 6 hours). Adjustments in insulin dose may be required to achieve glycemic control. Serum blood urea nitrogen (BUN), triglycerides, and electrolytes should be monitored at least daily. Hypokalemia, hypocalcemia, and hypomagnesemia have been reported in horses receiving PN, and it may be necessary to supplement these nutrients if parenteral feeding is used for more than 48 hours. Finally, body weight should be recorded daily or every other day.

### TRANSITION TO VOLUNTARY FEEDING

A decrease in AEF or PN is indicated when appetite returns (or when voluntary oral feeding is no longer contraindicated). Initially, small amounts of palatable (e.g., fresh grass or leafy hay) feed should be offered. If these feedings are tolerated, the level of tube or parenteral feeding can be gradually reduced as the provision of feed for voluntary consumption is increased. Nutritional support can be withdrawn when voluntary feed intake provides at least 75% of stall maintenance DE and protein requirements. As with any feeding program, all changes in diet should be gradual. Hay should be the primary, if not sole, component of the convalescent diet, preferably leafy hay with a fresh aroma. Grain or commercial grain-concentrate feeds should be offered only if hay alone does not meet requirements. An alternative to grain is to feed 1 to 2 lb/day of a high-protein product (approximately 20% to 25% CP, usually with added minerals and vitamins) as a supplement to hay.

## NUTRITIONAL MANAGEMENT OF THE ORPHANED OR SICK FOAL

### FOAL METABOLISM AND NUTRIENT REQUIREMENTS

The foal's nutritional requirements and dietary composition change substantially during the gradual transition from neonate to weanling. At birth the foal must transition from a continuous supply of nutrients provided by the dam by way of the placenta to intermittent absorption of ingested nutrients. At the same time, the metabolism of the neonate is no longer able to depend on the maternal glucose concentration to maintain normoglycemia, and the pancreas assumes responsibility for regulating glucose homeostasis.<sup>97</sup> These dramatic alterations in energy metabolism may not always occur smoothly, and the neonatal foal possesses limited energy reserves in the form of glycogen and fat. The result is that hypoglycemia occurs frequently in even the normal neonatal foal, and the sick foal is at risk for profound hypoglycemia if deprived of energy intake for even a few hours.<sup>97</sup>

The neonatal foal has a high metabolic rate and requires frequent ingestion of high volumes of milk to meet its energy requirements for maintenance and growth. In light breeds the average rate of daily gain over the first month of life is 1 to 1.5 kg/day. During the first week of life, calorie needs are as follows: approximately 150 kcal/kg/day, with a gradual decrease to approximately 120 kcal/kg/day at 3 weeks of age, and then to 80 to 100 kcal/kg/day by 1 to 2 months of age.<sup>81,82</sup> Healthy neonatal foals (<7 days of age) have up to 7 nursing bouts per hour, most lasting for 1 to 2 minutes. Subsequently, there is a gradual decrease in the frequency of nursing but an increase in the duration of each nursing bout. During the first 24 hours of life, foals consume approximately 15% Bwt as milk (i.e., 8 L in

a 50-kg foal), increasing to between 23% and 25% Bwt (15 L) by day 3 or day 4.<sup>98</sup> On a DM basis, mare's milk averages about 64%, 22%, and 13% sugar (as lactose), protein, and fat, respectively, as compared with cow's milk, which contains 38%, 26% and 30% sugar, protein, and fat, respectively. As a result, glucose (from lactose) is the primary source of energy for the foal.

Starting as early as the second day of life, foals begin ingesting small amounts of hay, grass, and grain while also ingesting maternal feces, which likely provides the initial microbial flora required to support digestion of these feedstuffs. It is unlikely that grain and roughage are well digested until at least several weeks of age, at which point the foal begins the gradual transition from a milk-based diet to a forage-based diet. The amount of milk produced by the mare peaks after approximately 2 months of lactation and then begins a steady decline, which continues until the time of weaning, when the foal must begin relying on solid feed for an increasing proportion of its nutritional requirements. Full maturation of hindgut function may occur by 3 to 4 months of age.

### NUTRITIONAL SUPPORT OF ORPHAN FOALS

The primary options for management of orphan foals are to raise by hand or foster to a nurse mare.<sup>98,99</sup> Fostering is the best option for a foal younger than 6 to 8 weeks of age. Draft or Draft-cross mares that are mild in temperament make good nurse mares. Any disparity between the stage of lactation and age of the foal should be noted. A mare that is 4 to 6 weeks into lactation may not have the quality of milk needed to sustain a neonate; it may be necessary to provide the neonatal foal with a mineral supplement when fostered to a mid-to-late lactation mare.

Hand rearing has several disadvantages, including the need for high labor input, the expense of milk substitute, and a high incidence of behavioral problems. The risk of behavioral problems can be mitigated by ensuring that the foal is raised with an equine companion (e.g., a quiet horse or pony or even another orphan foal). Teaching a foal to drink from a bucket is preferable to bottle feeding because it is less labor intensive for the owner and allows the foal to drink milk on demand. Feeding from a bucket also helps prevent some of the behavioral problems that develop in foals that have bonded to people. Bottle feeding may be the only option in newborn foals, but a quick transition to bucket feeding is recommended. It is also important to ensure adequate colostrum intake (and acquisition of passive immunity) in foals that are orphaned at birth.

Fortified cow's milk (by the addition of 20 g/L dextrose to 2% part skimmed milk); goat milk; and calf, lamb, and kid milk substitutes have been used to rear foals, but a high-quality mare-milk formula is preferred. On a DM basis foal milk replacers should contain approximately 15% fat and 22% CP, with a fiber content of less than 0.5%.<sup>99</sup> Milk replacers should be fed as a 10% to 15% solution when diluted with water. Milk replacers generally provide about 500 kcal/L when mixed according to the manufacturer's instructions. The volume of milk should be fed over a 7- to 10-day period. One recommendation is to start at 5% to 10% of Bwt, increasing to 20% to 25% Bwt by day 10. Intake of 20% to 25% Bwt/day as milk replacer will meet energy and nutrient requirements for growth. As a general guide, most light-breed foals need 14 to 17.5 L (4 to 5 gallons) of milk substitute each day during the first 2 to 3 weeks of life, and draft foals require 21 to 28 L (6 to 8 gallons). Foals may be fed as infrequently as two to

four times daily, although more frequent feedings (six to nine daily) are recommended for young foals and during the initial phase of hand rearing to keep from overwhelming the digestive tract. Feeding buckets should be thoroughly cleaned on a daily basis. Similarly, strict hygiene is required during the preparation of the milk substitute. Fresh water should be available at all times.

Body weight or linear measures that predict weight and height gain<sup>100</sup> should be monitored on a regular (e.g., weekly) basis. Expected rates of growth and weight gain are available for some horse breeds. Studies of hand-reared foals have demonstrated growth rates similar to those observed in foal reared with their dams.<sup>101</sup> Solid feed should be introduced as early as 2 to 3 weeks of age (e.g., small amounts of high-quality hay, milk-based pellets, or both). Up to 1 kg of milk pellets/day can be fed with a concomitant reduction in liquid milk feeding. Orphan foals can be weaned from milk at 10 to 12 weeks of age, with a transition to a diet of forage and a balanced foal feed (16% to 18% CP).

### NUTRITION OF THE SICK NEONATAL FOAL

The energy (calorie) requirements of sick, recumbent foals are less than those of healthy foals, in part because of their lower physical activity and a temporary decrease in growth rate compared with healthy neonates. In one study the metabolic rate of healthy foals was 130 to 140 kcal/kg Bwt/day, whereas metabolic rate in immature foals and foals with perinatal asphyxia syndrome was approximately 62 to 69 kcal/kg Bwt/day.<sup>81</sup> It is possible that sepsis and endotoxemia increase metabolic rate, although studies in neonatal humans indicate that critical illness is not accompanied by a hypermetabolic state. Currently providing critically ill, recumbent foals approximately 45 to 50 kcal/kg Bwt/day is recommended.<sup>98,102</sup> This "hypocaloric" approach to nutritional support may prevent complications associated with overfeeding, such as hyperglycemia and glucosuria, particularly in foals with sepsis wherein the systemic inflammatory response contributes to insulin resistance and carbohydrate intolerance. Neonatal foals require approximately 1.5 g protein/kg Bwt/day.

The adage "if the gut works, use it" also applies to the nutritional support of sick neonatal foals. Milk contains trophic substances that promote growth and development of the gastrointestinal tract. Additionally, enteral feeding is believed to lower the risk of sepsis associated with bacterial translocation. However, parenteral feeding is required in foals with poor gastrointestinal tract function.

### ENTERAL NUTRITION

Thorough assessment of gastrointestinal function is needed before institution of EN support, including abdominal auscultation and evaluation of abdominal distention and the presence of gastric reflux. Abdominal radiographs and ultrasonographic examination for evaluation of bowel dimensions and motility also may be indicated. Foals with evidence of gastrointestinal dysfunction such as gastric reflux, bowel distention, increased bowel wall thickness, and ileus are unlikely to tolerate enteral feeding. A conservative approach to enteral feeding is also indicated for premature or immature foals in which the gastrointestinal tract may not be completely developed. Foals with perinatal asphyxia syndrome or severe sepsis may be intolerant of enteral feeding as a result of intestinal ischemic injury.

Mare milk is the preferred substrate for enteral feeding; it is highly digestible and obviously provides the correct balance of nutrients for normal growth and development. Commercial mare milk replacers can be used, but practitioners should bear in mind that these products are bovine in origin and have lower digestibility compared with mare's milk. This may increase the risk of intestinal dysfunction associated with enteral feeding. Part skimmed (2% fat) cow's milk to which 20 g/L dextrose (corn sugar) is added can be used if mare's milk (or a mare's milk replacer) is unavailable. Foals that are unable to nurse the mare (or when no mare is available) may be fed through a bottle, bowl, or nasogastric feeding tube. Bottle feeding is recommended when the foal is expected to be transitioned to a mare within a short period of time. The practitioner should remember, however, that bottle feeding is very labor intensive and does carry some risk of milk aspiration if the milk flow rate from the bottle exceeds the foal's capacity to nurse properly. The risk of aspiration is lower with bowl feeding because the head is positioned with the nose down during drinking.

Many sick, recumbent foals have a weak or uncoordinated suck reflex and are at risk of milk aspiration and pneumonia. Milk should be administered to these patients through a feeding tube. Use of small-bore, indwelling nasogastric feeding tubes (e.g., NG1243-12fr × 108 cm [43 inches], MILA International, Erlanger, Kentucky) and feeding of small volumes at frequent intervals (e.g., every 20 minutes) is preferred over repeated passage of a nasogastric tube at 1- to 2-hour intervals. Large-bolus feedings may overwhelm digestive capacity, and repeated passage of a stomach tube is an unnecessary stress on the foal. Another advantage of the small-bore, indwelling tubes is that they do not interfere with the suckle response. Therefore the tube may be left in place as the foal is transitioned to feeding from the mare. The feeding tube should be inserted with the foal in sternal recumbency, and correct placement within the esophagus should be confirmed by radiography or endoscopy. The tube should be fastened to the external nares by sutures or may be retained using a circumferential elastic bandage around the muzzle. It is important to check at each feeding that the tube is still in place and there is no gastric reflux. The foal should be in sternal recumbency or standing when it is fed. Milk should be administered by gravity flow and followed by a small amount of clean water to flush the tube. The tube should be capped between feedings to prevent aspiration of air. Feeding tubes should be replaced every 1 or 2 days to reduce the risk of gastrointestinal tract infection.

A suggested initial rate of milk delivery is 2 to 3 ml/kg Bwt/hr or 100–150 ml/hr for a 50-kg foal, which will provide 2.4 to 3.6 L of milk to a 50-kg foal during the first 24 hours of enteral feeding (Table 5-6). Dextrose-containing fluids can be administered intravenously to provide additional calories during the transition to an adequate level of enteral feeding. The feeding rate can be gradually increased over the next 2 to 3 days (e.g., increase to 4 to 5 ml/kg/hr on day 2 and then to 6 to 8 ml/kg/hr on day 3), which represents a total daily intake of 10% to 15% Bwt. As the rate of enteral feeding increases, intravenous caloric support (dextrose) can be gradually withdrawn. This feeding level will likely meet the maintenance energy requirements of hospitalized foals. Depending on the rate of clinical improvement and the length of hospitalization, it may be possible to increase the volume of feeding to 22% to 23% Bwt/day, which approximates the milk intake of healthy neonatal foals. Clinical monitoring should include frequent assessments of gastrointestinal function, including gastric reflux, intestinal sounds, abdominal distention, and quantity and quality of feces. Gastric reflux, bloating, colic, diarrhea, or constipation can indicate intolerance to enteral feeding and the need for adjustments to the feeding program. Adjustments may involve a decrease in the volume or frequency of enteral feedings. Foals fed milk replacers appear to be more likely to develop loose feces than foals fed mare's milk. In some cases clinical improvement is observed after supplementation with 6000 units of lactase (Lactaid; McNeil Nutritionals, LLC, Ft. Washington, Pa.) per 50 kg foal every 3 to 8 hours, mixed into the milk replacer before feeding.<sup>103</sup>

#### PARENTERAL NUTRITION

Parenteral nutrition support is indicated for foals with poor gastrointestinal function and intolerance to enteral feeding. Short-term parenteral supplementation (less than 24 hours) does not require the use of a balanced PN solution that contains sources of carbohydrate, amino acids, and lipids. However, if PN is expected to be administered for a longer period, then a more complete formula should be used.

Short-term caloric supplementation can be accomplished by administrations of an intravenous fluid containing 5% dextrose (e.g., 5% dextrose in water [D<sub>5</sub>W], Lactated Ringer's solution with 5% dextrose, 0.45% saline with 5% dextrose), and hypotonic maintenance electrolyte solutions containing 5% dextrose.<sup>97</sup> Fluids containing dextrose should not be used for initial large volume fluid resuscitation because this often results in profound hyperglycemia. After initial fluid resuscitation the solutions containing electrolytes as well as

TABLE 5-6

#### Feeding Recommendations for Neonatal and Growing Foals

Foal Age (days)	Energy Requirement	Volume of Mare's Milk or Milk Replacer	Percentage of Body Weight Fed
0-1	150 kcal/kg/day	2-3 ml/kg/hr	5%-7%
2-3	150 kcal/kg/day	4-5 ml/kg/hr	10%-12%
4-7	150 kcal/kg/day	6-8 ml/kg/hr	14%-20%
8-30	120 kcal/kg/day	9-10 ml/kg/hr	22%
30-weaning	80-100 kcal/kg/day	Gradually decreasing and replaced with solid feed	

dextrose may be used as the primary fluids for maintenance therapy in foals with minimal ongoing fluid losses. As a maintenance solution, D<sub>5</sub>W is not a good choice because it lacks electrolytes; it is primarily useful in providing free water to patients suffering from hyperosmolar conditions. The caloric content of a 5% dextrose solution is 0.17 kcal/ml, so an infusion rate of 10 ml/kg/hr would be required to deliver approximately 40 kcal/kg/day (0.17 kcal/kg/hr × 24 hours/day = 41 kcal/kg/day). However, this rate of infusion is more than twice the maintenance fluid requirements of neonatal foals (4 to 5 ml/kg/hr). Therefore an infusion rate of 5 ml/kg/hr (providing approximately 20 kcal/kg/day) is a more appropriate target for partial caloric support using 5% dextrose solutions.<sup>97</sup> Caution is required when adjusting the infusion rate in response to changes in hydration state to prevent excessive dextrose administration, especially in premature or very sick foals that may be glucose intolerant.

An alternative approach involves the administration of a 50% dextrose solution by use of an infusion pump, provided that isotonic fluids are administered concurrently to minimize the risk of vascular endothelial injury caused by the hyperosmolar 50% dextrose solution. Use of 50% dextrose solution is not recommended unless an infusion pump is available. The caloric content of 50% dextrose solution is 1.7 kcal/ml; therefore an infusion rate of 1 ml/kg/hr will provide about 40 kcal/kg/day (1.7 kcal/kg/hr × 24 hours/day = 41 kcal/kg/day). At this low rate of infusion, the primary fluid needs of the patient can be met with a dextrose-free isotonic electrolyte-containing fluid, the infusion rate of which can be altered in response to changes in patient fluid status without concerns related to the requirements of the nutritional plan.<sup>97</sup>

Two approaches have been used for formulation of PN solutions for foals.<sup>97,98,104</sup> The first involves the exact determination of the anticipated metabolic needs of the patient, followed by the development of a formulation that will meet all of these needs using a mixture of dextrose, amino acids, and lipids. The second approach is simpler and more practical and uses one of two basic PN formulas (Table 5-7):

1. Solution I: a mix of equal volumes of 50% dextrose and 8.5% amino acid solutions, intended for short-term use (caloric density = 1.02 kcal/ml).
2. Solution II: a mix of 3 parts 50% dextrose, 4 parts 8.5% amino acid, and 1 part 20% lipid solutions. This solution is preferred for foals that are poorly tolerant of infused dextrose (caloric density = 1.08 kcal/ml).

As previously discussed, protein degradation in muscle tissue occurs during critical illnesses such as sepsis. Thus provision of adequate energy and amino acids to counter this catabolic response is an important goal of PN support. The recommended ratio for nonprotein calories to nitrogen is 100 to 200 nonprotein calories per gram of nitrogen.<sup>105</sup> In one

report the amount of protein provided affected weight gain of neonatal foals, with a negative association between the non-protein nitrogen calories: grams nitrogen ratio (NPC/g N) and the rate of weight gain.<sup>106</sup> Solution I provides 125 NPC/g N, and Solution II contains 131 NPC/g N.

The inclusion of lipids in the PN formulation allows for the provision of a larger number of calories per unit volume compared with solutions containing only dextrose. Another advantage of lipid emulsions is that they are isotonic, thereby moderating the hypertonicity of the PN formulation and potentially decreasing the risk of thrombophlebitis. In a recent report the use of lipid-containing PN solutions allowed for the provision of 40 to 92 kcal/kg/day (mean = 63 kcal/kg/day) to foals, compared with 25 to 66 kcal/kg/day (mean = 41 kcal/kg/day) with a dextrose-based solution.<sup>104</sup>

Methods for delivery of PN solutions have been discussed (see the section on nutritional support of sick horses). The catheter and catheter site should be monitored at least twice daily for heat, swelling, or exudation. Increased resistance to fluid flow in the catheter may be an indication of thrombosis deeper within the vasculature and will often necessitate the placement of a catheter in an alternative site, such as the opposite jugular vein, a cephalic vein, or a lateral thoracic vein. The rate of infusion (in ml/hr) is calculated on the basis of the desired kcal/kg/day to be administered. A reasonable initial goal is 40 to 50 kcal/kg/day; higher rates of energy administration often result in hyperglycemia and hyperlipidemia. The initial infusion rate of PN solutions should be 50% of the calculated final rate, and the rate should be gradually increased every 1 to 3 hours after monitoring of the blood glucose concentration to ensure that hyperglycemia (blood glucose >180 mg/dl) is not present.

Rectal temperature should be closely monitored during PN support because fever is a common early manifestation of systemic infection. Blood glucose concentrations should be closely monitored, the frequency of which depends on the stability of blood glucose concentrations. Blood glucose should be maintained between 90 and 180 mg/dl. Although the renal threshold for glucose is not well described in foals, glucosuria and diuresis will be observed in many when blood glucose levels exceed 180 mg/dl. Urine output should be monitored continuously, in combination with intermittent monitoring of urine glucose concentration, because of the risk of hyperglycemia-induced diuresis and glucosuria. Additional clinicopathologic monitoring should consist of daily complete blood counts and serum chemistry profiles in the critical case; these can be performed every 48 to 72 hours in more stable patients. Body weight should be assessed on a daily basis to ensure that the foal is at least maintaining body weight while on PN support.

Some critically ill foals are intolerant of even a conservative rate of dextrose administration because of insulin resistance.

TABLE 5-7

**Formulation of Parenteral Nutrition Solutions for Neonatal Foals**

Formulation	Composition	Caloric Density (kcal/ml)	Nonprotein calories/g nitrogen
Formula I	1500 ml 50% dextrose, 1500 ml 8.5% amino acids	1.02	125
Formula II	1500 ml 50% dextrose, 500 ml 20% lipids, 2000 ml 8.5% amino acids	1.08	131

The administration of insulin is needed to control hyperglycemia and allow attainment of the goal level of PN support.<sup>97</sup> Use of continuous rate infusion (CRI) for the administration of insulin is preferred to intermittent bolus dosing. An initial insulin infusion rate of 0.07 IU/kg/hr is generally well tolerated. If possible, simultaneous alterations in both the insulin and PN infusion rate should be avoided, because this can result in marked fluctuations in blood glucose concentrations. Blood glucose monitoring should be performed at least hourly for the first 2 to 3 hours after initiation of the insulin CRI, and if hyperglycemia (blood glucose >150 mg/dl) is persistent beyond the first 2 hours of insulin therapy, then the insulin infusion rate may be increased by 50%, followed by hourly blood glucose monitoring for an additional 2 or 3 hours. This procedure for increasing the insulin infusion rate may be repeated if hyperglycemia persists. Conversely, if hypoglycemia (blood glucose <60 mg/dl) is noted, then a bolus of 0.25 to 0.5 ml/kg of 50% dextrose solution should be administered intravenously over 3 to 5 minutes. The blood glucose level should then be reassessed every 30 minutes for at least 90 minutes. If hypoglycemia recurs, a second bolus of dextrose should be administered and the insulin infusion rate decreased by 50%. Close monitoring will then be required for an additional 60 to 90 minutes to assess the stability of blood glucose concentration. Further changes to the insulin infusion rate are not usually necessary once a steady state has been achieved, wherein the blood glucose level is stable and the desired rate of PN administration has been achieved.

When PN support is to be discontinued, it is recommended that the infusion rate be gradually reduced by 25% to 50% increments every 4 to 6 hours while gradually introducing enteral feeding. The monitoring of blood glucose must continue during this weaning process to prevent severe hypoglycemia.

## ☉ MANAGEMENT OF OBESITY

Obesity is an emergent problem in companion animal equid populations. Obesity has been associated with insulin resistance in horses and ponies, and both obesity and insulin resistance have been associated with increased risk of laminitis, particularly the pasture-associated form of this disease.<sup>8,9,107</sup> There is no universal definition of obesity in horses and ponies. According to the Henneke system, horses with a BCS of 8 (fat) or 9 (extremely fat) can be defined as obese, and animals with a BCS of 7 might be considered overweight, if not obese. Few studies have examined the prevalence of obesity in horse and pony populations. The 1998 National Animal Health Monitoring System (NAHMS) study estimated that 4.5% of the horse population in the United States was overweight or obese.<sup>108</sup> However, the accuracy of this estimate may be questioned because it was based on owner reports, not the results of physical examination. Anecdotal observations by equine veterinarians suggest that the prevalence of obesity is far higher than the NAHMS estimate. In support of this contention, a recent cross-sectional, prospective study of 300 mature horses (ponies were excluded) in southwestern Virginia reported obesity (BCS of 8 or 9) in 57 animals (i.e. a prevalence of 19%).<sup>109</sup> In a study of 319 pleasure riding horses in Scotland, 32% were obese and a further 35% were considered fat.<sup>110</sup>

The cause of obesity in horses and ponies is likely multifactorial. However, overfeeding and lack of physical activity are likely contributing factors. Many horses are kept in

confinement (e.g., stall, small pen) for much of the day, and even if used for riding activities 2 or 3 days per week, they may not require any more than maintenance energy intakes. Nevertheless, many of these horses are fed much more than the maintenance energy requirement, a problem that is compounded by the provision of grains, sweet feeds, and other feeds with high caloric density. Obesity also can be a problem in some horses and ponies given unrestricted access to pasture, particularly during the spring and fall, when pasture forage is actively growing, plentiful, and energy rich. In a study by Thatcher et al., more than 60% of the surveyed horses were maintained at pasture year round and were not used for any type of riding activity.<sup>109</sup>

Maintenance DE requirements for horses range between 30 and 36 kcal/kg Bwt (Table 5-8), with variation among horses resulting from differences in dietary composition, age, breed, environment, and body composition, among other factors.<sup>1</sup> Thus for a 500-kg (1100-lb) horse, minimum maintenance energy needs are 15.2 Mcal DE/day. This requirement can be met by about 7 kg (15 lb) of high-quality hay (i.e., no supplemental grain is required). To illustrate the impact of even moderate overfeeding on body weight, consider the effect of adding 1 kg of grain or sweet feed/day to this horse's ration for a 1-year period (i.e., an additional 3 Mcal/day or >1000 Mcal over the 1-year period); if it is assumed that 20 to 25 Mcal of DE *over maintenance* is required for 1 kg of weight gain, the horse in this example will gain upwards of 40 kg Bwt during this period (with a 1- to 1½-unit increase in BCS).

Genetics may be another factor in the predisposition to obesity. Horse owners and veterinarians often use the term *easy keeper* to describe a horse or pony that has a tendency to be overweight and appears to require fewer calories than most horses to maintain condition. Ponies and certain horse breeds (e.g., Morgans, Arabians, Paso Finos) appear to fit this description. One hypothesis is that certain lines of horses and ponies have inherited genetic traits that have facilitated survival on poor-quality forages or in the face of limited feed availability: the so-called thrifty genotype.<sup>8,111</sup> When these animals are supplied with abundant feed, particularly grains or pasture forage rich in NSC, weight gain and obesity result.

Obesity in horses and ponies is a risk factor for laminitis. Mechanical trauma caused by increased load on the feet is one possible reason that obesity is linked with laminitis. However, the increased risk of laminitis in obese equids is more likely related to the attendant insulin resistance. In one recent study of ponies, a phenotype characterized by generalized or regional adiposity (especially a cresty neck), hyperinsulinemia, and hypertriglyceridemia was associated with tenfold higher risk for development of pasture-associated laminitis. The clustering of these risk factors for laminitis is termed *prelaminitic syndrome*.<sup>8</sup> Similar associations between obesity, insulin resistance, and laminitis have been observed in horses, leading to the use of the term *equine metabolic syndrome*.<sup>112</sup> Obese ponies, donkeys, and miniature horses are prone to the development of hyperlipemia during times of stress or negative energy balance (e.g., concurrent disease, lactation). Other proposed effects of obesity include impaired thermoregulation in hot weather, reduced athletic performance, and increased risk of joint injuries, but evidence is lacking. In broodmares obesity and insulin resistance have been associated with prolonged luteal phase and lengthened interovulatory intervals,<sup>112</sup> but the impact of these alterations in the estrous cycle on reproductive performance has not been extensively studied.

TABLE 5-8

Type of Horse	Recommended Digestible Energy Intake by Mature Horses (Mcal/day)*		
	400 kg (880 lb)	Target Bodyweight 500 kg (1100 lb)	600 kg (1320 lb)
Adult sedentary†			
Minimum voluntary activity	12.1	15.2	18.2
Average voluntary activity	13.3	16.7	20.0
Elevated voluntary activity	14.5	18.2	21.8

From Committee on Nutrient Requirements of Horses, National Research Council: *Nutrient requirements of horses*, ed 6, rev, Washington DC, 2007, National Academic Press.

\*Recommended intakes for stallions and growing horses can be found in the NRC publication.

†Sedentary adults: Minimum = very inactive in stall/paddock, *easy keeper*; elevated = very active in stall/paddock, *hard keeper*. Light exercise: 1 to 3 hours/wk; walking, trotting. Moderate exercise: 3 to 5 hours/wk; walking, trotting, some canter; easy skills. Heavy exercise: 4 to 5 hours/wk; trotting, cantering; hard skills. Very heavy: racing; elite 3-day; endurance racing.

## WEIGHT MANAGEMENT PROGRAMS

In horses, as in humans, eating less and exercising more are the key strategies to improve body weight and condition. Important steps in the development of a weight management program include the following:

- Owner/trainer recognition that the horse or pony is overweight or obese: As the old adage states, "Beauty is in the eye of the beholder," and different equestrian disciplines and breeds have adopted different standards to evaluate body condition. Nonetheless, the effectiveness of any weight loss program is critically dependent on the willingness of the owner or caregiver to comply with the plan.
- Evaluation of the current feeding program and housing: this includes a thorough evaluation of the type of feed that is being provided (including supplementary feed, hay, pasture quality, and time allowed for grazing) and in what quantities.
- Assessment of the weekly workload and soundness for exercise: Is the horse or pony engaged in structured physical activity (e.g., being ridden)? If so, how much? Many obese equids receive little structured exercise. Information

on current activity level and soundness for exercise forms the basis for recommendations regarding physical activity.

- Set realistic goals for weight loss and regularly monitor progress: In this author's experience, there is wide variation in the response of obese horses and ponies to weight loss treatment programs. Some undergo a substantial loss of body weight and adiposity after 2 to 3 months of diet restriction and increased physical activity. In others, progress can be frustratingly slow, and further adjustments to diet and the level of physical activity may be needed for satisfactory improvement. As a guide, an effective weight loss regimen should result in the loss of approximately 25 to 30 kg over a 4- to 6-week period. This decrease in body weight may be accompanied by the loss of approximately 1 unit of BCS. However, initial weight loss may result from a decrease in abdominal fat or abdominal fat mass, and further weight loss may be required before noticeable changes in BCS occur. Body weight and body condition should be assessed regularly (e.g., every 2-4 weeks) during the *weight reduction* program so that progress can be monitored and the program adjusted accordingly.

- Make all dietary changes gradually, and avoid prolonged periods of feed withholding. Abrupt starvation in obese ponies, donkeys, and miniature horses carries the risk of hyperlipemia and hepatic and renal lipidosis.
- Develop an appropriate *weight maintenance* program once the target weight and body condition have been achieved. This includes monthly assessment of body weight and condition to ensure that the feeding program is appropriate to the current level of physical activity and other environmental influences on energy requirements (e.g., ambient conditions).

In obese people the combination of caloric restriction and regular physical activity can result in more substantial weight loss than either strategy alone. However, studies in human beings also have demonstrated that physical activity is beneficial even when weight loss does not occur, as demonstrated by improvements in insulin resistance, blood lipid profile, and markers of inflammation, all of which are risk factors for cardiovascular disease. Similarly, a study in a small number of obese mares demonstrated improvements in insulin sensitivity without a change in body weight after 7 days of round pen exercise (15 to 20 min/day).<sup>113</sup> Accordingly, a program of regular exercise is likely to be beneficial in the management of obese (but sound) horses and ponies. In the author's experience, weight reduction and subsequent control are improved when dietary restriction is combined with a program of riding or longeing. A suggested exercise regimen is to start with two or three exercise sessions per week (20-30 min/session), subsequently building to 4 or 5 times per week, with a gradual increase in the intensity and duration of exercise.

### FEEDING OBESE HORSES

Caloric restriction is of paramount importance in the management of obese equids; creation of a state of negative energy balance is needed to achieve loss of body weight. Several different dietary strategies can be applied depending on the horse's present and desired body condition and other individual circumstances. A certain amount of trial and reassessment is invariably required to achieve the goal weight and condition in an individual animal. Key considerations are the quantity and composition of the ration. Removal from pasture (e.g., to a large dry lot) is necessary for adequate control of dietary intake. Some nutritionists and veterinarians have recommended restrictive grazing as a means to decrease caloric intake in overweight equids. However, a study in obese pony mares reported no change in body weight when ponies were allowed access to pasture for 12 hours daily (either during day or night),<sup>114</sup> perhaps because of increased forage consumption during the restricted grazing period. In another study it was estimated that ponies could consume 40% of their daily DM intake during 3 hours of pasture turnout.<sup>115</sup> Strategies that allow turnout while minimizing forage intake include application of grazing muzzles, strip grazing behind other horses, mowing the pasture and removing clippings before providing access, putting a deep layer of wood chips over a small paddock, and using dry lots or indoor arenas. It is important to ensure that horses wearing grazing muzzles are able to consume water. In some obese horses and ponies, a return to less restricted pasture access is possible after attainment of goal body weight and condition. Even then, however, reduced grazing may be justified during periods of rapid growth (i.e., spring and fall) given the likelihood for weight gain and exacerbation of insulin resistance, with attendant increased risk of laminitis.

In general, rations for overweight and obese horses should be high in fiber and low in NSC. Horses at maintenance require approximately 2% Bwt as forage or forage plus supplement to meet daily nutrient requirements. As a first step toward calorie restriction and weight loss, grain and other concentrated sources of calories (e.g., commercial sweet feeds, feeds containing added fats) should be reduced (for overweight animals) or totally removed (for obese animals) from the diet. Excessive feeding of other treats, such as carrots and apples, also should be curtailed. Forage (as hay or hay substitute such as chop, chaff, or haylage) should be the primary, if not sole, energy-providing component of the ration. In some areas forage-based, low-calorie feeds complete with vitamins and minerals are available commercially; this type of feed is convenient and may be used as a substitute for hay or fed as a component of the ration along with hay. In a study of obese ponies provided a free-choice forage (chaff) diet during winter and summer, voluntary intake (DM basis) was about 2% of body weight, and BCS was unchanged during the study period.<sup>116</sup> As a general guide, therefore, hay or hay substitute should initially be provided at no more than 1.5% of current body weight per day (clients should be instructed to weigh the ration), with subsequent further reductions in feed depending on the extent of weight loss (e.g., 1% of *target* body weight). It is preferable not to decrease forage provision below 1% of body weight; feeding smaller amounts of forage can increase the risk of hind-gut dysfunction, stereotypical behaviors (e.g., wood chewing), ingestion of bedding, and coprophagy. The ration should be divided into three to four feedings per day.

Mature grass hay (i.e., with visible seedheads and a high stem-to-leaf ratio) has higher fiber and lower energy and NSC than immature hay and is suitable forage for the obese horse or pony. Alfalfa hay or other legumes, such as clover, are less preferred because, on average, these forages have higher energy and NSC content than grass hay. Ensiled forages generally have lower NSC contents than hay made from the same crop. However, despite the generally lower NSC content of haylage compared with hay, the high palatability of some haylages may result in higher total NSC intake. Ideally, the results of proximate nutrient analysis, including direct measurement of starch and ESC, should be reviewed before selection of the hay. An NSC content of less than 10% is recommended. Poorly digestible, highly silicated forages should be used with caution; according to anecdotal reports, this practice increases the risk of impaction colic in some animals.

Forage-only diets do not provide adequate protein, minerals, or vitamins. It is possible that the lack of protein over the long term could lead to the loss of muscle mass rather than fat. Therefore the forage diet should be supplemented with a low-calorie commercial ration balancer product that contains sources of high-quality protein and a mixture of vitamins and minerals to balance the low vitamin E, vitamin, copper, zinc, selenium, and other minerals typically found in mature grass hays. These products are often designed to be fed in small quantities (e.g., 0.5 to 1.0 kg/day); they can be mixed with chaff (hay chop) to increase the size of the meal and extend feeding time, which may alleviate boredom in animals provided a restricted diet.

Ponies, donkeys, and miniature horses must not be abruptly starved to reduce their body weight or prevented from eating for prolonged periods; these strategies have been associated with the development of hyperlipemia. This risk is increased at times of stress, such as during transportation, lactation,

pregnancy, and management changes. As mentioned, the target duration for weight loss should be weeks to months rather than days.

Additional factors should be considered when planning a weight reduction program, including strategies to extend feeding time and relieve boredom in the face of limited feed provision, the need for individual rather than group feeding, the potential need for a change in the type of bedding, and the potential use of pharmacologic agents (e.g., levothyroxine) purported to enhance weight loss or mitigate co-morbidities such as insulin resistance. Recent studies have demonstrated that levothyroxine sodium (48 mg/day for an adult horse) can enhance weight loss in healthy horses.<sup>117</sup>

Use of hay nets with small openings or double hay nets can extend feeding time in some horses. The size of the meal and duration of feeding can be increased by mixing the feed with chaff or chopped straw. In group housing situations it may be necessary to separate the obese horse or pony to allow strict control of feed intake. For animals housed in stalls, dietary restriction can promote intake of bedding. Because some straws retain some of the cereal heads, ingestion of bedding can substantially increase daily caloric intake (and possibly the risk of colic). In this situation use of shavings, paper, or other nonstraw alternatives for bedding is recommended.

## ☞ FEEDING THIN AND STARVED HORSES

Failure to meet a horse's energy (DE) requirements will result in weight loss. Prolonged nutritional restriction (energy and protein) will result in emaciation and, in severe cases, death. Chronically starved horses have low body condition (BCS of 2 or lower), with minimal subcutaneous fat and reduced muscle mass. The hair coat is often unthrifty in appearance, and muscle weakness may result in recumbency. Healthy horses starved of feed take approximately 60 to 90 days to become recumbent. After 36 to 48 hours of recumbency, horses are often in lateral recumbency, may not be able to raise their heads, and can display seizurelike activity. The prognosis for survival is very poor in horses recumbent for more than 72 hours, even when appropriate nutritional support and nursing care are instituted.<sup>118</sup>

Laboratory findings in chronically starved horses may include anemia, hypertriglyceridemia, hyperbilirubinemia (especially unconjugated bilirubin), high nonesterified fatty acid concentrations, lymphopenia, hypophosphatemia, and hypomagnesemia. Protein deficiency may result in hypoalbuminemia and low BUN concentration. When presented with a thin or emaciated horse, the clinician first must determine the cause (e.g., feed restriction versus medical problems such as intestinal parasites, malabsorption syndromes, poor dentition, and old age). Thorough clinical evaluation is therefore required to identify the cause of weight loss and emaciation. If the horse has been neglected, obtaining an accurate history of its diet and feeding program may be difficult. However, observation of the environment and other horses on the farm may indicate feed restriction as the cause of thin body condition or starvation. Herd mates also may be in poor body condition, pastures overgrazed, and hay quality poor or fed in quantities insufficient to meet the requirements of the individual or herd. Harsh environmental conditions (e.g., dry summer, cold winter) can contribute to feed restriction in horses kept at pasture.

Recommendations for feeding management of thin and emaciated horses vary depending on the severity and chronicity of starvation and appetite. Severely debilitated horses with poor appetite may require AEF with a slurry made from commercial complete feeds or PN support (as described earlier in this chapter). For horses in moderately poor body condition (BCS 3 or 4) with good appetite, a simple increase in energy intake will result in weight gain. The first step is to thoroughly evaluate the current ration, with particular reference to the adequacy of DE and protein intake (see [Figure 5-1](#) and [Table 5-8](#)). Requirements for weight gain can then be estimated. The relationships among energy intake, change in body weight, and change in BCS have not been well described. However, in light-breed horses it appears that each unit of body condition increase requires at least 20 kg of weight gain. Some experts suggest that 16 to 24 Mcal of DE are required per kilogram of gain in mature horses of about 500 kg (1100 lb) Bwt.<sup>1</sup> Using an average value of 20 Mcal DE/kg weight gain, a 1-unit increase in BCS (20 kg gain) will require 400 Mcal of DE over maintenance requirements—or an additional 6 to 7 Mcal per day for the 500-kg horse over a 60-day period. Using similar assumptions, a 2-unit increase in BCS (approximately 40 kg) may be achieved over a 90-day period by feeding an additional 9 to 10 Mcal of DE per day (see [Figure 5-1](#)). Note that these estimates have been derived from limited data, and individual responses are likely to vary. Also bear in mind that the efficiency of conversion of DE to usable energy for tissue deposition (net energy) varies among energy sources; less DE may be needed per unit of gain if a high-fat feed is provided as compared with a high-fiber feed such as grass hay. The addition of 3 kg of good-quality hay (e.g., alfalfa, DE 2.4 Mcal/kg on dry matter [DM] basis) or sugar beet pulp (2.8 Mcal DE/kg DM) to the ration will provide the extra DE required for a 1-unit increase in BCS over a 60-day period. Alternatively, a smaller amount of additional hay or beet pulp may be combined with vegetable oil (1.7 Mcal DE per standard cup [225 ml]). The provision of 2 to 2.5 kg per day of a commercial fat-supplemented feed (8% to 10% fat; typical DE of 3 to 3.5 Mcal per kg) is another option.

A more conservative approach is indicated for the initial nutritional support of starved horses. In malnourished human patients aggressive refeeding can result in potentially fatal shifts in fluids and electrolytes as a result of hormonal and metabolic responses to rapid refeeding, whether enteral or parenteral; this problem has been named *refeeding syndrome*. The hallmark biochemical feature of refeeding syndrome is hypophosphatemia, but other electrolyte abnormalities may occur, including hypokalemia and hypomagnesemia.<sup>119</sup> Thiamine deficiency is another possible feature of refeeding syndrome. During prolonged starvation the intracellular concentrations of these substances become severely depleted, although serum concentrations may remain within reference limits. With refeeding, glycemia leads to an increase in circulating insulin, which stimulates glycogen, fat and protein synthesis. These processes require co-factors such as phosphate, magnesium, and thiamine. Insulin stimulates cellular uptake of potassium, and magnesium and phosphate also move into the cells. Water follows by osmosis. Consequently, there can be marked decreases in serum phosphate, magnesium, and potassium, with potential development of cardiac dysfunction (e.g., arrhythmias, cardiac arrest) and neuromuscular complications.

The incidence of refeeding syndrome in chronically starved horses is unknown. Anecdotally, however, metabolic and electrolyte derangements similar to those observed in humans

with refeeding syndrome have been observed in starved horses provided a diet rich in starches and sugars (i.e., high NSC). Therefore some experts recommend restricting dietary NSC in the ration provided to chronically starved horses, specifically less than 20% NSC in the total diet.<sup>73</sup> One study evaluated the metabolic responses of chronically starved horses refed one of three diets: alfalfa hay, oat hay, or a diet of half oat hay and half an extruded (commercial) feed.<sup>120</sup> The diets were initially offered at 50% of estimated daily DE requirements and, over the subsequent 10-day period, gradually increased to 100% of daily needs. There were minimal differences among treatments with regard to metabolic responses (e.g., blood glucose, non-esterified fatty acid, and mineral concentrations), but serum insulin concentrations were higher in horses fed hay in addition to extruded feed. Weight gain over the 10-day period did not differ among treatments. Another study compared starved horses fed a diet of alfalfa alone and those fed alfalfa and corn oil.<sup>121</sup> Phosphorus intake was lower in horses fed the alfalfa and corn oil diet, which is associated with lower serum phosphorus concentrations.

In general, a diet consisting mostly of forage (e.g., hay) is recommended during the rehabilitation of chronically starved horses. Grass or legume hay (or a mixture of the two) should be fed. The NSC content of these forages is generally less than 15% DM. Alfalfa hay is a good choice for initial refeeding because it has a higher mineral content than grass hay. Grains (e.g., oats, corn, barley) and sweet feeds are not recommended because of their high NSC content. It is advisable to supplement the hay ration with a vitamin and mineral supplement or balancer pellet. The energy density of the ration may be increased by adding vegetable oil (e.g., ¼ to 1 cup per day, starting at the low end of this range) or providing a commercial fat-supplemented feed (8%-12% fat, as fed with NSC <20%). As previously mentioned, thiamine deficiency is thought to contribute to the pathophysiology of refeeding syndrome in humans. Accordingly, the administration of a B-vitamin preparation may be justified.

The DE (caloric) requirements should be calculated on the basis of *resting energy requirements* at the current body weight (22 to 23 kcal/kg/day) and the true maintenance requirements at the ideal body weight (30-36 kcal/kg/day; see Table 5-8). Starved, emaciated horses may have lost 25% to 30% of body weight; therefore maintenance DE needs for ideal body weight will be based on 125% to 130% of body weight measured at the time of first examination. A gradual increase in daily DE intake has been recommended,<sup>73</sup> starting at 25% to 50% of resting requirements at current body weight, building to 100% of resting requirements over the next 2 to 3 days, and followed by a gradual (over 7 to 10 days) transition to maintenance energy requirements for the ideal body weight. Energy provision should not exceed 100% of resting requirements if AEF is used for provision of the ration, with transition to true maintenance after the start of voluntary feed consumption. Regardless of feeding method (voluntary versus AEF), the ration should be divided into four to six feedings daily during the first 10 to 14 days of rehabilitation. Subsequently, the ration can be provided into two to three meals per day.

Regular (every 1 to 2 days) measurement of blood glucose, serum magnesium, phosphorus, and potassium is advised during the first 7 to 10 days of refeeding. Frequent assessment of hydration status and gastrointestinal function (e.g., borborygmi, quantity and character of feces) is also

recommended. Administration of intravenous fluids, oral electrolyte-mineral preparations, or both may be necessary to correct electrolyte imbalances.

# RECOGNIZING AND TREATING PAIN IN HORSES

## CHAPTER

*William Muir*

# 6

Attitudes, opinions, and therapeutic approaches concerning the treatment of pain in horses continue to evolve.<sup>1</sup> Traditionally, pain was used as a diagnostic and prognostic tool that helped determine the source and severity of disease (e.g., articular damage, laminitis, abscess, colic). More recently, however, pain has become appreciated for its ability to produce profound behavioral, neuroendocrine, metabolic, and immunologic effects. Chronic pain, for example, can produce avoidance and protective behaviors, poor performance, inappetence, and weight loss and predisposes to infection, resulting in a generalized “sickness syndrome,” which often contributes to the death or euthanasia of the horse.<sup>2</sup> Improved knowledge of the neuroanatomic and molecular mechanisms responsible for pain and the discovery that untreated pain induces changes in the central nervous system (CNS) that contribute to the development of chronic pain have focused attention on the development of more aggressive and effective analgesic protocols for horses.<sup>3-5</sup> Pain in horses should be considered an independent, rather than dependent, variable particularly when the cause of pain is uncertain (idiopathic pain), the pain is difficult to treat (e.g., myopathy or uveitis), or the cause of pain is impossible to eliminate (e.g., laminitis or osteoarthritis). Pain, like heart rate, respiratory rate, and temperature, should be considered a clinical sign that requires evaluation, documentation, and treatment. This approach will hasten the development of practical and clinically relevant diagnostic and evaluative methods that will aid in identifying the most efficacious therapies. This chapter presents an abbreviated review of the physiologic and pathophysiologic mechanisms responsible for pain and suggests clinically useful methods for evaluating and treating pain in horses.

## ☉ PAIN

*Pain* is defined as “an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage”<sup>6</sup> (Box 6-1). This definition encompasses those neurophysiologic processes that warn and protect the horse from actual or potential tissue damage, help prevent further injury, and promote healing. Clinically, pain results from two multifaceted components, nociception and perception.<sup>4</sup> Both facets are integrated to provide the immediate recognition and elimination (if possible) of the painful stimulus. Nociception is the detection of a noxious

(mechanical, thermal, chemical) stimulus and by itself is not pain, because the transformation of noxious stimuli to electric impulses (transduction), their transfer to the spinal cord (transmission), and their eventual projection to the brain do not ensure that the electric impulses will be recognized (perceived; e.g., as during anesthesia; Figure 6-1). Perception is the recognition that nociception has occurred or continues to occur and triggers responses that protect the horse from further insult and help maintain homeostasis. Pain perception or the actual registration of a noxious stimulus depends on external (environmental) and internal (patient-related) issues and is responsible for the secondary behavioral (vigilance, immobilization, fear), metabolic (hyperglycemia), neuroendocrine (cortisol, catecholamines), and physiologic (heart rate, respiratory rate, pupillary) responses that are frequently used to evaluate the severity of pain, determine stress, and ultimately ascertain the horse’s quality of life.

## PHYSIOLOGIC AND PATHOLOGIC PAIN

Under normal circumstances pain is caused by the activation of high-threshold (high stimulus intensity) pain receptors (nociceptors) located at the distal ends of unmyelinated (C) or poorly myelinated (A $\delta$ ) nerve fibers<sup>2,4</sup> (see Figure 6-1). The free nerve endings of these peripheral afferent nerve fibers encode noxious stimuli depending on the modality, intensity, duration, and location of the stimulus. The intensity of the stimulus required to produce painful sensations is considerably more than that required to produce nonpainful sensations (touch) and is the most important factor determining the severity of pain.<sup>2</sup> Pain that is not associated with tissue damage is referred to as *physiologic* or *nociceptive pain* and serves to warn and protect the horse from potential tissue damage. Pain that occurs in association with tissue or nerve damage is considered pathologic and is frequently categorized as inflammatory or neuropathic, depending on the primary causative factor.<sup>5</sup> Pathologic pain is exaggerated by the development of peripheral and central sensitization. The temporal aspects of pathologic pain are dynamic and characterized by a reduction in the intensity of the stimulus required to initiate pain (hypersensitivity), the persistence of pain after removal of the noxious stimulus (hyperpathia), and the sensation of pain by stimuli that do not normally provoke pain (allodynia).<sup>7</sup> Inflammatory and neuropathic

## BOX 6-1

## TERMS USED TO DEFINE AND DESCRIBE PAIN

1. **Pain:** Unpleasant sensory or emotional experience associated with actual or potential tissue damage or described in terms of such damage.
2. **Noxious stimulus:** Stimulus (mechanical, chemical, thermal) of sufficient intensity to threaten or overtly cause tissue damage.
3. **Nociception:** Process of pain perception via pain receptors (nociceptors), transmission of noxious (painful) stimuli. Includes transduction, transmission, modulation, and perception.
4. **Hyperalgesia:** Increased response (hypersensitivity) to a noxious stimulus, either at the site of injury (primary) or in surrounding undamaged tissue (secondary).
5. **Hyperesthesia:** Increased sensitivity to *non*-noxious stimuli.
6. **Hyperpathia:** Greatly exaggerated pain sensation to nociceptive stimuli.
7. **Allodynia:** Pain produced by *non*-noxious stimuli.
8. **Preemptive analgesia:** Prevention or minimization of pain by the administration of analgesics before the production of pain or before the introduction of a noxious stimulus (surgery) if pain already exists. The goal of preemptive analgesia is to provide a therapeutic intervention in advance of pain to prevent or minimize the central nervous system response to a noxious stimulus.
9. **Multimodal therapy:** Administration of multiple drugs that act by different mechanisms of action to produce the desired (analgesic) effect.

pain are often characterized by an exaggerated response (hyperalgesia) when a noxious stimulus is applied to the injured area.

## PERIPHERAL SENSITIZATION

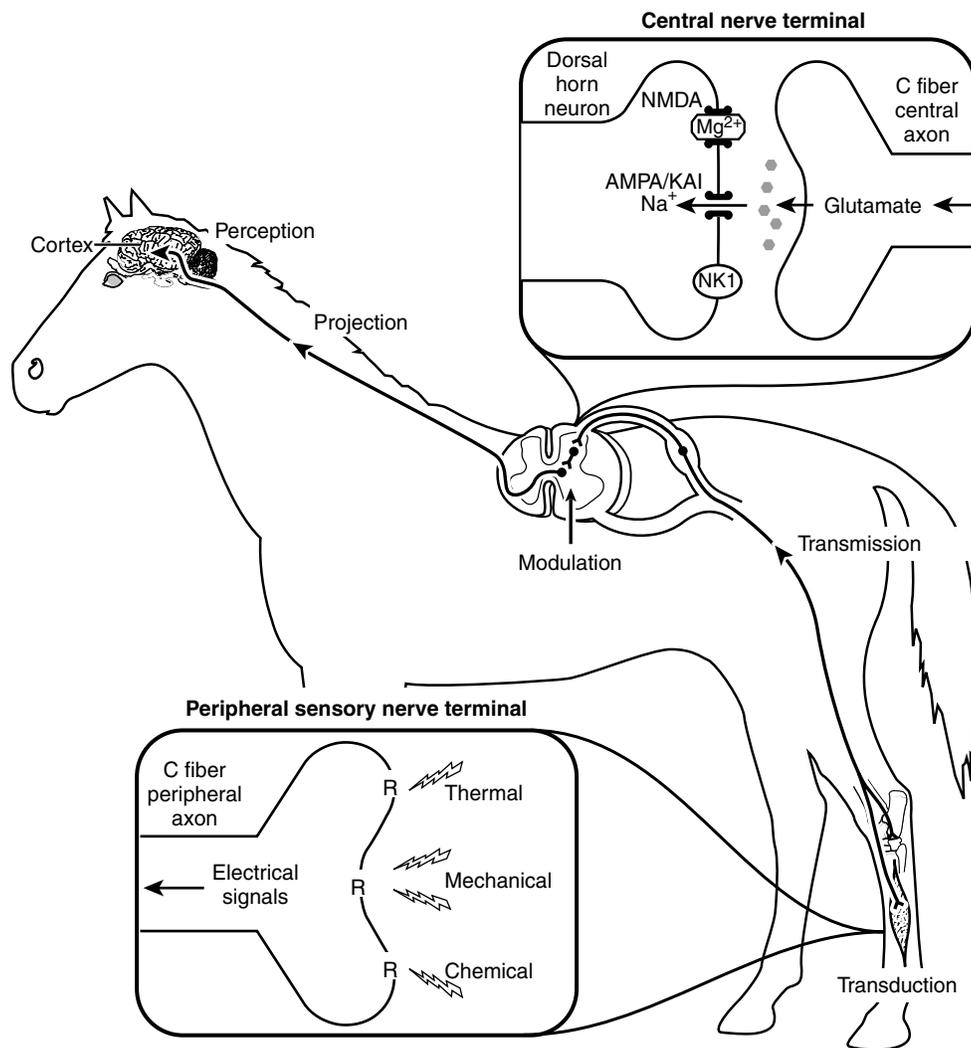

Peripheral sensitization is caused by the production and activation of enzymatic and reparative processes initiated by tissue damage and inflammation at the site of injury. The production or dissemination of the by-products of damaged tissues, the infiltration and activation of inflammatory cells (lymphocytes, neutrophils, mast cells, macrophages), and increased sympathetic nerve activity excites and increases the sensitivity (lower activation threshold) of peripheral nociceptors (Figure 6-2).<sup>4,8</sup> Tissue damage results in the production of prostaglandins, bradykinin, and neurotrophic growth factors, the local release and spread of adenosine, adenosine triphosphate and ions (H<sup>+</sup>, K<sup>+</sup>), and an exaggerated pain response. Leukocytes and macrophages release cytokines (interleukin-1 [IL-1], IL-6, tumor necrosis factor). Primary afferent sensory nerve fibers release neuropeptides (substance P, calcitonin gene-related

peptide) causing mast cells to degranulate, local vasodilation, and plasma extravasation, further amplifying the inflammatory response. Collectively, this “sensitizing soup” lowers nociceptor threshold and activates additional, so-called silent, nociceptors, thereby amplifying the pain response.<sup>8</sup> Peripheral sensitization is responsible for primary hyperalgesia or pain that is initiated by innocuous stimuli applied within the area of tissue injury.

## CENTRAL SENSITIZATION

Central sensitization results from the cumulative effects (temporal summation) of repetitive and sustained nociceptive inputs on the dorsal horn of the spinal cord.<sup>4,7,8</sup> Normally, temporary noxious stimuli generate fast but short-lived excitatory potentials within the CNS that indicate the onset, duration, intensity, and location of the painful stimulus. This fast excitatory transmission is transmitted by A $\delta$  and C fibers and is mediated by glutamate acting on  $\alpha$ -amino-3-hydroxy-5-isoxazole propionic acid (AMPA) and kainite (KA) receptors within the dorsal horn of the spinal cord. Sustained input from damaged tissue or injured nerves, however, releases neuropeptides (substance P, neurokinin A) in addition to glutamate that activate N-methyl-D-aspartate (NMDA) and tachykinin receptors, resulting in a gradual “windup” of neurons in the dorsal horn of the spinal cord and central sensitization (see Figure 6-2).<sup>8</sup> Windup, central sensitization, and biochemical changes that occur in the CNS associated with their development represent a continuum of the pain process that is initiated by an acute painful process or untreated acute or chronic pain. Central sensitization can last for hours to days and is believed to be responsible for increases in the receptive field and hypersensitivity to noxious stimuli outside the area of primary tissue damage (secondary hyperalgesia).<sup>8,9</sup> Changes in spinal cord segmental inhibitory input also contribute to dorsal horn hyperexcitability, resulting in the perception of pain from otherwise innocuous stimuli carried by A $\delta$  (touch) nerve fibers.<sup>8</sup> Central sensitization is fundamentally different from peripheral sensitization in that it enables low-intensity stimuli to produce pain because of changes in sensory processing in the spinal cord. The projection of electric impulses, initiated by a painful stimulus from the spinal cord to the brain, can modify memory and may be the reason that severe or untreated acute or chronic pain results in permanent behavioral changes.<sup>10</sup> The development of central sensitization has several clinically relevant implications, including a change in the therapeutic focus from peripheral (local anesthetics, nonsteroidal antiinflammatory drugs [NSAIDs]) to central sites (opioids,  $\alpha_2$ -adrenoceptor agonists), the selection of potent centrally acting analgesic drugs, and the introduction of strategies that help limit or prevent the development of central sensitization (preemptive and multimodal).<sup>5</sup> Once hyperexcitability (central sensitization) is established, larger doses of analgesics are required for longer periods of time for therapy to be effective. In other words, pain should be treated as early as possible and preemptively when possible.

In summary, peripheral sensitization is caused by the local production, release, and accumulation of chemicals (prostaglandins, leukotrienes, neuropeptides, nerve growth factors) that sensitize peripheral nerve fibers and activate additional (“silent”) pain receptors.<sup>4,8</sup> Some of the hypersensitivity at the site of injury and all of the hypersensitivity

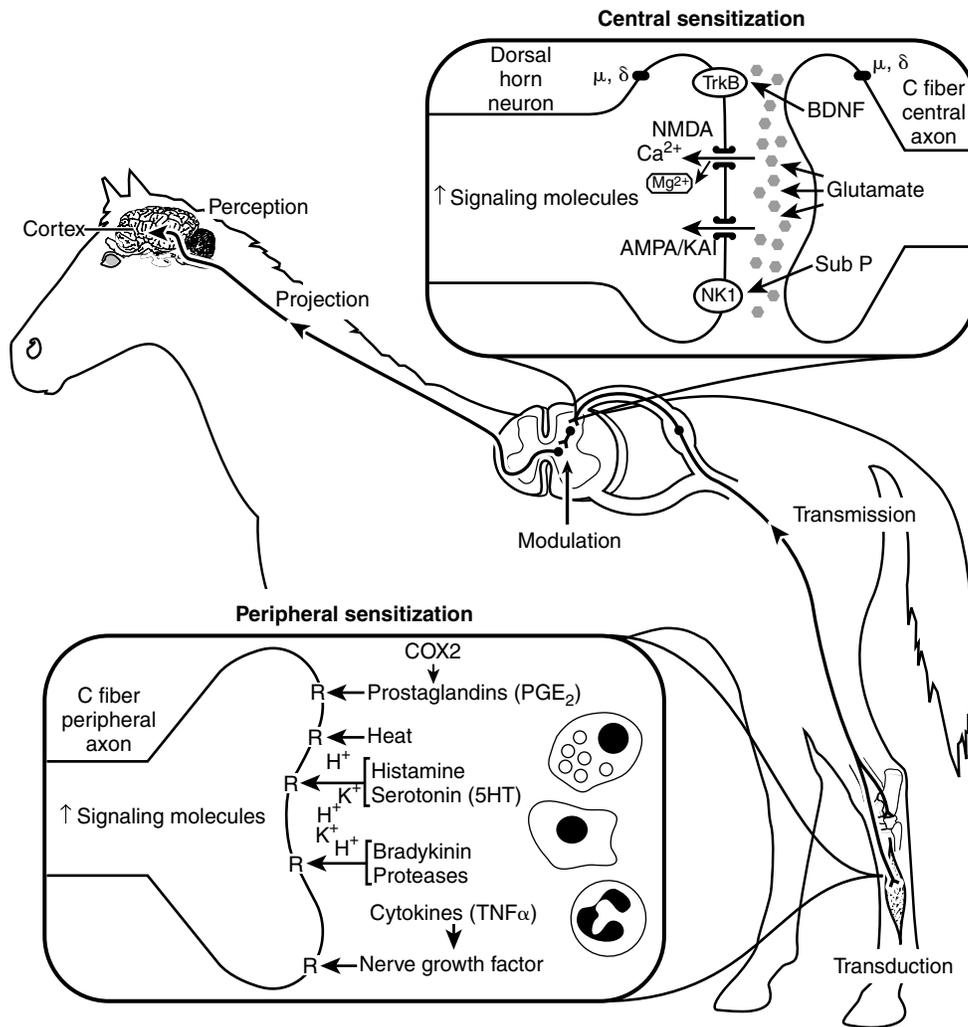

**FIGURE 6-1** Pain nociception and perception. Painful thermal, mechanical, and chemical stimuli are transduced to electric potentials (action potentials) that are transmitted to the spinal cord, where they are modulated and then projected to the brain (perception). The major excitatory neurotransmitter in the spine is glutamate, which normally activates  $\alpha$ -amino-3-hydroxy-5-isoxazole propionic acid (AMPA) and kainate (KAI) receptors. *NMDA*, N-methyl-D-aspartate; *NK1*, neurokinin.

outside the site of injury (secondary hyperalgesia) result from central sensitization.<sup>7-11</sup> The primary difference between peripheral and central sensitization is that the former activates and sensitizes nociceptors at the terminal ends of A $\delta$  and C fibers, whereas the latter changes sensory processing in the spinal cord, resulting in pain from stimuli that activate low-threshold sensory (touch) receptors.<sup>5,8</sup> Visceral pain (e.g., pain from intestine, liver, spleen, kidney, or bladder), unlike somatic pain, is transmitted by parasympathetic (principally vagal) and sympathetic splanchnic afferent nerve fibers.<sup>12,13</sup> The autonomic fibers involved in transmitting noxious inputs from visceral organs, including the distal colon, rectum, and bladder, are diffuse and extensively overlap. These differences from somatic transmission (transmission by parasympathetic and sympathetic nerves and extensive overlap) result in a significant autonomic response (tachycardia, tachypnea, mydriasis) and difficulty in localization of the site of pain.<sup>12</sup> Generalized or diffuse inflammation, ischemia, and mesenteric stretching or intestinal

dilation (e.g., of the stomach or cecum) can produce severe, unrelenting pain in horses.

## ⌘ STRESS AND DISTRESS

Pain associated with disease, accidental, or surgical trauma or originating from unknown causes can result in activation of the sympathetic nervous system, secretion of glucocorticoids (primarily cortisol), hypermetabolism, sodium and water retention, and altered carbohydrate and protein metabolism. The term given to this response is *stress*, which encompasses the biologic processes whereby the horse attempts to maintain homeostasis and cope with threats to its well-being.<sup>14</sup> Acute and chronic pain are capable of producing a significant stress response in horses, thereby reducing their quality of life. The stress response is an adaptive pattern of behavioral, neural, endocrine, immunologic, hematologic, and metabolic changes directed toward the restoration of homeostasis (Figure 6-3). During threatening circumstances the stress response prepares

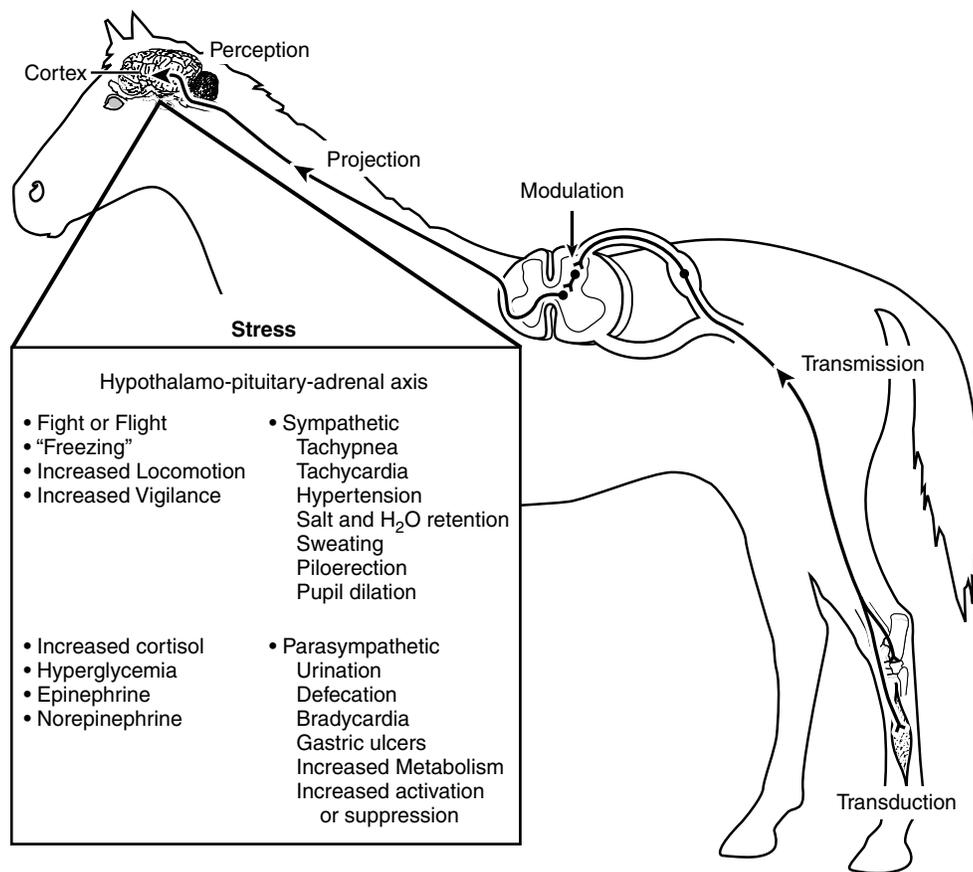

**FIGURE 6-2** Peripheral and central sensitization. Peripheral sensitization caused by tissue or nerve injury lowers the threshold of nociceptors and activates “silent” nociceptors, leading to primary hyperalgesia. Central sensitization caused by the temporal summation of nociceptive input activates N-methyl-D-aspartate (NMDA) receptors in the spinal cord, resulting in secondary hyperalgesia. *TrkB*, Tyrosine kinase B; *AMPA*,  $\alpha$ -amino-3-hydroxy-5-isoxazole propionic acid; *KAI*, kainate; *NK1*, neurokinin; *Sub P*, substance P; *COX-2*, cyclooxygenase 2; *5-HT*, 5-hydroxytryptamine; *TNF- $\alpha$* , tumor necrosis factor  $\alpha$ .

the horse for an emergency reaction that fosters survival in the face of immediate threats (fight or flight). Most stress in horses is temporary because of the removal or short duration of exposure to the stressor. Surgery and anesthesia are common sources of stress in horses that can be modified by appropriate selection and use of preanesthetic and anesthetic drugs.<sup>15</sup> Suffering occurs when horses are forced to endure the infliction or imposition of physical pain or develop the feeling of impending harm (fear).<sup>16</sup> Severe or chronic stress can become maladaptive, producing distress and triggering self-sustaining cascades of neural and endocrine responses that upset physiologic homeostasis and negatively affect biologic functions critical to the well-being of the animal (Box 6-2). Stress and distress negatively affect the well-being of horses, produce immune incompetence, and can lead to gradual physical deterioration and death.<sup>17</sup> At a minimum, all animals should be granted the “five freedoms”: freedom from hunger and malnutrition, freedom from discomfort, freedom from disease, freedom from injury, and freedom from pain.

## NEUROENDOCRINE AND AUTONOMIC STRESS

The noxious stimuli that produce acute and chronic pain induce stress that activates the hypothalamus-pituitary-adrenal axis.<sup>14</sup> This afferent information stimulates the secretion of corticotropin-releasing factor, vasoactive intestinal peptide, and adrenocorticotrophic hormone (ACTH). Corticotropin-releasing factor acts synergistically with vasopressin to stimulate the production of ACTH and  $\beta$ -endorphin, thereby enhancing cell survival and producing analgesic effects, respectively. Corticotropin-releasing factor also stimulates the adrenomedullary release of ACTH and catecholamines. Corticotropin-releasing factor is an excitatory neurotransmitter in the locus ceruleus that increases norepinephrine release and excitatory behaviors. Adrenocorticotrophic hormone stimulates the adrenal cortex to secrete cortisol, corticosterone, and aldosterone and also stimulates increased glucocorticoid production and the adrenomedullary secretion of catecholamines. Cortisol stimulates gluconeogenesis, increases proteolysis

**FIGURE 6-3** Pain produces stress that activates the hypothalamus-pituitary-adrenal axis, resulting in varied behavioral, neuroendocrine, metabolic, and immune responses.

and lipolysis, facilitates catecholamine effects, and produces antiinflammatory actions. It is important to note that many of these same factors (corticotropin-releasing factor, ACTH, and corticosterone) are significant modulators of learning and memory processes.<sup>18</sup> Increases in CNS sympathetic output increase respiratory rate, heart rate, and arterial blood pressure and produce sweating, piloerection, and pupillary dilation.

Catecholamines are released from the adrenal medulla into the systemic circulation, amplifying these effects. Increased concentrations of circulating catecholamines augment glycogenolysis, increase gluconeogenesis, inhibit insulin release, and promote insulin resistance. Skeletal muscle blood flow generally increases out of proportion to increases in blood flow to other organ systems, preparing the animal for fight or flight. Epinephrine causes glycogenolysis and gluconeogenesis and inhibits insulin release while promoting peripheral insulin resistance and lipolysis. Thyroid hormones stimulate carbohydrate metabolism and heat production and increase and sensitize  $\alpha$ -adrenergic receptors in the heart, thereby sensitizing it to the effects of circulating catecholamines.

#### METABOLISM

The neurohumoral changes produced by stress increase the secretion of catabolic hormones, promoting the production of food substrates from the breakdown of carbohydrates, fats, and protein.<sup>17</sup> Hyperglycemia is produced and may persist because of the production of glucagon and relative lack and resistance to insulin, although insulin levels may periodically increase. Cortisol, catecholamines, and growth hormone stimulate lipolytic activity, resulting in an increase in circulating glycerol and free fatty acids. Protein catabolism is a common occurrence and a major concern after severe trauma or extensive surgical procedures. Cortisol increases protein catabolism, resulting in the release of amino acids.

## IMMUNE SYSTEM

The immune system functions as a diffusely distributed sense organ that communicates injury-related information and the severity of stress to the brain. Pain therefore can modulate the immune response.<sup>19</sup> The key elements for determining the immune response to pain are its intensity and duration. The messengers of the immune system are cytokines (interleukin-1 [IL-1], IL-6, tumor necrosis factor  $\alpha$ ). IL-1 and IL-6 induce the release of acute phase (inflammatory) reactants, cause fever, and initiate prostaglandin production (PGE<sub>2</sub>). Severe stress from any cause can trigger the acute phase response.<sup>14</sup> The main feature of the acute phase response is the release of proteins from the liver that act as inflammatory mediators and scavengers in tissue repair. These proteins include C-reactive protein, fibrinogen, macroglobulin, and antiproteinases. IL-1 and IL-6 can stimulate the secretion of ACTH from the pituitary gland and the subsequent release of cortisol. Tumor necrosis factor  $\alpha$  produces signs of shock, including hypotension, hemoconcentration, hyperglycemia, hyperkalemia, and nonrespiratory acidosis, and activates the complement cascade. Excessive production of these proteins can contribute to systemic inflammatory response syndrome, as discussed in the chapter on gastrointestinal diseases in this text. The peripheral white blood cell count generally reflects a stress leukogram typified by an elevated number of immature polymorphonuclear leukocytes (left shift) and reduced numbers of lymphocytes. Chronic pain produces sustained increases in circulating concentrations of cortisol, epinephrine, norepinephrine, and glucagon and suppresses the humoral and cellular immune response.<sup>17</sup> The systemic release of endogenous opioids (endorphin and enkephalin) may contribute to immunosuppression.

## BEHAVIOR AND MORPHOLOGY

Pain produces changes in behavior, attitude, performance, and memory. Pain activates the locus ceruleus, limbic regions (hypothalamus, hippocampus, amygdala), and cerebral cortex, which are involved in the adaptive responses to stress.<sup>17</sup> Pain-induced increases of corticotropin-releasing factor in the hypothalamus, amygdala, and locus ceruleus, for example, produce an increased startle response, anxiety, and fear. Corticotropin-releasing factor therefore serves as an excitatory neurotransmitter in the locus ceruleus, resulting in release of cortical norepinephrine, dopamine, and 5-hydroxytryptamine with resultant behavioral hyper-responsiveness, hyperarousal, vigilance, and agitation. Prolonged stress impairs the desire and ability of the horse to perform or learn. Chronic stress caused by pain can result in phenotypic changes that include a failure to thrive, poor hair coat, weight loss, and an acceleration of aging.

## ☞ PAIN ASSESSMENT

Although truly rational therapeutic approaches cannot be developed until most, if not all, of the specific mechanisms responsible for the physiologic and pathologic causes of pain are known, the use of simple yet detailed pain-scoring systems can help categorize the intensity, duration, and location of pain, thereby suggesting potential treatments. Pain-scoring systems, however, are of little value in suggesting therapy until the evaluator has a general understanding of the behavioral

### BOX 6-3

#### POTENTIAL BEHAVIORAL INDICATORS OF PAIN IN HORSES

- Considerable restlessness, agitation, and anxiety
- Rigid stance and reluctance to move
- Lowered head carriage
- Fixed stare and dilated nostrils, clenched jaw
- Aggression toward own foal
- Aggression toward handlers, horses, objects, and self
- Decreased interactions with handlers
- Vocalization (deep groaning, grunting)
- Rolling
- Kicking at abdomen
- Flank watching
- Stretching
- Dullness and depression
- Weight-shifting among limbs
- Limb guarding
- Abnormal weight distribution
- Pointing, hanging, and rotating limbs
- Abnormal movement
- Reluctance to move
- Arched back
- Head shaking
- Abnormal bit behavior
- Altered eating; anorexia, quidding, food pocketing

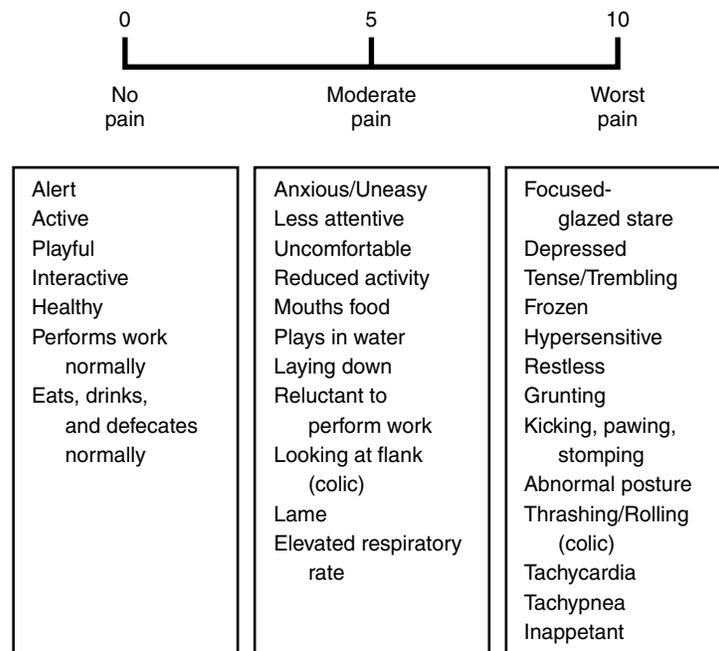

changes and physiologic and pathophysiologic processes involved in the production of pain (Box 6-3; Figure 6-4).<sup>7</sup> This includes an understanding of the reasons for tissue hypersensitivity, peripheral sensitization, central sensitization, primary and secondary hyperalgesia, allodynia, spontaneous and referred pain, and the differences between somatic and visceral pain. All the aforementioned changes modify the gain of the pain system, leading to permanent alterations in the neurochemical regulation of the CNS and phenotypic (physical characteristics) changes.<sup>8</sup> One of the most challenging problems in the clinical study of pain in horses is the development of a universally accepted method of classification. The absence of a universally accepted, clinically relevant pain-scoring system has made it difficult to categorize patients, prescribe therapy, evaluate treatment, and compare research trials. Pain classification systems based on anatomy, etiology, body system, severity, duration, behavior, or cause are descriptive but do not identify the mechanisms responsible for pain and therefore do not provide the type of information required for determining effective therapy. One classification system proposes to diagnose pain on the basis of the relationship among clinical signs, tissue type, disease, and the patient's response to predefined neurobiologic criteria.<sup>20</sup> This approach suggests

that pain should be classified as inflammatory, neuropathic, or both and that the presence of peripheral sensitization, central sensitization, allodynia, and hyposensitivity to pain be used to subcategorize patients further and guide therapeutic decisions. Application of this approach along with anatomic, etiologic, and time- and behavior-based schemes may lead to the development of more informative diagnostic methods.

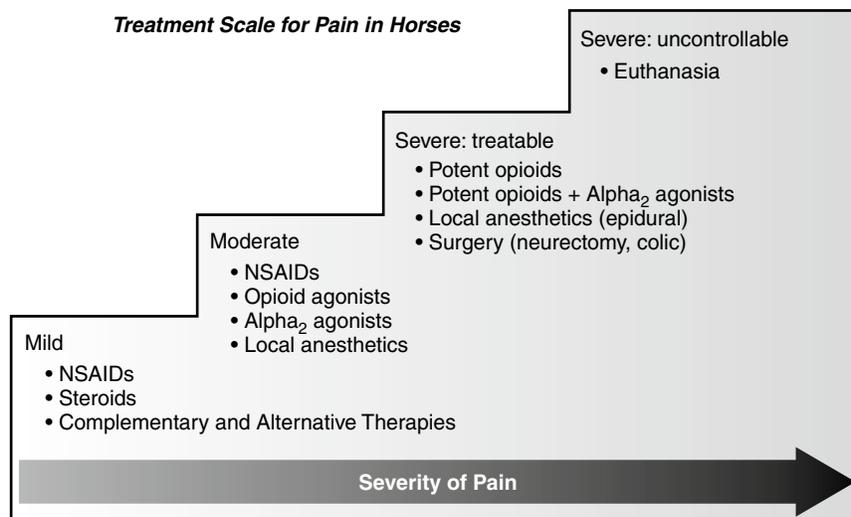

## ☞ DRUGS USED TO TREAT PAIN

A vast array of drug and complementary therapies are claimed to be efficacious in the treatment of pain in horses. Most evidence is anecdotal or reflects individual opinions and preferences.<sup>1</sup> Some therapies have been evaluated in experimental

pain models (balloon colic, heat lamp, hoof nail) using otherwise normal horses, but few therapies have been subjected to blinded, randomized, controlled clinical trials, and fewer still have been evaluated in horses with spontaneous disease.<sup>21-25, 26</sup> Regardless, a great deal of anecdotal data suggests that many of the same drugs used to treat pain in humans, dogs, and cats should be effective for treating pain in horses. Similarly, alternative therapies such as acupuncture, chiropractic, and nutraceuticals may provide pain relief in horses when applied in the right circumstances.<sup>2,27-31</sup> Pharmacologic approaches for the treatment of pain in horses derive their greatest benefits when drugs are selected for specific purposes (inflammation, nerve injury), scaled to the severity of pain, and used in combination (multimodal therapy) or preemptively (Figure

**FIGURE 6-4** The visual analog scale is a simple, practical method for evaluating the severity of pain and the efficacy of therapy.

**FIGURE 6-5** A drug treatment pain scale for horses. *NSAIDs*, Nonsteroidal antiinflammatory drugs.

6-5). Most drugs used to treat pain fall into one of five broad categories and include the steroidal antiinflammatory drugs, NSAIDs, opioids,  $\alpha_2$ -adrenoceptor agonists, and local anesthetics. To this arsenal can be added an expanding list of adjunct medications that produce anticonvulsants (gabapentin, pregabalin), opioid (tramadol), or calming (acepromazine) effects<sup>29</sup> (Tables 6-1 to 6-3). It is important to remember that a multimodal approach to pain management is often most effective, although the potential for drug-related adverse effects may be increased (see Box 6-1).

## ANTIINFLAMMATORY DRUGS

Antiinflammatory drugs are comparatively weak analgesics but are extremely effective for the treatment of acute inflammatory conditions.<sup>32-38</sup> Glucocorticosteroids produce antiinflammatory effects by inhibiting phospholipase A<sub>2</sub> and the breakdown of membrane phospholipids to arachidonic acid and subsequently to prostaglandins and leukotrienes (Figure 6-6).<sup>33</sup> Prostaglandins and leukotrienes exaggerate the inflammatory response and are key factors

TABLE 6-1

Commonly Used Analgesic Agents and Suggested Doses in Horses\*

Drug	Route	Dose	Comments
<b>ANTI-INFLAMMATORY DRUGS</b>			
<b>CORTICOSTEROIDS</b>			
Dexamethosone isonicotinate	IV	0.015-0.050 mg/kg	
Hydrocortisone sodium succinate	IV	1.0-4.0 mg/kg	
Prednisolone	IV	0.25-1.0 mg/kg	
<b>NON-STEROIDAL ANTI-INFLAMMATORY DRUGS</b>			
Carprofen	IV	0.5 mg/kg q12-24hr	
Firocoxib	PO	0.1 mg/kg q24hr	Selective COX-2 inhibitor. Decreased risk of gastrointestinal adverse effects compared with nonselective NSAIDs. Maintain adequate hydration.
Flunixin meglumine	IV, PO	0.25 mg/kg q6hr 0.5 mg/kg q8hr 1.1 mg/kg q12hr	Adverse gastrointestinal and renal effects possible. Maintain adequate hydration. Avoid IM use if possible.
Ketoprofen	IV, IM	2.2-3.3 mg/kg q24hr	Adverse gastrointestinal and renal effects possible. Maintain adequate hydration.
Phenylbutazone	IV, PO	2.2-4.4 mg/kg q12hr	Adverse gastrointestinal and renal effects possible. Maintain adequate hydration.
<b>OPIOIDS</b>			
Buprenorphine	IV	0.01-0.04 mg/kg	Little information available regarding clinical use in horses.
Butorphanol	IV	0.01-0.05 mg/kg q4hr	Adverse effects may include increased locomotion in adult horses, sedation in foals. May increase appetite. High doses or prolonged use may decrease GI motility.
	IM	0.04-0.1 mg/kg q4-6hr	
Meperidine	IV	0.2-1.0 mg/kg	
Methadone	PO	0.1-0.2 mg/kg	Used more commonly in Europe than in U.S.
Morphine	IV, IM	0.05-0.3 mg/kg	$\mu$ agonist. Adverse effects include decreased GI motility (constipation or impaction), excitation (especially when given intravenously). Combine with $\alpha_2$ agonists to lessen CNS effects.
<b><math>\alpha_2</math> AGONISTS</b>			
Detomidine	IV, IM	0.005-0.03 mg/kg q6-12hr	Sedative; higher doses for IM use. See text for adverse effects.
Romifidine	IV	40-120 $\mu$ g/kg	May provide insufficient analgesia for some procedures. See text for adverse effects.
Xylazine	IV, IM	0.2 – 1.1 mg/kg	Sedative; higher doses for IM use. See text for adverse effects.
<b>MISCELLANEOUS AGENTS</b>			
Gabapentin	PO	2.5-5 mg/kg q8-12hr	Originally marketed as an anticonvulsant agent. Probably most effective in treatment of neuropathic pain.
N-butylscopolamine	IV	0.3 mg/kg	Antispasmodic for GI tract disorders.

IV, Intravenous; PO, by mouth; NSAIDs, nonsteroidal anti-inflammatory drugs; GI, gastrointestinal; CNS, central nervous system.

\*The dose and route of administration used for each patient must be determined on the basis of the clinical problems, systemic status of the horse, concurrent drug use, and other relevant medical factors.

in the production of peripheral sensitization. Prostaglandins (PGE<sub>2</sub>, thromboxane A<sub>2</sub>) activate prostaglandin receptors throughout the body, producing pain, inflammation, and fever. Prostaglandins also are responsible for producing a protective gastric barrier to intraluminal acidity, sustaining normal gastric secretory activity, and maintaining normal gut motility. Prostaglandins regulate renal blood flow and maintain normal renal tubular function. Cyclooxygenase (COX) metabolizes arachidonic acid to prostaglandins. At least two types of COX (COX-1, COX-2) exist. COX-1 is constitutive in most tissues and helps maintain normal cell and tissue function. COX-2 is constitutive in the CNS, kidney, eye, and reproductive organs and is highly inducible in inflamed tissues. COX-2 is produced by inflammatory cells and is upregulated following tissue injury. Most NSAIDs produce their antiinflammatory and analgesic effects by differentially inhibiting both COX-1 and COX-2.<sup>33</sup> These drugs are discussed in more detail in the pharmacology chapter of this text. Inhibition of COX-1 is believed to be responsible for mild analgesic effects and NSAID toxicity (gastrointestinal ulceration). The availability of newer NSAIDs that are more selective for COX-2 versus COX-1; (firocoxib [Equioxx]) may provide COX-1-sparing effects, thereby

minimizing toxic effects on the gut.<sup>37</sup> Future pharmacologic manipulation of NSAIDs may result in the development of drugs that effectively inhibit both the COX and lipoxygenase pathways for inflammation in horses (see Figure 6-6). It should be emphasized that all NSAIDs are nephrotoxic. Gastrointestinal, renal, or liver toxicity and the potential for delayed clotting are important issues that are more common with chronic drug administration.<sup>36,39</sup> NSAIDs alter platelet function and may produce blood dyscrasias in sick or hemorrhaging horses. Toxicity is more common in very young or old, dehydrated, or immunocompromised horses or in horses with preexisting cardiovascular, renal, or liver disease.

## OPIOIDS

Opioids vary widely in their analgesic potency, clinical efficacy, and adverse effects.<sup>40-44</sup> Opioid agonist-antagonists and partial agonists produce  $\mu$ -receptor or morphinelike effects and are in general less toxic but less potent analgesics than morphine.<sup>44</sup> Opioid antagonists are relatively devoid of agonist activity and are used clinically to antagonize or reverse opioid effects. Morphine is considered the prototypic opioid to which all other opioids are compared.<sup>45,46</sup> Opioids produce their effects by activating opioid receptors ( $\mu$ ,  $\kappa$ ,  $\delta$ ).<sup>47</sup> Most opioids produce beneficial (analgesic, euphoric) pharmacologic effects by activating central and peripheral  $\mu$ -receptors, although evidence indicates that drugs with  $\kappa$ -receptor activity may be equally or more effective in treating gastrointestinal pain.<sup>43,46</sup> Butorphanol, an opioid agonist-antagonist with  $\kappa$ -receptor activity, for example, is excellent for the treatment of mild to moderate visceral pain.<sup>40,44,48,49</sup> The beneficial properties of opioids, however, are overshadowed by the requirement for special licensing and record keeping; the occasional development of ileus, constipation, and colic (morphine); and the potential for all opioids and especially  $\mu$ -opioid agonists to produce excitement (increased locomotor activity), disorientation, and ataxia in horses. Opioids delay gastric emptying and prolong intestinal transit time.<sup>43</sup> Increases in intestinal smooth muscle tone are caused by centrally mediated increases in vagal tone and activation of opioid receptors throughout the gastrointestinal tract. These effects are followed by a decrease in propulsive peristaltic activity and absorption of water from the intestinal lumen, predisposing horses to constipation and colic from impaction of the colon, a condition that becomes more prominent when opioids are administered for several

TABLE 6-2

Neuroleptanalogic Combinations for Intravenous Use in Horses	
Drug	Dose
Acepromazine	0.05-1.0 mg/kg
Butorphanol	0.05-0.1 mg/kg
Acepromazine	0.05-1.0 mg/kg
Burpenorphine	0.005-0.01 mg/kg
Acepromazine	0.05-1.0 mg/kg
Xylazine	0.2-0.5 mg/kg
Xylazine	0.5-1.0 mg/kg
Butorphanol	0.01-0.05 mg/kg
Xylazine	0.5-1.0 mg/kg
Morphine	0.1-0.5 mg/kg

TABLE 6-3

Drugs by Continuous Rate Infusion for Analgesia in Horses.			
Drug	Route	Dose	Comments
Lidocaine	CRI	Bolus 1.3 mg/kg; then 0.05 mg/kg/min	Overdose may result in seizures, CNS excitation. May be used for several days.
Detomidine	CRI	Bolus 8.4 $\mu$ g/kg; then 0.5 $\mu$ g/kg/min for 15 min; then 0.3 $\mu$ g/kg/min for 15 min; then 0.15 $\mu$ g/kg min thereafter	Will cause sedation, ataxia. For sedation and analgesia of 1-4 hr; not for long-term (days) use.
Butorphanol	CRI	Bolus 17.8 $\mu$ g/kg; then 10-15 $\mu$ g/kg/hr	Tolerance may develop; usually used for 12-24 hr.
Ketamine	CRI	0.4-1.2 mg/kg/hr	Ataxia and sensitivity to sound possible at higher doses.

CRI, Constant rate infusion; CNS, central nervous system.

days. Large or repeated doses of opioids can inhibit the urinary voiding reflex and increase external urethral sphincter tone, resulting in urine retention. Urine retention can be an important postoperative consideration in horses that have received large volumes of fluids during surgery and results in discomfort, agitation, and premature attempts to stand in horses recovering from anesthesia. Recommended dosages of opioids can produce sympathetic activation (sweating, mydriasis), nervousness, increased locomotor activity, agitation, and dysphoria in some horses.<sup>47,50</sup> These latter effects (excitement, disorientation, ataxia) are particularly troublesome when repeated dosages of  $\mu$ -opioid agonists are administered to young, untrained, or fractious horses. Opioids, especially morphine, produce profound analgesic effects when combined with  $\alpha_2$ -agonists (xylazine, detomidine).<sup>51</sup> The combination of opioids and  $\alpha_2$ -agonists (morphine, butorphanol, and xylazine, detomidine, romifidine) produces neuroleptanalgesia and has been administered preemptively to perform standing medical and surgical procedures that otherwise would require general anesthesia.<sup>51-53</sup> Fentanyl is a particularly potent  $\mu$ -opioid agonist with a short duration of action, making its clinical use impractical unless administered by constant rate infusion to horses in pain (severe colic, laminitis).<sup>54</sup> Alternatively, a fentanyl transdermal drug-delivery system (patch) is available, but clinical experience is limited, adequate or effective blood plasma concentrations may not be attained, and adverse effects such as agitation and tachycardia may occur with higher doses. Furthermore, it may be necessary to replace the patches every 24 hours in horses to maintain analgesia.

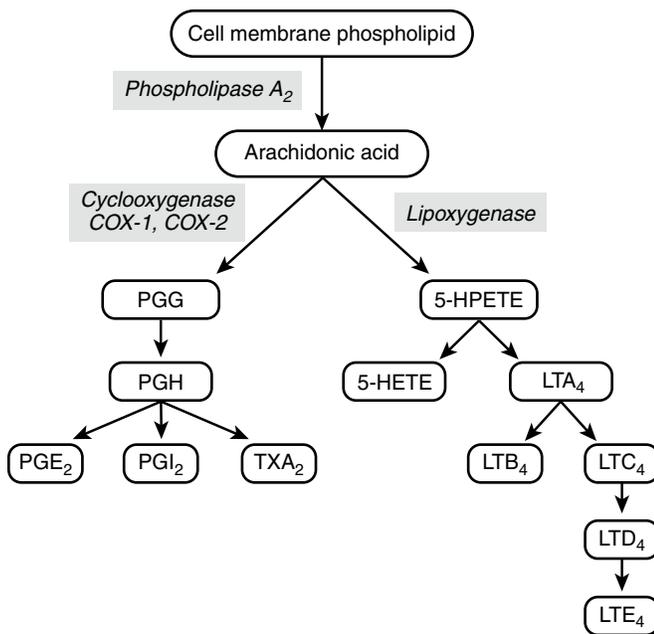

As previously suggested, different opioids produce their pharmacologic effects on the basis of their ability to combine with and differentially activate opioid receptors. Very little is

known about opioid receptor distribution, density, and selectivity in horses compared with other species. Furthermore, the potential for opioids to produce CNS agitation, increased locomotor activity, and inhibitory gastrointestinal effects when used alone or in combination with other sedatives or inhalant anesthesia may limit their potential usefulness as analgesics.<sup>47,50,55</sup> Finally, there are few comparative studies or large-scale randomized, controlled, and blinded multicenter clinical trials evaluating the efficacy of opioids in horses with naturally occurring disease, making their clinical use a trial-and-error process.<sup>26,41,48</sup>

## $\alpha_2$ -AGONISTS

$\alpha_2$ -Agonists (xylazine, detomidine, medetomidine, romifidine) produce sedation, muscle relaxation, and analgesia by activating various  $\alpha_2$ -receptors in the CNS and peripherally.<sup>56</sup> Sedation is attributed to activation of the CNS  $\alpha_2$ -receptors in areas of the brain that are responsible for awareness, arousal, and vigilance. Activation of  $\alpha_2$ -receptors in the brain and spinal cord decreases the release of excitatory neurotransmitters and interferes with sensory processing and transmission.<sup>56</sup> Individual drug effects vary according to chemical structure,  $\alpha_2$  versus  $\alpha_1$  selectivity, metabolism, and elimination. Xylazine is considered the prototypic  $\alpha_2$ -agonist and demonstrates a comparatively low  $\alpha_2$ -receptor selectivity and short half-life. Xylazine also produces local anesthetic effects, presumably because of its structural similarity to lidocaine. Analgesia is confounded, however, by mild to significant sedation that can result in stupor, ataxia, and reluctance to move. These effects may be beneficial but can mask clinical signs in horses suffering from colic.<sup>34,48,57</sup> Regardless,  $\alpha_2$ -agonists are particularly effective therapy for the acute treatment of moderate to severe pain (colic) and can be administered by infusion to treat acute injuries or intraoperatively to reduce injectable or inhalant anesthetic requirements.<sup>42,56</sup>  $\alpha_2$ -Agonists are particularly effective when administered with opioids (butorphanol, morphine) or acepromazine.<sup>51,53,58</sup> The effects of  $\alpha_2$ -agonists can be antagonized by the  $\alpha_2$ -antagonists yohimbine, tolazoline, and atipamezole.

Clinically, the administration of  $\alpha_2$ -agonists typically produces profound sedation, bradycardia, respiratory depression, and occasionally unexpected or aggressive behavior. Sinus bradycardia and bradyarrhythmias are common after the administration of  $\alpha_2$ -agonists. Decreases in heart rate and atrioventricular block are caused by the combined effects of decreases in CNS sympathetic output and increases in vagal tone.<sup>59</sup> Atropine or glycopyrrolate can help prevent bradycardia and atrioventricular block but generally are not required. Arterial blood pressure initially increases and then decreases from baseline values. Arterial hypertension is initiated by stimulation of peripheral vascular  $\alpha_1$ - and  $\alpha_2$ -receptors and increases in baroreceptor activity. The subsequent decrease in arterial blood pressure is caused by a decrease in CNS sympathetic output and heart rate.<sup>56,60</sup> Cardiac output decreases almost immediately in conjunction with decreases in heart rate.<sup>59</sup> Respiratory rate and tidal volume decrease as the horse becomes sedate and may contribute to the development of respiratory acidosis and hypoxemia. Relaxation of the muscles of the nostrils, pharynx, and larynx can result in respiratory stridor, snoring, irregular breathing patterns, inspiratory dyspnea, and upper airway obstruction in some horses, particularly those with upper airway disease.

**FIGURE 6-6** Tissue or nerve injury damages cell membranes, leading to the production of arachidonic acid, prostaglandins, and leukotrienes through the activity of phospholipase  $A_2$ , cyclooxygenase, or lipoxygenase enzymes, respectively. These enzymatic pathways are important for producing inflammation and pain. They can be inhibited by corticosteroids, nonsteroidal antiinflammatory drugs (NSAIDs), and lipoxygenase inhibitors.

$\alpha_2$ -Agonists produce immediate and pronounced decreases in gastrointestinal tone and motility that can be pronounced and last for 8 to 10 hours.<sup>61-63</sup> Gastrointestinal stasis is caused by stimulation of  $\alpha_2$ -receptors in the gut and increases in serum gastrin concentration. The decrease in gut motility is dose dependent but is believed to be responsible for postoperative ileus, gas accumulation, and the occasional development of colic in some horses and may require the administration of an  $\alpha_2$ -antagonist (yohimbine).<sup>64</sup>  $\alpha_2$ -Agonists promote diuresis in horses by increasing blood pressure and producing direct actions on the renal tubules to decrease renal tubular salt and water absorption. Labor can be delayed or prolonged because of sedative and muscle relaxant effects.<sup>65</sup>

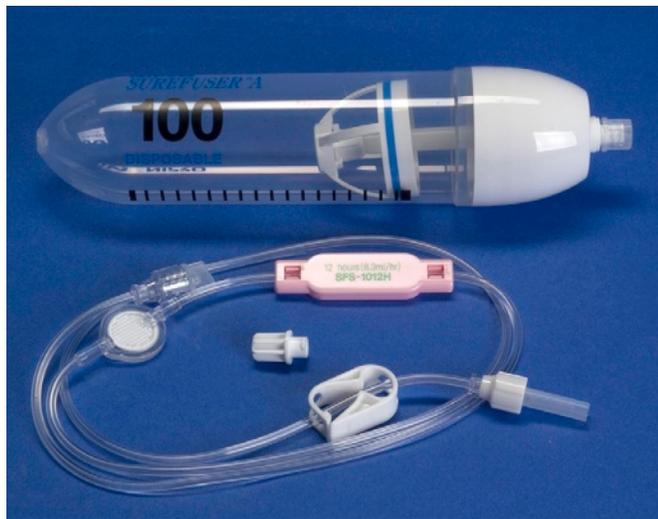

## LOCAL ANESTHETICS

Local anesthetics (lidocaine, mepivacaine) are frequently used alone or in combination with other analgesic drugs to produce a loss of sensation. They are administered at specific sites (topical, local) or on nerves (regional). Analgesia results from blockade of sodium ion channels, thereby preventing the initiation and conduction of electric activity (action potentials) in small-diameter (C, A $\delta$ ) sensory nerve fibers. Larger (clinical) dosages of local anesthetics also block electric activity in large fibers (A $\beta$ ), thereby producing loss of motor function and temporary motor paralysis. Most local anesthetic drugs produce mild CNS depression with antiarrhythmic, antishock, and gastrointestinal promotility effects.<sup>43,66-69</sup> They can be administered epidurally and systemically to decrease the need for additional analgesics (Table 6-4).<sup>43,66</sup> The systemic infusion of lidocaine decreases the requirement for inhalant (isoflurane,

sevoflurane) or injectable (ketamine, propofol) anesthetics (anesthetic sparing) and potentiates the analgesic actions of opioids or  $\alpha_2$ -agonists.<sup>65,67</sup> Mild sedation occurs because of membrane-stabilizing effects, a generalized decrease in neuronal activity, and a centrally mediated decrease in sympathetic tone. Local anesthetics have the potential to produce a loss of motor function (paralysis) that can become problematic in some surgical patients (rectal-vaginal fistula repair), leading to untoward behavioral responses. Local anesthetics produce minimal cardiovascular or respiratory effects in otherwise normal, healthy horses but can decrease cardiac output, arterial blood pressure, and heart rate when administered intravenously because of decreases in CNS sympathetic output, myocardial contractile force, and venous return.<sup>65,67</sup> These effects are more prominent in stressed or sick animals that depend on sympathetic nervous system activity for maintaining homeostasis. Although local anesthetics are considered to have antiarrhythmic effects, they can produce sinus bradycardia and bradyarrhythmias and hypotension when administered rapidly and intravenously. Significant differences exist among the various local anesthetics regarding these effects and their metabolism, elimination, and potential to produce CNS toxicity (disorientation, ataxia, seizures).<sup>69</sup> Horses are comparatively sensitive to the neurotoxic side effects of local anesthetics, and bolus dosages exceeding 2 mg/kg usually produce CNS stimulation typified by nervousness, excitement, agitation, disorientation, nystagmus, and seizures. These effects can result in death from respiratory paralysis. Local anesthetic drugs can produce respiratory paralysis when administered by epidural or spinal (subarachnoidal) routes. The migration of the local anesthetic cranially to the sixth cervical nerve roots

TABLE 6-4

Drugs Used for Epidural Analgesia			
Drug	Dose (mg/kg)	Duration of effect	Comments
<b>CAUDAL EPIDURAL ANALGESIA (FIRST COCCYGEAL SPACE)</b>			
Lidocaine		30-90 min	Ataxia or recumbency at higher doses.
Xylazine	0.03-0.35	3-5 hr	Perineal sweating is common.
Detomidine	0.06	2-3 hr	Sedation, ataxia, systemic effects.
Ketamine	0.1-2.0	30-90 min	
<b>COMBINATIONS FOR CAUDAL EPIDURAL ANALGESIA (FIRST COCCYGEAL SPACE)</b>			
Lidocaine	0.22	5-6 hr	Ataxia or recumbency; perineal sweating.
Xylazine	0.17		
Lidocaine	0.25	2.5 hr	Ataxia or recumbency.
Butorphanol	0.04		
<b>LUMBOSACRAL EPIDURAL ANALGESIA (VIA CATHETER)</b>			
Morphine	0.1-0.2 q8-18hr	8-24 hr	May cause skin wheals, pruritis.
Detomidine	0.03-0.06 q20-24hr	8-24 hr	May cause sedation, ataxia.
Ketamine	0.8		
<b>COMBINATIONS FOR LUMBOSACRAL EPIDURAL ANALGESIA (VIA CATHETER)</b>			
Morphine	0.1	8-24 hr	Sedation, ataxia possible.
Detomidine	0.03 mg/kg		
Ketamine	0.5 – 1.0	12-18 hr	Sedation, mild ataxia.
Morphine	0.1		
Ketamine	0.5 – 1.0	>2 hr	Mild sedation, bradycardia.
Xylazine	0.2		

**FIGURE 6-7** Photograph of a 100-ml balloon infuser and solution administration tubing with inline filter and fluid rate (8.3 ml/hr) controller (ReCathCo, LLC; Allison Park, PA: [info@recathco.com](mailto:info@recathco.com)).

can paralyze the diaphragm, resulting in hypoventilation and apnea.

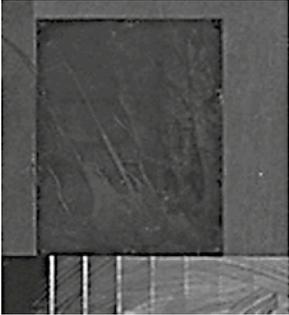

## NONTRADITIONAL ANALGESICS

New techniques (chiropractic) and drugs (gabapentin) are being evaluated for the treatment of acute and chronic pain in horses. New methods for continuous intravenous and, more important, peripheral site (local) drug administration are emerging (Figure 6-7). Anticonvulsants (gabapentin) and behavior-modifying drugs (chloripramine) have been administered to horses to produce adjunctive analgesic effects, but their efficacy and safety are unknown.<sup>70-71</sup> Alternative therapies such as acupuncture, chiropractic, and nutraceuticals are used to treat pain in horses as adjuncts to various drug regimens.<sup>72</sup> Several of these therapies are considered effective pain therapy by clinical experts, but most have not been evaluated carefully.<sup>2,27-31</sup>

# CRITICAL CARE

## CHAPTER

# 7

### APPROACH TO EQUINE CRITICAL CARE

*Peggy S. Marsh*

Critical care is provided in disease states of crisis or extreme complexity and involves thoughtful judgment and timely intervention. Typically, acute life-threatening conditions require this type of care. Because of the intricate, time-consuming, and often urgent nature of such situations, specially trained personnel are often best suited to deliver optimal care. This type of care is generally needed for days, rather than just a few minutes or hours, and therefore a team of health care providers is required. The provision of optimal diagnostic and monitoring alternatives is facilitated by access to a wide range of equipment. Segregating patients that need immediate as well as continuous attention in a particular area of a hospital or clinic, such as an intensive care unit (ICU), allows better use of resources. However, these are not absolute requirements for providing critical care. Adherence to a foundation principle that calls for serial evaluations of the entire patient, with particular attention to maintaining or restoring homeostasis for that individual, is at the heart of critical care medicine.

In equine practice there are no definitive universal guidelines to identify patients that would benefit from being treated in a centralized ICU by a team of specialized health care providers. In human medicine various studies have evaluated the potential benefits of such care. Most have shown increased efficiency, shorter duration of stay, and sometimes decreased cost when critical care patients are treated in a central hospital unit and managed by a specialized team of health care providers. The decision as to which equine patients would benefit from such care is based on a wide variety of criteria, including type of illness or trauma, degree of illness, availability of personnel and facilities, biosecurity measures, cost, and client preference. In veterinary medicine there is no clear evidence demonstrating when such care might improve outcome and efficiency or reduce cost.

\*The editors acknowledge and appreciate the contributions of Joanne Hardy, a former editor of this chapter. Her original work has been incorporated into this edition.

Even with a wide range of inciting problems, there are some aspects of critical care medicine that are common in all critically ill individuals. Therapeutic goals for all patients include providing appropriate care for the primary problems, anticipating complications and initiating appropriate preventive therapy, and providing appropriate supportive care for all vital body systems.

The purpose of this chapter is to provide an outline of therapeutic guidelines for use in equine patients with life-threatening medical problems or patients with complex disease processes that simultaneously involve multiple body systems. Diagnosis and therapy of many specific critical care topics are covered in more detail in other chapters of this book, and the reader will be referred to the relevant chapters as appropriate. The goal for this chapter is to outline an approach to the entire patient and all body systems that will facilitate creation of an action plan to help restore systemic function in the critically ill equine patient.

### ☞ EQUINE INTENSIVE CARE UNIT

Comprehensive care for critically ill horses can be provided anywhere, with some creativity and a large commitment of time; however, it can be argued that moving such patients to a hospital setting with experienced clinicians and a variety of diagnostic and therapeutic equipment allows for better use of resources and improved care. Equine ICUs are becoming increasingly prevalent in clinical practice. Common features include housing of patients according to type or severity of illness with appropriate biosecurity precautions; readily available equipment for diagnosing, monitoring, and treating the seriously compromised horse; and 24-hour staffing with professionals who have the knowledge and experience to treat these patients. The goals of these units are to pool resources, thereby increasing efficiency and reducing cost, and to improve patient outcomes.

The decision to offer ICU services should be based on the population needs and the economic environment of the hospital and community. Several recent studies describe the general case population and commonly performed procedures and treatments of patients admitted on an emergency basis to large university referral centers.<sup>1,2</sup> Because equine emergencies are relatively common among patients requiring

critical care, such information provides an initial database for understanding population dynamics. In general, these studies revealed that although acute abdominal crisis is the most common type of case encountered, many cases will not require surgical intervention. Also, a variety of other problems presented as emergencies, and the required skills to deal with these included experience with dysfunction of most all body systems. Reviewing the anticipated distribution of cases within a given area, as well as the monthly distribution of cases, is important. Such reviews ensure an appropriate allocation of staff and equipment tailored to the needs of the population.

Human ICU treatment requires a multidisciplinary team that includes intensivists (i.e., physicians who specialize in critical illness care), nurses, respiratory care therapists, dieticians, pharmacists, and other consultants from a broad range of specialties, such as surgery, internal medicine, and anesthesiology. Compared with human medicine, the number of equine cases is limited and is handled without the same degree of clinician specialization. The most common advanced training programs in equine practice are anesthesia, internal medicine, and surgery. Individuals trained in these areas typically have experience with critically ill equine patients. More recently, specialty training in the area of equine emergency and critical care has been developed. Although the care of many extremely sick horses is performed in the general practice setting, it is useful to know that the number of veterinarians with extensive experience and specialty training in the area of critical care is growing.

Besides clinicians, intensive and continuous care usually is provided by licensed veterinary technicians. In general, good nursing care is pivotal to successful outcomes. The technical staff should be trained to identify subtle changes in patient status and feel comfortable using a range of equipment. The ability to perform common techniques and to recognize changes in condition early is essential.

The equipment used for the care of critically ill equine patients should be based on the anticipated case population and the maximal level of care required for that population. Purchasing a ventilator would be a poor economic decision if mechanical ventilation is performed rarely. Renting medical equipment that might be needed only occasionally or seasonally may be a more practical choice. [Box 7-1](#) lists some equipment to consider when equipping an equine ICU. Regular review of equipment and training for all personnel on new equipment are essential.

Commonly performed procedures in equine critical care include monitoring, fluid administration, and pain control. Monitoring includes not only close, astute observation and serial physical examinations but also the use of appropriate equipment and laboratory support to monitor systemic health as appropriate for that patient. Fluid administration encompasses routine administration of a wide range of products, including crystalloids, synthetic colloids, blood, and blood substitutes. The selection of appropriate analgesia may vary widely depending on the origin of pain (e.g., musculoskeletal versus abdominal) and the possible adverse effects of different medications. All of these considerations should be based on the specific needs of the equine patient.

Emergency drugs should be readily available and mobile, possibly in a crash cart or box in the ICU. [Table 7-1](#) lists several emergency drugs and dosages used in adult horses. Keeping a specific list such as this one readily available in the crash cart for easy reference is advisable. In addition, assembling packs for specific anticipated emergency situations, such as all the

#### BOX 7-1

### EQUIPMENT LIST FOR DIFFERENT LEVELS OF EQUINE INTENSIVE CARE UNITS

#### Basic

- Fluid administration system
- Electrocardiogram
- Centrifuge
- Refractometer
- Glucose strips
- Urinalysis strips
- Ultrasound
- Oxygen tank and regulator

#### Intermediate

- Blood pressure monitor
- Cytologic exam/Gram stain
- Glucometer
- Intravenous fluid pump delivery systems
- Sling and hoist for down horses

#### Advanced

- Blood gas/electrolyte analyzer
- Pulse oximeter
- Mechanical ventilator
- Colloid osmometer
- Capnograph
- Syringe infusion pumps

necessary items for delivering supplemental oxygen or supplies to perform an urgent tracheotomy, and placing these packs in key areas are recommended.

Monitoring equipment commonly used in an ICU includes an electrocardiogram, a blood pressure monitor, a stallside glucometer and a lactate analyzer, a stallside electrolyte and chemistry analyzer, an ultrasound unit, a centrifuge for hematocrit determination, a refractometer for determining total protein and urine specific gravity, and urine test strips for urinalysis. Other monitoring tools to consider are a microscope with 100× magnification, equipment for cytological examination (including Gram stains), and a blood gas and electrolyte monitoring unit. A colloid osmometer is useful for determining colloid oncotic pressure in sick horses. If mechanical ventilation is routine, further monitoring units, including capnographs and pulse oximeters, are useful. Standard operating protocol should be established for each piece of equipment, and regular maintenance should be performed.

Advanced imaging is becoming more common, and the use of ultrasound has become an essential component of diagnosing and monitoring critically ill patients. Ultrasound can be used for identifying and monitoring effusions, intestinal distention, and motility; identifying umbilical structures; monitoring pregnancy; and visualizing ocular structures, among other anatomic areas. To enable imaging of a wide variety of structures, access to a variety of transducers ranging from 2.5 to 10 MHz, as well as a rectal probe, is recommended.

Oxygen ports for supplementation through nasal insufflation or for mechanical ventilation should be available. When installing a new ICU, the practitioner should consider placements of ports for oxygen, vacuum, and air, as well as a remote gas source and a pipeline system to allow delivery of oxygen. Compressed gas cylinders can be used, but these must be stored

TABLE 7-1

Emergency Drug Chart for Adult Horses				
Drug	Dose	Dose per 1000 lb	Route	Comment
Dobutamine (positive inotrope)	2-10 µg/kg/min (1 vial [250 mg] in 1000 ml = 250 µg/ml)	900-4500 µg/min	IV	Use diluted solution within 24 hours. It is compatible with most IV fluids. Do not mix with alkaline solution calcium chloride/gluconate.
Doxapram (respiratory stimulant)	0.2 mg/kg	4.5 ml	IV or topical under tongue	Do not mix with alkaline drugs/fluid.
Epinephrine (for anaphylaxis or asystole)	0.01-0.02 mg/kg; 0.1-0.5 mg/kg	4.5-9 ml	IV/IM/SQ/Intratracheal	Do not give with bicarbonate, hypertonic saline, or aminophylline. It does not need to be diluted when given intravenously to adults.
Glycopyrrolate (for bronchodilation and bradycardia)	0.005-0.01 mg/kg	10-20 ml	IV/IM/SQ	Do not mix with alkaline drugs/fluids.
Lidocaine (treatment of ileus)	1.3 mg/kg loading slowly over 5 minutes 0.05 mg/kg/min infusion	Loading: 30 ml Infusion: 67 ml/hr	IV	Ensure that product does not contain epinephrine.
Lidocaine (treatment of arrhythmias)	Bolus: 0.25-0.5 mg/kg (slowly) Infusion: 20-50 µg/kg/min	Bolus: 5-10 ml Infusion: 30-60 ml/hr	IV	Ensure that product does not contain epinephrine.

IV, Intravenous; IM, intramuscular; SQ, subcutaneous

and handled appropriately to prevent injury. For each cylinder type, knowledge of the capacity of the cylinder and the flow rate enables calculation of the amount of time provided. The small portable E cylinders contain 655 L of oxygen when full and can provide oxygen for 260 minutes when set at a flow rate of 5 L/min. Adult horses may require flow rates of 10 to 15 L/min to have any significant effect on the fraction of oxygen inspired (FIO<sub>2</sub>). Larger G or H cylinders containing 5290 or 6910 L, respectively, allow oxygen supplementation for longer periods.

The design of the ICU should accommodate the care of horses with a wide variety of problems. All stalls should have the equipment necessary for hanging large volume (e.g., 5 L) fluid bags. In addition, the design should include one or two stalls for easy unloading of down horses, and the structure must be able to withstand hoisting. If care of neonatal patients is expected to be routine, large foaling stalls should be available. These stalls may feature mobile separators to facilitate treatment of foals while allowing them access to their dams.

A central office facilitates oversight of the entire unit. For larger ICU facilities video monitoring of stalls from the central office is optimal. Sufficient storage space should be available to protect equipment that is not in use. A separate food preparation area should be available for preparation of enteral feeding. Staff members should pay attention to cleanliness in this area and particularly should refrain from washing their hands or contaminated material in the sink used for food preparation.

Although grouping critically ill patients in a single location allows for the greatest efficiency of personnel and equipment, maintaining biosecurity is essential. Grouping patients with similar disorders is therefore recommended. Strict disinfection and isolation protocols should be in place

to prevent nosocomial infections and the spread of infectious disease. Thorough hand washing is an important component of most biosecurity protocols. Hand rubbing with an alcohol-based solution is more effective than hand washing with an antiseptic, probably because it does not require rinsing and drying of hands.<sup>3</sup> Adoption of this practice significantly reduces cross-contamination among patients.

Guidelines for the judicious use of antibiotic regimens are available for human ICUs, and some of these guidelines apply to equine ICUs. These guidelines usually include recommendations for initial empirical selection of effective antibiotic regimens based on history, disease process, possibility of nosocomial infection, and knowledge of specific isolates for the hospital. Once culture results are available, therapy can be modified. Other methods that have been proposed to minimize antibiotic resistance and superinfections include cycling of antibiotics and restricted use of potent, broad spectrum therapies.

*Salmonella* organisms also can be a cause of nosocomial infection in the equine hospital. *Salmonella* shedding is greater in horses with colic, and the use of common equipment such as stomach tubes and pumps may promote transmission. Careful attention to hospital design and disinfection practices can help minimize the risk of hospital outbreaks.

## ☞ COMMON PHYSIOLOGIC FEATURES OF CRITICAL ILLNESS

Despite differing problems, the common denominator in the treatment of many critically ill patients is the need to maintain adequate delivery of oxygen to meet metabolic demand. Methods to return to a fully functional state include serial

systemic evaluations, even when the problem appears focal; attention to minimize adverse affects of treatments; and restoration of homeostasis, in particular working toward adequate delivery of oxygen and nutrients to cells.

Often a disease affects a single organ, and therapy can be focused on a specific process in that organ. A simple bacterial bronchopneumonia is often resolved with a course of appropriate antimicrobial medication and possibly the use of a nonsteroidal agent to help control inflammation. However, it is not unusual for the infection to induce fevers. Fevers may cause generalized malaise as well as inappetence. In horses fevers may be associated with signs of colic and altered gastrointestinal function. Although this is an obvious and relatively simple example of how a focal lesion creates systemic effects, it elucidates the need for evaluation of the entire body, even in patients with an obvious primary problem. Severely ill patients require sequential, thorough, and systemic evaluations. These evaluations are fundamental in critical care medicine.

A more severe consequence of focal problems causing systemic effects can occur when the initial insult is recognized as foreign by the body, and the various components of the immune system become activated to eliminate the threat. Most of the time this process is appropriate, and the various inflammatory mediator or coagulation cascades are activated in an orderly fashion. However, sometimes the progression is not balanced, and activation of certain systems, such as those governing inflammation and coagulation, can lead to unchecked release of mediators and a generalized reaction. In sick horses the most commonly cited example of this is systemic inflammatory response syndrome (SIRS), which can occur as a consequence of endotoxemia. These aspects of equine medicine are discussed in detail in Chapter 15.

Therapeutic misadventures can occur. The adverse affects of some therapeutic modalities can inadvertently cause significant systemic issues. A common example of this problem may be seen with the use of antibiotics in sick horses. It is not unusual for critically ill patients that are being treated with appropriate antimicrobial agents to develop significant, potentially life-threatening colitis. Understanding the potential effects of prescribed medication, carefully monitoring the patient's clinical progression, and making adjustments to the treatment plan and management strategies may ameliorate some of these problems.

Many severe problems cause alteration of normal body function and lead to misdistribution of supplies needed to maintain cellular metabolism. When the delivery or utilization of oxygen is inadequate to the metabolic needs of tissue beds, the term *dysoxia* is used. Clinically, this syndrome is recognized as shock. If left untreated, such states may lead to metabolic acidosis, organ dysfunction, and death.

Shock usually results from oxygen delivery that is insufficient to meet tissue oxygen consumption. Oxygen delivery can be defined as cardiac output multiplied by arterial oxygen content ( $DO_2 = CO \times CaO_2$ ). Cardiac output is measured as heart rate times stroke volume. Oxygen content is determined by both the amount of oxygen carried by hemoglobin in the red blood cells as well as the amount of oxygen dissolved within plasma. The formula for calculating arterial oxygen content is as follows:

$$[1.34 \times Hb \times (\text{saturation}/100)] + (0.003 \times P_aO_2)$$

It is important to note that the majority of oxygen that is delivered to tissues is carried in the red blood cells bound

to hemoglobin and the commonly monitored partial pressure of oxygen ( $PaO_2$ ; dissolved oxygen) represents only a small portion of total oxygen. This highlights the need to monitor anemia during critical illness.

The clinical condition of shock may be described or classified in several different ways, such as by stage of shock or by underlying etiology. The stages of shock include compensated, uncompensated, and irreversible. During the initial phase of compensated shock, vital organ function is maintained and blood pressure remains normal to increased. This is also called *warm shock*. During this time various compensatory mechanisms are activated, including baroreceptors and chemoreceptors, the renin-angiotensin system, humoral responses, and internal fluid shifts. When activation of these mechanisms fails to restore normal tissue oxygenation, microvascular perfusion becomes marginal and cellular function deteriorates. All of this leads to hypotension, the hallmark of shock. During this phase vasoconstriction predominates, and the term *cold shock* is used. When lack of perfusion becomes severe and is refractory to all attempts to correct it, organ dysfunction and failure occur. At this point the process is often irreversible despite all therapeutic attempts.

The categories of etiologies of shock include hypovolemia, cardiogenic, distributive, obstructive, and dissociative. It is important to consider these differential diagnoses of shock to help determine management strategies, but the goal for treatment of shock resulting from any cause is to improve perfusion. Attempting to restore normal physiology may be misguided in critically ill patients because such efforts can result in substantial iatrogenic risks; however, early goal-directed therapies have been shown to improve outcome.

## ☞ BASIC STEPS

An understanding of the physiologic and pathologic processes that may be occurring in critically ill patients is key to a successful outcome. The goal is to evaluate the patient, recognize current problems, anticipate impending issues, and then create an action plan. Because critical illness is generally dynamic, the plan also must also be dynamic. In the often highly emotionally charged period of initial patient evaluation, a systematic, thorough approach to each patient is beneficial. A basic 12-step plan for assessing and treating a critically ill patient is outlined in [Box 7-2](#).

### BASIC PROCEDURES IN ADULT EQUINE CRITICAL CARE

Joanne Hardy

Critical care for adult horses varies depending on the underlying problem being addressed. Expertise in a variety of technical procedures is advisable to facilitate diagnostic and therapeutic efforts.

## ☞ VASCULAR ACCESS AND ADMINISTRATION OF FLUIDS

Intravenous catheters are available in varying materials, constructions, lengths, and diameters ([Table 7-2](#)). In choosing a catheter, the practitioner should consider the desired

fluid rate, fluid viscosity, the length of time the catheter will remain in the vein, the severity of the systemic illness, and the size of the animal. The rate of fluid flow is proportional to the diameter of the catheter and inversely proportional to the length of the catheter and the viscosity of the fluid.

#### BOX 7-2

##### TWELVE-STEP PLAN FOR CRITICAL CARE ASSESSMENT AND TREATMENT

1. Evaluate.
2. Provide respiratory stabilization if needed.
3. Obtain venous access.
4. Provide cardiovascular support, including developing a fluid plan that addresses hydration and metabolic needs.
5. Provide pain relief, which may include analgesic or sedative medications and/or directly addressing the cause of the pain.
6. Measure effectiveness of the above and continue with diagnostic procedures.
7. Develop a plan to prevent secondary infection, in particular to help preserve the gastrointestinal mucosal barrier.
8. Develop a nutritional plan.
9. Develop a plan for monitoring the patient.
10. Evaluate systemic response and adjust plan as needed.
11. Address special circumstances such as recumbency.
12. Assess effectiveness, re-evaluate patient, revise plan.

Standard adult horse catheter sizes are usually 14 gauge in diameter and 5.25 inches in length. For more rapid administration rates, larger-bore catheters, such as 12- or 10-gauge, could be used, with the caveat that these larger sizes may be more traumatic to the vascular endothelium, which increases the risk of thrombosis. Plasma, blood products, and synthetic colloids, because of their increased viscosity, flow more slowly; if the horse requires volume replacement, the practitioner can combine administration of these fluids with a balanced electrolyte solution.

Teflon catheters should be changed every 3 days, whereas polyurethane catheters may remain in the vein for up to 2 weeks. Regardless of the type of catheter, the site of vascular access should be closely monitored several times daily (discussed in more detail later in this chapter). Horses that are very ill (e.g., bacteremic, septicemic, endotoxic) are more likely to experience catheter problems and benefit from polyurethane or silicone catheters.

One also must consider the catheter construction (Table 7-3). Through-the-needle catheters are most common for standard-size adult horses. An over-the-wire catheter is best used in foals and miniature horses or when catheterizing the lateral thoracic vein. Short and long extension sets are available, as well as small- and large-bore diameters. Using an extension set that screws into the hub of the catheter is best, to prevent dislodgment. In horses with low central venous pressures (CVPs), disconnection of the line can result in significant aspiration of air and cardiovascular collapse. Double extensions are available for horses that require administration of other medication with the fluids.

Common sites for insertion of intravenous catheters in horses include the jugular, lateral thoracic, cephalic, and saphenous veins. The lateral thoracic vein makes an acute angle as it enters the chest at the fifth intercostal space; therefore an over-the-wire catheter is best to use when catheterizing this vein. Catheters placed in any location other than the jugular vein require more frequent flushings (every 4 hours) because they tend to clot more easily. Leg catheters usually are bandaged because they are more prone to dislodgment than jugular catheters.

In adult horses a catheter is usually not covered with a bandage so that potential problems can be quickly identified. The practitioner may need to apply bandages to foals if they are tampering with the catheter. A triple-antibiotic ointment may be applied at the insertion site to decrease infection. Catheters should be flushed with heparinized saline (10 IU/ml)

TABLE 7-2

List of Available Catheter Materials		
Material	Example	Comment
Polypropylene	PE tubing, Medicut	Highly thrombogenic not recommended
Teflon	Angiocath	Less thrombogenic
Polyurethane	Mila	Much less thrombogenic
Silastic	Centrasil	Least thrombogenic

TABLE 7-3

List of Commercially Available Catheter Constructions			
Type	Description	Advantage	Disadvantage
Butterfly	Needle attached to tubing	Ease of use	Laceration of vessel; vessel puncture and extravascular administration
Over-the-needle	Stylet inside catheter for venipuncture	Available in large diameter, ease of insertion	Limited length of catheter, not flexible, break at catheter and hub junction
Through-the-needle	Short needle inserted; catheter threaded through needle	All lengths available, flexible, peel-away needle	Technically more difficult to insert
Over-the-wire	Needle serving as guide to insert wire, which serves as guide for catheter	Flexible, long catheters available, ensures proper catheter placement	More technical expertise required to place catheter, expensive

four times per day if they are not used for fluid administration. When administering a medication, the clinician should wipe the injection cap with alcohol before inserting the needle and change the injection cap daily. The clinician should culture catheters if catheter site infection is suspected for identification of the causative organism and to facilitate early recognition of possible nosocomial infection.

Coil sets are used for stallside fluid administration for most adult horses. These are advantageous because they allow the horse to move around, lie down, and eat without restraint. An overhead pulley system with a rotating hook prevents fluid lines from becoming tangled.

Administration sets are used for short-term fluid or drug administration and are available at 10 drops/ml and 60 drops/ml. When using a calibrated fluid pump, one should take care to use the appropriate set calibrated for the brand of pump. Long coiled extension sets can then be used to connect fluids to the horse. Foal coil sets that deliver 15 drops/ml are also available.

Special foal fluid administration sets are available as pressurized bags that allow delivery of fluids at 250 ml/hr. These bags can be placed in a special harness on the foal's back, thereby preventing entanglement with the mare.

Calibrated pumps allow delivery at various rates. These pumps have alarms that signal air in the line, an empty fluid bag, or catheter problems. The maximal fluid rate that these pumps can deliver is 999 ml/hr, which is insufficient for most adult horses. The pumps are useful for recumbent foals or for combined drug infusions. For large volume fluid delivery, peristaltic pumps are available that can deliver up to 40 L/hr. One must supervise these pumps constantly when in use because they continue to run even if fluids run out. Large-bore catheters should be used to prevent trauma resulting from the jet effect on the endothelium of the vein.

## BASIC FLUID THERAPY

Fluid administration for maintenance or replacement is one of the mainstays of equine critical care and should be readily available in any equine hospital. The availability of commercial materials and fluids for use in large animals makes fluid administration easy and cost-effective in most situations. This section provides a review of available materials and principles that should be followed when planning fluid administration.

### DESIGNING A FLUID THERAPY REGIMEN

Fluids can be administered for maintenance or replacement purposes. Horses usually receive maintenance regimens orally, and electrolyte formulations are available for this purpose.

Intravenous maintenance fluids are lower in sodium and higher in calcium, potassium, and magnesium than replacement fluids. Replacement regimens replace fluids lost through dehydration and ongoing losses. When designing a fluid therapy regimen, the clinician must consider the following questions:

- What volume of fluid must be given?
- What type of fluid will be given?
- What will be the rate of administration?

The volume of fluids to give equals the maintenance requirements plus the correction for dehydration and ongoing losses.

### MAINTENANCE

In the adult horse maintenance fluid requirements have been estimated at 60 ml/kg/day. This figure probably overestimates the actual needs of a resting, fasted animal but appears to be safe in most situations. In horses with renal failure, in which elimination of excess fluids is problematic, monitoring of body weight and CVP is indicated. If weight gain, edema, or increased CVP is evident, the fluid administration rate should be decreased.

### DEHYDRATION

Evaluation of dehydration is at best a subjective estimate, and the clinician must understand that this estimate must be adjusted on the basis of monitoring parameters. [Table 7-4](#) lists useful parameters for evaluating acute, extracellular dehydration.

After obtaining an estimate of dehydration, the clinician can calculate the amount of fluids to be given as follows:

$$\text{Volume of fluid (L)} = \text{Estimate of dehydration (\%)} \times \text{body mass (kg)}$$

### ONGOING LOSSES

Sometimes the clinician can measure and record ongoing losses (e.g., for nasogastric reflux), but ongoing losses usually must be estimated. The clinician monitors the patient to determine whether the calculated fluid volume is meeting the ongoing losses. Patients receiving fluids intravenously should be monitored at least twice a day, including assessment of heart rate and measurement of packed cell volume and total protein; the clinician should monitor patients more frequently (every 2, 4, or 6 hours) depending on the severity of cardiovascular compromise. The clinician should also monitor creatinine concentration once daily when initially elevated to ensure adequate return to normal. Additional means of monitoring

TABLE 7-4

**Parameters Used for Estimation of Dehydration in the Horse**

% Dehydration	Heart Rate (Beats per Minute)	CRT (Seconds)*	PCV/TP (%/g/L)*	Creatinine (mg/dl)
6	40-60	2	40/7	1.5-2
8	61-80	3	45/7.5	2-3

12	>100	>4	>50/>8	>4

\*CRT, Capillary refill time; PCV, packed cell volume; TP, total protein

adequate fluid delivery may include measurement of CVP, arterial blood pressure, and urine output.

### TYPE OF FLUID

The type of fluid to administer depends on evaluation of the chemistry profile and disease state. The first step is to decide on the baseline fluid (saline or balanced electrolyte solution), and the second step is to decide on the types of additives to add to the baseline fluid, which depends on specific deficits or excesses, such as hyponatremia or hypernatremia, hypokalemia or hyperkalemia, hypocalcemia or hypercalcemia, hypoglycemia, and acid-base disorders.

Two categories of fluids commonly are used for fluid replacement: 0.09% saline and balanced electrolyte solutions (BESs). Table 7-5 lists the composition of various commercially available fluids. In general, BESs are chosen when serum electrolytes are close to normal. All BESs contain some potassium. Saline is higher in sodium and much higher in chloride than serum concentrations and is used when sodium is lower than 125 mEq/L. Saline also is used in disease processes associated with high potassium levels, such as hyperkalemic periodic paralysis or renal failure, in which a potassium-free solution is preferable. In cases of long-term fluid maintenance therapy (greater than 4 to 5 days), if the oral route is not available, the practitioner should consider half-strength basic fluids to which potassium and calcium are added. Long-term fluid therapy with routine BESs results in hypernatremia, hypokalemia, hypomagnesemia, and hypocalcemia.

In horses routine fluid replacement includes calcium and potassium supplementation, in particular when the horse receives no oral intake because of gastrointestinal disease. Both electrolytes are important for smooth muscle function and vascular tone. Recently, magnesium supplementation also has received interest, particularly with fasting and ileus.<sup>1,2</sup>

Horses with metabolic acidosis also may require bicarbonate supplementation. Because the most common cause of nonrespiratory acidosis is lactic acidemia resulting from poor perfusion, providing fluid replacement should be the first and principal means of correcting this problem. Rules of thumb for bicarbonate supplementation in acute metabolic acidosis are as follows:

- Normal respiratory function: If the horse is unable to exhale the generated carbon dioxide (CO<sub>2</sub>) because of a respiratory problem, the acidosis will worsen.
- pH lower than 7.2: In acute acidosis associated with dehydration, fluid replacement results in restoration of urine output, and renal compensation follows and usually is complete if the pH is greater than 7.2.
- Half of the calculated amount is rapidly administered, followed by the remainder over 12 to 24 hours.
- Intravenously administered bicarbonate and calcium-containing solutions are incompatible.

In chronic metabolic acidosis, particularly with ongoing losses of bicarbonate (e.g., diarrhea), the horse usually requires the full calculated amount, partly because the bicarbonate

loss is distributed over all fluid compartments, not just the extracellular fluid. Orally administered bicarbonate is a good means of dealing with ongoing losses in horses with diarrhea.

Bicarbonate can be given orally as a powder, where

$$1 \text{ g NaHCO}_3 = 12 \text{ mEq of HCO}_3$$

### RATE OF ADMINISTRATION

For patients in severe shock, the clinician should give a shock dose of fluids in the first hour (60 to 80 ml/kg), which can be done only with pressurized bags or a pump.

In other situations the rate of administration is based on 24-hour requirements and estimates as a volume per hour. Keeping tally of the fluids given is important to ensure that the correct amount is administered.

### ORALLY ADMINISTERED FLUIDS

Oral fluid therapy should be administered using the fluid composition shown in Table 7-6. One should administer calcium separately because it causes precipitation of the solution. This electrolyte solution meets daily needs for an adult horse and can be given through a small, preplaced nasogastric feeding tube or by intermittent intubation.

## FLUIDS USED TO EXPAND CIRCULATING BLOOD VOLUME

### ISOTONIC CRYSTALLOIDS

Intravenous administration of isotonic crystalloids immediately reconstitutes circulating volume. However, because the fluids are crystalloids, they distribute to the entire extracellular compartment within a matter of minutes. Because the extracellular fluid compartment is three times the volume of blood, one must administer three times as much isotonic crystalloid to gain the desired amount of volume expansions. The dose is 60 to 90 ml/kg/hr, and the fluid types usually are BESS such as lactated Ringer's solution.

### HYPERTONIC CRYSTALLOIDS (7.2% NA CL)

Hypertonic crystalloids are approximately eight times the tonicity of plasma and extracellular fluid; their immediate effect is to expand the vascular volume by redistribution of fluid from the interstitial and intracellular spaces. However, this effect is short lived. As the electrolytes redistribute across

the extracellular fluid, fluids shift again and the patient becomes hypovolemic again. Because the principal effect is fluid redistribution, a total body deficit still exists that must be replaced. The duration of effect of hypertonic solutions is directly proportional to the distribution constant, which is the indexed cardiac output. The dose is 4 ml/kg, administered as rapidly as possible, and the fluid is 5% or 7% saline. Because of its short duration of effect, one must follow hypertonic saline administration with isotonic volume replacement.

### COLLOIDS

Colloids are fluids that contain a molecule that can exert oncotic pressure. These molecules do redistribute to the extracellular fluid but at a much slower rate than crystalloids, so that the duration of effect is prolonged compared with that of crystalloids. Table 7-7 describes the different colloids available.

A disadvantage of natural colloids (plasma or albumin) is that they are more antigenic and can cause allergic reactions. Synthetic colloids have a much lower antigenicity, but they can cause bleeding disorders because of their tendency to coat platelets or by causing a decrease in coagulation factor. In the horse Dextran 40 can cause anaphylactoid reactions. Hetastarch administration can cause a decrease in coagulation factors and prolong clotting times, particularly at high doses (20 ml/kg).<sup>3</sup> The dose is 10 ml/kg of 6% solutions.

Synthetic colloids do not register on a refractometer. Accurate evaluation of oncotic pressure requires use of a colloid osmometer. If one is not available, the clinician must use clinical evaluation (e.g., observing presence of edema and poor circulatory volume and pressure).

### BLOOD SUBSTITUTES

Blood substitutes are hemoglobin solutions. Currently, only one commercial hemoglobin solution (oxyglobin, which is made from bovine hemoglobin) is available. The major advantage of oxyglobin is that it does not depend on 2,3-diphosphoglycerate for oxygen-carrying capacity, such that it can be stored and is immediately able to transport oxygen. The duration of effect is approximately 18 hours in horses, after which point another dose or a blood transfusion must be considered.<sup>4,5</sup> Unfortunately, cost limits the usefulness of oxyglobin in horses.

### WHOLE BLOOD

Whole blood is the ideal fluid for blood loss or platelet loss, provided that it is fresh blood and has been crossmatched. It is important to remember that stored blood loses its oxygen-carrying capacity and that it can take several hours to restore it after administration.

Ideally, the ICU should maintain blood donors that are free of antigenic determinants, particularly Aa and Qa, and of isoantibodies. The practitioner can perform a major and minor crossmatch to select an appropriate donor, provided that complement is added to the test for hemolysin detection. Interpretation of the minor crossmatch may be difficult if autoagglutination is present. If crossmatch is unavailable, one can use a non-Thoroughbred gelding. A volume of 20 ml/kg can be safely collected every 3 weeks in adult horses,<sup>3</sup> and whole blood can be collected in sodium citrate using sterile technique. Commercial blood collection kits are also available. Complications of blood transfusion include acute anaphylactic reactions, allergic reactions, hemolysis, fever, tachypnea, and hypocalcemia caused by citrate chelation.

## MONITORING ARTERIAL BLOOD PRESSURE

The practitioner can measure arterial blood pressure by direct catheterization of a peripheral artery or by indirect measurements that depend on a cuff placed over an artery and cuff inflation until blood flow is occluded. Measurement of arterial blood pressure is one of the indirect estimates of tissue perfusion, using the mean pressure as the driving pressure. Horses may have low mean arterial pressure (MAP) as a result of hypovolemia, SIRS, heart failure, or any of a wide variety of disorders.

Most monitoring equipment provides an estimation of systolic arterial pressure, diastolic pressure, and MAP. MAP is a calculated value determined by integrating the area under the pressure waveform and dividing this by the duration of the cardiac cycle.

Pulse pressure is the difference between systolic and diastolic pressure and is responsible for the palpable pulse. A bounding pulse pressure results from an increased systolic pressure, a decreased diastolic pressure, or both.

Ultimately, the clinician is interested in oxygen delivery to tissues, which depends on adequate perfusion of tissues, which in turn depends on functional capillary density and blood flow in capillaries. In the clinical arena measurement of tissue perfusion or of tissue blood flow is impractical. Therefore clinicians use blood pressure as an estimate of adequate blood flow and tissue perfusion. The problems with this assumption are as follows:

- Tissue blood flow is regulated locally; an adequate systemic blood pressure may not reflect local blood flow if vasocon-

striction, shunting, poor capillary recruitment, edema, or thromboembolism exist. An example is the central redistribution of blood flow in shock, with preferential shunting of abdominal organs.

- Blood flow depends on pressure differential. If vasoconstriction is generalized, blood pressure may be normal but flow may be poor.
- Blood flow through a vessel depends on the viscosity of the fluid (blood) and the radius of the vessel. At high viscosity blood flow may be impaired. Severe vasoconstriction, although maintaining blood pressure, may impair flow.

## DIRECT OR INVASIVE BLOOD PRESSURE MEASUREMENT

An over-the-needle catheter configuration is preferable for direct or invasive blood pressure measurement to prevent bleeding at the site of puncture. A small (20- or 22-gauge) catheter is preferable to minimize hematoma formation on catheter removal. The radial artery over-the-needle catheter (Arrow International, Reading, Pa.) with a wire guide is suitable for arterial catheterization of peripheral vessels in the horse. As an alternative, an over-the-wire catheter sheath that calls for a Seldinger technique for insertion (Seldinger technique transradial artery catheter, Arrow International) may be used. The catheter is connected to noncompliant tubing filled with heparinized saline, which is linked to a pressure transducer.

Suitable arteries for arterial catheterization in the horse include the transverse facial, facial, and greater metatarsal arteries. In the standing horse the transverse facial or the facial artery are most practical (Figure 7-1).

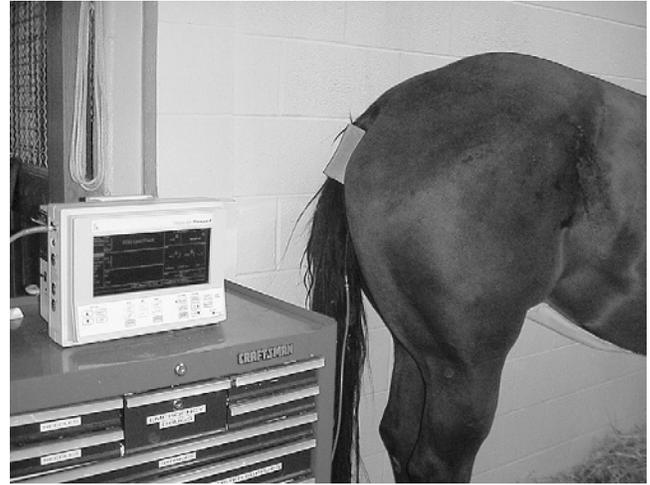

**FIGURE 7-1** An adult horse with an arterial catheter in the transverse facial artery for direct blood pressure monitoring.

The reference unit for blood pressure is millimeters of mercury (mm Hg), meaning the force exerted by the blood against an area of the vessel wall to raise a column of mercury by a certain number of millimeters. Occasionally, centimeters of water (cm H<sub>2</sub>O) is used. One mm Hg equals 1.36 cm H<sub>2</sub>O. The mercury manometer is too slow, however, to record changes in blood pressure rapidly. Therefore a continuous method of pressure recording is preferable for clinical use. A transducer transforms the pressure signal to an electronic signal that can be displayed continuously. The transducer and flush device (Pressure Monitoring Kit with Truwave disposable pressure transducer; Edwards Lifescience, Irvine, Calif.) then can be used for continuous blood pressure measurement. One should place the transducer at the level of the heart base, as estimated by the point of the shoulder.

In addition to blood pressure measurement, invasive blood pressure measurement enables evaluation of the pressure waveform, which in turn can provide insight regarding the status of the stroke volume and peripheral vascular tone.

### INDIRECT MEASUREMENT

Indirect blood pressure measurements depend on a cuff placed around the tail or the metatarsus. The diameter of the cuff influences the accuracy of the measurement, with cuffs that are too wide resulting in underestimation of the blood pressure. An ideal cuff width-to-circumference ratio of 0.25 to 0.35 has been recommended for use on the tail or limbs of horses. Cuff widths are available for neonate, pediatric, and adult horses. Once the cuff is in place, the practitioner measures blood pressure by recording the signal emitted by the changing blood frequency during the pulse wave. The following sections describe noninvasive blood pressure measurement methods.

**FIGURE 7-2** Indirect oscillometric blood pressure measurement in a horse using a cuff placed on the tail.

### DOPPLER

Doppler uses a small ultrasound probe placed on a peripheral artery, and a piezoelectric crystal within the probe converts the pulse wave into an audible signal. The probe must be placed over a shaved area (usually under the tail of the horse) after application of a coupling gel. Doppler allows measurement of only systolic pressure and is therefore not as useful as other methods.

### OSCILLOMETRIC SPHYGMOMANOMETRY

Oscillometric sphygmomanometry relies on the recording of the change in oscillations generated by the change in blood flow during deflation of the cuff. Oscillations start as the cuff pressure reaches systolic pressure, are maximal at mean pressure, and disappear when the cuff reaches diastolic pressure. The meter records and displays systolic, diastolic, and mean pressures. When placing the meter on the tail, one can use tape or a bandage below the cuff to prevent its slipping, but should not restrain the cuff itself (Figure 7-2).

### PHOTOPLETHYSMOGRAPHY

Photoplethysmography relies on the detection of arterial volume by attenuation of infrared radiation. Photoplethysmography originally was designed for use in human fingers and has been validated for use in small dogs and cats but has not been evaluated for use in horses.

### TRANSESOPHAGEAL ULTRASOUND

Transesophageal ultrasound is a method of hemodynamic monitoring that uses a transesophageal probe with two ultrasound transducers (HemoSonic; Arrow International). An M-mode transducer continuously measures the aortic diameter, and a pulsed Doppler measures the flow velocity, providing hemodynamic measurements, including MAP. Although transesophageal Doppler echocardiography has been evaluated for determination of cardiac output in horses, the accuracy and repeatability of the combined probes for blood pressure determination have not been evaluated (Vingmed Sound, Horten, Norway).

## GOALS OF BLOOD PRESSURE MEASUREMENT

The goal of blood pressure measurement is to identify hypotension and follow the response to therapy after interventions. Blood pressures of greater than 70 mm Hg are targeted in the adult, and greater than 60 mm Hg are targeted in neonates. In horses hypertension rarely is identified, other than after giving high doses of pressor agents such as phenylephrine.

## PITFALLS

When using direct pressure monitoring, the clinician should ensure that a good waveform is visible on the oscilloscope. Dampening of the pressure waveform by an air bubble or improper catheter placement leads to flattening of the pressure waveform and falsely low pressure measurements. Alternatively, long connector tubing lengths (>4 feet) can lead to a resonant system that records a falsely elevated systolic pressure. The flush test can help determine whether the recording system is distorting the pressure waveform.

## ☞ MONITORING CENTRAL VENOUS PRESSURE

Central venous pressure is the pressure in the central veins of the patient and is most often measured within the intrathoracic portion of the cranial vena cava. The CVP is affected by vascular volume, venous tone, and cardiac function. Monitoring CVP is most useful for patients in which the veterinarian is attempting to maintain adequate vascular volume without fluid overload. For example, assessment of CVP may be useful in horses with oliguric or anuric renal failure, horses with large volume gastric reflux, and horses predisposed to edema formation.

Central venous pressure is measured by using an intravenous catheter placed in the jugular vein and terminating in the intrathoracic portion of the cranial vena cava. The catheter is attached via an extension set to a water manometer positioned such that the pressure at the level of the base of the heart or point of the shoulder is zero.

## ☞ TRACHEOSTOMY

Box 7-3 lists the materials needed for an emergency tracheostomy pack. If possible, the clinician should clip, prepare, and infiltrate with local anesthetic the planned incision site. In cases of acute respiratory distress, this may not be possible, however. The clinician makes an 8- to 10-cm longitudinal incision at the junction of the proximal and middle third of the neck, just above the V made by the junction of the sternothyrohyoideus muscles. It is important to stay on midline to favor drainage, separating the sternothyrohyoideus muscles on the midline and exposing the trachea. The clinician makes a transverse incision between two tracheal rings, taking care not to damage the tracheal cartilages. If the head of the horse is supported in elevation during the procedure, the clinician should make the tracheal incision distal in relationship to the skin incision to keep from covering the incision when the head is lowered. In emergency situations a J-type tracheostomy tube is used because of its ease of insertion. When the horse is calm, or if the situation is not critical, a self-retaining tube is preferable for maintenance because J-tubes tend to fall out. If the

### BOX 7-3

#### MATERIALS NEEDED FOR AN EMERGENCY TRACHEOSTOMY PACK

- Local anesthetic
- Needle and syringe
- Sterile, disposable surgical blade
- Scissors
- Hemostats
- J-type tracheostomy tube

animal is to be ventilated, a silicone-cuffed tube is preferable to allow for closed-system ventilation.

The tracheostomy tube should be cleaned daily and changed as needed. Petroleum gel applied around the incision prevents skin scalding. In general but particularly in foals, tracheostomy tubes should be removed as early as possible to avoid permanent tracheal deformity. To help decide when to remove the tube, the clinician can occlude the tube temporarily to see if the horse can breathe without it. After the tube is removed, the site should be cleaned of exudate twice daily and allowed to heal by second intention. The wound generally closes in 10 to 14 days and heals in 3 weeks.

## ☞ THORACOCENTESIS

Thoracic drainage is an essential part of managing pleural effusion and can be lifesaving in cases of severe effusion. Pleural effusion is identified by typical increases in area of cardiac auscultation; dullness in the ventral area of auscultation; and, if unilateral, a discrepancy in auscultation between the two hemithoraxes. The clinician can use percussion, although ultrasound typically provides the best method of identifying fluid in the chest. Pleural fluid is drained through a cannula or by placement of a chest drain. The clinician clips, prepares, and infiltrates the site with a local anesthetic. An incision is made in the skin cranial to the proposed point of entry, and the trocar is inserted through the skin. The clinician moves the incision in a caudal direction to a point between two ribs and, using pressure, pushes the trocar into the chest. One hand serves as a stop to control depth of entry. After obtaining the fluid, the clinician places a Heimlich valve on the end of the tube and sutures the tube in place using a Chinese finger trap pattern.

Pneumothorax is classified as open (external wound) or closed. The pleural pressure equilibrates with atmospheric pressure, resulting in lung collapse. Tension pneumothorax develops when air continuously enters the chest without evacuation. The pleural pressure can reach supra-atmospheric levels and can be life threatening.

In open pneumothorax sealing of the chest must occur, followed by evacuation of air. The clinician can seal the chest with sheets of plastic wrapped around the site of entry or close the wound if possible. The chest is evacuated by placing a small trocar, or a 14-gauge catheter, in the dorsal twelfth intercostal space, and the trocar is removed once the air has been evacuated satisfactorily. In closed pneumothorax or tension pneumothorax, the catheter must be kept in place until the source of air entry can be sealed.

## ☞ NASOGASTRIC INTUBATION

Nasogastric intubation is an essential and possibly lifesaving procedure performed in cases of equine colic. The horse should be adequately restrained, with a twitch and sedation if needed. The clinician should stand on the side of the horse, with the hand closest to the horse placed on the nose, and the thumb in the nostril. With the other hand, the clinician passes the tube in the ventral meatus, using the thumb to keep it directed correctly. If a hard structure is encountered, it is the ethmoidal area, and the tube should be redirected ventrally. On reaching the pharynx, the practitioner should feel a soft resistance. The tube can be turned 180 degrees to direct its curvature dorsally. The clinician stimulates the horse to swallow by gentle to-and-fro movement or by blowing in the tube. Keeping the head of the horse flexed at the poll is helpful. Once the horse swallows, the clinician pushes the tube into the esophagus. Blowing into the tube to dilate the esophagus facilitates insertion. If the horse coughs, the clinician withdraws the tube and repeats the procedure until the tube is positioned correctly. There are three ways to determine that the tube is placed correctly in the esophagus: gentle suction, which should elicit a negative pressure; shaking of the trachea, which should not elicit a rattle; and visual confirmation of correct placement. Direct observation is the safest method. The tube is advanced until it is in the stomach (fourteenth rib). If the clinician encounters difficulty in passing the cardia, 60 ml of mepivacaine may be injected into the tube. Once the tube is in place, the practitioner must force the horse to reflux if reflux is not spontaneous. Medication should never be administered by nasogastric tube to a horse with colic without checking first for reflux. To do this, one fills the tube with water using a pump and directs the end of the tube downward to verify the presence of gastric contents. Subtracting the amount pumped in from the amount obtained is useful to determine the net amount of reflux.

One removes the tube by first occluding it (putting a thumb on the end or folding it) to prevent its contents from spilling out in the pharynx and possibly the trachea as it is withdrawn. Gentle traction is then applied in a direction parallel to the nose. If bleeding occurs, a towel can be placed over the horse's nose. The bleeding, even if severe, is self-limiting.

Nasogastric reflux is not normal. Occasionally, a small amount of reflux (1 L or less) is obtained if a horse has had a tube in place for a long time. When reflux occurs, the clinician should note the amount, character, and timing in relation to the onset of colic. In addition, the clinician should note the response to gastric decompression. Reflux originating from the small intestine is alkaline, whereas reflux composed of gastric secretions is acidic. Typically, *reflux* refers to small intestinal ileus, functional or mechanical. Lesions of the proximal small intestine produce large amounts of reflux early in the onset of the colic. With lesions of the distal small intestine (ileum), one initially obtains no reflux, and as the condition persists, one obtains reflux but usually several hours after the onset of the colic. Occasionally, large colon disease can be associated with reflux if the colonic distention exerts pressure on the duodenum as it curves over the base of the cecum.

The clinician should note the amount of reflux obtained because this factors into ongoing losses, and the volume of fluids given intravenously must be adjusted accordingly. Horses with functional ileus need gastric decompression usually every 4 hours, although if the condition is severe, they may require decompression every 2 hours. The nasogastric tube should

be left in place only as long as required because some horses develop pharyngeal and laryngeal irritation associated with its presence.<sup>6</sup> These horses then have pain when swallowing when they resume feeding.

## ☞ ABDOMINOCENTESIS

Abdominocentesis is important for evaluating abdominal disease, whether it is colic, weight loss, or postoperative problems. **Box 7-4** provides the materials needed to perform this procedure.

The clinician clips a 2×2-inch area approximately 3 cm caudal to the xyphoid and 1 to 2 cm to the right of midline. With sterile gloved hands, the clinician inserts an 18-gauge needle through the skin and gently advances it into the abdomen. If no fluid is obtained, another needle can be inserted next to the first one. If no fluid is obtained this time, a bitch catheter, cannula, or dialysis catheter may be tried. Obtaining fluid from very dehydrated horses is often difficult.

To insert a teat cannula, bitch catheter, or dialysis catheter, the clinician places a bleb of local anesthetic at the site, punctures the skin and abdominal wall with a 15-gauge scalpel blade using sterile technique, and then inserts the chosen device in the abdomen. Two points of resistance will be encountered: as the device goes through the abdominal wall and as it goes through the peritoneum. The clinician collects the fluid in ethylenediamine tetraacetic acid (EDTA; shaken out of the tube so that the amount in the sample is not excessive) and, if the fluid is cloudy, in a culture tube.

Normal values for abdominocentesis are as follows: total protein should be less than 2.5 g/dl, and white blood cells should be less than 5000 cells/ $\mu$ l. On cytologic examination neutrophils make up approximately 40% of cells, the rest being lymphocytes, macrophages, and peritoneal cells.

With intestinal strangulation, the protein increases first (in the first 1 to 2 hours) such that the fluid is clear but more yellow. After 3 to 4 hours of strangulation, red blood cells also leak, and the fluid is more orange. After 6 hours or more, white blood cells increase gradually, with the progression of intestinal necrosis.

Enterocentesis sometimes occurs and must be differentiated from intestinal rupture. With enterocentesis a cytologic examination reveals plant material, bacteria, and debris but no cells. The clinical condition of the horse is not consistent with rupture, although in early rupture clinical signs may not reflect rupture (2 to 4 hours are necessary for manifestation of signs). Cytologic examination of abdominal fluid with intestinal rupture shows neutrophils, bacteria, and bacteria that have been phagocytized by neutrophils.

### BOX 7-4

#### MATERIALS NEEDED FOR ABDOMINOCENTESIS

- 18-gauge, 1 ½-inch needle
- Teat cannula
- Bitch catheter
- Dialysis catheter
- Sterile gloves
- EDTA and culture tubes
- Sterile, disposable scalpel blade

EDTA, Ethylenediaminetetraacetic acid.

Blood contamination can result from the procedure and must be differentiated from internal hemorrhage or severely devitalized bowel. Blood from skin vessels usually swirls in the sample and spins down when centrifuged, leaving the sample clear. If an abdominal vessel is punctured, blood also spins down. All fresh blood contamination shows platelets, which are not present with blood older than 12 hours. If the spleen is punctured accidentally, centrifugation reveals a packed cell volume higher than the peripheral packed cell volume. In internal hemorrhage blood is hemolyzed such that the supernatant is reddish after centrifugation; the sample has no platelets and shows erythrophagocytosis. Ultrasonography also reveals fluid swirling in the abdomen.

Excess EDTA in the sample falsely elevates the total protein. When performing an abdominocentesis, the clinician should shake out the EDTA from the tube to avoid this sampling error.

Abdominal surgery increases the total protein level and white blood cell count for some time after surgery. Typically, if no enterotomy occurred, the white blood cell count increases greatly for 4 to 7 days and returns to normal by 14 days. The total protein level may remain elevated for 3 to 4 weeks after surgery. Neutrophils appear to be nondegenerate. After an enterotomy or an anastomosis, degenerate neutrophils and occasional bacteria may be seen in the first 12 to 24 hours. Subsequently, the white blood cell count remains elevated for approximately 2 weeks, but on cytologic examination the neutrophils appear to be nondegenerate and no bacteria are apparent. The total protein level remains elevated for 1 month after surgery. If septic peritonitis is present, clinical signs are consistent with bacterial infection (i.e., fever, depression, anorexia, ileus, pain, endotoxemia). The white blood cell count and total protein level are elevated greatly. On cytologic examination greater than 90% of cells are neutrophils, and they appear to be degenerate. Free and phagocytized bacteria are visible.

## ☞ TROCARIZATION OF THE LARGE COLON

Trocarization of the large colon is occasionally useful to decompress the abdomen for abdominal compartment syndrome (i.e., severe distention associated with pain and dyspnea). Box 7-5 lists the materials needed for this procedure.

Trocarization should be performed only for large colon distention and never to decompress the small intestine. Before deciding on trocarization, identifying the segment of intestine involved is important. In adult horses, such identification can be made by rectal palpation, and in foals or small horses, radiographs or ultrasound can be used. The distended segment of large colon also must be close to the body wall so that it can be reached safely.

The most common site for trocarization is the right upper flank area, just cranial to the greater trochanter at the location of the cecal base. The clinician clips, prepares, and infiltrates with a local anesthetic a 4 × 4-cm area of skin. With gloved hand, the clinician inserts a 14-g catheter with an extension tube perpendicular to the skin. The clinician places the end of the extension in water so that gas bubbles are visible when the tip of the catheter is positioned correctly. When gas is obtained, the trocar part of the catheter should be withdrawn slightly to keep from lacerating the bowel. It may be necessary to reposition the catheter several times when gas is not obtained. After decompression the clinician removes the

- Extension tubing
- Small water container (syringe case works)

trocar and infuses an antibiotic (e.g., gentamicin) while withdrawing the catheter.

Peritonitis and local abscessation are the two most common problems encountered after trocarization. The horse should be observed for 24 hours for signs of peritonitis. If the practitioner suspects peritonitis, confirmation is with abdominocentesis, and systemic broad spectrum antibiotics should be administered to the horse until the condition resolves. If a local abscess develops, the practitioner can drain it externally.

## ☞ URINARY CATHETERIZATION

Measurement of urine output in adult horses is an infrequent procedure, compared with foals, but it may be useful in horses with oliguric renal failure or when 24-hour volumetric measurements are needed. Male horses with neurologic disorders that make them unable to express their bladder may require bladder decompression.

In the mare, urine is easily collected by placing a Foley catheter that is connected to collection tubing. One can make a closed system by using a solution administration set and empty fluid bag. In geldings one can insert a male urinary catheter and suture it in place using a Chinese finger trap pattern. If the horse is recumbent and thrashing, leaving as little as possible of the catheter protruding to keep it from being pulled out is important. Normal horses produce 1 to 2 ml/kg/hr of urine.

## SUPPORT OF CARDIOVASCULAR FUNCTION\*

Peter R. Morresey

## ☞ REVIEW OF CARDIOVASCULAR PHYSIOLOGY

Cardiac output, the volume of blood pumped through the heart per minute, is calculated as the product of heart rate and stroke volume. Heart rate is determined by a number of neurologic, endocrinologic, and physical factors. Stroke volume is the

\*The author wishes to acknowledge two excellent sources that were particularly helpful in the formulation of this manuscript: Magdesian's article on monitoring the critically ill equine patient published in *Veterinary Clinics of North America* in 2004,<sup>47</sup> and an article by Coley, Donaldson, and Durando on cardiac output technologies in the horse that was published in the *Journal of Veterinary Internal Medicine* in 2003.<sup>56</sup>

amount of blood expelled from the heart with each contraction (i.e., the difference between end-diastolic volume [maximal filling] and end-systolic volume within the ventricle [peak contraction]). The quantity of blood arriving as the arterial supply of a tissue depends on cardiac output.

Resistance to arterial blood flow varies among tissues. As a result, cardiac output is not evenly distributed throughout the body. Contraction of the smooth muscle of the arterioles largely determines that this resistance functions to maintain a pressure gradient across the tissue capillary beds, allowing flow from arterioles to venules. Systemic vascular resistance can be considered a measure of vasomotor tone and hence vascular capacity.

Delivery of oxygen to the tissues becomes inadequate when the cardiovascular system is dysfunctional, because the oxygen delivered is a product of blood flow through the tissue and arterial oxygen content. In patients with reduced blood flow and peripheral perfusion, fluid therapy is used to increase circulating volume. Increased venous return leads to an increased stroke volume, increasing cardiac output and therefore tissue blood flow. When fluid therapy fails to improve tissue perfusion as a sole therapeutic approach, the use of vasoactive drugs (e.g., vasopressors, inotropes) may be indicated.

## ☉ CARDIOVASCULAR INSUFFICIENCY: SHOCK STATES

If the cardiovascular system fails to meet the demands of the animal for adequate oxygen delivery to tissues, a state of shock ensues. Shock is classified into four major types: hypovolemic shock, cardiogenic shock, obstructive shock, and distributive shock.<sup>1</sup> The first three of these categories of shock are associated with a decrease in cardiac output and uniform circulatory disturbances in the arterioles, venules, and capillaries. Anaerobic tissue metabolism ensues as a result of diminished oxygen delivery. The fourth type of shock, distributive or vasodilatory shock, is associated with a heterogeneous disturbance of blood flow in the microcirculation and areas of shunting.<sup>2</sup>

Hypovolemic shock results from a loss of intravascular volume, whether by systemic dehydration with resultant hemoconcentration, loss of fluid into a third space, or by loss of whole blood through hemorrhage. Decreased circulating volume leads to diminished venous return, reducing cardiac preload. This reduction in preload decreases myocardial fiber length, with resultant decreased contractility and therefore cardiac output. Reduced tissue perfusion results.

Cardiogenic shock is the result of impaired ventricular function with resultant decreased cardiac output. Myocarditis, myocardial infarction, valvular pathology, or arrhythmias may be responsible.<sup>3</sup> Inflammatory cytokines, including tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) and interleukin (IL)-2 and IL-6, decrease the contractility of cardiac myocytes, effects shown experimentally to be mediated by nitric oxide.<sup>4</sup>

Obstructive shock (of the heart, arteries, or large veins) results from a lack of blood flow. With respect to the heart, blood flow is decreased or prevented from entering the heart, culminating in circulatory failure and a cessation of blood pumping through the body.<sup>5</sup> This type of shock may be precipitated by conditions such as vascular thrombosis, pericardial constrictive diseases, and pneumothorax.<sup>6</sup>

Distributive (vasodilatory) shock, manifested as an abnormal distribution of microvascular blood flow, may be septic, anaphylactic, or neurogenic in origin.<sup>5</sup> Shunting of blood in

the microcirculation occurs, resulting in tissue hypoxia and metabolic derangement. This may occur in the presence of normal or increased cardiac output.<sup>2</sup> Central to the pathogenesis of distributive shock is endothelial dysfunction, the result of neutrophil-generated cytokines, proteases, lipid mediators, and oxygen-derived free radicals. Neutrophil adherence to the endothelial surface, migration into underlying tissues, and tissue injury result.<sup>7</sup>

Regardless of the type of shock, if it is prolonged and severe, the terminal physiologic disturbance will manifest as distributive shock.<sup>8</sup> Successful management of shock depends on early recognition and aggressive intervention.<sup>9</sup>

## ☉ THERAPEUTIC GOALS IN THE CARDIOVASCULAR PATIENT

### PRINCIPLES OF MANAGEMENT

Treatment of patients with cardiovascular compromise centers on identification of the underlying cause followed by fluid resuscitation to restore an appropriate circulating volume and administration of vasoactive drugs (e.g., vasopressors, inotropic agents) to normalize cardiac output and restore adequate tissue perfusion (Table 7-8).<sup>10</sup> Fluid resuscitation, which optimizes cardiac preload and hence cardiac output, is the preferred first line of defense in the treatment of hypovolemia and hypotension. If the patient does not respond fully to fluid resuscitation, further improvement in cardiac output is achieved through augmentation of systemic vascular resistance and increasing cardiac contractility by administration of vasopressors and inotropes, respectively.<sup>3</sup>

### FLUID THERAPY FOR RESUSCITATION

The optimal fluid for resuscitation of the patient with shock combines the oxygen-carrying capacity of blood, the ability to provide volume expansion in the circulating pool, and constituents sufficient to replenish and maintain the composition and quantities of all body fluid compartments.<sup>11</sup> Because the ideal fluid has not yet been identified, fluid resuscitation is most commonly initiated with polyionic intravenous fluids.

Two basic types of intravenous fluids are available to correct dehydration and restore circulating volume: crystalloids and colloids. Crystalloids may be obtained as either replacement or maintenance fluids. *Replacement* fluids rapidly distribute to the compartments of the extracellular fluid (ECF). They are isotonic and should be used to replace deficits in hypovolemic and dehydrated animals. *Maintenance* fluids provide free water that distributes to both the intracellular fluid (ICF) and ECF. They should be used to maintain fluid balance after rehydration in horses that need ongoing intravenous support.

#### CRYSTALLOIDS: REPLACEMENT FLUIDS

Crystalloid replacement fluids are polyionic isotonic fluids formulated to have an electrolyte composition similar to that of plasma in healthy animals.<sup>12</sup> Examples include the following:

**Lactated Ringer's Solution** Lactated Ringer's solution (LRS) is useful in patients requiring rapid restoration of fluid volume. Sodium concentration is lower than in equine plasma, and Cl<sup>-</sup> concentration is higher. Although K<sup>+</sup> concentration is relatively low (4 mEq/L), LRS should not be given to patients with hyperkalemia. Lactate in LRS is metabolized by

TABLE 7-8

Useful Drugs in Cardiovascular Critical Care		
Type	Dose	Comments
Vasopressors		
Norepinephrine	0.05-1 $\mu\text{g}/\text{kg}/\text{min}$ intravenously	
Epinephrine	0.02-0.05 mg/kg intravenously	
Dopamine	1-5 $\mu\text{g}/\text{kg}/\text{min}$ intravenously	Renal dopaminergic receptors
	5-10 $\mu\text{g}/\text{kg}/\text{min}$ intravenously	$\beta_1$ -Adrenergic stimulation
	> 10 $\mu\text{g}/\text{kg}/\text{min}$ intravenously	$\alpha$ -Adrenergic stimulation
Phenylephrine	3 $\mu\text{g}/\text{kg}/\text{min}$ intravenously over 15 minutes	
Vasopressin	0.4-0.8 units/kg intravenously	
Inotropes		
Dobutamine	1-20 $\mu\text{g}/\text{kg}/\text{min}$ intravenously	
Plasma volume expansion		
Crystalloids		
Isotonic	50-100 ml/kg intravenously	
Hypertonic saline	4-8 ml/kg intravenously	
Colloids		
Plasma	5-10 ml/kg intravenously	
Hetastarch	5-10 ml/kg intravenously	

Adapted from Orsini JA and Divers TJ: *Manual of equine emergencies*, ed 2, St Louis, 2003, Saunders.

the liver to glucose or  $\text{CO}_2$  and water. In theory, lactate may accumulate and contribute to metabolic acidosis in patients with hepatic dysfunction. Calcium ions present in LRS may precipitate with citrate and bicarbonate additives.

**Plasmalyte 148 and Normosol-R** Plasmalyte 148 and Normosol-R are similar to LRS, but they contain magnesium rather than calcium and can therefore be used when precipitation with concurrently administered anticoagulants may occur. The alkalinizing agents in these fluids are acetate and gluconate, respectively. Relative to LRS,  $\text{Na}^+$  concentration is increased and  $\text{Cl}^-$  concentration is decreased.

**Normal saline (0.9% NaCl)** Normal saline is an isotonic fluid consisting solely of Na and Cl. Concentrations of both  $\text{Na}^+$  and  $\text{Cl}^-$  (154 mEq/L of each) are higher than those of plasma. As a mildly acidifying solution, the use of normal saline in patients with hyperkalemia and metabolic alkalosis is indicated. Care should be taken when normal saline is used for treatment of hyponatremia because gradual correction of plasma  $\text{Na}^+$  concentration is recommended to prevent the excessive osmotic draw of water from cells.

**Hypertonic saline (7% NaCl)** Hypertonic saline is a useful adjunct to other crystalloid fluids for use in the rapid restoration of intravascular fluid (IVF) volume. Administration of hypertonic saline causes a rapid but transient (30- to 60-minute duration) plasma volume expansion as a result of osmotic redistribution of fluid from the interstitial fluid (ISF) space. The rapid increase in vascular volume improves cardiac output and tissue perfusion with rapid administration of only a relatively small volume of fluid. However, to maintain tissue perfusion, concurrent or subsequent administration of isotonic replacement fluids is required for patients with hypovolemia. Iatrogenic hypernatremia and hypokalemia may occur after

hypertonic saline is administered; therefore plasma electrolyte concentrations ideally should be evaluated in the patient before and after administration of hypertonic saline.

#### CRYSTALLOIDS: MAINTENANCE FLUIDS

Crystalloid maintenance fluids are polyionic isotonic or hypotonic fluids formulated for long-term use in patients needing chronic fluid support.<sup>12</sup> The high concentration of  $\text{Na}^+$  and relatively low concentration of  $\text{K}^+$  in replacement fluids may result in hypernatremia and hypokalemia in patients receiving high volumes of these fluids over several days' time. In contrast, maintenance fluids contain a lower  $\text{Na}^+$  concentration and a higher  $\text{K}^+$  concentration, maintaining isotonicity with the addition of dextrose. Maintenance fluids also contain increased concentrations of  $\text{Ca}^{++}$  and  $\text{Mg}^{++}$  compared with replacement fluids. Examples fluids include *Plasmalyte 56* and *Normosol-M. Half-strength dextrose and saline* (0.45% NaCl and 2.5% dextrose) is an isotonic fluid that provides free water as dextrose is metabolized. This fluid is useful for long-term management in patients with hyperkalemia.

#### COLLOIDS

Colloids are fluids that induce a more rapid expansion of IVF than occurs with the administration of similar volumes of crystalloid fluids. Colloid fluids contain large-molecular-weight particles that are unable to diffuse quickly across cellular barriers, thereby maintaining or increasing colloid oncotic pressure. This allows a more effective volume expansion that persists over a longer period of time than that possible with the administration of crystalloids alone. In emergency situations small-volume colloid infusion can draw fluid from the ECF, allowing rapid plasma volume expansion in the early

stages of volume replacement. Colloids expand plasma volume without increasing interstitial water.<sup>13</sup> The utility of colloids for human fluid resuscitation is controversial; the mortality rate was either unchanged compared with that observed in patients receiving only crystalloids or even increased in some subgroups of trauma and nontrauma patients.<sup>14</sup>

**Plasma** *Plasma* is a colloid fluid that contains a variety of essential proteins as well as osmotically active albumin. However, albumin is effective as an osmole only if it remains within the intravascular space. Plasma administration can therefore worsen edema if albumin is rapidly lost from the vascular space, as might occur in patients with increased capillary permeability (vasculitis), gastrointestinal protein loss, or marked proteinuria or in patients with very low plasma oncotic pressure. Other important constituents of plasma include clotting factors, immunoglobulins, and antithrombin. Plasma proteins also provide carrier sites for exogenous (drugs) and endogenous (hormones) compounds. In addition to the relatively short duration of effect of plasma when administered for oncotic effect, disadvantages of plasma administration in horses include the potential for adverse reactions and the relatively high cost for large volume administration in adult horses.

**Hetastarch** *Hetastarch* (6% hydroxyethyl starch) is often a more cost-effective colloid replacement than plasma. The large starch molecules maintain their plasma oncotic effect for a relatively long time as the molecules are gradually removed from circulation through renal elimination. However, unlike plasma, there are no functional molecules present in hydroxyethyl starch solutions. Hetastarch can be given as a series of rapid bolus doses for plasma volume expansion, in contrast to plasma itself, which must be administered slowly. For this reason it offers an attractive way to rapidly ameliorate the effects of acute blood loss. However, one retrospective study suggests that intraoperative use of Hetastarch in human cardiac surgery may increase bleeding and subsequent blood transfusion requirements.<sup>15</sup> Levels of factor VIII and von Willebrand's factor were decreased in horses receiving Hetastarch.<sup>16</sup>

**Blood** Blood can be considered the ultimate colloid replacement fluid, providing replacement of lost circulating volume, oncotic activity in the form of plasma proteins, oxygen-carrying capacity, a vehicle for therapeutic drug transport, and replenishment of coagulation factors.<sup>5</sup> However, its use requires selection of an appropriate donor, with careful collection and administration technique.<sup>17</sup> In addition, use of citrate-based anticoagulants may lead to hypocalcemia in recipients after blood or plasma administration. Care must also be exercised in the choice of concurrently administered intravenous fluids because calcium chelation may occur in shared intravenous lines. The technique of donor selection and blood administration has been well reviewed by Slovis.<sup>17</sup>

## PRACTICAL CONSIDERATIONS AND COMBINATION FLUID THERAPY

When time allows, the initial fluid selection will be made on the basis of the biochemical profile and the clinical appearance of the patient. The initial resuscitation is usually an isotonic crystalloid fluid such as LRS or an equivalent with a bicarbonate precursor. In patients with hyperkalemia (e.g., uroperitoneum, acute renal failure), 0.9% NaCl, a K-deficient fluid, is preferred. The use of hypertonic saline is beneficial for transient IVF expansion where ISF is still adequate.

Concurrent or sequential administration of both crystalloids and colloids is useful for restoring hydration and circulating volume. Crystalloids distribute to the ECF space, with approximately 75% distributing to the ISF space, allowing interstitial rehydration in patients where this fluid shift has occurred. Consideration should be given to the existing oncotic pressure because high volume crystalloid fluid administration to a patient with low plasma oncotic pressure may precipitate significant edema formation as a consequence of further decreases in colloid oncotic pressure.

After administration colloid fluids remain largely restricted to the intravascular space. Rapid expansion of IVF is therefore possible during hypovolemic shock. The administration of colloids increases oncotic pressure by allowing increased retention of crystalloid fluids within the IVF compartment. As suggested previously for hypertonic saline therapy, administration of isotonic crystalloids is usually recommended before or concurrently with colloid fluid administration to ensure adequate fluid volume redistribution to interstitial spaces.

The use of crystalloid versus colloid fluids in situations requiring rapid large volume fluid resuscitation is controversial. The decrease in oncotic pressure that may occur after administration of large volumes of crystalloid fluids is widely thought to promote pulmonary edema; however, some clinical evidence suggests that the lung is relatively resistant to edema because of the effects of hemodilution and decreased oncotic pressure.<sup>18</sup> Other studies of fluid resuscitation of hypovolemic shock patients with normal saline demonstrate increased pulmonary edema compared with patients who were resuscitated with colloid solutions.<sup>19</sup>

In patients with hemorrhagic shock, two scenarios are possible. With controlled hemorrhagic shock, the bleeding source has been occluded after hemorrhage. Uncontrolled hemorrhagic shock occurs where bleeding is ongoing. Hypertonic saline administration to patients with controlled hemorrhagic shock leads to a desirable increase in blood pressure and cardiac output; however, in patients with uncontrolled hemorrhage, hypertonic saline increases bleeding from injured blood vessels and increases the risk of death.<sup>20</sup>

## ☿ VASOACTIVE DRUGS

Vasoactive drugs may be administered in an attempt to increase cardiac output if response to primary intravenous fluid resuscitation is inadequate. Desirable qualities of vasoactive drugs (e.g., vasopressors and inotropes) used to combat hypotension include a short onset of action and rapid metabolism, which enable these drugs to be administered as continuous-rate infusions in order to titrate their effects in response to rapid changes in patient condition.

## RECEPTOR PHYSIOLOGY

Vasopressors and inotropes can be divided into adrenergic and nonadrenergic agonists. Adrenergic receptors targeted by vasoactive therapy include  $\alpha_1$ -,  $\alpha_2$ -,  $\beta_1$ -, and  $\beta_2$ -adrenergic receptors and dopaminergic receptors. Nonadrenergic mechanisms include activation of vasopressin-specific receptors (chiefly  $V_1$ ) and effects on phosphodiesterase activity.<sup>3</sup>

$\alpha_1$ -Adrenergic receptor stimulation results in vasoconstriction caused by contraction of smooth muscle surrounding blood vessels.<sup>21,22</sup>  $\alpha_1$  Activity is also associated with metabolic

changes and increased cardiac contractility.<sup>23</sup> Postsynaptic  $\alpha_2$ -receptor stimulation results in vasodilation.<sup>24</sup>

$\beta_1$ -Adrenergic receptor stimulation results primarily in cardiac effects with increases in both heart rate (chronotropic effect) and contractility (inotropic effect). Chronotropic effects result from increased conductivity at the sinoatrial node and within the cardiac ventricular muscle. Inotropic effects increase stroke volume, thereby improving cardiac output.  $\beta_2$ -Receptor stimulation causes relaxation of smooth muscle with consequent vasodilation of the arteries of coronary vessels, visceral organs, and skeletal muscle. Slight chronotropic and inotropic improvement after  $\beta_2$ -stimulation is also seen.<sup>25</sup>

Dopaminergic receptors improve myocardial contractility and, at certain doses, increase heart rate.<sup>26</sup> Several types of dopaminergic receptors have been identified, and specific effects vary depending on receptor type. Other notable effects include renal stimulation, resulting in diuresis and naturesis ( $D_1$  and  $D_2$  receptors).<sup>27</sup>

Vasopressin receptors ( $V_1$ ) are present throughout the vascular system, and their stimulation results in vasoconstriction, especially at peripheral arterioles.<sup>28,29</sup> After normal physiologic  $V_1$  stimulation, resulting vasoconstriction leads to no net change in blood pressure as a result of modulation by reflex activation of the baroreceptors.<sup>28,29</sup> However, during hypovolemic shock, markedly increased levels of  $V_1$  stimulation lead to significant increases in vascular resistance, an important mechanism for restoration of arterial blood pressure.<sup>30</sup>

## VASOPRESSORS

Vasopressors increase MAP, improving perfusion pressure and distribution of cardiac output. Decreased venous compliance increases venous return, which improves cardiac output.<sup>21,22</sup> Vasopressor use must be closely monitored because excessive vasoconstriction increases cardiac afterload, increasing cardiac workload while decreasing stroke volume and therefore cardiac output.

## ADRENERGIC VASOPRESSORS

### NOREPINEPHRINE

Norepinephrine has predominantly  $\alpha_1$ -adrenergic agonist activity. It is useful to improve organ perfusion pressure during distributive and vasodilatory shock, especially in patients nonresponsive to fluid resuscitation or inotrope administration. Systemic vascular resistance and MAP are increased, with greater arterial constriction (and therefore resistance increase) than occurs with epinephrine. Vasoconstriction increases cardiac afterload, potentially decreasing cardiac output; however, this effect is countered by the  $\alpha_1$ -effects of norepinephrine, which facilitate increased stroke volume.<sup>31</sup>

### EPINEPHRINE

Epinephrine is a strong  $\alpha$ - and  $\beta$ -adrenergic agonist, making it a potent vasopressor. Splanchnic blood flow is decreased compared with norepinephrine.<sup>32</sup> Coronary and renal blood flow is also reduced. Myocardial irritability is increased, with resultant increased risk of arrhythmia. Postresuscitation myocardial depression and increased myocardial oxygen consumption are reported.<sup>33</sup>

Repetitive doses of epinephrine have not been shown to have significant additive pressor effect. High-dose epinephrine

induces disproportionate increases in systolic and pulmonary vasculature pressure. Pulmonary edema may result.<sup>24</sup>

### DOPAMINE

Dopamine is active at adrenergic ( $\alpha$ -,  $\beta$ -) and dopaminergic receptors, with differing effects recognized depending on the dosage administered. High infusion rates of dopamine tend to result in a predominance of  $\alpha$ -adrenergic effects and a vasopressor response.  $\beta$ -Adrenergic effects predominate at lower infusion rates with principally an inotropic response. Low infusion rates are purported to stimulate dopaminergic receptors, improving splanchnic perfusion with concurrent effects on the afferent renal vasculature.<sup>35,36</sup> Plasma concentrations of dopamine vary widely among individuals. As a result, the effect of any particular infusion rate may be highly variable.<sup>34</sup> Considerable controversy exists regarding the utility of dopamine administration, with variable experimental evidence of improved renal perfusion and meta-analysis data showing increased mortality in some subsets of patients.<sup>5,37,38</sup>

### PHENYLEPHRINE

Phenylephrine is primarily an  $\alpha$ -agonist. Systemic vascular resistance and MAP increase after administration, but cardiac output decreases as a result of a decreased heart rate with an unchanged stroke volume. When phenylephrine is used as a vasopressor, concurrent use of a  $\beta$ -agonist (e.g., norepinephrine, dobutamine) is often beneficial.

## NONADRENERGIC VASOPRESSORS

### VASOPRESSIN

Vasopressin, or antidiuretic hormone, is a peptide whose primary role is to regulate the body's retention of water. Released in response to dehydration, vasopressin acts at the kidneys, binding  $V_2$  receptors promoting water conservation in the collecting tubule and thereby concentrating and reducing urine volume.

Vasopressin binds to peripheral  $V_1$  receptors, causing vasoconstriction. Although catecholamines may be increased during sepsis, their vasoconstrictor effect can be reduced; this effect, however, can be restored by administration of vasopressin. Human research demonstrates beneficial effects of vasopressin when used concurrently with the catecholamines.<sup>21,33</sup>

Stimulation of  $V_1$  receptors has been suggested to decrease blood flow in the gastrointestinal tract. Experimental studies have shown a detrimental effect in volume-deficient animals; however, in test subjects receiving aggressive fluid resuscitation,  $V_1$  stimulation improved visceral circulation.<sup>39</sup> Therefore  $V_1$  agonists may be unsuitable for use in horses that remain hypovolemic. It is vital to ensure adequate fluid resuscitation before administration of these drugs.<sup>39</sup> Current evidence suggests that vasopressin should be used in combination with a catecholamine vasopressor.<sup>40,41</sup> Reports of vasopressin use and physiology in the horse are few in number.<sup>42-44</sup>

## INOTROPES

The mode of action of inotropic drugs is to increase cardiac stroke volume. This is achieved by increased myocardial contractility, which increases ventricular emptying and decreases

end-systolic volume. Cardiac workload and oxygen consumption are increased, which is of concern in hypoxemic patients. If response to fluid resuscitation is inadequate, inotropes provide another means to increase cardiac output and oxygen delivery.<sup>3</sup>

### DOBUTAMINE

Dobutamine is a synthetic catecholamine that has primarily  $\beta_1$ -adrenergic receptor stimulating action with weak  $\alpha$  and  $\beta_2$  affinity. Dobutamine is useful in patients with diminished cardiac output or decreased central venous oxygen tension despite adequate fluid volume restoration. Beneficial effects include increased stroke volume and heart rate, with improved splanchnic perfusion and urine output. Blood pressure effects are variable.<sup>3</sup>

## ☞ MONITORING CARDIOVASCULAR FUNCTION IN THE CRITICAL PATIENT

### PHYSICAL EXAMINATION

Compromised cardiovascular function is suggested by poor peripheral pulse quality, discoloration of the mucous membranes with or without delayed refill time, cold extremities, and signs of generalized weakness. Heart rate and rhythm are likely disturbed, with cardiac auscultation revealing murmurs. Body weight may increase as a result of edema formation. In addition to these, other suggestive findings are discussed in the subsequent sections.

### JUGULAR PULSATION

In the normal standing horse, jugular pulsation is restricted to the caudal one third of the neck. Increased jugular pulsation indicates tricuspid regurgitation or increased CVP.<sup>45</sup> The former can be distinguished by occlusion of the jugular vein proximally and stripping of blood down toward the heart. Should the jugular vein refill while occluded in this fashion, tricuspid regurgitation is likely.

### VENTRAL OR PERIPHERAL EDEMA

Subcutaneous edema in dependent sites may form in patients with volume overload. Alternatively, increased capillary permeability or decreased colloid osmotic pressure (COP) may be responsible.<sup>12</sup>

### URINE PRODUCTION

Urine production is considered a reflection of renal blood flow and hence cardiac output. This can be considered an indication of the adequacy of overall organ and tissue perfusion.<sup>46</sup> However, during vasopressor therapy urine output and glomerular filtration rate are unreliable indicators of human renal function.<sup>36</sup>

Specific gravity can vary widely, although when dehydration is present, urine should always be concentrated. In patients with renal compromise, isosthenuric urine is produced. In normal horses urine output is highly variable, depending on fluid intake and diet. Reported ranges in the horse are 0.6 to 1.25 ml/kg/hr.<sup>47</sup>

### LABORATORY VALUES

Hematocrit, protein concentrations, and electrolyte concentrations (especially  $K^+$ ,  $Mg^{++}$ , and  $Ca^{++}$ ) should be monitored and normalized if possible in horses with cardiovascular

compromise. Oxygen delivery to tissues, potential for edema formation, and cardiac rate and rhythm are dependent on appropriate values.

### LACTATE

Lactate is the terminal product of anaerobic glycolysis. Increased blood lactate concentration results from inadequate delivery of oxygen to peripheral tissues. This may be the result of hypovolemia, hypoxemia, alterations in hemoglobin concentration, decreased perfusion pressure, or a combination of these factors. Increased tissue demands for oxygen may be secondary to sepsis or increased metabolic rate.<sup>48</sup> Tissue oxygen consumption may be impaired, leading to increased lactate production.<sup>49</sup> Therefore blood lactate concentration is an indication of the adequacy of peripheral perfusion and oxygen delivery to tissues. The need for and response to blood transfusion can be assessed by analysis of plasma lactate.<sup>50</sup>

Lactate measurement is useful clinically to monitor the response to fluid therapy and vasoactive drug treatments in patients with poor tissue perfusion. Decreases in plasma lactate concentration are considered to temporally follow improvements in cardiovascular performance; therefore the trend in changes in plasma lactate concentration is most clinically useful. In situations of appropriate volume restoration in which lactate concentration remains increased, unresolved inflammatory stimulus and uncontrolled sepsis should be suspected.

### ARTERIAL BLOOD PRESSURE

Arterial blood pressure is the product of cardiac output (itself the product of heart rate and stroke volume) and systemic vascular resistance (vasomotor tone). Mean blood pressure, not systolic or diastolic blood pressure, is considered most important for organ and tissue perfusion (Table 7-9).<sup>47</sup>

Arterial blood pressure can be measured by direct (invasive) and indirect (noninvasive) means, as described earlier in this chapter. Trends in arterial blood pressure, as opposed to individual readings, should be used to guide therapy. Consideration of physical findings should also be given when altering therapy.

### CENTRAL VENOUS PRESSURE

Central venous pressure is determined by central venous blood volume, muscular tone of the venous system, and the balance between venous return and cardiac output. The technique for

TABLE 7-9

Cardiovascular Parameters	
Type of Blood Pressure	Blood Pressure Reading
Arterial pressure	
Mean arterial pressure	> 60 mmHg
Systolic (indirect)	111.8 ± 13.3 mmHg
Diastolic (indirect)	67.7 ± 13.8 mmHg
Central venous pressure	mean 12 cmH <sub>2</sub> O

Data from Cook VL, Bain FT: Volume (crystalloid) replacement in the ICU patient, *Clin Tech in Equine Pract* 2:122–129, 2003, and Magdesian KG: Monitoring the critically ill equine patient, *Vet Clin North Am Equine Pract* 20:11–39, 2004.

measuring CVP in horses is described earlier in this chapter. Central venous pressure is a measure of blood pressure within the intrathoracic cranial vena cava, estimating right atrial pressure and cardiac preload.

Central venous pressure can be used to guide fluid replacement therapy in patients with hypovolemia. The tendency to form edema in patients that are hypooncotic, have increased capillary permeability, or have diminished cardiac function can also be monitored. As with measurements of arterial blood pressure, the trend in CVP seen through repeated monitoring is most informative regarding restoration of fluid volume administration and attempts to manage cardiac failure.

Low CVP values are consistent with vasodilation or hypovolemia. Lack of an increase in CVP in response to a challenge fluid bolus is consistent with hypovolemia. Decreased CVP also occurs during inspiratory efforts that result in decreased intrathoracic pressure. Central venous pressure can be increased in patients with fluid overload (iatrogenic), increases in blood volume (renal failure, renin-angiotensin-aldosterone activation), systemic venoconstriction (sympathetic activation), and right-sided heart failure. Restrictions to cardiac filling, such as pericardial or pleural effusion, forced expiration, and positive pressure ventilation, may increase CVP. Increased CVP may falsely result from ventricular catheterization and air within the manometer or fluid lines.

### COLLOID OSMOTIC PRESSURE

Colloid osmotic pressure, also referred to as *oncotic pressure*, results from the osmotic force caused by macromolecules within the intravascular compartment. This pressure is essential to retain appropriate intravascular volume. Proteins and colloid molecules retain water within the vasculature by virtue of their osmotic draw. They are sufficiently large in mass to limit their permeability across the vascular endothelium. In addition, the Gibbs-Donnan effect, wherein sodium cations are attracted to negative residues on protein (albumin), adds further to the intravascular osmotic draw.

Loss of plasma proteins resulting from increased capillary permeability can lead to a hypooncotic state. Severe loss of proteins leads to hypovolemia caused by simultaneous loss of plasma. Fluid resuscitation with crystalloids dilutes plasma proteins. In horses with hypoproteinemia, this further dilution leads to an increase in interstitial fluid volume and therefore to ventral and tissue edema with potential for reduced blood volume.<sup>16,51</sup>

Colloid osmotic pressure can be measured or calculated, with reasonable agreement in healthy but not hospitalized horses.<sup>52</sup> Because albumin is the major contributor to COP, alterations in the albumin-to-globulin ratio alter COP at any given total plasma protein concentration. Calculated COP in horses with hypoproteinemia (hypoalbuminemia) is therefore likely inaccurate.<sup>51</sup> Direct measurement of COP is necessary after synthetic colloid (hetastarch) administration because these starch molecules have considerable osmotic effect but are not measurable by refractometry.

### VENOUS BLOOD GAS

Arterial blood gas values are required to assess pulmonary gas exchange, as described elsewhere in this chapter; however, in patients with cardiovascular compromise in which severe hypoperfusion may be present, tissue level

hypercapnia and acidemia are more accurately represented in central venous blood.<sup>53</sup> Venous hypercapnia results from increased tissue CO<sub>2</sub> production and transference to blood in the capillaries of the hypoperfused peripheral tissues and a diminished CO<sub>2</sub> excretion because of pulmonary hypoperfusion.<sup>54</sup>

### ELECTROCARDIOGRAM

Indications for electrocardiogram (ECG) monitoring of equine patients with cardiac compromise include dysrhythmias and marked electrolyte abnormalities (especially hyperkalemia); ECG is also useful to monitor response to vasoactive drug therapy. The base apex lead system is most commonly used in equine medicine. Telemetry units allow remote monitoring of horses free in stalls and are most convenient when seeking to diagnose an intermittent dysrhythmia.<sup>45,47</sup> A more complete review of the cardiovascular system and its monitoring is available in Chapter 10.

### ECHOCARDIOGRAPHY

Echocardiography is extensively reviewed in Chapter 10. Visualization of the heart, pericardial space, and intrathoracic vessels gives invaluable insight into cardiac integrity and function.

Monitoring cardiac output in the horse is possible by Doppler echocardiography.<sup>55</sup> This technique allows determination of the velocity, turbulence, and direction of blood flow in the heart. Change in frequency between the emitted and the reflected ultrasound wave is used to calculate the velocity of the blood cells, and hence a measure of cardiac output can be made. Correct alignment of the waveform is essential for an accurate estimate of cardiac output, with the beam needing to be aligned as close to parallel to blood flow as possible.<sup>56</sup>

### CARDIAC OUTPUT MEASUREMENTS

The use of advanced technologies such as lithium dilution, indicator dilution, bioimpedance, and pulse contour analysis for assessment of cardiac output has been extensively reviewed.<sup>56</sup> These techniques are impractical in the clinical setting or have not been validated for the horse.

Briefly, dilution techniques rely on injection of a known amount of an indicator dye into a vein upstream of the heart. The indicator is diluted by the blood passing through the heart. Once diluted, the concentration of indicator is measured in a peripheral artery; the volume of blood and therefore the cardiac output can be calculated as related to the area under the concentration-time curve of the indicator downstream of the heart.

Transthoracic electric bioimpedance is a noninvasive method of measuring cardiac output. Because blood has a relatively high electrical conductivity compared with solid tissues and air, alterations in arterial blood flow lead to changes in thoracic impedance. The amount of change relates to the amount of blood flowing (cardiac output). This change is measured as alterations in the conductivity of a small electric current applied to the thorax. Bioimpedance has not been used to measure cardiac output in horses.<sup>56</sup>

Pulse contour analysis calculates the cardiac output from arterial pressure waveforms, using the area under the arterial pressure tracing during systole to represent blood flow in the catheterized vessel. This is therefore a measure of cardiac output.<sup>57</sup>

## SUPPORT OF RESPIRATORY FUNCTION

Bonnie Barr

A core skill in critical care medicine is rapid and thorough assessment of respiratory and cardiovascular function firmly grounded by the understanding of physiologic and pathophysiologic processes in each of these organ systems. The major function of the respiratory system is gas exchange and, in conjunction with the cardiovascular system, delivery of oxygen to tissues and elimination of CO<sub>2</sub> generated by tissue metabolism. Oxygen and CO<sub>2</sub> are exchanged between the inspired air and blood to maintain normal arterial partial pressure of oxygen (PaO<sub>2</sub>) and CO<sub>2</sub> (PaCO<sub>2</sub>). The respiratory control system maintains PaO<sub>2</sub> and PaCO<sub>2</sub> within a narrow homeostatic range despite the body's wide variety of demands. Adequate ventilation requires the complex interaction among central respiratory centers, spinal pathways, peripheral respiratory nerves, and primary respiratory muscles.<sup>1</sup> Under normal conditions the primary driving force of alveolar ventilation is changes in the PaCO<sub>2</sub>, which are sensed by central chemoreceptors in the brainstem.<sup>1</sup> Changes in PaO<sub>2</sub>, which are sensed by peripheral chemoreceptors in the carotid and aortic bodies, also have an impact on alveolar ventilation but typically only in states of marked hypoxemia.<sup>1</sup>

The basic components of the respiratory system are the upper airways, the respiratory passageways, and the alveolocapillary membrane. The upper airways and the respiratory passageways are not involved in gas exchange and therefore are referred to as *anatomic dead space*.<sup>1</sup> The alveolocapillary membrane is the primary area involved in gas exchange, although occasionally areas are ventilated but not perfused, resulting in physiologic dead space.<sup>1</sup> The alveolocapillary membranes are made up of the alveoli and the pulmonary capillaries, which form a dense network intertwined with the alveoli. This allows for maximum exchange of oxygen and CO<sub>2</sub>. Factors that affect the rate of gas diffusion include thickness of the membranes, surface areas of the membrane, the diffusion coefficient of the gas, and the pressure difference between the two sides of the membrane.<sup>1,2</sup>

### ☞ OXYGEN DELIVERY TO THE TISSUES

Oxygen is delivered to the alveoli, where it diffuses down a pressure gradient into the pulmonary capillary system and is delivered to the tissues. Under normal conditions approximately 97% of oxygen is transported in the blood bound to hemoglobin.<sup>1,2</sup> In the pulmonary capillaries the PaO<sub>2</sub> is high, and therefore oxygen binds with hemoglobin but when PaO<sub>2</sub> is low, in the tissues, oxygen is released. The oxygen-hemoglobin dissociation curve depicts the association between PaO<sub>2</sub> plotted on the x axis and percentage of oxygen saturation of hemoglobin plotted on the y axis. The resulting curve is sigmoid in shape, with the plateau portion at high PaO<sub>2</sub> values. At this point in the curve, a decrease in PaO<sub>2</sub> results in minimal changes in oxygen saturation within erythrocytes. In contrast, the steep part of the curve indicates that a relatively small decrease in PaO<sub>2</sub> in this range results in a very large decrease in the amount of oxygen bound to hemoglobin and resultant oxygen transfer to tissues at the

level of the tissue capillary bed. Factors such as pH, temperature, and the concentration of 2,3-diphosphoglycerate can result in a shift of the curve increasing or decreasing oxygen affinity of hemoglobin.<sup>1,2</sup>

In its strictest definition *hypoxemia* refers to the condition of decreased oxygen content in the blood. Oxygen in the blood is present either combined with hemoglobin (Hb) in the erythrocyte or as dissolved oxygen (P<sub>a</sub>O<sub>2</sub>). Total oxygen content (CaO<sub>2</sub>) is calculated as follows:

$$\text{CaO}_2 = (1.34 \times \text{Hb} \times \text{SaO}_2) + (\text{P}_a\text{O}_2 \times 0.003)$$

where 1.34 is the oxygen-binding capacity of hemoglobin, SaO<sub>2</sub> is the percentage of saturation of hemoglobin with oxygen, and 0.003 is the solubility constant for dissolved oxygen in plasma.<sup>1,2</sup> Disorders that affect the binding of oxygen to hemoglobin (e.g., carbon monoxide toxicity, methemoglobinemia) have a tremendous impact on oxygen delivery to the tissues. Relying solely on assessment of P<sub>a</sub>O<sub>2</sub> can result in significant errors in clinical judgment. In spite of this important consideration, and because P<sub>a</sub>O<sub>2</sub> is more easily and frequently referenced in most laboratory and clinical situations than is total oxygen content, *hypoxemia* is often used to refer to a condition of decreased dissolved oxygen in the blood (decreased P<sub>a</sub>O<sub>2</sub>), which is how that term will be used in the remainder of this discussion.

### ☞ CAUSES OF HYPOXEMIA

Hypoxemia (low PaO<sub>2</sub>) occurs for one of five reasons: decreased inspired oxygen content, diffusion impairment within the lungs, hypoventilation, right-to-left shunting of blood, or ventilation-perfusion mismatch. Horses breathing room air inspire sufficient quantities of oxygen to maintain adequate dissolved oxygen unless they are housed at extremely high altitudes. Occasionally, decreased inspired oxygen content may be a problem in horses under general anesthesia that are inhaling inadequate gas mixtures. However, for practical purposes decreased inspired oxygen is a very rare primary cause of hypoxemia.

Diffusion impairment occurs when the capillary-alveolar interface does not permit adequate gas exchange. This occurs with pulmonary diseases such as pulmonary fibrosis and consolidation that decrease the area or increase the thickness of the alveolocapillary membrane. Because CO<sub>2</sub> normally diffuses about 20 times more rapidly than O<sub>2</sub> across the alveolar-capillary interface, decreased diffusion results in hypoxemia before there is significant hypercapnia. However, oxygen is very diffusible, and under typical resting conditions in a normal horse, the partial pressure of O<sub>2</sub> in the blood is nearly identical to that of alveolar gas when the red cell is only one third of the way along the capillary. Pulmonary disease must be quite severe before diffusion will limit gas exchange in horses; therefore diffusion impairment as a primary cause of hypoxemia in resting horses is uncommon. However, in horses undergoing maximal exercise, oxygen transfer is likely to be diffusion limited because the extremely high cardiac output causes blood to pass through the pulmonary capillaries too quickly to permit complete oxygenation.

Hypoventilation occurs when there is a reduction in the amount of air entering and exiting the alveoli, resulting in decreased gas exchange. Alveolar ventilation is the amount of air that reaches the alveoli and participates in

gas exchange. Because metabolic production of  $\text{CO}_2$  is fairly constant under normal metabolic circumstances, the blood  $\text{CO}_2$  level is primarily controlled by its rate of elimination through the lungs. A partial pressure gradient between the capillary venous blood and the alveoli of the lungs results in diffusion of  $\text{CO}_2$  into the alveoli. Carbon dioxide is then removed from the alveoli by ventilatory exchange of atmospheric air with alveolar gases. Because  $\text{CO}_2$  is highly diffusible, the partial pressure of  $\text{CO}_2$  in alveolar gas and arterial blood are virtually identical and the  $\text{PaCO}_2$  accurately reflects the current status of alveolar ventilation. In other words, hypoventilation always causes an increased alveolar, and therefore arterial, partial pressure of  $\text{CO}_2$ . Hypoventilation can also result in varying degrees of decreased  $\text{PaO}_2$  and respiratory acidosis. Causes of hypoventilation include disorders of the central nervous system, resulting in depression of the respiratory center and disorders of the thoracic cavity, respiratory tract, and respiratory muscles.<sup>1,2</sup> Central nervous system depression can be due to the administration of certain medications, brain and spinal cord trauma, or space-occupying lesions in the brain. Impairment of respiration can result from upper airway obstruction, pleural space disease, neuromuscular disease, thoracic pain, and severe abdominal distention.

Hypoxemia caused by right-to-left shunt occurs when venous blood bypasses gas exchange areas of the lungs (alveoli) and mixes with oxygenated arterial blood, resulting in hypoxemia. Shunt can result from either right-to-left cardiac shunt (extrapulmonary; e.g., Tetralogy of Fallot) or atelectatic or consolidated lung lobes (intrapulmonary).<sup>1,2</sup> The latter mechanism is a result of severe ventilation-perfusion mismatch.

The most common cause of hypoxemia in the horse is ventilation-perfusion mismatch. This occurs when alveolar ventilation and blood flow are not closely matched, resulting in inefficient gas exchange. A high ventilation-perfusion mismatch occurs when regions of the lung are ventilated but not perfused, causing an increase in the physiologic dead space of the lung.<sup>1,2</sup> A low ventilation-perfusion mismatch occurs when regions of the lung are perfused but not ventilated. Ventilation-perfusion mismatch may result from all forms of pulmonary disease. For example, pulmonary thromboembolism can cause high ventilation-perfusion mismatch, whereas bronchopneumonia with consolidation results in a low ventilation-perfusion mismatch.<sup>1,2</sup> If ventilation-perfusion mismatch is severe, the functional result is a right-to-left intrapulmonary shunting of blood.<sup>1,2</sup>

## ☞ CAUSES OF TISSUE HYPOXIA

Hypoxemia is only one of several possible causes of oxygen deficiency at the tissue level, a condition referred to as *hypoxia*. Tissue hypoxia may result from any condition that causes decreased oxygen delivery to the tissues. Horses with decreased cardiac output, such as that which occurs in any shock state; decreased blood oxygen-carrying capacity, such as that which occurs with anemia or in the presence of abnormal hemoglobin; peripheral arterial-venous shunting; histotoxic changes (e.g., inhibition of the cytochrome chain); increased peripheral oxygen consumption; hypermetabolic conditions (e.g., hyperthermia, seizures, sepsis); and localized obstruction of blood flow, may experience generalized or localized tissue hypoxia in the face of normal  $\text{PaO}_2$ .<sup>1,2</sup>

## ☞ ARTERIAL BLOOD GAS ANALYSIS

Arterial blood gas analysis is the most common method for assessment of pulmonary function and acid-base status in horses that are critically ill. In the adult horse the sample may be obtained from the facial artery or transverse facial artery (see Figure 7-1).<sup>3</sup> If continuous samples are to be obtained, an indwelling arterial catheter may be placed. Alternatively, a sample may be carefully obtained from the carotid artery in some horses.

Arterial blood gas analysis measures the amounts of oxygen and  $\text{CO}_2$  in arterial blood, reflecting the functional efficiency of the lungs and response to oxygen therapy.<sup>2,3</sup> Correct interpretation of the arterial blood gas information allows one to assess the status of ventilation and oxygenation in the patient and determine whether an acid-base disorder is present. This can greatly facilitate appropriate diagnostic, therapeutic, and prognostic decision making for the patient.

Samples for blood gas analysis must be collected and handled appropriately to ensure accurate results. A small amount of heparin is used to coat the hub of the needle before aspiration of the sample. Excessive heparin dilutes the sample and may cause inaccurate results, including decreased pH,  $\text{PaCO}_2$ , and bicarbonate. After collection the sample should be stored anaerobically by removing the needle and placing a syringe cap over the tip of the syringe. Prolonged exposure to air bubbles can result in a decrease in  $\text{PaCO}_2$  and an increase in  $\text{PaO}_2$  as the sample equilibrates with room air in the bubble.<sup>2,3</sup> A sample stored at room temperature should be analyzed within 10 to 15 minutes.<sup>4</sup> In samples stored at 37° C,  $\text{PaCO}_2$  will increase by approximately 0.1 mm Hg per minute and  $\text{PaO}_2$  will increase at approximately 0.5 to 2.3 mm Hg per minute.<sup>2,3</sup> Delaying analysis for 1 hour will provide useful information only about acid-base status, not about oxygenation. If the sample is immediately stored on ice to decrease metabolic activity of cells, it should be analyzed within 2 hours. Exceeding these times may result in an increased  $\text{PaCO}_2$ , decreased pH, decreased glucose, and increased lactate as blood cells continue to metabolize nutrients.

## ☞ BLOOD GAS ASSESSMENT OF RESPIRATORY FUNCTION

A systematic evaluation of blood gas values includes consideration of pH,  $\text{PaO}_2$ , arterial oxygen saturation (usually a calculated value),  $\text{PaCO}_2$ , and bicarbonate concentration. Normal blood gas measurements in the awake horse on room air are shown in Table 7-10.

The  $\text{PaO}_2$  is the partial pressure of oxygen dissolved in arterial blood and is a reflection of pulmonary oxygenating capability.<sup>1-3</sup> Hemoglobin or its binding state do not affect  $\text{PaO}_2$ ; once  $\text{O}_2$  is bound to hemoglobin, it cannot exert any gas pressure. Causes of low  $\text{PaO}_2$  (hypoxemia) are discussed in preceding sections and include decreased inspired oxygen content, hypoventilation, diffusion impairment, right-to-left shunting of blood, and ventilation-perfusion mismatch. The  $\text{PaCO}_2$  is the partial pressure of  $\text{CO}_2$  dissolved in the plasma of arterial blood and is a reflection of the balance between alveolar minute ventilation and metabolic  $\text{CO}_2$  production.<sup>1-3</sup>

The first step in blood gas interpretation for evaluation of respiratory function is to assess ventilatory status. Increased  $\text{PaCO}_2$  indicates hypoventilation, and decreased  $\text{PaCO}_2$  indicates hyperventilation. Hypoventilation and hyperventilation are not clearly correlated with respiratory rate or effort and

TABLE 7-10

### Normal Range of Arterial Blood Gas Values for Adult Horses

Variable	Normal Range
pH	7.4 ± 0.2
PaCO <sub>2</sub>	40 ± 3 mmHg
PaO <sub>2</sub>	94 ± 3 mmHg
Base excess	0 ± 1 mmHg
SpO <sub>2</sub>	98-99%

From Aguilera-Tejero E, Estepa JC, Lopez I, et al: Arterial blood gases and acid-base balance in healthy young and old horses. *Equine Vet J* 30:352, 1998.

cannot be accurately assessed on the basis of physical examination. Hypoventilation may be caused by central apnea (central nervous system disease), obstructive apnea (upper respiratory tract disease), increased dead space ventilation (shunt, decreased cardiac output), reduced lung compliance (low lung volume), respiratory muscle weakness or fatigue, poor control when mechanical ventilation is employed, thoracic pain, or abdominal distention. Hyperventilation, with decreased PaCO<sub>2</sub>, may result from pain, hypoxemia of any cause, pulmonary disease, or neurologic disease.

Oxygenation status is determined by assessment of the PaO<sub>2</sub> in light of the partial pressure of inspired oxygen, which is determined by the proportion of total volume of gas (fraction of inspired oxygen, or FiO<sub>2</sub>) and the atmospheric pressure. Because most equine patients reside at elevations with reasonable atmospheric pressure, the most important variable to consider is FiO<sub>2</sub>. PaO<sub>2</sub> is typically four to five times the FiO<sub>2</sub>. If the patient is breathing room air (FiO<sub>2</sub> = 21%), expected PaO<sub>2</sub> concentration is approximately 80 to 100 mm Hg; if the patient is breathing 100% oxygen (FiO<sub>2</sub> = 100%), expected PaO<sub>2</sub> is approximately 400 to 500 mm Hg.

For many patients it is useful to calculate the alveolar-arteriolar oxygen difference (A-a difference) to determine whether the lungs are functioning properly with regard to gas exchange.<sup>1,2</sup> In the normal horse breathing room air, the PaO<sub>2</sub> should be only slightly less than the alveolar oxygen concentration (P<sub>A</sub>O<sub>2</sub>) with an A-a difference of 5 to 20 mm Hg.

The formula for calculating the A-a difference is as follows:

$$[P_iO_2 - 1.2(P_aCO_2)] - P_aO_2$$

The alveolar oxygen concentration (P<sub>A</sub>) in this equation is reflected as [P<sub>i</sub>O<sub>2</sub> - 1.2(P<sub>a</sub>CO<sub>2</sub>)], indicating that for any given PiO<sub>2</sub>, as PaCO<sub>2</sub> (ventilation) changes, there will be changes in P<sub>A</sub>O<sub>2</sub>. PiO<sub>2</sub> is the partial pressure of inspired oxygen as determined by the equation FiO<sub>2</sub> × (P<sub>b</sub> - 47), where FiO<sub>2</sub> is the proportion of inspired oxygen (0.21 when breathing room air; 1 when breathing 100% oxygen), P<sub>b</sub> is the barometric pressure, and 47 is the water vapor pressure. Barometric pressure may be approximated as average pressure for the altitude (approximately 760 mm Hg at sea level). These calculations can be simplified to approximate an A-a difference for an expected PiO<sub>2</sub> within most reasonable atmospheric pressures:

$$(150 - 1.2 P_aCO_2) - P_aO_2$$

Calculating the A-a difference is particularly helpful in patients that are hypoventilating (increased PaCO<sub>2</sub>) to determine whether hypoxemia (decreased PaO<sub>2</sub>) is due solely to hypoventilation or whether there are concurrent pulmonary factors contributing to hypoxemia. If the A-a difference remains within normal limits in the face of hypoventilation, then the hypoxemia is likely attributable solely to hypoventilation. If the patient is hypoventilating (increased PaCO<sub>2</sub>) and hypoxemic (decreased PaO<sub>2</sub>) with an increased A-a gradient, then the hypoxemia is due to hypoventilation in combination with ventilation-perfusion mismatching, right-to-left shunting, or diffusion impairment.

If decreased PaCO<sub>2</sub> (hyperventilation) is present in combination with decreased PaO<sub>2</sub>, oxygen should be administered both as treatment and as a diagnostic aid. If the administration of oxygen fails to increase the PaO<sub>2</sub> about 100 mm Hg, right-to-left shunting should be suspected and appropriate diagnostic testing employed. Improvement of PaO<sub>2</sub> above 100 mmHg with oxygen administration suggests ventilation-perfusion mismatch or a diffusion disturbance, and additional diagnostic testing is employed. If hyperventilation is present and PaO<sub>2</sub> is normal, pH and bicarbonate should be carefully evaluated because the hyperventilation may be occurring in an attempt to maintain normal pH in the face of metabolic alkalosis, as discussed later in this chapter.

Arterial blood gas analysis will also provide a value for oxygen saturation (SaO<sub>2</sub>) reported as a percentage. This value reflects the proportion of all heme-binding sites saturated with O<sub>2</sub>. Its value is determined by PaO<sub>2</sub> and other factors that alter the oxygen hemoglobin dissociation curve. Because total blood oxygen content (total of dissolved and hemoglobin-bound oxygen) depends largely on the total quantity of hemoglobin that is present, it is possible to have normal PaO<sub>2</sub> and normal SaO<sub>2</sub> despite profound deficiencies in total blood oxygen content (e.g., in the profoundly anemic patient). One should not assume that the total oxygen content is normal because the PaO<sub>2</sub> and oxygen saturation are normal.

Venous blood gas analysis has limited usefulness for evaluation of respiratory tract disease. However, PvO<sub>2</sub> may provide some information about tissue oxygenation in horses. If values fall between 28 and 35 mm Hg, there is likely limited oxygen reserve in the tissues. Values below 27 mm Hg often indicate the presence of anaerobic metabolism. A PvO<sub>2</sub> value greater than 60 mm Hg in an animal breathing room air suggests the possibility of decreased oxygen delivery to tissues, which may occur in some patients with poor peripheral perfusion caused by shock or sepsis.

## ☞ PULSE OXIMETRY

A useful adjunct to arterial blood gas analysis is pulse oximetry, a technique that relies on reflection of different wavelengths of light to detect and differentiate oxygenated and unoxygenated hemoglobin; the measurement is reported as SpO<sub>2</sub>. Pulse oximeters provide an estimate of hemoglobin saturation with oxygen, which is related to the PaO<sub>2</sub>, as described by the oxygen-hemoglobin dissociation curve. Generally, oxygen saturation greater than 91% is considered indicative of an arterial oxygen level within physiologically normal limits.<sup>2,5</sup> When hemoglobin saturation exceeds 90%, the oxygen-hemoglobin dissociation curve is relatively flat, and large changes in PaO<sub>2</sub> are associated with small changes in hemoglobin saturation. Therefore pulse oximetry has a

limited sensitivity for determining changes in pulmonary gas exchange at ranges above 90% hemoglobin saturation. As saturation falls below 91%, the curve sharply decreases, representing increasingly severe reductions in arterial oxygen levels.<sup>2,5</sup>

Pulse oximeters measure hemoglobin saturation by sensing the difference between light absorption at two different frequencies: red and infrared. The measurements are obtained by attaching a probe containing the light emitter and detector to a suitable site, such as a nasal septum, white lip, or vulva. Reports have indicated that below 90% oxygen saturation, pulse oximetry can either overestimate or underestimate SaO<sub>2</sub> in horses.<sup>6</sup> The accuracy is influenced by several factors, including dark-pigmented skin, hypoperfusion at the measurement site, anemia, hypothermia, and motion. These limitations become more problematic in a conscious, standing horse. Artificially increased results may result because the machine cannot differentiate oxyhemoglobin from carboxyhemoglobin and methemoglobin. Because of the limitations of pulse oximetry, response to treatment in a patient with critical hypoxemia is best monitored with arterial blood gas analysis.

## ☞ ASSESSMENT OF ACID-BASE STATUS

An evaluation of blood gas results is not complete without assessment of the patient's acid-base status. The body must maintain blood pH within a fairly narrow range for metabolic processes to function smoothly. Because of this, the body has developed a variety of mechanisms to control the amount of acid present in the blood: (1) the chemical buffers system, the most important of which is bicarbonate; (2) respiratory elimination of CO<sub>2</sub> generated by cellular metabolism; and (3) renal excretion of excess acid or alkali.

The pH of blood is a logarithmic expression of hydrogen ion concentration that can be calculated using the Henderson-Hasselbalch equation:

$$\text{pH} = \text{pK}_a + \log \left[ \frac{[\text{HCO}_3^-]}{(\text{PaCO}_2 \times 0.03)} \right]$$

This equation indicates that the pH of blood is determined by the ratio of bicarbonate to arterial CO<sub>2</sub>. If the pH is to remain the same for any given change in bicarbonate, the P<sub>a</sub>CO<sub>2</sub> needs to change in the same direction, and vice versa. This relationship between CO<sub>2</sub>, water, and bicarbonate is reflected in the carbonic acid equilibrium equation:

There are four primary acid-base disturbances that may occur in a patient: respiratory acidosis (hypoventilation or increased P<sub>a</sub>CO<sub>2</sub>), respiratory alkalosis (hyperventilation or decreased P<sub>a</sub>CO<sub>2</sub>), metabolic acidosis (decreased HCO<sub>3</sub><sup>-</sup>), and metabolic alkalosis (increased HCO<sub>3</sub><sup>-</sup>). These may exist as sole disorders or in combination (mixed disorders). In a simplified approach to blood gas analysis of acid-base status, the clinician first determines whether the blood pH is normal (approximately 7.40) or whether acidemia or alkalemia exist. If the blood pH is decreased (acidemia), the primary acid-base abnormality present in that patient is likely to be either respiratory acidosis or metabolic acidosis. If the blood pH is increased (alkalemia), the primary acid-base abnormality is probably respiratory alkalosis or metabolic alkalosis.

Differential diagnoses for primary hyperventilation and hypoventilation are discussed in preceding sections. It is clear that these disorders can significantly affect blood pH, and therapies to improve ventilation or treat underlying disorders will usually resolve these problems.

Metabolic acidosis is usually recognized as a decreased blood HCO<sub>3</sub><sup>-</sup> concentration. It results from addition of a strong acid to body fluids (most frequently lactic acid) or from loss of bicarbonate through the kidneys or gastrointestinal tract. When this occurs, the body will often compensate by increasing ventilation to eliminate CO<sub>2</sub>. The kidneys will also attempt to compensate by excreting excess acid and conserving HCO<sub>3</sub><sup>-</sup>. It is important to note that lactic acid accumulation is the most common cause of metabolic acidosis in horses. This is often secondary to dehydration and decreased tissue perfusion. In most cases of mild to moderate metabolic acidosis, re-establishment of normal circulating blood volume will enhance clearance of lactic acid from the blood and decrease production of new lactic acid. Lactic acid is cleared from the blood by the liver. As the liver metabolizes lactate, it produces bicarbonate. As a result, metabolic acidosis secondary to lactic acidosis resulting from poor tissue perfusion will usually respond promptly to rehydration of the patient with replacement fluid therapy.

Metabolic alkalosis is associated with an increased blood HCO<sub>3</sub><sup>-</sup> concentration and often a reciprocal decrease in plasma Cl<sup>-</sup> concentration. The most common causes of metabolic alkalosis in horses are high volume nasogastric reflux, overzealous administration of chloride-wasting diuretics, or exhausted horse syndrome (with excessive Cl<sup>-</sup> losses in sweat). These horses are treated with restoration of extracellular volume, including replacement of Cl<sup>-</sup> and K<sup>+</sup> deficits.

## ☞ APPROACH TO THE PATIENT WITH RESPIRATORY DISTRESS

Respiratory dysfunction may be the primary reason that a veterinarian is consulted, or it may occur while the horse is hospitalized for treatment of another problem. *Respiratory distress* is defined as an inappropriate degree of breathing effort, based on an assessment of respiratory rate, rhythm, and character. Causes of respiratory distress may be respiratory or nonrespiratory in origin, and the physiology of this condition is discussed in detail in Chapter 3.

Upper respiratory disorders that result in respiratory distress usually do so because of respiratory tract obstruction; [Box 7-6](#) contains a partial list of differential diagnoses. Complete upper airway obstruction is a true emergency, insofar as the negative intrathoracic pressures resulting from inspiratory efforts against a closed airway lead to upper airway collapse and the inability to inspire or to pulmonary edema, which can be fatal even if the initial airway obstruction is resolved.<sup>7</sup> Diagnosis is usually based on physical examination and endoscopy of the upper airway. Most affected horses require an emergency tracheotomy. Additional therapies to consider are antimicrobial agents and antiinflammatory agents, including steroids.

Lower airway disease that may be associated with respiratory distress are shown in [Box 7-7](#). Diagnosis is based on a thorough physical examination, thoracic ultrasound or radiographs, transtracheal aspirate, and arterial blood gas analysis. Treatment depends on the nature of the primary disorder and may include antimicrobial agents, antiinflammatory agents,

- Acute respiratory distress syndrome
- Silicosis
- Smoke inhalation

**Extrapulmonary Disorders**

- Pleural effusion
- Intrathoracic hemorrhage
- Pneumothorax

and oxygen administration. Diseases involving the pleural space may respond to thoracic drainage or, in cases of a pneumothorax, placement of a drain dorsally. Diagnosis and treatment of specific disorders are described in Chapter 9.

Nonpulmonary causes of respiratory distress include anemia, compensation for metabolic acidosis, pain, anxiety, and hyperthermia. Diagnosis of nonpulmonary causes of respiratory distress must start with a thorough history, physical examination, and bloodwork. After the initial evaluation, further diagnostic testing might include endoscopy, ultrasound, and radiographs.

**☞ OXYGEN THERAPY IN ADULT HORSES**

Administration of oxygen by nasal cannula is the most common means of oxygen supplementation in adult horses. Initial studies of the efficacy of this form of oxygen administration in the adult horse produced equivocal results. However, a more recent study revealed that use of a nasal cannula to deliver oxygen increased both the fractional inspired oxygen concentration and  $P_aO_2$  in control horses and horses with moderate to severe recurrent airway obstruction (RAO).<sup>8</sup> The nasal cannula is passed into the nasopharynx to the level of the medial canthus of the eye. At a flow rate of 30 L/min,  $P_aO_2$  increased to 319 mm Hg in control horses and 264 mm Hg in RAO-affected horses.<sup>8</sup> This study indicated that flow rates of 10 to 20 L/min were well tolerated but higher rates produced irritation.<sup>8</sup> Thus if higher rates are needed, delivery should be through two cannulas. If a tracheotomy is present, oxygen can be delivered directly into the tracheotomy tube. With either method of administration, serial arterial blood gas measurements will determine the response to treatment.

**☞ INHALATION THERAPY**

Inhalation therapy is an available method of treatment for horses with respiratory disorders, especially lower airway disease. Bronchodilators and corticosteroids administered with metered-dose inhalers are now common treatment modalities for horses with recurrent airway obstruction.<sup>9</sup> Horses with bacterial pneumonia or pleuropneumonia may benefit from aerosol administration of antimicrobial agents because the medication is delivered directly to the lungs. Additional advantages to aerosol administration include a rapid onset of action, decrease in the dose administered, and reduction in the incidence of adverse reactions. Proper administration requires an ultrasonic nebulizer. McKenzie and Murray reported that aerosol administration of gentamicin resulted in gentamicin levels in bronchial fluid that were higher than those observed after intravenous administration of the drug.<sup>10</sup> Thus inhalation therapy provides a good adjunctive therapy for the critical care patient.

**SUPPORT OF GASTROINTESTINAL FUNCTION**

*Bonnie Barr*

The gastrointestinal tract is the portal through which nutritive substances, vitamins, minerals, and fluids enter the body. Normal function of the gastrointestinal tract includes appropriate motility, absorption, and digestion so that food can be used for energy. Movement of the food through the gastrointestinal tract involves a complex interaction among the nervous system, the endocrine system, and the musculature of the gastrointestinal tract. The gastrointestinal tract has its own intrinsic enteric nervous system involved in motor control and intestinal secretions. In addition, the intestine receives extrinsic innervation from the autonomic nervous system. Digestion of food involves a large number of digestive enzymes that are found in glands throughout the gastrointestinal tract. The products of digestion are absorbed across the mucosa into the circulatory system or the lymphatic system.

The gastrointestinal mucosa forms a barrier between the body and a luminal environment, which not only contains nutrients but also is laden with potentially hostile microorganisms and toxins. Thus normal function also requires that nutrients be transported across the epithelium while excluding passage of harmful molecules and organisms.

Gastrointestinal complications are common in the critically ill horse and occasionally occur in postoperative elective patients. Those that are more at risk to develop gastrointestinal complications include horses that are septic or endotoxemic or suffer from poor perfusion. Many of the common complications have already been discussed, including ileus, endotoxemia, tympany, diarrhea, and gastric ulceration. Inappetence is probably the most common complication in the critical equine patient. Horses refuse to eat for many reasons, including physical factors such as pain, infection, and an inability to eat and psychological factors such as stress. The regulation of appetite is an immensely complex process involving the gastrointestinal tract, central and autonomic nervous systems, and many hormones. The hypothalamus is the main regulatory organ for appetite depending on the interaction between the feeding center and satiety center. Neurosubstances involved in regulation of appetite include neuropeptide Y, melanocyte-concentrating hormone, catecholamines, and leptin.<sup>1</sup> Gastrointestinal hormones involved in appetite regulation include glucagon, somatostatin, and cholecystokinin (CCK).<sup>1</sup> Loss of appetite can be caused by a variety of conditions and diseases. Some of the conditions are temporary and reversible, such as loss of appetite from the effects of medication. Some of the conditions are more serious, such as trauma to the head. Systemic mediators, such as TNF- $\alpha$ , IL-1 and IL-6, and corticotropin-releasing hormone have a negative influence on appetite. Many of these mediators are present in the critically ill patient because of inflammation, endotoxemia, and sepsis.

Methods used to recognize gastrointestinal dysfunction in the critically ill horse include changes in the physical examination, abdominal ultrasonography, and clinical pathologic evaluation. Serial physical examinations will identify changes in vital parameters, mentation, behavior, fecal production, and abdominal size. Some of the changes may not be specific for the gastrointestinal tract, but when combined with more specific changes, an abnormality of gastrointestinal function must be considered. An increase in heart rate can indicate pain, dehydration, endotoxemia, and decreased venous return. Increases in respiratory rate are not specific for gastrointestinal disease but do indicate that a systemic change has occurred in the horse. A decreasing temperature with rapid, weak pulse indicates the development of shock, which may be due to endotoxemia. An increase in temperature with additional signs of gastrointestinal dysfunction suggests colitis or acute peritonitis. Increased borborygmi may indicate a simple obstruction or hyperperistalsis associated with enterocolitis. A decrease or absence of borborygmi is associated with inflammation and ischemia, which may be due to postoperative ileus, peritonitis, or enterocolitis. Decreased or sudden changes in manure production or consistency indicate deterioration of the gastrointestinal motility or function. A normal 500-kg horse passes approximately 5 to 7 piles of manure per day, although one that is inappetent will pass less. Administering mineral oil and noting its presence in the feces can approximate transit time through the gastrointestinal tract. Urine output may be decreased if fluids are being sequestered to the gastrointestinal tract. Transabdominal ultrasound can be used to evaluate the

anatomic location, contents, wall thickness, and motility of various regions of the intestine. In evaluating the small intestine, the clinician will see organized waves of motility when observing the intestinal walls and contents over a few seconds. Amotile bowel is observed with strangulating lesions, postoperative ileus, and enteritis. With mechanical lesions the small intestine is amotile with ingesta settled ventrally in the lumen of the intestine. The small intestinal wall may be thickened in patients that have enteritis, peritonitis, inflammatory bowel disease, and strangulating lesions. With colitis the large intestine may contain fluid ingesta, and the wall may be thickened. Gastrointestinal disorders may be accompanied by loss of integrity to the intestinal barrier, resulting in changes in the peritoneum and peritoneal cavity. The presence of peritoneal fluid, the echogenicity of the fluid, and the quantity of fluid can be assessed by transabdominal ultrasound. The presence of peritoneal fluid warrants abdominocentesis and fluid analysis to determine if the fluid is a transudate or exudate.

Hematologic alterations associated with gastrointestinal dysfunction are often nonspecific, reflecting systemic response to inflammation, endotoxemia, or sepsis. During the early stages of endotoxemia, an increase in the circulating concentrations of inflammatory mediators, epinephrine, and cortisol produces changes in the leukogram. The characteristic change includes leukopenia with neutropenia and a left shift, toxic changes in the neutrophilic cytoplasm, and lymphopenia. In later stages of disease a neutrophilia may be present because of enhanced myeloid proliferation of the bone marrow. Major fluid shifts occur when fluid accumulates in the small intestine, colon, or peritoneal cavity. These fluid shifts occur at the expense of the plasma volume, resulting in hemoconcentration and decreased circulating volume. Endotoxemia can cause redistribution of plasma volume into the splanchnic capillary beds and hypersecretion into the bowel lumen or peritoneal cavity. Increased capillary permeability leads to loss of albumin and water into the extravascular space, further depleting the plasma volume and intravascular oncotic pressure. Acute protein loss commonly results from damaged bowel in cases of enterocolitis and enteritis. Strangulating lesions can result in mucosal necrosis and leakage of plasma proteins into the lumen. Hypoproteinemia also occurs with inflammatory bowel disease because of inflammation of the bowel and the inability to absorb necessary protein owing to inappetence or inflammation of the bowel. Hyperfibrinogenemia occurs with generalized gastrointestinal inflammation or localized inflammation such as peritonitis or salmonellosis. Electrolyte imbalances are due to sequestration of sodium-rich fluids, anorexia, and changes in circulating volume. Serum biochemical changes result from dehydration, poor perfusion, and hypoxemia.

Severe illness or injury has been associated with hypermetabolism characterized by a pronounced catabolic state that is compounded by patients that are unable or unwilling to eat. Fatty acids are the primary source of energy in fully adaptive simple starvation, but in severe illness activation of a complex neurohormonal response results in utilization of body protein. This response is caused by inflammatory cytokines, such as TNF and ILs, which augment the effects of catecholamines and glucocorticoids associated with stress.<sup>2,3</sup> Inflammatory mediators increase the metabolic rate, contributing to the inefficient use of oxygen and calories, and may also directly dictate the body's normal response to starvation. The increased need for protein, specifically amino acids,

as an alternative energy source compromises lean muscle mass and normal organ structure. Clinically and experimentally, the effects of negative energy balance have been well documented. Negative energy balance depletes the body of structural and functional protein, thereby impairing wound healing, immune function, and other normal organ functions. Negative energy balance leads to deficiencies in nonspecific and specific immune functions; gut mucosal atrophy; loss of visceral and muscular protein with consequent weakness and abnormal function; decreases in albumin, fibrinogen, complement proteins, and globulin; and poor wound healing. In addition, negative energy balance leads to depletion of glycogen stores; gastrointestinal ileus; disruption of the gastrointestinal barrier; and decreases in high turnover cell populations such as leukocytes, gastrointestinal mucosal cells, and fibroblasts. Inadequate nutrition sets the stage for serious complications resulting in sepsis, multiple organ failure, and death. In human critical care nutritional support has become a routine part of the care of the critically ill patient. Numerous reports in human-medicine literature document that nutritional support, especially early nutritional support, hastens recovery, diminishes some of the complications of the critically ill, and decreases length of stay.<sup>2-4</sup> The goal of aggressive early nutrition is to maintain host defenses by supporting the hypermetabolism and preserving lean body mass.

Assessment of the nutritional status of the critically ill equine patient at presentation and at regular intervals during hospitalization is necessary to identify patients that would benefit from early nutritional support. Horses with adequate nutritional status may not require nutritional support as early as underweight or obese horses. In addition, certain disease states, such as those associated with a severely compromised gastrointestinal tract and severe central nervous system disorders, may benefit from immediate nutritional support. Obese horses are prone to the development of hyperlipidemia when fasted after only a short period. Horses in poor body condition are especially vulnerable to impairment of immune function, poor tissue healing, and additional weight loss if deprived of nutrients for even a short period of time. Although horses in optimal body condition can tolerate periods of fasting, nutritional support may decrease complications and improve outcome.

In human critical care medicine, body composition is estimated and monitored by midarm circumference (i.e., muscle) and skin-fold thickness (i.e., fat); unfortunately, methods for monitoring nutritional status in the equine patient are not as sophisticated. The most practical methods in the equine are body weight measurement and body condition score. A body weight measurement, preferably on a walk-on scale, should be performed at admission and at regular intervals during hospitalization. If a walk-on scale is not available, a weight tape used to measure girth circumference can provide a reasonable estimate of body weight. Body condition score (BCS) is a subjective semiquantitative method of evaluating body fat and muscle mass by visual inspection and palpation of certain areas of the body. In 1983 Henneke developed the most commonly used BCS for horses. This score is positively correlated to body fat but not to weight or height. A total of nine scores are assigned: 1 is poor (extreme emaciation), and 9 is extremely fat.<sup>5</sup> An ideal BCS is 4 to 6.<sup>5</sup> The appropriate assessment and monitoring of nutritional status would include both the body weight and BCS.

The nutritional requirements of a critically ill horse have not been determined. Energy requirements can be calculated

on the basis of size, age, condition, and metabolic stress. The daily energy expenditure is expressed as the basal energy requirement, which is the amount of energy used for maintenance of body function in a resting state in a thermoneutral environment. In small animal and human medicine, the basal energy requirement is often doubled for certain patients who have a higher caloric need, such as burn patients and multiple trauma patients. Maintenance requirements for healthy adult horses are estimated to be 35 to 40 kcal/kg/day.<sup>6,7</sup>

Enteral feeding is preferred if the gastrointestinal tract is completely or even partially functional. There are numerous advantages of enteral feeding, making it superior to parenteral feeding. Early enteral feeding is the current trend in human critical care patients because the nutrients are directly delivered to the gastric mucosa, preserving mucosal integrity and improving gastrointestinal function.<sup>2-4</sup> Enteral feeding is more physiologic, with nutrients being digested and absorbed by the gut and metabolized by the liver. Because enteral feeding stimulates insulin secretion, hyperglycemia is a less likely complication. Without local nutrients the gastrointestinal mucosa becomes leaky, and enterocytes are unable to maintain normal intercellular borders and immune function, thus creating a greater risk of secondary sepsis from translocation of bacteria and toxins. Enteral feeding also decreases the risk of intravenous catheter complications and reduces cost. In the horse voluntary intake is preferable to forced nasogastric feeding, but sometimes the actual caloric intake is difficult to estimate with voluntary intake. This problem can be overcome by weighing the feed and hay offered and the feed remaining in the stall, which allows for calculation of the calories ingested. If consumption is below 75% of the maintenance requirements for 48 hours or if the horse is anorexic or dysphagic, feeding by nasogastric tube is required.<sup>7,8</sup> The best enteral diet is a slurry of complete pelleted feed, which is inexpensive and well balanced for the horse and contains fiber to maintain gastrointestinal activity and growth. Vegetable oil can be added to increase the caloric density. (Chapter 5 contains appropriate enteral diet regimens). Complications of indwelling and repeated passage of nasogastric tubes include chronic irritation and trauma to the pharyngeal and esophageal region. An indwelling esophagostomy feeding tube is a good option if the horse is dysphagic and unable to swallow a nasogastric tube or if prolonged feeding is expected. Liquid diets designed for people have been fed to horses, although the efficacy of these diets is unknown. These diets offer the advantage of easy administration by a small-diameter nasogastric tube and administration of a known quantity of nutrients. Reported adverse effects of the commercial liquid diets include diarrhea and laminitis.<sup>7,8</sup> It is recommended that enteral feeding begin gradually, with a goal of reaching maintenance requirements over 5 to 7 days.<sup>7,8</sup> As with any diet, rapid changes may result in colic or diarrhea.

Parenteral nutrition is indicated for critical patients that cannot tolerate enteral feeding because of gastrointestinal dysfunction. Other candidates for parenteral nutrition include aged animals off their feed, pregnant or lactating mares off their feed, and horses with a body score off 3 or less.<sup>9-11</sup> The goal of parenteral nutrition is to provide a portion of daily nutritional requirements intravenously. Parenteral nutrition is a combination of nutrients designed to meet the energy requirements of the horses. Partial parenteral nutrition can be provided by supplementation with dextrose alone or with amino acids. Total parenteral nutrition includes dextrose,

amino acids, and lipids. Carbohydrates and fats are used for energy requirements, and protein is used for protein synthesis and reduction of endogenous protein breakdown. Horses at risk for hyperlipidemia or those in poor body condition may benefit from the early addition of dextrose (2.5% to 5%) to crystalloid fluids. Dextrose supplementation may be beneficial even in healthy horses undergoing elective surgery that require prolonged withholding of feed.

Carbohydrates are the primary source of energy and are essential nutrients for certain tissues in healthy patients. Glucose is necessary for the body to oxidize free fatty acids by way of the citric acid cycle. In parenteral nutrition glucose is provided as a dextrose solution. Hyperglycemia is the most common complication reported in horses administered parenteral nutrition. A slow introduction of the fluid should allow an appropriate endogenous insulin response to occur, thus minimizing or eliminating the onset of hyperglycemia. Blood glucose levels should be monitored every 4 to 6 hours because if the renal threshold of glucose (180 to 220 mg/dl) is exceeded, glucosuria and osmotic diuresis can occur. A sudden onset of hyperglycemia in a patient that had been tolerating the parenteral nutrition can indicate the presence of complications, such as infection or sepsis. Protein is provided as an amino acid solution. Healthy adult horses require 0.7 to 1.5 g/kg/d of protein.<sup>9,10</sup> This amount is likely to increase in a critically ill horse, although the exact requirement is unknown. Supplementation of essential branched-chained amino acids (valine, leucine, and isoleucine) decreases trauma- and sepsis-induced muscle catabolism and improves nitrogen balance. Lipid emulsions are the most calorically dense nutrient and are a source of essential fatty acids. Fatty acids are required for several physiologic functions, including prostaglandin and leukotriene synthesis; surfactant production; wound healing; and the integrity of skin, hair, and nerves. Other components added to parenteral nutrition include vitamins (A, D, and E) and minerals. B-complex vitamins should be supplemented because they are required for carbohydrate metabolism. Macrominerals such as calcium and magnesium are best added to crystalloid fluids because divalent cations destabilize in lipids.

In choosing the amount of each component to be included in the solution, the practitioner must consider the energy requirement of the horse, the changes in nutrient utilization that accompany the specific disease, and the proper blend of nutrients to facilitate utilization. Dextrose, protein, and lipids can all be utilized as energy sources. The caloric density is as follows: dextrose provides 3.4 kcal/g, protein 4 kcal/g, and lipids 9 kcal/g. It is best to provide adequate nonprotein nitrogen as an energy source to permit efficient use of endogenous and exogenous proteins. A mixed-fuel system with 40% to 60% of the non-nitrogen calories as dextrose and 50% to 60% as lipid enables proteins to be utilized efficiently.<sup>9-11</sup> Chapter 5 contains a discussion of appropriate parenteral nutrition regimes.

Complications with parenteral nutrition include thrombophlebitis, hyperglycemia, hyperlipidemia, and hypokalemia. Patients with hyperlipidemia, hyperlipemia, and severe liver disease may not be able to tolerate lipids in the parenteral nutrition. Horses with severe endotoxemia or SIRS may also be lipid intolerant. Metabolic clearance of lipids involves the hydrolysis of triglycerides by lipoprotein lipase, an enzyme present in capillary endothelial cells. Bacterial endotoxins may induce inflammatory cells to release mediators that suppress lipoprotein lipase activity. In either of these cases, a diluted mixture of dextrose and amino acids (1:1) can be administered.<sup>11</sup>

Hyperglycemia can be prevented by routine monitoring of blood glucose levels. In addition, slow and gradual introduction of parenteral nutrition might establish better tolerance in the patient. If hyperglycemia persists, endogenous insulin therapy should be considered. Electrolyte abnormalities, specifically hypokalemia, can result from decreased intake of food and the delivery of a high concentration of dextrose, which drives the potassium into the cell.

## SUPPORT OF RENAL FUNCTION

*Bryan Waldrige*

Critical patients frequently are receiving multiple medications that may adversely affect renal function, such as nonsteroidal antiinflammatory drugs (NSAIDs), polymyxin B, and aminoglycosides. If the patient appears dehydrated, then renal function should be assessed before administration of potentially nephrotoxic drugs. Once the fluid deficit is corrected or clinicopathologic indices of renal function are within normal ranges, then treatment can proceed more safely. Patients that are at risk for dehydration or are receiving multiple drugs that can have adverse renal effects are probably best managed with at least maintenance rates (60 to 70 ml/kg/day) of intravenous fluids to prevent dehydration and support urine production. Specific treatment and diagnosis of acute renal failure is discussed in greater detail elsewhere in this text.

### NONSTEROIDAL ANTIINFLAMMATORY DRUGS

The dehydrated horse depends on production of prostaglandins to maintain renal perfusion and glomerular filtration. Cyclooxygenase 1 (COX-1) is a constitutive enzyme that produces vasodilatory prostaglandins (PGE<sub>2</sub> and PGI<sub>2</sub>) in response to decreased renal blood flow.<sup>1</sup> With the exception of firocoxib, other NSAIDs used in horses are not selective for COX-2, which is induced by inflammatory stimuli.<sup>1</sup> Therefore most NSAIDs inhibit activity of both enzymes to some degree, which blocks renal production of prostaglandins and prevents the compensatory increase in renal blood flow during dehydration. The mechanism of action and toxicity for NSAIDs is discussed in detail in Chapter 4.

### AMINOGLYCOSIDE ANTIBIOTICS

Aminoglycoside antibiotics (e.g., gentamicin, amikacin, polymyxin B) are freely filtered at the glomerulus and excreted into the urine.<sup>2</sup> Renal proximal tubular cells actively take up aminoglycosides in the filtrate. Acute tubular necrosis and renal failure can occur with aminoglycoside therapy as a result of tubular cell organelle damage and blockage of tubules with necrotic debris.<sup>2</sup> These mechanisms of toxicity are discussed in Chapter 4.

### PIGMENT NEPHROPATHY

Pigment nephropathy is relatively uncommon but can occur in horses with rhabdomyolysis (myoglobin) or intravascular hemolysis (hemoglobin). When either of these pigments

is excreted into the urine, it may polymerize in the distal tubules and physically obstruct them. Additionally, myoglobin and hemoglobin induce renal vasoconstriction and are iron-containing pigments that may lead to hydroxyl radical production and further tubular damage.

## ☞ METHODS TO RECOGNIZE RENAL PROBLEMS

Assessment of renal function is easily overlooked in critical care patients. It is advisable to measure serum blood urea nitrogen (BUN) and creatinine concentrations at least every 48 hours to assess glomerular filtration and renal function. Regular measurement of BUN and creatinine concentrations and assessment of results in light of physical examination findings (e.g., evidence of dehydration) and results of urinalysis are the most readily available methods to monitor renal function in equine critical care patients. Increases in serum creatinine concentration as small as 0.3 mg/dl can be significant.<sup>3</sup>

Dilute urine (specific gravity  $\leq 1.012$ ) concurrent with azotemia generally indicates decreased renal function. Urinary indicators of tubular damage include granular casts in urine, an increased urinary  $\gamma$ -glutamyltransferase-to-creatinine ratio ( $>25$ ), and increased fractional excretion of electrolytes such as sodium and chloride.<sup>3</sup> Increased protein in urine ( $>1+$  on dipstick test) can occur with glomerulonephritis; however, sulfosalicylic acid precipitation is a more specific test for urinary protein. Laboratory assessment of renal function is discussed in detail in Chapter 19.

Monitoring for appropriate urination, especially in response to fluid therapy, is essential. Patients with anuria or oliguria after appropriate intravenous fluid volume replacement are at risk for pulmonary and peripheral edema. If fluid therapy to replace deficits and meet maintenance requirements does not stimulate urination, then the administration of diuretics or vasopressor agents should be considered, as outlined in Chapter 19.

## ☞ TREATMENT GOALS AND MEASURING EFFECTIVENESS

Many cases of acute renal failure are reversible and will respond to fluid therapy and supportive care. Replacement of fluid deficits and administration of maintenance fluids should result in diuresis and gradual resolution of azotemia. Fluid rates can be increased to 1.5 to 2 times the maintenance rate to further stimulate diuresis and urination. At these fluid rates serum BUN and creatinine concentrations should generally decrease by approximately 50% within 24 hours.

If fluid therapy does not produce the expected increase in urine output, then diuretics (furosemide, 1 mg/kg, administered intravenously) can be administered. Urination should be expected within 30 minutes of furosemide administration. Diuretics may be most indicated in cases of pigmentary nephropathy to induce diuresis and physically clear clogged tubules of polymerized hemoglobin or myoglobin. However, it is imperative that adequate volume replacement occur before administration of diuretic agents; otherwise, the resultant diuresis will contribute to potentially severe dehydration and diminished peripheral perfusion and exacerbate renal damage.

Hypotension can be an unrecognized cause of decreased urine production. MAP should be maintained above 70 mm

Hg to preserve tissue perfusion, glomerular filtration, and urine production.<sup>4</sup> Low-dose vasopressor therapy (dopamine at 2 to 5  $\mu\text{g}/\text{kg}/\text{min}$ , constant-rate infusion; dobutamine up to 5  $\mu\text{g}/\text{kg}/\text{min}$ , constant-rate infusion) will dilate renal capillaries without significant cardiac or systemic vascular effects.<sup>3,4</sup> Blood pressure should be measured in patients at risk for hypotension and those that fail to produce urine despite appropriate therapy. CVP may be monitored to assess the potential for fluid overload and edema formation in the horse with oliguric or anuric renal failure.

Aminoglycoside toxicity is best prevented by ensuring appropriate dosing regimens and limiting the use of aminoglycosides to hydrated animals without preexisting renal dysfunction.<sup>4</sup> Administering aminoglycoside antibiotics every 24 hours decreases the amount of time that renal tubular cells are exposed to higher concentrations of aminoglycosides. Therapeutic drug monitoring allows for detection of elevated trough (usually 24 hours after the previous dose) concentrations, which are more likely to cause toxicity than elevated peak concentrations. The dose of aminoglycoside may need to be reduced or the treatment interval prolonged if trough concentrations are elevated. High trough concentrations after an appropriate dose can indicate decreased glomerular filtration or glomerulonephritis.<sup>2</sup>

Once it appears that patients have responded well to therapy for acute renal failure, they can be gradually weaned from intravenous fluids and allowed to maintain hydration by voluntary water intake. A few days after discontinuing intravenous fluids, measurement of serum BUN and creatinine concentrations, urine specific gravity, and urinalysis can be repeated to determine if renal function has returned to normal. Some patients may have persistently elevated renal indices; however, this cannot be determined without repeated serum chemistry examinations.

## SUPPORT OF NEUROLOGIC FUNCTION

*Yvette S. Nout*

Any horse with neurologic disease can present as an emergency. Neurologic disorders that have developed acutely warrant immediate veterinary attention, but deterioration of existing neurologic conditions may also require emergency veterinary attention. In particular, disorders that result in abnormal behavior or severe ataxia require emergency care. It is sometimes difficult to differentiate neurologic from non-neurologic disease because some conditions appear to be induced by a neurologic disorder when in fact they are not. Examples are recumbency caused by cardiovascular or respiratory diseases and gait abnormalities caused by musculoskeletal diseases such as bone fractures, rhabdomyolysis, or laminitis.

Emergency neurologic disease may arise from the central nervous system or peripheral nervous system, or they may be multifocal. The most commonly seen emergency neurologic conditions with a neuroanatomic location cranial to the foramen magnum are head injury, (myelo)encephalitis, and vestibular disease. Abnormal behavior caused by hepatic encephalopathy, seizure activity, neoplasia, abscessation, or toxicosis can also have an acute onset and therefore present as an emergency. Disorders that stem from the central nervous

system distal to the foramen magnum include cervical vertebral stenotic myelopathy, equine degenerative myelopathy, trauma, and neoplasia. Except for spinal cord trauma, it is especially this group of disorders that typically would not manifest as emergencies because of the gradual onset of clinical signs. However, if onset is acute or clinical signs deteriorate, emergency care is required. Multifocal neurologic diseases such as equine protozoal myeloencephalitis, equine motor neuron disease, and botulism all can have acute severe onsets of clinical signs or progress to a degree that requires immediate veterinary attention. Peripheral nerve damage in horses is not uncommon and most often involves the suprascapular, radial, ulnar, femoral, and selected cranial nerves. Occasionally, the brachial plexus can be injured after a collision accident. Often, the cause of the nerve injury is traumatic, and horses should be examined carefully (e.g., for bone fractures).

Abnormal neurologic function can cause secondary excitement, agitation, and stress in the patient and worry for the owner or caretaker. When treating a neurologic emergency, the practitioner must first ensure protection and care of the people involved with the patient and limit further (self-inflicted) damage to the patient by protection and administration of drugs.

## DIAGNOSTICS

Until a diagnosis is made, many emergency neurologic patients should be treated as rabies suspects. This requires that the number of people involved with the animal should be minimized and that all involved should be wearing protective clothing such as gloves and coveralls. Performing a thorough neurologic examination is critical. To come to a diagnosis, the practitioner performs a careful neurologic examination followed by appropriate ancillary diagnostics. Ancillary diagnostics used in emergency situations typically include hematology and serum chemistries, radiographs, and potentially cerebrospinal fluid analysis. When available, these patients may require further diagnostic tests such as computed tomography, magnetic resonance imaging, electrodiagnostics, or a combination thereof.

A neuroanatomic localization of the disease should be made after a thorough examination,<sup>1,2</sup> as described in Chapter 12. The neuroanatomical localization can be simplified by determining whether there is central nervous system, peripheral nerve, or multifocal nerve disease. In the case of central nervous system disease, it is helpful to determine whether the lesion is localized cranial or caudal to the foramen magnum (i.e., whether there is brain involvement). If there is brain involvement, it may be possible to further differentiate among cerebral, cerebellar, vestibular, or brainstem disease. If disease is localized caudal to the foramen magnum, the disease may be located in the cervical spinal cord or in the spinal cord caudal to T2.

Under emergency conditions the most important goal is stabilization of the patient before thorough neurologic evaluation. Figure 7-3 is a flowchart for management of the horse with an acute neurologic condition. Ideally, the practitioner examines the horse, diagnoses a disease, and treats the patient. Often, however, this is not so straightforward, and sedation or stabilization of the patient is required before continuing the evaluation. Also, it is likely that a final diagnosis cannot be reached on an emergency basis, which leaves the veterinarian to then select a treatment that benefits the horse and will not

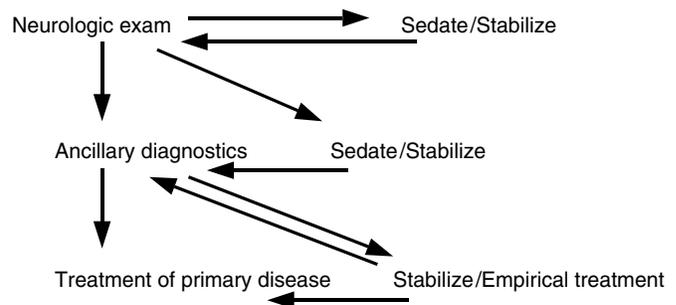

interfere too much with follow-up neurologic examinations. These empirical treatments will be based on differential diagnoses formed after the initial neurologic examination.

## TREATMENT

During emergency situations, basic concepts of treatment and care should be followed. The ultimate goal is to optimize delivery of oxygen and nutrients to tissues. For the neurologic horse, sedation may be required to handle and examine the horse in a safe fashion or to treat seizure activity. Stabilization of hemorrhagic and hypovolemic conditions is necessary in trauma patients. Medical treatment of specific primary conditions is described in detail in Chapter 12. This section discusses select groups of drugs that are commonly used in horses with acute neurologic disease.

Sedatives and anesthetics are used to tranquilize the equine patient. Short-acting sedatives may be required for restraint during examination. Longer-term sedation or anesthesia is frequently required to avoid self-trauma in fractious horses. The use of tranquilizers or anesthetics may also be indicated to control abnormal behavior or seizure activity. Analgesic drugs are indicated if horses experience pain (e.g., in traumatic disease). NSAIDs are the mainstay drugs in equine medicine because of their antiinflammatory and analgesic properties. Opioids should be considered when additional analgesia is required or when analgesia is required in situations of suspected NSAID toxicity or when the risk of developing NSAID toxicity is high (e.g., dehydration). Opioids do not have specific antiinflammatory effects. The pharmacology and use of NSAIDs and opioids are described in detail in Chapters 4 and 6.

Corticosteroids, alone or in combination with other drugs, are still the classic drugs of choice for acute neurologic disease. Reported dosages of dexamethasone for horses range between 0.1 to 0.25 mg/kg, administered intravenously every 6 to 24 hours for 24 to 48 hours. A favorable response is expected within 4 to 8 hours after CS administration. Horses being given corticosteroid therapy should be monitored closely for the development of laminitis or secondary infection. If improvement in clinical signs is observed, the horse may be placed on oral prednisolone therapy (0.5 to 1.0 mg/kg daily tapered over 3 to 5 days) to decrease the chance of adverse effects. The neuroprotective effect of corticosteroids is thought

**FIGURE 7-3** Flowchart for management of the acutely neurologic horse. Optimally, a neurologic examination is followed by ancillary diagnostics and treatment of the disease. However, in many acute neurologic horses, this is not so straightforward, and adjustment of this “optimal” path by using sedatives or therapeutic stabilization strategies is necessary before further assessment of the horse can continue.

primarily to be mediated by free radical scavenging.<sup>3</sup> Recently, it has been shown that, similar to methylprednisolone, dexamethasone decreases apoptosis-related cell death in rats that were subjected to traumatic spinal cord injury.<sup>4</sup> Other potential beneficial effects of corticosteroids include reduction in the spread of morphologic damage, prevention of the loss of axonal conduction and reflex activity, preservation of vascular membrane integrity, and stabilization of white matter neuronal cell membranes in the presence of central hemorrhagic lesions. Furthermore, their antiinflammatory properties may be useful in reducing edema and fibrin deposition, as well as their ability to reverse sodium and potassium imbalance caused by edema and necrosis. Methylprednisolone sodium succinate (MPSS) is a synthetic glucocorticoid with four times more antiinflammatory activity and 0.8 times less mineralocorticoid action compared with cortisol. Beneficial effects of MPSS on neural tissue include inhibition of lipid peroxidation, eicosanoid formation, and lipid hydrolysis, including arachidonic acid release, maintenance of tissue blood flow and aerobic energy metabolism, improved elimination of intracellular calcium accumulation, reduced neurofilament degradation, and improved neuronal excitability and synaptic transmission. Apparently, it is the cell membrane antilipid peroxidation effect of MPSS that is most beneficial. The dose of MPSS used in human trials (30 mg/kg) exceeds that necessary for activation of steroid receptors, which suggests that MPSS acts through mechanisms that are unrelated to steroid receptors. Investigators have concluded that high-dose MPSS treatment within 8 hours of spinal cord injury improved neurologic recovery.<sup>5,6</sup> However, controversy regarding the beneficial effects of MPSS remains.<sup>7,8</sup>

Osmotic diuretics such as 20% mannitol (0.25 to 2.0 mg/kg, administered intravenously over 20 minutes) and glycerol (0.5 to 2.0 mg/kg, administered intravenously every 6 to 12 hr for 24 hr) are effective in combating cerebral edema and increased intracranial pressure. These have a rapid onset of action (10 to 20 minutes) and work because of their hyperosmolar nature. Animals receiving osmotic diuretics should be adequately hydrated. Although mannitol administration is very effective in reducing intracranial pressure, there are technical limitations to the administration of this osmotic diuretic. Furthermore, the administration of multiple doses of mannitol can lead to intravascular dehydration, hypotension, reduction of cerebral blood flow (CBF), and elevation of spinal fluid osmolarity.<sup>9,10</sup> Therefore current research is focused on the use of hypertonic solutions that reduce intracranial pressure and support intravascular volume.<sup>11</sup> Hypertonic saline administered early in the treatment of shock associated with head trauma may enhance return of cerebral blood flow and cell membrane function. Effects of hypertonic saline are due to its ability to move water out of cells and decrease tissue pressure and cell size by osmotic plasma expansion. These effects result in a lowering of intracranial pressure and cerebral water content. Hypertonic saline may in fact be the maintenance fluid of choice in head injury. Hypertonic saline is associated with significant decreases in intracranial pressure and cerebral water content compared with isotonic fluid treatment. Another study comparing the effects of a hypertonic saline hydroxylethyl starch solution and mannitol on increased intracranial pressure found that the hypertonic saline hydroxylethyl starch reduced the intracranial pressure more effectively than mannitol.<sup>12</sup> Induction of prolonged hypernatremia using 3% hypertonic saline

administered as a continuous infusion appears to be a promising therapy for control of cerebral edema.<sup>13</sup> Hypertonic saline may be given to head trauma horses in shock as a 5% or 7% sodium chloride solution in a 4- to 6-ml/kg bolus intravenous dose over 15 minutes.

Dimethyl sulfoxide (DMSO) 1 g/kg, administered intravenously as a 10% to 20% solution for 3 consecutive days followed by three treatments every other day, may be of benefit in acute neurologic disease. Reported benefits of DMSO include increased brain and spinal cord blood flow, decreased brain and spinal cord edema, increased vasodilating PGE<sub>1</sub>, decreased platelet aggregation, decreased PGE<sub>2</sub> and PGF<sub>2</sub>, protection of cell membranes, and trapping of hydroxyl radicals. The exact mechanism of DMSO remains unknown. This treatment remains controversial; some researchers have found no positive effects on neurologic outcome after the use of DMSO.<sup>14</sup> Although the antioxidants vitamin E and selenium have been shown to be beneficial in neurologic disease, they do not appear useful in acute injury because of the length of time required to achieve therapeutic concentrations in the central nervous system. Beneficial effects of vitamin E and selenium include reduced lipid peroxidation and free radical scavenging.<sup>3</sup>

Antimicrobial drugs may be required to treat the primary disease process (e.g., in bacterial meningitis); they may also be indicated for treatment of secondary complications, such as pneumonia and decubital sores in recumbent animals. The choice of antibiotic should be based on culture and sensitivity testing. Good empirical choices for broad spectrum coverage include trimethoprim-sulfamethoxazole at 30 mg/kg, administered orally or intravenously every 12 hours, or penicillin at 22,000 IU/kg, administered intramuscularly every 12 hours or intravenously every 6 hours in combination with gentamicin at 6.6 mg/kg, administered intramuscularly or intravenously every 24 hours. Appropriate monitoring for aminoglycoside toxicity should be undertaken with their use. In cases of meningitis caused by gram positive organisms, penicillin or ampicillin can be used. The use of penicillin is recommended only in cases of highly susceptible organisms because therapeutic cerebrospinal fluid concentrations are difficult to achieve. Third-generation cephalosporins are highly effective against gram negative cerebrospinal fluid pathogens. Fluoroquinolones also have adequate cerebrospinal fluid penetration. Sulfonamides are a cheaper alternative and have good cerebrospinal fluid penetration. Gentamicin and tetracyclines have poor cerebrospinal fluid penetration.

Treatment and prevention of decubital ulcers are critical in recumbent animals. The etiology of decubital ulcers, or pressure sores, is through prolonged or repeated unrelieved pressures to skin that result in damage and ischemia to underlying tissues and subsequent tissue ulceration. Prevention of decubital ulcers is aimed at protection of tissues and reduction of ischemic injury.<sup>15-18</sup> Microvascular thrombosis and ischemic necrosis occur and may result in secondary bacterial infection. Pressure ulcers usually occur over bony prominences. In horses the most common sites of decubital ulcers are the tuber coxae, the points of the shoulder, and the zygomaticotemporal protuberance. Furthermore, pressure sores can occur along the distal extremities. For horses preventive strategies include appropriate padding and bedding, frequent changes in body positioning (i.e., turning), efforts to improve mobility, frequent examination of skin, maintenance of a well-balanced diet, and skin that is kept dry. Pressure sores generally heal well once the horse is able to stand.

Surgical intervention may be required in, for example, head injury cases in which dislocation of bones has occurred. Indeed, a recent report described aggressive medical and surgical treatment of a horse with an open fracture of the calvarium. In this horse initial surgical débridement appeared successful; however, the horse succumbed to infection and necrosis of remaining brain matter.<sup>19</sup> The demand for and commitment of veterinarians and owners to advance our abilities in treating equine neurologic disease are growing. This will allow the field to move forward and continue with important basic and clinical research, with the goal of improving care of these horses.

## ☞ CARE OF THE RECUMBENT HORSE

Examination, assessment, and subsequent management of a recumbent horse may be difficult and challenging. The horse is a “fight or flight” animal, and the combination of being debilitated and being in a strange environment surrounded by people may cause anxiety or fear, both of which can contribute to dangerous situations. Furthermore, the horse’s primary disease can lead to an abnormal mentation and subsequent abnormal or dangerous behavior. The safety of all involved should be considered when working with a recumbent horse. If there is a risk of infectious or zoonotic disease, appropriate precautions should be taken, including wearing protective clothing and minimizing human exposure. Management of a recumbent horse requires a combination of intensive supportive care and specific treatment aimed at the underlying or complicating disease processes.<sup>20,21</sup> Supportive care is mainly directed at protection of the animal and maintenance of adequate hydration and nutritional status. Care of down horses is time consuming and more difficult if the horse is very large.

Prevention and care of muscle compartmental injury, peripheral nerve injury, and decubital ulcers are important aspects in the management of a down horse, insofar as these are frequent consequences of prolonged recumbency. Bedding should be absorbent, nonabrasive, and conformable. It may be necessary to adjust the type of bedding when the horse makes (successful) attempts to stand or is standing in the sling. Then it is very important that the bedding provide adequate footing. Deep bedding in those situations may hinder the horse’s attempts to stand or ambulate, and straw may be slippery. The down horse should be turned regularly (every 2 to 6 hr) to provide adequate perfusion of the skin and musculature of the down side and improve perfusion and ventilation of the down lung. If the horse is able to maintain a sternal position, this should be encouraged and if necessary assisted with the placement of straw bales or other materials. Protection of the head is often required in recumbent horses, primarily to protect the eyes. Protection may be accomplished by use of adequate padding or of helmets or bandages. Damage to the eyes can occur directly by pressure to the eye or from bedding material. Furthermore, specific diseases may result in a horse’s inability to blink (e.g., botulism, Horner’s syndrome, facial nerve paralysis). The most common ophthalmic disorders seen in recumbent horses are corneal ulcers and keratitis. Eyes should be examined daily and assessed and treated carefully.

Unless horses can maintain themselves standing or in sternal recumbency long enough to drink, their water intake will not be sufficient to meet their maintenance requirement. Maintenance requirements for down horses may be slightly lower (50 ml/kg/day) than what is considered normal. Fluid therapy can be provided intragastrically by using

a permanently placed small-bore feeding tube or by regular repeated nasogastric intubation, or fluids can be administered intravenously. Depending on the dietary protocol that is used, electrolytes and glucose may be added to the fluids. Recumbent animals lose body condition rapidly when no nutrition is provided. Dramatic changes are often noticeable within 1 week. Adequate nutrition is important in recumbent horses and may be beneficial for wound healing<sup>22</sup> and maintaining muscular strength and adequate immunity. Diets and routes of administration vary, depending on patient compliance, dietary tolerance, and budget. Dietary options can be divided into four categories.<sup>21</sup> Some horses are able to ingest a sufficient amount of roughage ( $\pm 2\%$  of bodyweight) with or without grain while they are in sternal recumbency or standing with sling assistance. The dietary intake and fecal output should be monitored closely, but in general no additional support is required. Many recumbent horses and horses that are dysphagic, however, are not able, or should not be allowed, to meet the required intake in this way. For these horses a soaked pellet gruel (30 cal/kg/day), liquid diet (Osmolite; Ross Products Division, Abbott Laboratories, Columbus, Ohio, or Critical Care Meals™ MD’s Choice Inc., Louisville, Tenn.), or parenteral nutrition may be used. Further discussion of nutritional support for sick horses is included in Chapter 5.

Down horses are prone to developing impactions of the cecum, large colon, or small colon. Reduced fecal output may be a preliminary sign of impaction, and the administration of laxatives such as magnesium or sodium sulfate solutions or mineral oil is indicated. Some horses may develop ileus, and this may have consequences for hydration and nutrition regulation. Urine and fecal retention may occur (e.g., in herpesvirus myeloencephalitis), and frequent emptying of rectum and bladder is then required. Alternatively, an indwelling urinary catheter can be placed.

Ensuring adequate ventilation, maintaining a clean stall environment, and preventing aspiration of food are important factors to reduce the chance of respiratory tract disease. A dysphagic horse should not be allowed to eat but should be offered an alternative source of nutrition. Antimicrobial drug therapy should be initiated when respiratory disease is present and may be indicated in a dysphagic horse. Regular turning of the horse may minimize development of lung disease. In addition to decubital ulcers, the development of aspiration pneumonia is the most common complication seen in horses with botulism.<sup>23</sup>

Physiotherapy is an important aspect of supportive care and the rehabilitative process of injured horses. Physiotherapy can be provided in the recumbent animal by manipulating limbs, depending on the horse’s attitude, or assisting the horse to stand with a sling. Controlled exercise allows the unaffected parts of the nervous system to compensate for the affected parts by increasing strength and conscious proprioception. Exercise is especially helpful in improving weakness, ataxia, spasticity, and hypermetria.

A sling is an important tool in the assessment and management of a recumbent horse. When a horse is unable to rise, but otherwise appears to have a normal mentation (i.e., unaltered behavior), it may be very helpful in the examination to assist the horse to stand with a sling. The presence of lameness, weakness, and ataxia as well as the number of affected limbs are much more easily assessed when the horse is in an upright position. The horse may be able to stand freely and demonstrate clinical signs that may help in determining

a diagnosis. Furthermore, using the sling to assist a horse to stand may provide valuable information for short-term management purposes. Deterioration or improvement of disease may be determined relatively easily by daily sling assistance in order to provide short-term recommendations and prognosis. For long-term management the sling can be useful, depending on the horse's primary disease and compliance. Horses may become used to using the sling and can be comfortably managed in the sling until they have regained sufficient control to ambulate freely. Periodic sessions of semistanding with sling assistance may function as a form of physiotherapy, and manipulation of limbs can occur during this time. Moreover, increasing the time that a horse can be maintained in an upright position decreases the detrimental effects of continuous pressure on skin and muscle. The time a horse is upright should also be used to clean and dry the horse and assess its food and water intake.

# EPIDEMIOLOGY

## CHAPTER 8

Noah Cohen

Like the field of equine medicine, the discipline of epidemiology is diverse. The previous edition of this textbook contains an excellent review of important epidemiologic concepts and principles relevant to equine medicine, including diagnostic testing, measures of disease association, causality, sample design and size, and basic statistical constructs. Those topics will not be revisited in this chapter, and readers interested in those aspects of epidemiology are directed to Chapter 21 in the previous edition. This chapter is devoted to the introduction of principles, techniques, and limitations of evidence-based medicine (EBM) and its essential and underlying role in epidemiology.

### ☞ EVIDENCE-BASED MEDICINE

The concept of EBM was developed by clinical epidemiologists more than 20 years ago.<sup>1</sup> Since then, EBM has become very popular. Whereas a Medline search of EBM in 1993 yielded only six citations,<sup>2</sup> a search in early 2008 yielded more than 29,000 citations. The *Equine Veterinary Journal* currently dedicates a section to EBM, and the term *EBM* is increasingly used in presentations and publications. Recently, EBM has been described as “the integration of the best research evidence with our clinical expertise and our patient’s unique values and circumstances.”<sup>3</sup> The emphasis of EBM is on acquiring, assessing, and utilizing evidence to improve clinical decision making. A fundamental principle of EBM is that, whenever possible, evidence for clinical activities should be derived from well-designed studies of patients with spontaneous disease (i.e., epidemiologic studies).

The practice of equine medicine has traditionally been empiric and driven by the knowledge, wisdom, and experience of experts. The field has depended largely on combining an understanding of the pathogenesis and mechanisms of disease with authority, theory, logical deduction, and intuition. The human medical profession has moved away from these traditions toward a medical practice that is based on clinically relevant evidence.<sup>2,3</sup> The principle of EBM is to base all clinical decisions regarding prevention, diagnosis, treatment, and prognosis of disease on the use of the best existing evidence. It is difficult to dispute the value of this approach, which aims to discourage a reliance on authority (“I treat horses with equine protozoal myeloencephalitis [EPM] this way because that is what I was told” by a textbook or expert) and promote instead a reliance

on the best available evidence (“Why do I treat EPM this way?” and “What is the most successful approach to treating EPM?”). Currently, *EBM* refers not only to this laudable principle but also to a methodology by which the principle is realized.

### METHODOLOGY

---

The methodology of EBM consists of five steps: (1) defining, or asking, a clinical question; (2) searching for evidence to answer the question; (3) critically appraising the evidence gathered; (4) applying the results of answering the question; and (5) auditing the outcome of applying the results (i.e., how well did the EBM-derived answer work?).<sup>2</sup> Each of these steps is considered in turn. As will be discussed later, the state of development of the methodology is highly variable among steps.

#### STEP 1: ASKING THE QUESTION(S)

The first step in EBM is defining the question that pertains to the clinical circumstances of the patient. This is not always as simple as it might initially seem. A question that is too broad (e.g., “How do I treat pneumonia in horses?”) may yield numerous citations that are not germane, whereas a question that is too focused (e.g., “How do I treat *Pneumocystis carinii* pneumonia in a foal with selective IgM deficiency?”) may yield no results at all. Typically, veterinarians ask several questions about a given patient, including questions described as background and foreground varieties. Background questions are general knowledge questions, such as “How does cervical stenosis or instability develop in horses?” and “What causes abscessing pneumonia of foals?” Foreground questions are more specific to the particular case, such as “In a mare with congestive heart failure and atrial fibrillation that developed coincident with developing pleuropneumonia, what is the best approach for treating the arrhythmia?” Generally, veterinarians pose fewer background and more foreground questions as they gain experience with a particular condition.

Any clinical encounter will generate a number of questions pertaining to signalment and history (e.g., “Does the signalment suggest that certain disorders will be more common?” “Does the herd history help eliminate certain causes?”), clinical examination findings (e.g., “How do I interpret a head tilt and signs of facial nerve paralysis in this horse?”), etiology and differential diagnosis (e.g., “What might cause these signs?”);

“What is the cause of these signs?”), diagnosis (e.g., “What tests are most meaningful in a patient with this clinical complaint?”), treatment (e.g., “What is the best way to treat temporohyoid osteoarthropathy?”), prognosis (e.g., “What is the probability that this horse will return to use?”), prevention (e.g., “What can be done to prevent recurrence?”), experiences and meanings (e.g., “Have I effectively communicated with the clients?”; “Does the client perceive that I empathize?”), and improvement (e.g., “Have I learned new information about managing this case from the experience?”; “Did my patient benefit?”).

Attempting to answer all relevant questions simultaneously will be unrewarding for the clinician, client, and patient. Veterinarians must learn to prioritize their efforts. Often, first addressing certain questions of case management (i.e., history, physical examination and diagnosis) seems logical; however, the client’s needs may also influence the order of the questions (e.g., matters of prognosis or experience and meaning). Moreover, veterinarians must consider which questions may feasibly be answered within the time and setting of the clinical encounter. The veterinarian should consider recording those questions that must be postponed so that they will not be forgotten.

The process of carefully considering questions to ask, prioritizing them, and saving unanswered ones to be answered later might seem like an inconvenience and a waste of time: Veterinarians do much of this already without needing to spend a lot of time formulating and recording their clinical inquiries. The principal advantage to the process is that it will help identify evidence-based solutions for the clinical problems that veterinarians face. With experience veterinarians become more proficient and expeditious in answering questions, and the process necessitates remaining current on new developments, such as new medical and surgical approaches to temporohyoid osteoarthropathy (and their evaluation) and new diagnostic tests for EPM.

Perhaps the most important principle of EBM is that veterinarians need to ask themselves what evidence exists for their clinical activities. Breaking away from the tradition of authority and empiricism in equine medicine will not be easy, and it will happen only if veterinarians are willing to question what they really know about their clinical decisions and interpretations.

## STEP 2: SEARCHING FOR EVIDENCE

Once a question has been posed, it is important to find the best available evidence using a review of the literature that is as comprehensive as possible. Relying on book chapters or review articles will not suffice for at least two important reasons. First, new knowledge emerges more quickly than it can be incorporated into textbooks. Of course, well-written textbooks remain excellent resources for many background questions (e.g., pathophysiology of diseases, etiology of diseases with well-defined causes) and often will be fairly current in a field such as equine medicine, wherein the pace at which new information is generated is fairly slow. Unfortunately, it is often difficult to determine which information in these textbooks is current and which is outdated. Furthermore, authors of review articles have their own particular prejudices, beliefs, and perceptions, and these biases influence their interpretations and recommendations. Practitioners must guard against biases that may result in selecting reports that conform to their preexisting beliefs and perceptions, which is easier said than done.

In human medicine a hierarchy of *resources* for EBM has been proposed (note that this is a hierarchy of resources, not of evidence).<sup>2</sup> The highest tier of this hierarchy is a computerized decision support system (CDDS) in which clinical information from a patient’s records is automatically linked to all relevant, important research findings pertaining to the patient’s circumstances. The next highest-level resource is synopses of individual studies or reviews. These synopses are designed to be concise and precise distillations of the important facts needed by busy clinicians. The next level is syntheses of reports based on exhaustive searches for evidence, implementation of explicit scientific criteria for review, and systematic assembly of the evidence. Syntheses are epitomized by the Cochrane Reviews ([www.Cochranelibrary.com/](http://www.Cochranelibrary.com/)). At the bottom of this hierarchy are individual scientific reports.

Equine practitioners currently operate primarily at the level of individual reports. Although a veterinary CDDS will likely be developed in the future, it is not clear when. Synopses of numerous studies on a given topic are not likely to be available soon, primarily because numerous studies for a given topic do not yet exist. The same problem arises for systematic reviews: Although there are examples,<sup>4</sup> they are exceedingly rare. The advantage of relying on individual reports is that the information is generally current (whereas it can take many months or years to develop the evidence on which synopses and systematic reviews are based). The disadvantage is that the evidence is weaker from individual studies, and it puts the onus on the reader to critically appraise each study. Critical appraisal is discussed in greater detail in the next section, but first it is important to consider resources for finding information.

Those practitioners who are fortunate to work at institutions with appropriate licenses for digital publications will find that a great deal of information can be retrieved electronically with little effort, and librarians are generally available to assist. In settings without such licenses, it may still be possible to gain access to the necessary resources through colleges or universities. Regardless, veterinarians will find a considerable amount of high-quality information on the Internet through resources such as PubMed (<http://www.ncbi.nlm.gov/PubMed/>) and BioMed Central (<http://www.biomedcentral.com>). It is important to remember, however, that the Internet also offers much in the way of low-quality information. Relying on subscription journals is generally inefficient: There are simply too many journals with too many articles appearing each month that are relevant to the daily activities of equine specialists. Moreover, important articles are often published in journals to which few veterinarians subscribe. For example, not many veterinarians subscribe to the journal *Genomics*, but many would be interested in reading about the mutation that causes polysaccharide storage myopathy.<sup>5</sup>

## STEP 3: CRITICAL APPRAISAL

**Introduction** Although the first two steps, formally stating questions and searching for the evidence, are fairly straightforward, the third step, critical appraisal, is more complex. It is also vitally important in equine EBM because the evidence for much of what equine practitioners do is sparse and primarily derived from observational (epidemiologic) studies or experiments (using horses or other animal species) from which practitioners must then extrapolate results to the clinical setting. These sources of evidence are not only low in terms of the hierarchy of resources for searching but also relatively low in

the hierarchy of evidence that has been proposed for EBM.<sup>6</sup> Before further discussion of this hierarchy, it is necessary to briefly review these epidemiologic (patient- or population-based) study designs.

**Study Designs** EBM places a premium on information derived from patient-based epidemiologic studies. Epidemiologic study designs have been summarized in the previous edition, and a full discussion of all possible study designs and their strengths and limitations is beyond the scope of this chapter. Thus designs are reviewed briefly herein. Epidemiologic study designs can be defined as either experimental or observational (Box 8-1).

Experimental epidemiologic studies are ones in which the investigators control the exposure (e.g., a treatment group) to which patients are assigned. Assignment is most often at the level of the individual but may occasionally be at the level of population (e.g., fluoride added to the water of some communities but not others to evaluate effects on dental caries). Assignment of exposure should be randomized in an effort to render the treatment groups as similar as possible for both measured and unmeasured factors that may be independently associated with the outcome of interest. Randomization, however, does not ensure that there will not be significant differences among groups that occur by chance alone, and the chance of differences occurring is greater when the study population is small. In general, the randomized, controlled clinical trial (RCT) is considered the highest form of evidence from an individual study because of the extent to which biases are reduced through the processes of randomization, a priori specification of primary study outcomes, and so-called blinding of patients and clinicians assessing primary study outcomes. An example of an RCT is the report by Smith et al. regarding incisional complications after celiotomy.<sup>7</sup> It is worth noting that the term *RCT* is often used in equine medicine to refer to experimental studies involving research horses, rather than patients. At the time of this writing, a PubMed search for the term “randomized controlled trials and horses” yielded 518 results, of which fewer than a score were patient-based studies. The term *RCT* should be reserved for patient-based clinical studies to avoid imprecision in professional communications.

A modification of the RCT is the N of 1 RCT design. The N of 1 RCT design is one in which individual patients are assigned to pairs of treatment periods: They receive a target treatment in one period and an alternative treatment (or placebo) during the other period. The approach continues until both patient and clinician are convinced that a given treatment (whose identity to which they may be blinded) is deemed to be effective for that patient.<sup>2,6</sup>

Unfortunately, experimental epidemiologic studies are exiguous in equine medicine, most likely because the resources to fund these generally expensive studies are often lacking. Thus the bulk of our evidence is derived from observational epidemiologic studies. Observational designs include cohort, case-control, and cross-sectional designs.

A cohort study is one in which investigators first define the exposure status of each group (cohort), and then the experiences of each cohort are followed over time for the occurrence of disease, such that disease incidence is determined. When more than one cohort is followed, comparisons can be made regarding the incidence of disease. The ratio of the risk in a cohort with an exposure of interest (e.g., a group of horses treated with omeprazole) relative to a reference cohort (e.g., a group of horses not treated with omeprazole) is termed the *relative risk* (RR), and it indicates how many times more likely the disease is to occur in the exposed cohort than in the unexposed cohort. The reader is encouraged to review the chapter on veterinary epidemiology in the second edition of this textbook for further discussion of the RR and other measures of risk in cohort studies.

Cohort studies may be prospective (concurrent), retrospective (nonconcurrent), or both. A prospective cohort study is one in which exposure status is determined during the present and horses are followed into the future for development of disease. A retrospective study is one in which exposure is determined in the past and individuals are monitored up to the present time for development of disease. A modification of the cohort study is the self-controlled case-series study in which the history of individual cases during defined periods of risk are studied; in this way each individual acts as its own control. For example, a practitioner might look at the association of colic with anthelmintic administration by identifying cases of colic, defining “at-risk periods” as the 3-day period after anthelmintic administration, and determine the incidence of colic during these risk periods for the individual horse.

In a case-control study disease status (whether a horse is a case of the disease of interest or is a member of the control group used for comparison) is first determined, and then the history of the exposure of interest. As a result of the selective sampling of cases, the incidence of disease (and thus the RR) generally cannot be determined in a case-control study. However, it is possible to determine the odds of exposure in cases relative to controls, which is equivalent to the odds of disease among exposed relative to unexposed, otherwise known as the *odds ratio* (OR). The OR will approximate the RR when the included cases are representative of all cases, controls reflect the reference population, and the disease is rare.

Case-control studies may be prospective, retrospective, or both. A prospective case-control study is one in which incident (new) cases of disease are compared with contemporaneously identified controls. Retrospective case-control studies are ones in which cases occurred before initiation of the study. The case-crossover design is a self-controlled equivalent of a case-control study. In this design exposures immediately

#### BOX 8-1

### DESIGNS OF EPIDEMIOLOGIC STUDIES

#### Experimental Designs

- Randomized, controlled trial
- Population-based
- N of 1 randomized, controlled trial

#### Observational Study Designs

- Cohort study
  - Prospective
  - Retrospective/nonconcurrent
  - Self-controlled case-series
- Case-control study
  - Case-control
  - Case-crossover
- Cross-sectional study
- Reports of case series
- Reports of individual cases or case series

preceding a disease event are compared with exposures occurring during earlier “control” periods when an event did not occur. The differences between the self-controlled case-series and the case-crossover studies may seem subtle, but they are technically important.

Cross-sectional studies are ones of a target population at a particular point in time: Exposure and disease status are determined simultaneously in cross-sectional studies. This design is best for descriptive studies and is considered particularly weak because, as a result of determining the outcome and exposure simultaneously, it is impossible to determine causality (because a cause must be demonstrated to precede its resultant effect).

**Critical Appraisal: Identifying Bias** Critical appraisal of studies entails trying to determine if the study results are valid and applicable to the clinical setting. Epidemiologic studies of patients generally contain estimates of a measure of association (e.g., the OR or RR) or other population parameter (e.g., the cumulative incidence of disease). Studies are considered valid when the observed or estimated parameter is the same as the true, or actual, value. The term *bias* refers to a systematic error in the study relating to its design, the means by which data were collected, or the way the study data were analyzed.<sup>8</sup> This type of systematic error is distinct from random error resulting from the imprecision of the device or devices (e.g., questionnaire, serum chemistry analyzer, blood pressure monitor) used for collecting data. Random error generally does not cause bias, and it can be reduced by increasing sample size. The fact that we never know the true value of the population parameter and cannot perform the infinite replicates needed for valid estimation means that we must use judgment and knowledge to identify potential biases in studies. Although a surfeit of biases have been identified, biases in epidemiologic or patient-based studies generally fall into one of three categories: selection bias, information bias, and confounding bias.<sup>8</sup>

**Critical Appraisal Based on Study Design** The study design can be used as a criterion for evaluating the quality of data. The ensuing discussion will proceed from designs with the weakest sources of information to those with the strongest. Because empiric observations can be misleading and experts can be wrong, anecdotes and recommendations should be considered as evidence of the weakest variety. It is important to remember, however, that many important clinical innovations have arisen because of an individual insight that proved valid, and experts also are often right.

Experimental research to describe biologic (e.g., physiologic, pathologic, pharmacologic) phenomena contributes significantly to our understanding of disease processes and potential interventions. Nevertheless, these studies are considered weak sources of evidence, particularly when they involve heterologous species of animals, for a number of reasons, including the disparities between experimental models of disease and spontaneous disease. In many instances, conclusions drawn from an experimental model that seem logical or plausible do not prove to be true when applied to patients. For example, although folate supplementation seemed logical (and was advocated by experts) in horses receiving folic-acid inhibitors to treat EPM, the practice appeared to pose a risk to fetuses of supplemented mares.<sup>9</sup> It is a basic tenet of EBM that, whenever possible, clinical decisions are based on evidence derived from patient-based studies, preferably those that are as similar as possible to the patients being treated.

Individual case reports are often important because they highlight new diseases, disease manifestations, potential therapies, and so forth. Because of their singularity, however, replication of their findings is important. In this way, case series are generally stronger evidence than individual case reports because they provide more information about variation among individuals with respect to clinical signs, diagnostic test results, and treatment responses. Case series can be very helpful in describing the clinical course and may represent the best available evidence for rare conditions. Nevertheless, bias may occur in the selection of cases and the subjective interpretation of findings. More important, these studies lack a comparison group for drawing inferences.

Although controlled studies are generally a preferred source of evidence, studies that use historical controls should be considered a very weak source of evidence because the controls and the group to which they are being compared are very likely different: Many factors change over time and can influence both exposure and disease. An exception is the circumstance in which mortality is essentially 100%. For example, it might be reasonable to compare a new treatment of rabies to the treatment of historical controls.

The case-control study design uses controls and is practical for studying rare diseases and identifying prognostic factors; however, this study design is subject to numerous biases. With respect to information bias, the historical nature of exposure data creates ample opportunities for error: Because data are not typically collected from patients for the purpose of future scientific study, data may be lacking in quality (e.g., incomplete dietary history among horses with colic) or absent (e.g., serum amyloid A concentrations in horses with various types of colic). With respect to selection bias, the representativeness of cases and controls can be problematic, particularly for the control group. Finally, confounding bias also can be a problem in case-control studies because the data regarding exposure to important confounding variables may be missing or of poor quality. Whenever possible, case-control studies should be designed to account for known risk factors to prevent confounding effects; when known variables associated with the disease of interest are not accounted for, study results should be interpreted with caution. Generally, the extent of the impact of ignoring confounders will be commensurate with the magnitude of the association of the confounder (e.g., activity level) and the outcome (e.g., colic). Consistency of the observed association also should be considered when readers attempt to assess the magnitude of the impact of ignored confounders: If a confounder has been repeatedly associated with an outcome, it may be particularly important to account for this confounder. Clearly, it is not always possible for investigators to collect data on all variables previously associated with the outcome of interest. Failure to account for a known confounder does not vitiate the value of a study, but readers should be aware that it will be necessary to substantiate the results of reports in which confounders are not accounted for because the magnitude and statistical significance of observed associations may be altered after accounting for confounding.

Cohort studies are superior to case-control studies in that the temporal association of exposure and disease tends to be better defined. Cohort studies are well-suited to identifying risk factors for disease, studying the outcome of an intervention, and examining the natural history of disease. Prospective cohort studies are generally superior to retrospective studies because of the problems associated with historical

exposure data from the latter design. Other forms of information bias can occur but are much less likely when the study is well designed than in case-control studies. Given that the cohorts are chosen, some degree of selection bias should be expected in any cohort study. It is important to scrutinize the criteria for including and excluding cases to understand how representative the exposed and unexposed control groups are. Confounding biases also may occur, as discussed previously in reference to the case-control study design.

The RCT design is considered to be the superior design for patient-centered research because of its presumed ability to render study groups similar with respect to measured and unmeasured factors by way of randomization, thereby minimizing or eliminating confounding bias. Information biases may still occur in the RCT, but they are minimized or eliminated in well-designed studies. Selection biases also can occur, as discussed for cohort studies. As mentioned, RCTs are relatively rare in equine medicine because they are expensive as well as administratively and practically challenging to conduct. To reduce costs and complexity, the sample size of an RCT may be restricted. However, the favorable attributes of RCTs do not circumvent the problem of lack of power: RCTs of small sample sizes may lack sufficient power to detect clinically important differences among study groups.

**Critical Appraisal Based on Clinical Activity** The primary clinical activities of equine medicine are choosing and interpreting diagnostic tests, selecting treatments, and making prognoses. The types of evidence practitioners use varies to some extent by activity, and thus evidence can be considered for each activity.

**Diagnostic Studies** When appraising an article that relates to a diagnostic test, practitioners must evaluate three critical aspects: (1) the spectrum of disease patients represented in the population studied, (2) whether the reference standard (a.k.a. the “gold standard”) was applied irrespective of the results of the diagnostic test, and (3) whether the reference standard was measured independently.<sup>2</sup>

It is not unusual for studies of diagnostic tests to assess the performance of the test to severe forms of disease (e.g., necropsy-confirmed cases of EPM) and horses free of signs of disease. Although the use of such case-control studies is useful for initial evaluation of tests, they are of limited clinical value. Useful evaluation of diagnostic tests will reflect the full spectrum of disease to which the test is to be applied, including patients with milder as well as florid forms of the disease, in early as well as late stages of disease, and among both treated and untreated patients. Thus case-control studies are generally weak sources of evidence for evaluating diagnostic tests. The best sources of evidence for diagnostic tests are prospectively designed studies of consecutive patients undergoing prespecified diagnostic testing criteria against a reference standard that is consistently applied (as described later in this chapter). Studies in which diagnostic testing criteria are developed in a consecutive series of patients should be considered as a valuable but lesser source of evidence. When patients are not consecutively evaluated, there is potential for bias in the selection of cases included; thus studies of nonconsecutive patients should be viewed as weaker evidence.

When a patient has a negative test, investigators are tempted to forego testing with the reference standard, especially when the latter is more invasive. For example, in a study evaluating the diagnostic sensitivity and specificity of thoracic ultrasound for detecting subclinical *Rhodococcus equi*

pneumonia, it is probably not desirable to perform tracheobronchial aspiration to obtain a sample for microbiologic culture and cytologic evaluation in an apparently healthy foal from a farm with endemic *R. equi* pneumonia whose thoracic ultrasound findings were normal. However, failure to perform such testing introduces a bias that is an important limitation. One solution to this problem is conducting thorough follow-up: If the clinical outcome of interest is clinical signs of pneumonia, the foals not tested with the reference standard could be monitored throughout the period when signs are most likely to develop (e.g., until weaning or until the subject goes to the yearling sale); documenting the absence of clinical signs in foals that did not have tracheobronchial aspirates would minimize the limitation of differential ascertainment of the reference standard based on the results of the test being evaluated.

It is important that the diagnostic test and the reference standard be assessed independently. Caution is urged in evaluating results of studies in which the reference standard relies on expert opinion, such as the interpretation of biopsy results. It is best that the results of the diagnostic tests be unknown to those conducting the reference standard (and vice versa). Thus studies in which the same individuals are performing both tests should be regarded with suspicion. This is particularly important when either test has subjective levels for categorizing results (e.g., absent, mild, moderate, or severe; or negative, weak positive, moderate positive, strong positive).

It bears remembering that a good understanding of the principles of sensitivity, specificity, predictive values (positive and negative), and likelihood ratios (positive and negative) is essential in the interpretation of test results. If the study design is valid, it is necessary to ensure that the test can accurately distinguish patients with and without the disease. Although review of these topics is beyond the scope of this discussion, they are considered in the previous edition of this text and elsewhere.<sup>3,10</sup>

**Therapeutic Studies** From the standpoint of individual studies, the reference standard for treatment evaluation is the RCT.<sup>1,3,6</sup> However, just because a study is an RCT does not mean that the results of the study should be accepted as valid. As with other designs, RCTs are subject to biases. Individual RCTs should be evaluated for validity by answering each of the questions posed in Box 8-2. The importance of randomization has already been discussed. Ideally, the randomization

#### BOX 8-2

#### CRITERIA FOR EVALUATING RANDOMIZED CLINICAL TRIALS

1. Was treatment assignment randomized?
2. Was randomization concealed?
3. Were the groups similar at baseline?
4. Was follow-up adequate?
5. Were patients analyzed according to assigned treatment?
6. Were those involved in the study (e.g., patients, veterinarians, farm staff, hospital staff) kept blind with respect to treatment?
7. Apart from the treatment of interest, were the groups managed similarly?

procedure should be described in the materials and methods section of the report. When randomization has not been used for assignment, the trial should be interpreted with greater caution. If the effect of treatment in the nonrandomized trial is very large and compelling, results are unlikely to be invalid. When nonrandomized trials reveal absence of effect or harm, it also may be reasonable to accept the study conclusions, because false-negative results from nonrandomized studies are uncommon.

Ideally, allocation of treatment should be concealed from those managing and evaluating patients. Doing so makes it less possible that those assigning treatments might consciously or unconsciously distort the balance of treatment groups. The bias introduced by failing to conceal randomization cannot be predicted a priori: It may result in the treatment appearing more or less effective than it truly is. Although randomization should render treatment groups very similar at the onset of the study, it is possible that, due to chance alone, factors will be unequally distributed among groups. Thus it is important to examine the extent to which the study groups are similar at the time the study is initiated. If the groups differ for putative or known risk factors for the disease of interest, it will be important to ensure that efforts to account for confounding for these factors have been demonstrated.

Evaluation of the extent to which patients were followed is important. The proportion of patients lost to follow-up should be small because these patients may have had outcomes that would have influenced the results of the study. For example, if patients are withdrawn from the study preferentially from the group receiving the treatment of interest because that treatment caused adverse effects, the apparent efficacy of the treatment may be overstated. Although there is no magic number, studies in which more than 20% of patients are lost to follow-up should be viewed with caution. One approach to assessing the impact of losses to follow-up is to perform a sensitivity analysis in which each lost patient is assigned the worst possible outcome (e.g., developed the disease of interest); if the results of analysis are not significantly altered in magnitude or statistical significance of the association by this approach, the results are likely valid. When losses exceed 20%, results of the described type of sensitivity analysis to yield agreement cannot be expected to agree with the original results.

It is also important to assess that the duration of follow-up was adequately long for the disease process of interest. For example, a 4-week follow-up period may be inadequate for a study to evaluate the response to treatment for equine pleuropneumonia. It also is important to determine that follow-up is administered similarly to all patients regardless of treatment group and that all patients are monitored similarly irrespective of treatment group assignment. Failure to account for these factors can introduce information biases that may affect study results.

After random assignment events may occur unrelated to treatment that can affect the likelihood that a patient develops the disease of interest. Thus it is imperative that patients be considered in analysis according to the group to which they were assigned (even if it is known that the patient was inadvertently assigned another treatment or failed to take the assigned treatment). To many this approach seems overly conservative, if not illogical. The rationale for this process of analysis by assignment (intention to treat) is that patients that get crossed over to another treatment group or that do not take their treatments may possess characteristics such that the

remaining members of their assigned group may no longer be comparable to the other group (or groups) as determined at the time of random assignment.

The term *blinding* refers to awareness of treatment assignment. To avoid biased interpreting and reporting, those administering treatment and monitoring patients must be unaware of which treatment is being given to each patient. This is particularly important when the outcome being assessed is subjective, such as a severity score or owner satisfaction. When blinding has not occurred among those administering the treatment, the study should be evaluated to determine if those assessing the outcome were blinded to treatment status (e.g., a farm-based study comparing two treatments for *R. equi* pneumonia wherein the farm staff administers the drugs and is aware of treatment status, but the veterinarian evaluating the foals for evidence of disease is kept blind to the treatment status). Jargon such as “double-blinding” should be avoided when describing studies because of its ambiguity; rather, the report should specify which individuals were specifically blind to treatment.<sup>11</sup>

Although it is important to know whether the groups were managed similarly apart from the treatment of interest, this information may not be collected or reported. If blinding is adequate, it is to be hoped that addition of treatments has not occurred.

In an effort to improve standards for documenting results of RCTs in human medicine, an international collaborative effort produced the Consolidated Standards for Reporting Clinical Trials (CONSORT). Interested readers may wish to review these standards ([www.consort-statement.org](http://www.consort-statement.org)) and the associated checklist and flow diagram because they are helpful in the assessment of strengths and weaknesses of reported trials.

If the results of a clinical trial seem valid, the reader should then ask whether the magnitude of treatment effect appears clinically important. Numerous measures of strengths of effect and association exist, as described previously. One useful measure that was not considered in the previous edition is the number needed to treat (NNT). The NNT is the number of patients that need to be treated during the period of the trial to prevent one additional case of disease.<sup>3</sup> The NNT is calculated by determining the inverse of the absolute value of the absolute risk difference. For example, in an RCT of azithromycin for prevention of *R. equi* pneumonia, the absolute risk difference through weaning between foals that received azithromycin and those that did not was 16%, such that the estimated NNT was 6.25 (1/0.16).<sup>12</sup> Thus it is estimated that at least six foals would need to be treated to prevent one new case of *R. equi* pneumonia from developing from birth to weaning. The NNT should always be reported in the context of a follow-up time. Moreover, it is important to recognize that NNTs are parameters estimated from data and should have confidence intervals calculated for them (as is done for RRs, ORs, and so on). For the *R. equi* chemoprophylaxis example, the 95% confidence interval for the estimated NNT was 4 to 12; thus we are 95% confident that the true NNT for the period from birth to weaning for azithromycin was between 4 and 12. It also merits noting that the NNT usually cannot be directly estimated from a case-control study because incidence is not measured using this design.

Given that all treatments have the potential for adverse effects, it is also possible to estimate the number needed to cause harm (NNH).<sup>3</sup> The NNH is calculated as the inverse of

the absolute value of the absolute difference in risk of harm. For example, if the absolute risk difference of diarrhea in the aforementioned azithromycin trial is 1%, the NNT is estimated to be 100 (i.e., 100 foals would have to be treated for one foal to develop diarrhea from birth through weaning as a result of treatment).

Finally, if the study results seem valid and the observed effect appears important, it is still necessary to determine the extent to which the results of the trial are relevant to a given patient. The extent to which patients studied are representative of a given patient or patients in the veterinarian's practice must be assessed by carefully reviewing which patients were included and which were excluded and by applying clinical judgment. The patients in RCTs are not always representative of the full spectrum of patients with the condition of interest, let alone from the same environment or time period. Thus practitioners may have difficulty finding evidence that directly relates to their patients.

Unfortunately, valid RCTs are rarely available for most of the treatments used in equine medicine. Consequently, veterinarians rely heavily on weaker forms of evidence. In the absence of RCTs, veterinarians should try whenever possible to use evidence from well-designed cohort studies. Except for the absence of randomization, the principles of evaluating cohort studies for treatment should be the same as those for RCTs, including assessment of validity (summarized in [Box 8-2](#)), clinical importance of effects, and the extent to which the results apply to equine patients. Case-control studies should be viewed as weaker sources of evidence for evaluating therapies because they are more subject to biases. Equine practitioners should view case series and individual case reports as no more than preliminary and particularly prone to misinterpretation with respect to treatment effects.

**Prognosis** Practitioners must determine whether the results of a study for prognosis were valid, clinically important, and relevant to their patients. Cohort studies are considered the best design for assessing prognosis, although the case-control design may be useful for rare diseases or disorders for which follow-up must be very long.

The representativeness of patients selected for the cohort study depends on the criteria for inclusion and exclusion and the case definitions used. It is important that patients be included relatively early in the disease process to prevent missing out on more severely affected patients that might die before being included. The way in which individuals were identified for inclusion is critical for evaluating the potential for selection bias: Were all eligible horses with the disease included? Were the horses in some way selected? If so, was the selection process unbiased?

As for clinical trials, it is important for cohort studies that the follow-up procedures are consistent among groups, that losses to follow-up are not excessive, that events of interest are not missed, and that the length of the study period is appropriate for the disease of interest. Evidence that those lost to follow-up were compared with the baseline population and that the groups appeared similar enhances the validity of a cohort study. As for RCTs, the 20% guideline may be applied. Although assessing death is relatively objective, defining the cause of death or other outcomes for prognosis (e.g., failure to return to racing, infertility) may be more subjective and less accurately determined. Thus clear definitions for objective assessments of outcomes enhance the validity of prognostic studies.

If a prognostic cohort study is valid, it will need to be assessed for importance. Data pertaining to prognosis are generally of the time-to-event variety. Thus description of the timing of events may yield clear evidence of the importance of the findings. In general, graphic representation (e.g., Kaplan-Meier curves) of data is likely to be more informative than summary statistics (e.g., the median survival time or the proportion surviving for 1 year).<sup>3</sup> The precision of the estimated prognosis also must be provided so that confidence in the reported results can be properly assessed. Typically, this precision would be represented as a 95% confidence interval for estimated parameters or survival curves. Finally, it is important to consider the similarity of the patients studied to the patient being treated.

**Grading Evidence** In human medicine efforts have been made to develop grading systems for evidence.<sup>2,3,6</sup> Although similar systems may be developed for veterinary medicine, the need for application of these grading systems (e.g., formulating treatment policies or formal treatment guidelines) in equine medicine is unclear and likely premature.

#### STEP 4: APPLYING THE RESULTS

Ideally, the results of the first three steps would render the process of applying results relatively simple. Unfortunately, the framework of EBM becomes less stable with respect to application. Part of the problem with the application of results in equine medicine is the paucity of evidence derived from patient-centered studies on which to base treatment decisions; practitioners often must resort to weaker forms of evidence. The principal problem with this step, however, is that, although the basis for the first three steps (i.e., asking questions, finding information, and applying criteria to evaluate the evidence from clinical research studies) is well-defined and in many respects recursive, specifications for the proper application of results are not well-defined operationally. Inasmuch as equine practitioners must consider their clinical impressions and expertise as well as the preferences and particular circumstances of patients and clients, the process of how to apply results requires further development. Despite this limitation, awareness of the principles of clinical epidemiology and EBM will, it is to be hoped, lead to greater emphasis on the conduct of patient-centered studies in equine medicine and in the mentoring of trainees in the design, conduct, analysis, reporting, and interpretation of such studies. At the very least, principles of EBM will force equine practitioners to recognize the limitations of the evidence on which they act and accept these limitations with appropriate measures of skepticism and humility.

#### STEP 5: ASSESSING THE OUTCOMES

Clinicians often think of outcome assessment in terms of the patient: Did the horse survive? Did the disease resolve as a result of treatment? Did the horse return to use? Outcome assessments, however, should also include the perceptions of horse owners. Practitioners are sometimes irritated when owners ask them to implement certain treatments, particularly unfamiliar ones. However, in the absence of strong evidence for much of what equine practitioners do, it is important to recognize that clients' preferences may be as legitimate as those of veterinarians in terms of evidence. Moreover, clients' perceptions of their interactions with the veterinarian may influence their assessment of outcome as much as objective measurements of health or disease. All these types of outcome

assessments (e.g., patient health, owner perceptions), when systematically evaluated, can help practitioners determine the extent to which their efforts benefit their patients and clients. Although there are some sophisticated outcome assessment studies of the impact of EBM on selected health disorders of human beings, such objective assessment is lacking in equine medicine. However, it is not unlikely that the success of EBM in human medicine will also hold true for horses.

### **LIMITATIONS OF EVIDENCE-BASED MEDICINE**

Although the case for EBM is compelling, it has many limitations. Of those that will be mentioned, foremost is the lack of strong evidence in the form of well-designed, rigorously conducted clinical trials and observational studies on which to base clinical decisions. There are many explanations for the paucity of EBM resources. The roots of clinical veterinary medicine have been in the discipline of animal experimentation, and application of epidemiologic principles and methods for clinical investigation remains unfamiliar and troubling to many. The incentive for the pharmaceutical industry to develop a drug or biologic for horses is limited because of the small market share that horses represent relative to other companion animals or food-producing animals. The resources for conducting large clinical trials or observational studies are limited.

The definition of *EBM* remains vague, and it seems more intention based and motivational than stipulative or operational. It is easy to define the domain of a surgeon or a theriogenologist, but can we clearly identify an EBM practitioner?<sup>13</sup> A problem with ill-defined terms is that, no matter how noble the concept they represent, they can be inappropriately or inaccurately invoked to render credible or persuasive any particular point or effort.

The definition of *evidence* is also vague. It is wrong to think that EBM introduced evidence to medical practice. Clinicians have always used evidence in medicine, such as that derived from clinical experience, experimental research findings, and logical extrapolations or deductions of pathologic and physiologic knowledge. In general, the term *evidence* in the phrase *EBM* refers to clinical research findings, primarily those derived from patient-based studies. Some mistakenly interpret *evidence* in EBM to mean RCTs, others the most recent report pertaining to the topic, regardless of the design. The validity of EBM is largely determined by the extent to which *evidence* itself can be defined. Similarly, what is meant by “best,” with respect to available evidence, is ill-defined. Just because there is a clinical trial germane to a research topic of interest does not mean that it is the best source of information: RCTs can have important deficiencies in terms of design and analysis (internal validity) or relevance to other populations of horses (external validity). Similarly, there can be sufficient evidence in the absence of clinical trials. A comical example was reported in the *British Medical Journal* in 2003: The authors identified the absence of RCTs to document the effectiveness of parachutes in preventing injuries during free fall from airplanes.<sup>14</sup> They concluded that RCTs of parachutes were needed to meet the criteria of some EBM adherents, and they proposed that these EBM proponents be recruited as participants for the trial. Although the report was intended to be humorous, the point that other sources of evidence than RCTs are valid bases for making

clinical decisions is serious and important (and particularly relevant to equine medicine).<sup>15</sup>

Another limitation is that the process of EBM requires incorporating clinical experience and expertise, the expectations of clients, and the particular circumstances of each patient into the decision-making process.<sup>13</sup> However, no clear operational framework exists that explains how to accomplish this. EBM is compelling with respect to intent, but practitioners do not have much guidance in applying its findings.

Another limitation of EBM is that, although the principles are logical and commendable, it is impossible to know whether the approach will make any difference. Clinical trials comparing use of EBM with not using EBM for patient management are lacking. From the standpoint of outcome assessment, EBM is as much a system based on belief and credence as are other approaches that rely on credence of perceptions and authority of expert opinion.

### **CONCLUSION**

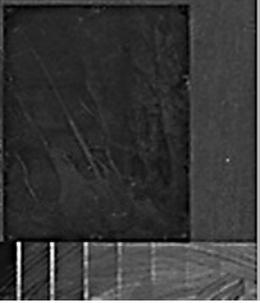

The discipline of EBM developed as an extension of principles of clinical epidemiology during the early 1990s, and awareness of and interest in the application of EBM to equine medicine have grown in recent years. This chapter was intended to introduce the principles and techniques of EBM and to consider its limitations, with an emphasis on possible applications to equine medicine. The principal advantages of EBM for equine internal medicine appear to be twofold. First, the approach forces practitioners to question the basis for what they do at all steps in case management and thus to think more carefully about what they know or believe they know. Second, awareness of EBM has helped move practitioners away from the traditional approach of using their understanding of disease mechanisms in conjunction with their experiences, the opinions of experts, and logical deductions or extrapolations for basing their clinical decisions and toward an approach that relies more heavily on information derived from clinical research involving patients (but *not* experimental animals). Patient-based (epidemiologic) studies, even RCTs, are prone to biases. The paucity of systematic reviews and meta-analyses addressing most clinical questions in equine medicine means that our best evidence is primarily derived from individual studies, often ones that are observational in nature. Thus all who wish to apply EBM require the ability to critically appraise these studies. In this way, placing value on EBM should lead to better-informed, more careful evaluation of evidence.

Although the framework for the first three steps of EBM is well-established, EBM has some important limitations. The last two steps (application and assessment) are not well characterized from an operational standpoint, and the ambiguity of the definitions of the terms *EBM*, *evidence*, and *best evidence* may lead to confusion and imprecision.

There are good and bad aspects to EBM in its current state of development. The process of applying EBM to equine medicine is like the Neurathian predicament of trying to construct a ship while already at sea. The traditions of empiricism and authority are deep and their currents strong, whereas the resources for building equine EBM are thin and often tenuous. Despite these frailties, the principle of thinking critically about medical decisions and the evidence on which these decisions are based should benefit equine medicine.

**DISORDERS OF  
SPECIFIC BODY  
SYSTEMS**

# DISORDERS OF THE RESPIRATORY SYSTEM

## CHAPTER 9

*Dorothy M. Ainsworth, Jonathan Cheetham*

Disorders of the respiratory system are second in importance only to those of the musculoskeletal system in limiting the athletic performance of the horse. Early detection and treatment of respiratory problems is essential to reduce economic losses and to prevent premature retirement of the horse from athletic performance.

### ☞ DIAGNOSTIC APPROACH TO RESPIRATORY DISORDERS

#### HISTORY

The clinician should direct questions to the person most familiar with the performance and medical history of the horse. Accurately defining the problem, devoid of subjective impressions, can be the most difficult part of taking the history.

#### AGE AND BREED

The age of the animal exhibiting respiratory-related signs may provide clues as to the problem. Congenital defects (nasal septal deviations, choanal atresia, subepiglottic cysts, and hypoplastic lungs) are typically evident at birth, whereas other conditions, such as chronic bacterial pneumonia (*Rhodococcus equi*), may not be evident until the foal is 1 to 3 months of age. Viral and bacterial upper respiratory tract infections tend to occur in the weanling and yearling, whereas conditions such as inflammatory airway disease, pleuropneumonia, and exercise-induced epistaxis are found more commonly in performance horses 2 years or older. In contrast, recurrent airway disease (heaves) or neoplasia of the respiratory tract is diagnosed primarily in the middle-aged or older horse.

Breed considerations are also important in investigating respiratory disorders. For example, one should evaluate young Arabian foals with chronic infections for combined immunodeficiency syndrome, a heritable condition in which cell-mediated and humoral limbs of the immune system are deficient. In addition, solitary defects in the humoral immune system also predispose horses to develop chronic respiratory and enteric infections. Selective immunoglobulin M (IgM) deficiency tends to occur more frequently in Arabians and Quarter Horses than in other breeds, whereas agammaglobulinemia has been documented in Thoroughbreds and Standardbreds.<sup>1,2</sup>

#### ENVIRONMENT

One should ascertain the environment to which the horse was or presently is exposed. For example, is the horse stabled at a racetrack where population turnover is high and the potential for viral respiratory outbreaks is increased, or is the horse a sole inhabitant of a small pasture, seldom exposed to other horses? Does the farm have a history of endemic infections, as often occurs with *Streptococcus equi* subsp. *equi* outbreaks? Has the horse been exposed to pastures grazed by donkeys? This, along with information regarding the diet (hay, pelleted rations, or pasture), the nature of the bedding materials (straw, peat, or shavings), and the amount of time the horse is stabled are important considerations in establishing the risk factors for some respiratory disorders such as recurrent airway obstruction or lungworm infections. One should also obtain the deworming and vaccination schedules. Young horses are at risk for developing verminous pneumonia resulting from *Parascaris equorum* migration. Nematode eggs can survive for prolonged periods on a pasture. Thus establishing whether the foal was exposed to pastures grazed by yearlings or 2 year olds may help in establishing the diagnosis and treating the problems. If the horse is a performance animal and is at an increased risk for developing upper respiratory tract infections, one should determine how frequently equine influenza and equine herpesvirus type 1 (EHV1) and type 4 (EHV4) vaccinations are administered.

#### PRIOR MEDICAL PROBLEMS

Does the horse have a history of illness or trauma that might be related to the present complaint? Viral respiratory conditions often precede the development of bacterial pneumonia. Sequelae to *S. equi* subsp. *equi* infections include internal abscessation, guttural pouch empyema, retropharyngeal abscesses, and purpura hemorrhagica, which may ultimately affect the respiratory, cardiovascular, and gastrointestinal systems. Trauma may be implicated in the development of diaphragmatic herniae, pneumothorax, or tracheal injury and subsequent stricture formation.

#### PRESENT MEDICAL PROBLEM

Questions should be focused on defining the exact problem, establishing the chronicity of the disorder and the rapidity of its development. Is the problem insidious in onset or an acute

disorder of less than 2 weeks' duration? Is the onset associated with a stressful event such as racing or a prolonged van ride? Does the farm have new arrivals that have not been quarantined? One should also determine the effect of the respiratory complaint on the expected athletic performance: Are clinical signs evident during eupneic (resting) breathing, or are they noticeable only during the hyperpnea of exercise? Has the horse received any medication, and did the clinical condition improve? Amelioration of signs during therapy suggests that the previous treatment protocols were not of sufficient duration or that an underlying immunodeficiency exists.

## PHYSICAL EXAMINATION

Before physically examining the horse, it is helpful to simply step back and observe the demeanor and mental status (alert or depressed), posture, and manner of movement of the horse. Has the horse adopted a particular stance (extended head and neck), or is it reluctant to move because of pain (pleurodynia)? Are changes in the pattern of breathing from the normal eupneic state obvious (Box 9-1)? Is the breathing pattern rapid and shallow? Does nostril flaring accompany a pronounced expiratory effort? The normal respiratory rate of the adult horse varies from 8 to 15 breaths per minute, with a slightly noticeable abdominal component during expiration (an active process in the horse).

Abnormalities of the respiratory system are evident also by the production of unusual sounds associated with respiration; the presence of a cough; a nasal or ocular discharge; lymphadenopathy; epistaxis; facial, pharyngeal, or cervical swellings; and discolored mucous membranes. Ataxia or reluctance to move, the presence of ventral thoracic or limb edema, halitosis, and weight loss may occur with respiratory disorders.

During the physical examination, the clinician should assess the airflow from both nostrils to rule out potential masses that are obstructing the nasal cavity. This assessment is a very important and easily overlooked step of the physical examination. One can detect atheromata, which may restrict airflow during exercise, by palpating the false nostrils. Any peculiar breath odors are detectable at this time.

Percussion of the frontal and maxillary sinuses, performed by gently tapping over the sinuses while one holds the mouth of the horse slightly open, may reveal a dullness because of accumulations of fluid or inflammatory products. The absence of a percussible change does not rule out a sinus disorder. One also should assess evidence of swelling in the submandibular space (lymphadenopathy) or in the pharyngeal (guttural pouch or retropharyngeal disorders) and cervical areas (presence of accessory lungs).<sup>3</sup> Palpation of the laryngeal cartilages is important. Notably, the palpation of a more prominent muscular process of the arytenoid cartilage, caused by dorsal cricoarytenoid muscle atrophy, is subjective and may not be a good predictor of the presence of recurrent laryngeal neuropathy (RLN). A surgical scar can be detected by picking up and rolling the skin at the potential surgical site between the thumb and index finger. These sites include the dorsal lateral larynx (laryngoplasty), the intermandibular space in the midline and level with the vertical rami of the mandibles (laryngeal tie-forward) and cricothyroid notch (arytenoidectomy, vocal cordectomy). Any disparity in the angle of the lashes of the upper eyelids should also be noted. Vertical eyelashes and eyelid drooping in one eye (ptosis as a result of Horner's syndrome) suggest dysfunction of Müller muscle caused by

### BOX 9-1

#### BREATHING PATTERNS

**Eupnea.** The normal quiet and seemingly effortless breathing pattern adopted by the healthy horse at rest. Inspiration and expiration in the horse are active processes.

**Tachypnea.** A breathing pattern characterized by rapid frequency and shallow depth or small tidal volume.

**Hyperpnea.** A breathing pattern characterized by an increase in the depth and rate of breathing, as might be found during exercise.

**Apnea.** A time period in which no discernible respiratory effort is made and airflow has ceased. Apnea may accompany sleep-related disorders or excessive ventilation (hypocapnia-induced apnea).

**Hypoventilation.** A pattern of breathing that alters gas exchange sufficiently to cause hypercapnia or elevations of arterial carbon dioxide tension.

**Hyperventilation.** A pattern of breathing that increases alveolar ventilation and results in arterial hypocapnia.

**Respiratory Distress.** A breathing pattern that appears to reflect difficulty in breathing. The animal appears to be distressed, and increased work of breathing is obvious.

damage of the vagosympathetic trunk.<sup>4,5</sup> Tracheal palpation is routine and should not elicit coughing episodes in the normal horse. The patency of the jugular veins should also be checked. Any evidence of perivascular injections that may contribute to upper respiratory tract obstructions by involving the recurrent laryngeal nerve or vagosympathetic trunks should be noted.

The clinician then should conduct a complete physical examination, paying attention to all organ systems (not simply focusing on the respiratory system). In respiratory emergencies, one conducts an abbreviated initial examination, making certain that a patent airway is established and that the patient is stabilized until such time when a more thorough physical examination can be conducted.

#### AUSCULTATION OF THE LUNG FIELDS

Examine the horse during eupneic and hyperpneic (by use of a rebreathing bag) breathing. Normal breath sounds are those produced by turbulent air movement through the tracheobronchial tree and vary in intensity and quality depending on the portion of the lung field auscultated. The vesicular sounds, over the middle and diaphragmatic lung lobes, are the quietest sounds; the bronchial sounds, over the trachea and the base of the lung, are the loudest.<sup>6-8</sup> In the normal horse, one can hear breath sounds more easily on the right side than on the left. Considerable variation exists between normal patients in the intensity of the breath sounds. For example, vesicular sounds are often barely audible during eupneic (normal) breathing in the obese patient and are perceived as soft rustling sounds. However, one may hear breath

sounds easily in the thin or young animal because of less attenuation of lung sounds by the chest wall. The intensity of breath sounds also increases with increased airflow. Thus breath sounds are accentuated in febrile or excited animals or in animals hyperpneic from a variety of causes (exercise, hypoxia, pain). However, auscultatory findings do not always correlate well with the degree of alveolar ventilation.<sup>7</sup> For example, in horses with lung consolidation, the transmission of breath sounds from adjacent areas gives the false impression that that region is well ventilated. Breath sounds also may become more difficult to hear in cases of (1) alveolar overinflation in which the aerated tissue of the lung is a poor conduction medium of sound or (2) pneumothorax and pleural effusions in which the sound is reflected at the pleural surface (acoustic impedance).<sup>7</sup>

Adventitious lung sounds are abnormal sounds superimposed on the normal breath sounds and have been described as crackles or wheezes. Crackles are short, explosive, discontinuous sounds that have been likened to the sound of salt thrown in a hot frying pan or the sound of cellophane being crumpled. They are usually of low intensity and are audible during the inspiratory phase of respiration. Their production has been attributed to the sudden equalization of pressure in two compartments after airways have reopened. Crackles are often audible in horses with pneumonia, pulmonary edema, or recurrent airway obstruction. Breathing 100% oxygen also may produce crackles because the nitrogen stent maintaining alveolar distention is eliminated.<sup>9</sup> Crackles are also audible in horses with subcutaneous emphysema. Wheezes are musical sounds thought to arise from the vibration of airway walls or tissue masses in close contact with the airway walls and may be audible during inspiration or expiration. Wheezes may be monophonic or polyphonic, the latter indicative of multiple sites of airway obstruction. Pleuritic friction rubs have been described as sandpaper-like sounds generated by the movement of the visceral and parietal pleurae across each other. One may detect them (infrequently) in the early stages of *dry* pleuritis, before the effusive stage.

### PERCUSSION OF THE THORAX

Percussion of the thorax is accomplished by evaluating the type of sounds produced as one systematically taps the intercostal spaces of the thorax using a plexor and pleximeter (foals) or a large spoon and neurologic hammer (adults). Alternatively, an Azary pleximeter that is made of horn and a metal percussion hammer with a rubber tip may be used because of its improved sound quality.<sup>10</sup> Aerated tissues produce a resonant sound, whereas fluid-filled structures (bowel, heart, lung abscesses, consolidated lung) produce a dull sound. One should identify the transitional site where the sound quality changes during percussion (the site is marked with a piece of tape) and then compare with the normal limits in a healthy horse. The cranial limit is the shoulder musculature, the dorsal limit is the back musculature, and the caudoventral limits are the seventeenth intercostal space at the level of the tuber coxae, the sixteenth intercostal space at the level of the tuber ischii, the thirteenth intercostal space at the mid thorax, the eleventh intercostal space at the level of the scapulohumeral articulation, and the sixth intercostal space at the olecranon.<sup>11</sup> Defining the caudal lung borders of the lung field by thoracic percussion, at least in healthy horses, agrees well with the more routinely used method of ultrasonography.<sup>10</sup> Occasionally, the gas content of the large colon on the left side or of the cecum on the right side

precludes detection of the caudal lung border in the sixteenth intercostal space in some horses.<sup>10</sup> Thoracic percussion should not be painful; resentment by the horse may indicate pleuritis or rib fractures. A ventral dullness suggests pleural effusion, pleural thickening, lung consolidation, masses, or pericardial effusion. Occasionally, caudal borders may be expanded, suggesting alveolar overinflation, which may accompany recurrent airway disease.

### ENDOSCOPY

Fiberoptic endoscopy is an essential tool for assessing the equine respiratory tract. Endoscopy is helpful in establishing (1) the origin of respiratory noises that accompany laryngeal hemiplegia, dorsal displacement of the soft palate, epiglottic entrapment, rostral displacement of the palatopharyngeal arches, arytenoid chondritis, tracheal collapse or stenosis, and pharyngeal narrowing; (2) the existence of congenital defects such as subepiglottic cysts, cleft palate, or choanal atresia; and (3) the source of exudate or hemorrhage occurring with guttural pouch mycosis or empyema, ethmoidal hematoma, pulmonary epistaxis, retropharyngeal abscessation, and chronic pulmonary disease. Endoscopy also enables one to extract foreign bodies from the tracheobronchial tree and to obtain biopsies of tissues or masses in the respiratory tract. Endoscopic visualization of exudates within the pharynx or the trachea after exercise suggests the presence of inflammatory airway disease. Endoscopy is also used to obtain tracheobronchial aspirates (guarded swabs or catheters)<sup>12</sup> or to perform bronchoalveolar lavage (see later discussion). Several different fiberoptic endoscope models are available, but an 11-mm (outer diameter) endoscope is usually used in adult horses, and a smaller, 7.8-mm (outer diameter) pediatric scope is recommended for foals.

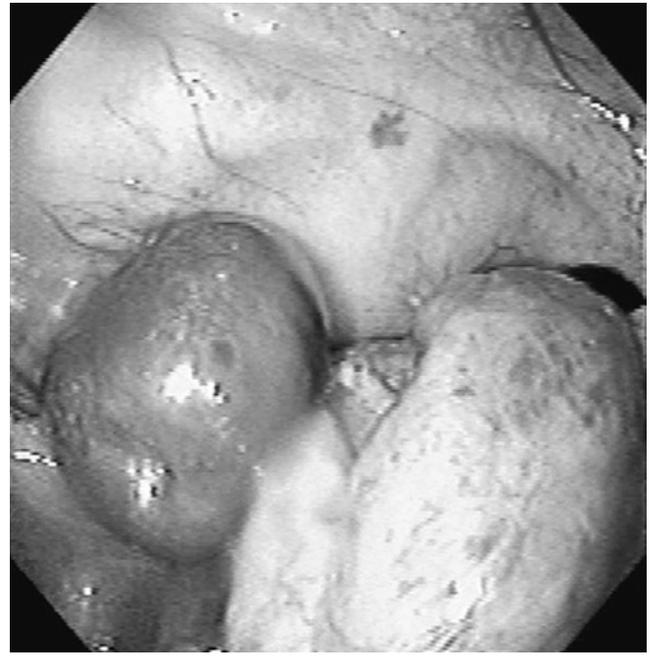

Videoendoscopic examination of the upper respiratory tract during maximal treadmill exercise (12 to 14 m/s) is a routine diagnostic modality at many referral centers, allowing visualization of dynamic collapse of the upper airway structures during exercise. Several studies have described the presence of multiple sources of airway collapse at high speed, including the aryepiglottic folds, vocal cords, and arytenoid cartilages.<sup>13-15</sup> Frequently, an abnormality in one structure produces narrowing of the airway, making inspiratory pressures more negative and leading to collapse of other structures. In one study, more than one abnormality was identified in 49% of the horses.<sup>15</sup> Accurate identification and appropriate treatment of these complex cases is not possible without a treadmill examination.

### SINUSCOPY

Sinuscopy entails direct examination of the interior of the paranasal sinuses using an endoscope or an arthroscope that is introduced through a small trephine opening and is useful for diagnosing or treating sinus disease.<sup>16,17</sup> In selected cases, sinuscopy may be a diagnostic or therapeutic alternative to flap sinusotomy. The caudal maxillary sinus can be approached at a point 2 cm rostral to the midpoint of a perpendicular line drawn from the medial canthus of the eye to the facial crest. The rostral maxillary sinus can be accessed 2 cm caudal to the midpoint of a line drawn from the rostral end of the facial crest to the infraorbital foramen. The frontoconchal sinus is accessible through a portal placed 40% of the distance of a perpendicular line drawn from 0.5 cm caudal to the medial canthus from the midline. The site affords excellent visualization of the

**FIGURE 9-1** Sinusoscopic view of the caudal maxillary sinus in 16-year-old Thoroughbred gelding with a history of epistaxis. A large fungal colony is on the infraorbital canal, and several small blood clots are visible. (Courtesy R. P. Hackett, Ithaca, N.Y., 2001.)

frontoconchal sinus and, via the large frontomaxillary opening, the caudal maxillary sinus. After sedation of the horse and surgical preparation and local anesthesia of the selected site, the clinician makes a small skin incision and opens the bone with either a 0.25-inch Steinmann pin (for a 4-mm diameter arthroscope) or a 10-mm trephine (for a 9-mm endoscope). The endoscope provides better illumination and a greater field of view. In addition to direct examination of the sinus interior for diagnosis (Figure 9-1), sinuscopy allows the examiner to biopsy tissues under direct visualization and to apply therapeutic procedures such as formalin injection of mass lesions (Figure 9-2), cyst removal, and removal of sequestered bone fragments. After the examination, the clinician may close the portal with cutaneous sutures or leave it open for therapeutic lavage.

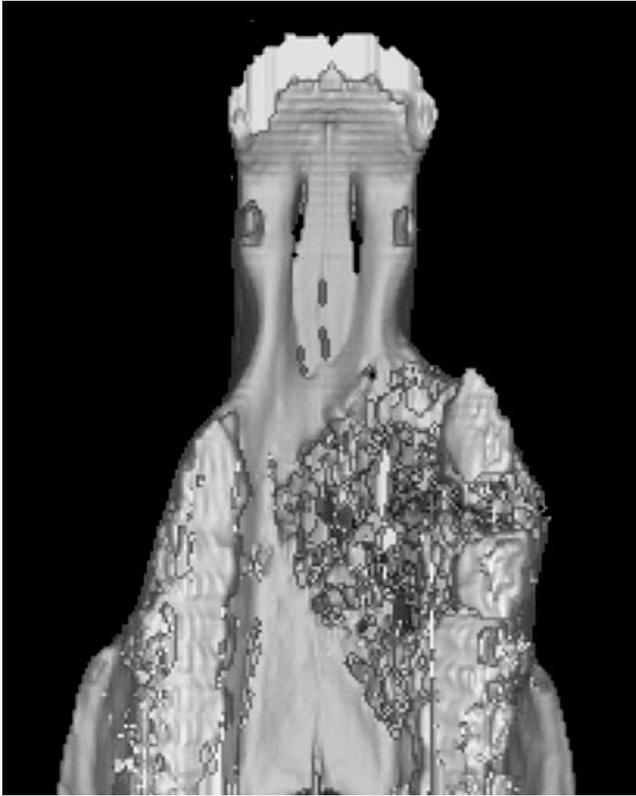

### COMPUTED TOMOGRAPHY

Interpretation of conventional radiographs of the equine head is notoriously difficult because of the complex anatomy and the spectrum of radiographic densities: air, soft tissue, bone, and tooth. Radiographs and clinical examination may not define accurately the location and extent of lesions in the head region, necessitating computed tomographic (CT) scans.<sup>18</sup> CT uses a rotating, highly collimated x-ray beam to generate digital cross-sectional images.<sup>19,20</sup> These cross-sectional images afford a much better evaluation of normal and pathologic anatomy than can be achieved through conventional radiographs (Figures 9-3 to 9-5). Additionally, the digital format enables three-dimensional reconstruction of structures and manipulation of images to optimize interpretation (see Figure 9-4). Constraints for this technique are its expense and limited availability and the need for general anesthesia of the horse.

**FIGURE 9-3** Cross-sectional image of an ameloblastoma involving the upper left premolars of a 4-year-old Warmblood gelding. A large soft tissue mass is encroaching on the nasal passages, and significant osseous destruction of the hard palate, ventral concha, and premaxilla is visible. (Courtesy R. P. Hackett, Ithaca, New York, 2001.)

Computed tomography has proved particularly useful for examining the anatomically complicated structures of nasal turbinates, paranasal sinuses, teeth, nasopharynx, and guttural pouches and for evaluating areas obscured by overlap of adjacent structures on conventional radiographs.<sup>18,21-25</sup> CT

**FIGURE 9-4** Three-dimensional reconstruction of the premaxilla in Figure 9-3. The extent of osseous destruction of the hard palate can be delineated clearly, as can separation of the second and third premolars. (Courtesy R. P. Hackett, Ithaca, N.Y., 2001.)

is better than plain radiography for the diagnosis of dental disease caused by inherent avoidance of superimposition of the opposite dental arcade, excellent bone density characterization, and good spatial resolution.<sup>26</sup> Improved evaluation of these structures has enhanced considerably the clinician's ability to determine an accurate diagnosis, select optimal surgical approaches, and render an appropriate prognosis.

Computed tomography has been of limited usefulness in evaluating the lower respiratory tract in adult horses because of the size constraints of the gantry. However, CT is an excellent diagnostic modality for detecting and defining the extent of pulmonary or mediastinal masses in the thorax of foals, ponies, and miniature horses.<sup>27</sup>

### MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) is another modality that can be used to investigate upper respiratory tract disorders. Magnetic resonance images represent a map of tissue protons that, under the influence of a magnetic field, are excited by brief pulses of radiofrequency waves.<sup>19</sup> As the magnetized excited protons relax back to their original magnetized state, a signal is emitted, the intensity of which is converted to a gray-scale image. MRI provides excellent cross-sectional evaluations of soft tissue structures, although it also provides useful information about bony structures. Contrast enhancement can be achieved by injecting an intravenous derivative of gadolinium during the T1-weighted scans.<sup>19</sup> Magnetic resonance images of the equine sinuses and nasal passages have been

**FIGURE 9-5** Cross-sectional image of an adenocarcinoma affecting the ethmoid turbinate in a 23-year-old hinny. (Courtesy R. P. Hackett, Ithaca, N.Y., 2001.)

previously described,<sup>28</sup> although these images were obtained from cadaver heads. More recently, a detailed MRI study of horses with neurologic signs localized to the cerebrum, brainstem, or both was published demonstrating that equine skull structures can be imaged.<sup>29</sup> The authors note that compared with MRI in small animals, this imaging technique requires additional modifications with respect to the use of the contrast agent (gadolinium-diethylene triamine pentaacetic acid dose) and the scanning room, which must accommodate an anesthetized horse positioned on a nonmetallic support table. Because of equipment size constraints, MRI would likely be used only to evaluate thoracic structures in foals or miniature horses.

### SAMPLING OF RESPIRATORY TRACT SECRETIONS

**Centesis of the Paranasal Sinuses** The clinician should perform centesis of the paranasal sinuses when radiographic or CT examination reveals fluid lines or soft tissue densities in the sinuses. In the sedated horse, the technique is performed aseptically using a Steinmann pin that has been advanced through a site that has been infiltrated with local anesthesia. One enters the rostral maxillary sinus at a site 2.5 cm dorsal to the facial crest and 2.5 cm caudal to the infraorbital foramen. One enters the caudal maxillary sinus, which communicates with the frontal sinus, at a site 2.5 cm dorsal to the facial crest and 2.5 cm rostral to the medial canthus. The clinician should submit aspirates for cytologic examination and bacterial culture.

**Guttural Pouch Catheterization and Culture of the Exudate** One performs guttural pouch catheterization in cases of empyema, chondroids, or distention of the pouches or in suspected cases of *S. equi* subsp. *equi* infections. With the horse sedated, the clinician passes a fiberoptic endoscope into the guttural pouch using the biopsy instrument or a Chambers catheter as a guide for the endoscope. One obtains a sample of

the exudate with a triple-guarded catheter or protected swab. A technique for obtaining percutaneous aspirates of the guttural pouches recently has been described, but the authors prefer to use endoscopic visualization for sample collection.<sup>30</sup> Cytologic examination of guttural pouch aspirates from normal horses demonstrates the presence of mucus, a predominance of ciliated columnar epithelial cells, neutrophils, and a few (<1%) macrophages, lymphocytes, and eosinophils. Aspirates are not normally sterile; common bacterial isolates include  $\beta$ -hemolytic *Streptococcus*, *Staphylococcus*, and *Moraxella* species.<sup>31</sup> *S. equi* subsp. *equi* is not a normal inhabitant of the guttural pouch.

In horses suspected of having guttural pouch epistaxis, one should exercise caution regarding catheterization or endoscopic examination of the pouch. The procedure may dislodge a blood clot and cause fatal hemorrhage.

**Sampling of Tracheobronchial Secretions** Several techniques have been advocated for obtaining tracheobronchial samples. The choice of site for sample collection (tracheal versus bronchoalveolar) depends on the nature of the respiratory disorder. The appropriateness of using tracheal samples to evaluate chronic inflammatory disorders has been challenged because little correlation exists between tracheal and bronchoalveolar lavage cytologic findings or between tracheal and pulmonary histopathologic findings.<sup>32,33</sup> In contrast, a good correlation exists between bronchoalveolar lavage cytologic findings and pulmonary histopathologic findings.<sup>34</sup>

Tracheobronchial aspirates remain the method of choice for the investigation of infectious lower respiratory tract disorders. Collection of culture samples by fiberoptic endoscopy simplifies the procedure and eliminates some of the complications formerly associated with the transtracheal technique, such as cellulitis and pneumomediastinum. Guarded tracheal swabs<sup>35</sup> and the telescoping plugged catheter of Darien<sup>12</sup> are convenient techniques for obtaining representative samples. However, oropharyngeal contamination may still occur when one obtains tracheobronchial aspirates endoscopically using telescoping plugged catheters.<sup>36,37</sup> The authors prefer to obtain tracheobronchial aspirates percutaneously.

Characterization of the normal bacterial isolates from tracheobronchial aspirates in healthy horses has been well documented. When examining a horse with suspected respiratory disease, one must evaluate culture results in light of the cytologic findings and clinical examination. The tracheobronchial aspirates of approximately 8% of normal horses (pastured

or stabled) were found to be culture positive for *Klebsiella*,  $\beta$ -hemolytic streptococci, *Pasteurella* species, and *Pseudomonas aeruginosa*. For a microorganism to be implicated in a lower airway disorder, one would expect (1) to obtain a moderate to heavy growth of the organism on culture ( $\geq 1 \times 10^3$  colony-forming units), (2) to identify organisms within phagocytic cells, and (3) to have evidence of degenerative neutrophils. In contrast, anaerobes, which are a normal component of the oropharyngeal flora, are normally not isolated from aspirates of healthy horses, emphasizing their importance in disease processes when recovered from respiratory cases. Based on their studies, Sweeney, Beech, and Roby<sup>38</sup> also have described a group of transient bacterial flora of questionable pathogenicity such as *Enterobacter*, *Bacillus*, *Acinetobacter*,  $\beta$ -hemolytic streptococci (except for *Streptococcus pneumoniae* type 3), and *Staphylococcus epidermidis*, which may be isolated from tracheobronchial aspirates. In contrast, *S. pneumoniae* is now recognized as a pathogen of the respiratory tract in horses.<sup>39-41</sup> Fungal hyphae may be found free or engulfed within mononuclear cells in normal horses.

**Bronchoalveolar Lavage** This procedure is indicated in the investigation of chronic inflammatory diseases but may be performed with collection of transtracheal aspirates if one cannot dismiss an infectious process. Table 9-1 shows representative cytologic findings from bronchoalveolar lavage studies of normal horses. Before performing the bronchoalveolar lavage, the horse is sedated. Either a fiberoptic endoscope, which permits direct visualization of the lung segment to be lavaged, or a thick-walled flexible tube with a cuffed end, which is passed blindly into the distal airways, is wedged into the distal airway. Then, 20 to 35 ml of 2% lidocaine may be infused into the airways to desensitize the lung segment being sampled. Approximately 60 (foal) to 300 ml (adult horse) of physiologic saline solution is instilled and then aspirated. In healthy horses, nearly 75% of the fluid can be retrieved for cytologic examination. This volume is more difficult to obtain in horses with airway inflammation and mucus plugs.

## RADIOGRAPHY

This technique may be helpful (1) in detecting soft tissue masses (abscesses, granulomata, neoplasms, hematomas, polyps) or fluid accumulations within the paranasal sinuses, the nasal cavity proper, the guttural pouches, and the retropharyngeal areas and (2) in evaluating orofacial deformations or

\*Percent of total white blood cell count plus-or-minus standard error or standard deviation.

fractures after trauma. Radiography also allows assessment of the anatomic dimensions of the pharyngeal and laryngeal structures (thickened soft palate, hypoplastic epiglottis, hyoid bone fractures). When nasal or sinus disorders are suspected, one should take lateral, dorsoventral, and oblique views. The clinician can usually achieve proper restraint of the horse for positioning of the cassette with xylazine, detomidine, or butorphanol sedation. In the horse that can be anesthetized safely, one may obtain a more thorough definition of the extent of nasal and upper respiratory tract diseases using CT scans.

Radiographic evaluation of the equine thorax remains preferable to ultrasonography for detecting diffuse parenchymal diseases such as interstitial pneumonia, pulmonary edema, and chronic airway disorders and for detecting deep parenchymal abscesses.<sup>42</sup> Imaging the thorax of the standing horse requires three to four overlapping lateral radiographs. However, compared with human or small animal medicine, in which correlations between the pulmonary disorders and the radiographic findings are well established, the radiographic changes in equine respiratory disorders tend to be rather nonspecific and lack predictive value in inflammatory airway diseases.<sup>43</sup> In addition, many pulmonary diseases such as inflammatory airway disease, exercise-induced pulmonary hemorrhage, lungworm infections, and recurrent airway obstruction may not have detectable radiographic abnormalities.<sup>43</sup>

Four types of radiographic patterns have been described: alveolar (airspace), interstitial, bronchial, and vascular. In the alveolar pattern, opaque areas coalesce and completely obliterate the vessels and bronchi. Air bronchograms may be notable. This pattern occurs with pneumonia, pulmonary edema, hemorrhage, or neoplastic infiltration. Interstitial patterns are found most commonly and are associated with a variety of conditions. This pattern causes a blurring of the edges of the pulmonary vessels, a diffuse increase in lung opacity, and variable reticular, linear, or nodular opacities.<sup>43,44</sup> A reticular pattern occurs with viral, bacterial, or parasitic pneumonia; pulmonary edema; interstitial pneumonia; and pulmonary fibrosis. An irregular linear pattern occurs with resolving bronchopneumonia, and a nodular pattern occurs with abscesses, granulomata, or neoplasms. Bronchial patterns alone are not found commonly but usually occur in association with interstitial patterns. Paired linear opacities or numerous small circular opacities represent thickening of the large- and medium-sized airways or of the septa around the lobules. This pattern occurs in cases of equine bronchitis. Bronchiolitis is generally not recognized radiographically.<sup>45</sup> Variations in the size, shape, and number of the pulmonary vessels cause a vascular pattern and may be visible in horses after exercise or in horses with left-to-right cardiac shunts.

Extraparenchymal disorders that are evident radiographically include the presence of free pleural fluid or of free gas (pneumothorax) represented by the separation of the right or left or both caudal lung lobes from the dorsal and dorsolateral body wall by a free-air density. Pleural fluid is characterized by an increased opacity in the ventral lung fields.

## ULTRASONOGRAPHY

Thoracic ultrasonography is useful for diagnostic, therapeutic, and prognostic evaluation of peripheral parenchymal lung or pleural disorders. Unlike thoracic radiography, which requires technology limited to specialty practices or veterinary medical teaching hospitals, ultrasonography is a method readily

available to the practicing veterinarian. Ultrasonography is considered to be superior to thoracic radiography for detecting pleural effusion, pulmonary consolidation, pulmonary or mediastinal abscesses, tumors, or granulomata<sup>42</sup> and should be performed when clinical examination or thoracic percussion reveals pain and areas of dullness within the thorax.

Normal lung tissue reflects the ultrasound beam, producing an echogenic pulmonary periphery (thin white line) and reverberation artifacts or concentric equidistant echoes. Normal pleural fluid appears as an anechoic (black) area separating the parietal pleura from the lung tissue, and one commonly detects a small amount of pleural fluid in the ventral thorax of racehorses.<sup>46</sup> In respiratory disorders, one may detect accentuated amounts of anechoic or hypoechoic (gray) pleural fluid. The clinician can determine the character of the pleural fluid, the presence of fibrin or gas, the degree of loculation, and the existence of pleural adhesions during the examination. Pulmonary abscesses appear on ultrasonography as encapsulated cavitated areas filled with fluid or echogenic (white) material, whereas areas of pulmonary consolidation appear as dense patterns of homogeneous internal echoes with a gray tone.<sup>47</sup> Depending on the degree of consolidation, one may visualize bronchial and vascular structures more easily on the sonogram, as well as mediastinal masses. Detection of caudal mediastinal masses improves when pleural effusion is concurrent, because the aerated caudal lungs impair examination. One may visualize masses located in the cranial mediastinum at the third right intercostal space in the absence of pleural effusions.

Diagnostically, certain limitations are inherent in ultrasonography. One may not detect a deep parenchymal lesion if the overlying aerated lung reflects the ultrasound beam. In addition, cases of pneumothorax may be difficult to identify because the free air in the dorsal thorax and the aerated ventral lung appear similar with ultrasound.<sup>42</sup> One also may use ultrasonography prognostically. The detection of free gas echoes (associated with anaerobic bacterial infections or bronchopleural fistulae), extensive fibrinous tags, or areas of loculations within the pleural fluid are associated with a poor prognosis, requiring a more extensive therapeutic regimen.<sup>48</sup>

## THORACOCENTESIS

Sampling of the pleural fluid by means of thoracocentesis is beneficial for diagnostic, prognostic, and therapeutic purposes. Abnormal pleural fluid accompanies numerous respiratory disorders, including pulmonary abscessation (pleuropneumonia), chronic pneumonia, systemic mycoses, neoplasia, pulmonary granulomata, and equine infectious anemia. One may perform the technique easily at the sixth or seventh intercostal space approximately 10 cm dorsal to the olecranon by aseptically inserting a teat cannula through an anesthetized site in the intercostal space, just cranial to the border of the rib. To reduce the amount of air aspirated into the pleural cavity, one attaches a three-way stopcock to the cannula. The clinician should take samples from both sides of the thorax and submit the aspirate for cytologic and microbiologic examination. One may obtain up to 100 ml of pleural fluid, although smaller amounts (10 to 30 ml) are more routine.<sup>49</sup> Normal pleural aspirates contain less than 10,000 nucleated cells per  $\mu\text{l}$  (60% of which are neutrophils) and less than 2.5 g/dl of protein. Samples should be cultured aerobically and anaerobically. Fluid with a putrid odor is associated with anaerobic bacteria and carries a less-favorable prognosis for the horse.<sup>50</sup>

## NUCLEAR MEDICINE IMAGING

Scintigraphy, or nuclear medicine imaging, is a specialized technique available at some university and practice facilities. Using gamma-emitting radioisotopes such as krypton-81m or technetium-99m, the clinician can assess pulmonary ventilation and perfusion in the horse.<sup>51,52</sup> The horse, breathing through a closed circuit, inhales aerosolized technetium particles generated by a nebulizer. Aerosolized particles are of sufficiently small diameter to be deposited in the alveoli and small airways. Thus their distribution mirrors ventilation. A gamma camera records the sites of deposition within the lung fields. For the perfusion scan, one injects technetium-labeled macroaggregated albumin intravenously. The large protein particles lodge in the blood capillaries of the lung, enabling imaging of the pulmonary perfusion by the gamma camera. Hence lung scintigraphy permits evaluation of the ratio of regional ventilation to perfusion ( $\dot{V}/\dot{Q}$ ) not possible by radiography or ultrasonography. Scintigraphic images may provide additional insights into the diagnosis and pathogenesis of such disorders as recurrent airway obstruction or exercise-induced pulmonary hemorrhage (EIPH) or in the evaluation of the horse with poor performance.<sup>53,54</sup> For example, horses with EIPH appear to have a perfusion deficit in the caudodorsal lung lobe that results in a high ( $\dot{V}/\dot{Q}$ ) area.<sup>53</sup> Horses with recurrent airway obstruction may produce several patterns, including ( $\dot{V}/\dot{Q}$ ) deficits in the costophrenic angle (caudoventral diaphragmatic margin), ventilation deficits in the mid dorsal lung area, or patterns similar to those seen in EIPH.<sup>55</sup>

In addition to assessment of pulmonary ventilation and perfusion, scintigraphy can show tracheal mucus transport after intratracheal injection of technetium. One performs the technique by timing the movement of the radioactive bolus over a given tracheal distance.<sup>56,57</sup> Normal values for the unsedated horse range between 16.6 to 20.7 mm/min. Further studies are needed to examine alterations in tracheal mucus transport during disease. For further information, the reader is referred to additional reviews.<sup>56</sup> Nuclear scintigraphy is not more useful than radiographs for the assessment of sinus disorders.<sup>58</sup>

## PULMONARY FUNCTION TESTING

Measurements of mechanical properties of the respiratory system, airway hyperreactivities, and arterial blood gas determinations have been used to assess the lower respiratory tract in horses and are generally available only at specialized pulmonary units associated with referral centers. The conventional techniques of pulmonary function testing require that (1) the horse wear a breathing apparatus to which an airflow meter has been attached and that (2) pleural pressure changes are measured by a catheter placed in the mid-esophagus, exteriorized through the nares, and attached to a pressure transducer. By integrating airflow relative to time, one obtains the inspiratory and expiratory volumes. Additional parameters obtained from measurements of airflow include inspiratory and expiratory times, breathing frequency, and peak airflows. In general, the simple measurement of tidal volume, breathing frequency, or minute volume (the product of tidal volume and breathing frequency) provides limited information regarding the functionality of the lung because these values

tend to be maintained near normal limits until respiratory disease is advanced.<sup>59</sup>

Measures of lung distensibility (dynamic compliance) and airway obstruction (pulmonary resistance) provide meaningful information regarding pulmonary health. One measures dynamic compliance ( $C_{dyn}$ ) by dividing the tidal volume by the change in pleural pressure occurring between the start and end of inhalation. One measures pulmonary resistance by several different techniques, depending on whether one measures the resistance at peak airflow or at specific ventilatory volumes (e.g., 50% tidal volume), and calculates it by dividing airflow by the change in pleural (esophageal) pressure. Alterations in these two values can provide information on the nature of the lung disorder. For example, in obstructive disorders of the tracheobronchial tree, dynamic compliance decreases and pulmonary resistance increases. A decrease in dynamic compliance in the absence of a change in pulmonary resistance suggests that the lung parenchyma has been stiffened by alveolar disease or by obstruction of the peripheral bronchioles. (Recall that peripheral bronchioles, because of their immense cross-sectional area, contribute little to the resistance of breathing until the disorder is well advanced.) Conversely, an increase in pulmonary resistance in the absence of a change in dynamic compliance suggests that the obstruction exists in the upper airway, trachea, or bronchus.<sup>60</sup>

An alternative and less-invasive technique for measuring pulmonary function uses the forced-oscillation method (or its modification, the impulse-oscillation method). While the horse wears an airtight facemask, an external test signal is imposed on the horse's breathing efforts that generate pressure-flow responses from the respiratory system. The mechanical properties derived from this technique over a wide range of frequencies (other than that of the horse's own breathing frequency) include total respiratory system impedance ( $Z_{rs}$ ), respiratory system resistance ( $R_{rs}$ ) and respiratory system reactance ( $X_{rs}$ ).<sup>61,62</sup> The impedance represents the *impediment* that the system presents to oscillatory flow and consists of  $R_{rs}$  (resistive properties of the respiratory system) and  $X_{rs}$  (elastic and inertive properties of the respiratory system).

Measures of airway hyperreactivity are often obtained in conjunction with pulmonary function testing.<sup>63-66</sup> In this technique, one determines the dose of a nebulized bronchoconstrictor agent, such as histamine or methacholine, that causes a 35% increase in baseline  $R_{rs}$  or a 35% decrease in baseline lung compliance. As might be predicted, the dose to achieve this value in a horse with inflammatory airway disease or recurrent airway disease is much smaller than that needed to achieve a similar effect in a healthy horse. Measurement of airway hyperreactivity requires that the horse be sedated and outfitted with an airtight breathing mask. Laboratory assistants should wear protective masks to prevent inhalation of the bronchoconstrictor agent.

Pulmonary function testing of exercising horses and its use in assessing the poor performer is a new diagnostic approach offered at select referral centers. With the availability of high-speed treadmills and the ability to measure airflow during exercise,<sup>67</sup> analysis of tidal volume, breathing frequency, dynamic compliance, lung resistance, end-expiratory lung volume, and flow-volume and pressure-volume loops may provide additional insights into the cause of the poor performance, the recognition of expiratory flow limitation, and the documentation of EIPH on respiratory mechanics.

## LUNG BIOPSY

A histopathologic diagnosis may prove useful in the therapeutic management of certain lung disorders. Percutaneous lung biopsy has been used to investigate (1) disorders characterized radiographically by a pulmonary miliary pattern and (2) disorders for which radiographic or ultrasonographic results are compatible with pulmonary neoplasia or granuloma.<sup>68</sup> Raphel and Gunson originally described the methods used,<sup>69</sup> which has since been modified because of the routine use of ultrasound during tissue sampling. The horse is sedated and biopsy locations are selected after ultrasonographic confirmation of landmarks (heart, diaphragm) and assessment of tissue accessibility. The biopsy instrument is aseptically advanced through the intercostal space (cranial to the rib) to the depth of the desired tissues, and samples are obtained for culture and for fixation in 10% formalin. In a study comparing biopsy instruments (manual Tru-cut versus automated biopsy needle), the investigators found airway bleeding developed in approximately one third of the cases sampled with the manual device and one tenth of the cases biopsied using the automated instrument.<sup>70</sup> The technique is not recommended in patients that are tachypneic, are in respiratory distress, exhibit uncontrollable coughing, or have bleeding disorders. The technique is not indicated in horses with pulmonary abscessation, pleuropneumonia, or pneumonia.<sup>68</sup> In a recent review of percutaneous lung biopsies performed in 66 horses, this technique yielded a definitive antemortem histologic diagnosis of pulmonary disease in 82% of cases.<sup>71</sup> In the same study, no complications were recognized in 91% of horses sampled.<sup>71</sup> The most common complications observed with lung biopsy are coughing, epistaxis, pulmonary hemorrhage, tachypnea, and respiratory distress. Hemothorax or accidental sampling of abdominal organs (liver, stomach) may occur.<sup>70-72</sup> When horses in respiratory distress are sampled using an automated instrument, epistaxis occurred in 13%, airway bleeding in 39%, and pneumothorax in 4% of patients.<sup>70</sup>

## THORACOSCOPY

Thoracoscopy or pleuroscopy is a diagnostic technique that is used in the standing sedated horse to visualize the intrathoracic structures that include the aorta, esophagus, intercostal vessels, sympathetic trunk, vagus nerves, lymph nodes, mainstem bronchi, pulmonary and azygous veins (right hemithorax), diaphragm, and dorsal and lateral surfaces of the lungs. The procedure is used to sample thoracic masses or nodules, to transect pleural adhesions, to place drains for the treatment of pleural abscesses, to repair diaphragmatic hernias, and to resect lung segments either for therapeutic or for diagnostic purposes.<sup>73-77</sup> Using thoracoscopy, one is able to obtain larger biopsy sizes and hence assess parenchymal and peripheral airway morphologic features better.<sup>78</sup>

Thoracoscopy is performed using aseptic procedures. An area in the eighth to twelfth intercostal space just ventral to the serratus dorsalis muscle is surgically scrubbed and infiltrated with local anesthetic to place an endoscopic portal.<sup>79</sup> Before insertion of the endoscopic portal (cannula), a pneumothorax is gradually created by inserting a teat cannula first through this intercostal space. The smaller cannula is replaced by a larger one through which a 10-mm (30-degree) rigid laparoscope connected to a video camera and light source can be

advanced. Additional portals for biopsy or resection procedures are aseptically placed as needed. In most adult horses, the mediastinum is thought to be incomplete, thus a bilateral pneumothorax may ensue during this procedure. Hemodynamic effects of a unilateral thoracoscopy in healthy horses have been described.<sup>79</sup> In sedated healthy horses, thoracoscopy (and pneumothorax) produces a mild systemic hypertension and arterial hypoxemia. After completion of the examination or retrieval of samples or both, the pneumothorax is reduced, the lung is reinflated, and the skin is closed after removal of the laparoscope. Analgesic and antimicrobial agents should be administered to the horse after this procedure.

## DISORDERS OF THE UPPER RESPIRATORY TRACT

A variety of disorders are encountered in the upper respiratory tract in horses. Presenting complaints for upper airway disorders include respiratory distress (especially during inspiration), nasal discharge, dysphagia, lymphadenopathy, swelling or pain in the throatlatch region, or decreased exercise tolerance. Endoscopic or radiographic examination of the head and upper airway facilitates a diagnosis of most upper respiratory disorders.

### SINUS DISORDERS

#### SINUSITIS

Diagnosis and treatment of diseases of the paranasal sinuses are complicated by their large size, complex anatomy, difficult surgical access, and the advanced state of many diseases before a diagnosis is made.<sup>80</sup>

**Anatomic Considerations** Six pairs of sinuses communicate with the nasal cavity: dorsal, middle, and ventral conchal and maxillary, frontal, and sphenopalatine.<sup>81</sup> The frontal sinus has a large communication rostrally with the dorsal conchal sinus and thus forms the conchofrontal sinus. This drains through the frontomaxillary opening into the caudal maxillary sinus. The ventral conchal and rostral maxillary sinuses communicate over the infraorbital canal and drain through the nasomaxillary opening into the middle nasal meatus. The caudal maxillary sinus has a small opening medially into the middle conchal sinus. The sphenopalatine sinus drains over the infraorbital canal into the caudal maxillary sinus. In horses younger than 5 years, the last three cheek teeth—the first, second, and third molars (108-111 and 208-211)—occupy most of the maxillary sinus.<sup>80</sup> As the horse ages and the residual root decreases, the sinus cavity enlarges, and its rostral limit approaches the infraorbital foramen.

The sphenopalatine sinus has thin walls and a close relationship to the brain, pituitary gland, and cranial nerves II, III, IV, V, and VI.<sup>82</sup> The sinuses are lined by a respiratory epithelium—pseudostratified ciliated columnar—interspersed with goblet cells and underlying serous glands.<sup>83</sup> The nasomaxillary opening is a narrow slit that is easily occluded from inflammation of the mucosa, and this occlusion can lead to accumulation of exudate within the sinuses. Most clinically important conditions involve the maxillary or frontal sinuses.

**Causes** Primary sinusitis involves accumulation of exudate within the sinus cavities and is a sequela of viral or bacterial upper respiratory tract infections. Streptococcal (and rarely staphylococcal) organisms are the most frequent bacterial isolates. Secondary sinusitis is most commonly caused by

dental disease or may be associated with sinus cyst, neoplasia, foreign body, or trauma.<sup>17,84-87</sup>

Dental sinusitis is associated with infection of the tooth root, fractured teeth, and patent infundibula.<sup>85</sup> The first molar is the most commonly involved tooth.<sup>85,88,89</sup> Sinus cysts act as a space-occupying lesion and have a variable wall that may be mineralized.<sup>87,90,91</sup> Neoplasia of the paranasal sinuses include squamous cell carcinoma (which, in some cases, can arise in the oral cavity and spread to the maxillary sinuses), adenocarcinoma, bone and dental tumors, fibrosarcoma, and hemangiosarcoma.<sup>84,92</sup> Although rare, fungal granulomata induced by *Cryptococcus neoformans* may cause secondary sinusitis.<sup>80</sup>

**Clinical Signs** Clinical signs depend on the inciting cause, location, and chronicity of the disorder. Clinical signs include nasal discharge that may be unilateral or bilateral, malodorous, or mucopurulent; reduced nasal airflow; epiphora; and facial swelling.<sup>80,85</sup> Sinus cysts and neoplasia are significantly more frequently associated with gross deformity of the nasal passages and facial bones than other disorders, which explains the high incidence of epiphora, reduced nasal airflow, and facial deformity in those conditions.<sup>85</sup> Dental sinusitis is strongly associated with malodorous nasal discharge.<sup>80,85</sup>

**Diagnosis** Diagnosis is based on the clinical history, age of the animal, and nature of the clinical signs. Percussion of the sinuses may reveal dullness. Culture and cytologic examination of the sinus fluid or biopsy of the tissue mass is helpful in the diagnosis, although differentiating between a neoplastic or dysplastic process and an inflammatory reaction may be difficult.

Endoscopic examination helps eliminate other potential causes of nasal discharge and demonstrates the presence of a discharge from the nasomaxillary opening, which confirms that the discharge originates from the sinus compartment. A thorough dental examination should be performed in all cases of suspected sinus disease. The presence of fractured or displaced teeth, receding gum lines, exudate around a specific tooth, or patent infundibula suggests that dental disease may be the cause of the disorder.

Lateral and lateral-oblique radiographs (30 to 45 degrees to the horizontal plane) are helpful in diagnosing sinusitis and may demonstrate single or multiple horizontal fluid-air interfaces, abnormalities of the teeth, lysis of alveolar bone, or any combination of these signs (Figures 9-6 and 9-7).<sup>85,90</sup> Dorsoventral radiographs are useful in selected cases (e.g., those with suspected empyema of the ventral conchal sinus). Strong diagnostic radiographic signs are present in approximately 57% of dental sinusitis cases.<sup>85</sup> In contrast, radiographs are strongly diagnostic of sinus cysts in only 35% of cases.<sup>85</sup> CT is the imaging diagnostic procedure of choice for diseases of the paranasal sinuses. The main advantage of CT is excellent cross-sectional imaging with no superimposition of structures.<sup>93,94</sup> Nuclear scintigraphy is not significantly more useful than radiographs for the assessment of sinus disorders.<sup>58</sup>

**Treatment** Treatment requires surgical removal of the primary cause (tooth, cyst, granulation tissue or neoplasia), the establishment of good drainage, and copious lavage. Nasofrontal surgical flaps provide good access to the majority of the paranasal sinuses<sup>95,96</sup> and can be performed in the standing horse. In the largest published case series, resolution of signs was obtained after surgery in 84% of primary sinusitis, 78% of dental sinusitis, and 93% of sinus cysts.<sup>86</sup> With neoplastic lesions, surgical resection or ablation achieves a low rate of success because of extensive infiltration of the neoplasm or recurrence of the tumor.<sup>97,98</sup>

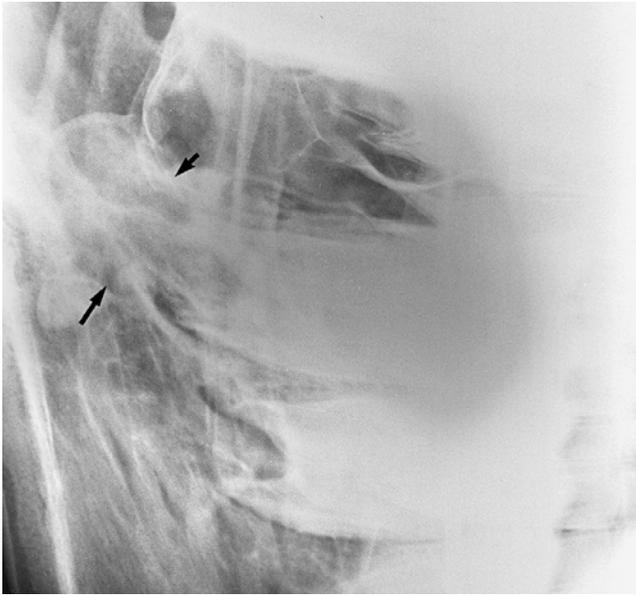

### PROGRESSIVE ETHMOIDAL HEMATOMA

**Definition and Epidemiology** Progressive ethmoidal hematoma (PEH) is characterized by encapsulated, expansive masses that usually arise from the submucosa of the ethmoidal labyrinth.<sup>99,100</sup> The mass is composed of blood and fibrous tissue, is encapsulated by respiratory epithelium,<sup>101</sup> and may extend into the paranasal sinuses.<sup>99,101-103</sup>

The condition occurs in 4% to 6% of horses with diseases of the nose and sinus.<sup>85,100</sup> The inciting factor in their development is not known, although they have been hypothesized to be associated with repeated episodes of submucosal

**FIGURE 9-6** Five-year-old Thoroughbred with 7-month history of left-sided nasal discharge. **A**, Air-fluid interface (arrows) in the caudal maxillary sinus on the lateral radiograph is consistent with maxillary sinusitis resulting from dental disease. **B**, Increased soft tissue opacity in the left (L) maxillary sinus on the dorsoventral radiograph is notable. (Courtesy D. S. Biller, Manhattan, Kan., 1991.)

**FIGURE 9-7** Lateral oblique radiograph of mid maxillary cheek teeth. The fourth cheek tooth had been removed previously. Sclerotic bony reaction (*arrows*) surrounds the root of the third cheek tooth. (Courtesy D. S. Biller, Manhattan, Kan., 1991.)

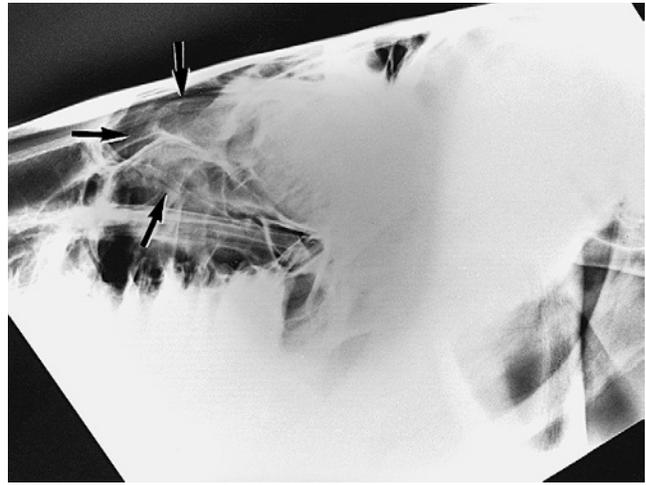

hemorrhage. PEH appear bilaterally in 50% of cases and are more prevalent in older horses.<sup>103,104</sup>

**Clinical Signs** The most common clinical sign caused by PEH is intermittent, serosanguineous discharge from the affected nasal passage.<sup>101,103,105</sup> Other clinical signs include facial swelling, halitosis, respiratory distress, and coughing.<sup>101,103,105</sup>

**Diagnosis** Diagnosis is based on the clinical signs, endoscopic examination, radiographic evaluation,<sup>101-103,105</sup> and, in some cases, CT findings to determine the extent of the lesion.<sup>106</sup> Endoscopy (see [Figure 9-2](#)) reveals a variably green-colored, smooth glistening mass originating from the ethmoid region. The mass may protrude beyond the nasal septum (and in such cases may cause a bilateral nasal discharge). Radiographs reveal a space-occupying soft tissue density with smooth margins and may demonstrate extension into the paranasal sinuses ([Figure 9-8](#)). Confirmation of the diagnosis is by histopathologic study of the removed tissue,<sup>91,104</sup> although the clinical appearance is highly suggestive.

**Treatment** Treatment options include formalin injection, surgical resection, and laser ablation. Smaller lesions (<10 cm in diameter) can be treated effectively by the intralesional injection of 4% to 10% formalin.<sup>86,99,101,107</sup> Most cases require multiple injections to achieve full resolution.<sup>86,101</sup> This procedure can be performed in the standing horse, has a low complication rate, and is associated with 60% resolution after a median of five injections.<sup>101</sup> Severe neurologic complications can, however, occur if the cribriform plate is fenestrated by the chronic pressure of a large PEH. CT may be indicated to determine the extent of the lesion before treatment.<sup>107</sup>

Surgical removal via a frontal sinus flap is associated with extensive hemorrhage and may require pre- or postoperative blood transfusions.<sup>99,100,105</sup> A preoperative crossmatch is warranted, and the horse may also require a postoperative tracheotomy if extensive packing of the nasal cavity is necessary to

**FIGURE 9-8** Ethmoidal hematoma. Focal increased soft tissue opacity (*arrows*) adjacent to the ethmoids is notable. (Courtesy D. S. Biller, Manhattan, Kan., 1991.)

effect hemostasis. After surgical removal, approximately 20% to 50% of ethmoidal hematomas recur.<sup>86,103-105</sup> Postoperative complications may include facial incisional dehiscence, suture periostitis, facial bone sequestration, persistent nasal discharges, fungal sinus plaque formation, and encephalitis.<sup>103,105</sup> Laser excision has also been used to treat PEH, with a recurrence rate of 20% described in one report.<sup>102</sup> Recurrence is higher in bilateral PEH than other forms.

## GUTTURAL POUCH DISORDERS

### ANATOMIC CONSIDERATIONS

The paired guttural pouches are diverticula of the external auditory tubes. Some investigators have suggested that the pouches play a role in cooling the arterial blood supply to the brain.<sup>108</sup> Each pouch has a capacity of 475 ml and is divided into medial and lateral compartments by the stylohyoid bone.<sup>109</sup> Each pouch fills on inspiration via the plica salpingopharyngeus. The mucosal lining of each pouch is secretory and covered by ciliated pseudostratified epithelium with goblet cells and glands.<sup>110</sup> The medial compartment is three times bigger than the lateral compartment and contains the internal carotid artery and a fold that encloses cranial nerves IX, XI, and XII. The pharyngeal branch of the vagus nerve (X) traverses the floor of the medial pouch, and the cranial sympathetic ganglia are also found within it. The rectus capitus ventralis and longus capitus muscles run just medially to the guttural pouch, and tearing of these muscles after a poll injury can be identified endoscopically as blood in the associated pouch. The lateral compartment of the guttural pouch contains the external carotid and maxillary artery. Branches of the facial nerve (VII), vestibulocochlear (VIII), and mandibular branch of the trigeminal nerve (V) run close to the wall of the lateral compartment.

### TYMPANY

**Definition** Tympany is a nonpainful unilateral or bilateral distention of the guttural pouch by air that may produce an external swelling in the parotid region. Congenital tympany occurs in young foals (predominantly fillies), and acquired tympany uncommonly affects older horses.<sup>111</sup>

**Causes** The cause of congenital guttural pouch tympany is unknown. Tympany is more likely a functional defect rather than an anatomic defect because no abnormality is visible endoscopically or during surgical exploration. The condition may have a genetic component in Arabians.<sup>112</sup> Acquired tympany is typically associated with upper respiratory infection and is thought to be caused by swelling of tissues around the pharyngeal orifice, producing a unidirectional valve and trapping air or fluid within the pouch. This problem is transient, and rarely does pouch distention become severe.

**Clinical Signs** Clinical signs depend on the degree of pouch distention and hence the degree of compression of the nasopharynx. If distention is significant, the foal may exhibit stertorous breathing, respiratory distress, dysphagia, nasal discharge, or evidence of pneumonia caused by aspiration. Regurgitation of milk from the nostrils also may be evident.<sup>113</sup> Endoscopic examination may reveal significant compression of the nasopharyngeal area because of distention of the pouches.

**Diagnosis** Confirmation of the diagnosis is by the presence of tympanitic swelling in the area of Viborg's triangle. Radiographs reveal a large, air-filled guttural pouch with or without fluid accumulation (Figure 9-9). The distinction as to whether the problem is unilateral or bilateral can be difficult to make. Catheterization of one guttural pouch should correct the problem if a unilateral tympany exists. Dorsoventral radiographic views may help in diagnosing bilateral involvement.

**Treatment** Guttural pouch tympany can be relieved temporarily by percutaneous aspiration or placement of an indwelling catheter. Definitive treatment requires surgical correction. If percutaneous aspiration or indwelling catheter placement is unsuccessful, then surgical correction is required. For unilateral tympany, fenestration of the median septum, separating the two guttural pouches, by conventional or transendoscopic laser surgery allows movement of air into the normal pouch.<sup>114</sup> For bilateral tympany, a fistula can be made with a transendoscopic laser, just dorsal and caudal to the guttural pouch ostium, over a Chambers catheter placed in the pouch. A Foley catheter is then placed for 7 to 10 days. This technique is associated with complete resolution of clinical signs with one (70%) or two (30%) surgeries.<sup>111</sup> Prognosis for uncomplicated cases is good; however, the presence of aspiration pneumonia or dysphagia is associated with a guarded prognosis.

## MYCOSIS

**Definition** Guttural pouch mycosis is characterized by development of fungal plaques on the mucosal walls of the guttural pouches. The majority of plaques are located on the roof of the medial compartment, associated with the internal carotid artery, and less frequently on the lateral wall of the lateral compartment of the pouch, associated with the external carotid or external maxillary artery.

**Clinical Signs** Many horses do not present until they experience significant spontaneous epistaxis caused by erosion of the fungal plaque through the arterial wall. Horses may also present with nasal discharge, dysphagia, RLN, Horner's syndrome, abnormal head extension, swelling in the parotid region, facial paralysis, mycotic encephalitis, and atlantooccipital joint infections.<sup>115-119</sup> Although guttural pouch mycosis is uncommon in the young horse, it has been reported in foals younger than 6 months.<sup>120</sup> Repeated episodes of epistaxis can be fatal in approximately 48% of horses, and definitive surgical treatment should be sought urgently.<sup>121</sup>

**FIGURE 9-9** Guttural pouch tympany. Lateral radiograph of 5-month-old Arabian colt demonstrating a greatly distended gas-filled pouch. (Courtesy D. S. Biller, Manhattan, Kan., 1991.)

**Pathogenesis** The events leading to the formation of fungal plaques are not known. Some researchers have suggested that aneurysmal dilations of the vasculature, visualized radiographically, provide a suitable environment for fungal organisms to proliferate.<sup>122</sup> Fungal colonization leads to erosion of the underlying mucosa and vascular structures or injury to the adjacent nerves.

**Diagnosis** Confirmation of the diagnosis is by endoscopic observation of a fungal plaque in the guttural pouch. Shortly after an acute bout of epistaxis, endoscopic examination can confirm the presence of blood at the guttural pouch ostium, but attempts to visualize the interior of the pouch may be unsuccessful if blood obscures the visual field. Some risk exists of dislodging a blood clot during endoscopic examination of the pouch.<sup>123</sup> The presence of RLN or dysphagia should be documented at the initial examination because both are associated with a poor prognosis.<sup>124</sup> RLN is usually permanent, although some horses recover from dysphagia over 6 to 18 months. Horses may also recover from facial nerve paralysis and Horner's syndrome. Radiographs of the guttural pouch may show evidence of fluid accumulation or osteolytic changes in the stylohyoid bone or may suggest mycotic plaque formation.

**Treatment** Treatment depends on surgical occlusion of the affected vessel or vessels. In an emergency situation with acute epistaxis, ligation of the common carotid artery is contraindicated if the hemorrhage is from the internal carotid artery; flow in the internal carotid artery, from the circle of Willis, will be increased with ligation of the common carotid artery. Several different techniques have been advocated for occlusion.<sup>124-129</sup> Current therapies of choice use a coil or intravascular balloon to obliterate arterial flow proximal and distal to the fungal lesion.<sup>117</sup> The placement of transarterial coils, via an incision in the common carotid artery under fluoroscopic guidance, is associated with 84% survival and 71% return to performance.<sup>124</sup> If fluoroscopic guidance is not available, correct placement of the occluding balloon is essential to prevent postoperative complications, including blindness.<sup>130,131</sup> Correct placement can be difficult in the presence of aberrant

vessels.<sup>127,132</sup> The fluoroscopic technique allows identification of such vessels before the occluding coils are placed.

Horses that have dysphagia, in which treatment is elected, may need enteral support via nasogastric intubation or esophagostomy. Medical treatment alone, with topical or parenteral antimycotic drugs, is not effective in eliminating the mycotic plaques.

### EMPHYEMA

**Definition** Empyema is an accumulation of exudate within the guttural pouches and is usually a sequela of upper respiratory tract infections (*Streptococcus* spp.). *Streptococcus equi* subsp. *equi* was isolated from 32% of cases evaluated for empyema in a large case series.<sup>133</sup> Empyema may also result from the rupture of abscessed retropharyngeal lymph nodes into the pouches or may accompany cases of guttural pouch tympany.<sup>113</sup> The condition may be unilateral or bilateral.

**Clinical Signs** The most common presenting sign is a nasal discharge that may be unilateral or bilateral.<sup>133</sup> Other clinical signs include lymphadenopathy, painful distention in the parotid region, stertorous breathing, dysphagia, and occasionally epistaxis.<sup>113</sup> Inspissation of the material may occur with chronic infections, forming masses called *chondroids* in approximately 20% of cases.<sup>133</sup>

**Diagnosis** Confirmation of the diagnosis is by radiographic examination or endoscopy. Radiographs demonstrate a fluid line or opacity in the pouch (Figure 9-10). Inspissated material also may be evident radiographically (Figure 9-11). Endoscopic examination may reveal a purulent material at the pharyngeal orifice of the auditory tubes and within the medial or lateral compartments of the guttural pouches. Distortion of the pharynx may occur if distention is significant.

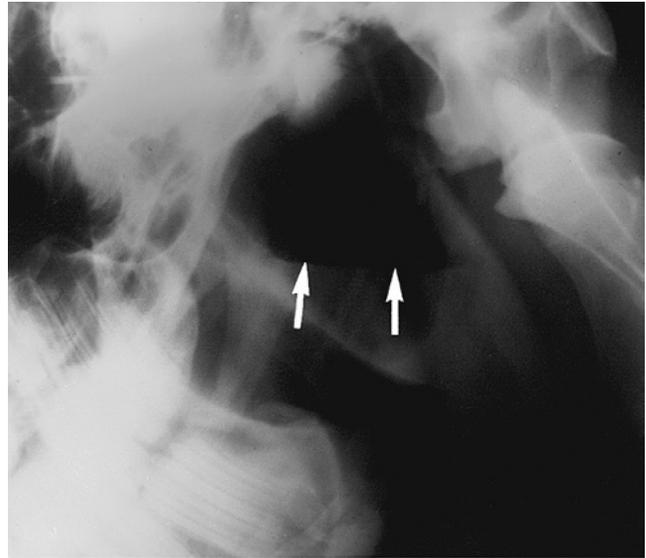

**Treatment** Given that *S. equi* subsp. *equi* may be involved, the clinician should isolate affected horses and take precautions to prevent spread of the bacteria (see discussion on strangles). Treatment may entail medical and surgical modalities. In acute cases, daily irrigation with physiologic saline is usually effective.<sup>133</sup> The horse should be sedated to enhance lowering of its head and to improve drainage of flush materials. Administration of both topical and systemic benzylpenicillin improves treatment success. A gelatin-penicillin mixture can be instilled through a catheter inserted endoscopically into the guttural pouch.<sup>134</sup> A 50-ml mixture is prepared by first heat dissolving 2 grams of gelatin in 40 ml of sterile water and then cooling to 45° to 50° C. To this mixture is added 10 million units of sodium benzylpenicillin that have been reconstituted with 10 ml of sterile water. The mixture is dispensed in syringes and stored overnight at 4° C to set. For each treatment, 25 ml of the mixture is instilled.

One may attempt removal of chondroids with an endoscopic snare, preventing the complications or risk of surgery and minimizing the cost of treatment. However, this task is difficult if the chondroids are numerous.<sup>134,135</sup> Surgical removal of chondroids is effected via a modified Whitehouse approach or by using a transendoscopic laser to establish a permanent pharyngeal fistula into the guttural pouch.<sup>136,137</sup>

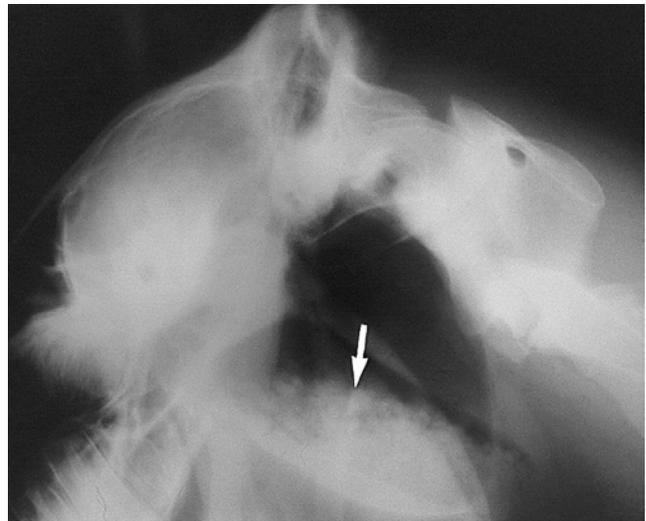

## PHARYNGEAL AND LARYNGEAL DISORDERS

### PHARYNGEAL LYMPHOID HYPERPLASIA

**Causes** The cause of chronic pharyngeal lymphoid hyperplasia (PLH) is not understood but is most likely multifactorial. The location of the nasopharynx exposes it to multiple

**FIGURE 9-10** Guttural pouch empyema. Lateral radiograph shows a fluid line (arrows) or air-fluid interface within the guttural pouch. (Courtesy D. S. Biller, Manhattan, Kan., 1991.)

**FIGURE 9-11** Guttural pouch chondroids. Lateral radiograph demonstrates irregular soft tissue opacities in the ventral guttural pouch outlined by gas (arrow). (Courtesy D. S. Biller, Manhattan, Kan., 1991.)

allergens, irritants, and viral or bacterial agents. The local lymphoid tissue responds by stimulating mucus-producing cells and local immunoglobulins.

**Epidemiology** Pharyngeal lymphoid hyperplasia is predominantly a condition of young horses, and its prevalence decreases with age.<sup>138-140</sup> PLH is less severe if horses are housed on pasture rather than stabled.<sup>141</sup> PLH has been reproduced experimentally with inoculation of EHV2,<sup>142,143</sup> and although this virus can be isolated from young racehorses with PLH, its causality remains to be proven.<sup>144</sup>

**Clinical Signs** Some horses may show coughing, a nasal discharge, and mild mandibular lymphadenopathy.<sup>145</sup> PLH is diagnosed endoscopically by the appearance of raised hyperemic

## BOX 9-2

## GRADING SCHEME FOR LYMPHOID HYPERPLASIA

Grade I: A small number of inactive, white follicles scattered over the dorsal pharyngeal wall. The follicles are small and inactive, a normal finding in horses of all ages.

Grade II: Many small, white inactive follicles over the dorsal and lateral walls of the pharynx to the level of the guttural pouch. Numerous follicles that are larger, pink, and edematous are interspersed throughout.

Grade III: Many large pink follicles and some shrunken white follicles are distributed over the dorsal and lateral walls of the pharynx, in some cases extending onto the dorsal surface of the soft palate and into the pharyngeal diverticula.

Grade IV: More numerous pink and edematous follicles packed close together covering the entire pharynx, the dorsal surface of the soft palate and epiglottis, and the lining of the guttural pouches. Large accumulations appear as polyps.

(From Mansmann RA, McAllister ES, editors: *Equine medicine and surgery*, Santa Barbara, CA, 1982, Veterinary Publications.)

## BOX 9-3

## GRADING SCHEME FOR LARYNGEAL ANATOMY

Grade I: Synchronous full abduction and adduction of left and right arytenoid cartilages.

Grade II: Asynchronous movement such as hesitation, flutters, adductor weakness of the left arytenoid during inspiration or expiration or both, but full abduction induced by swallowing or nasal occlusion.

Grade III: Asynchronous movement of the left arytenoid during inspiration or expiration or both, but full abduction not induced and maintained by swallowing or nasal occlusion.

Grade IV: Significant asymmetry of the larynx at rest and lack of substantial movement of the left arytenoid.

(From Ducharme NG, Hackett RP: The value of surgical treatment of laryngeal hemiplegia in horses, *Compend Cont Educ Pract Vet* 13:472, 1991.)

and edematous follicles distributed throughout the nasopharyngeal walls (Box 9-2).<sup>141,145,146</sup> The condition, unless severe, has not been associated with poor performance per se,<sup>138,139</sup> although severe PLH has been proposed as a cause of dorsal displacement of the soft palate in young horses as a result of the proximity of the pharyngeal branch of the vagus nerve.<sup>147</sup>

**Treatment** Treatment options include rest, reducing the allergen content of the air through improved management, turnout to pasture, and throat spray (see section on chondritis).

TABLE 9-2

## Function and Innervation of Muscles Controlling the Tone of the Equine Soft Palate

Muscle	Function	Innervation
Tensor veli palatini	Tenses the rostral aspect of the soft palate	Mandibular branch of the trigeminal nerve
Levator veli palatini	Elevates the palate during swallowing and closes the nasopharynx	Pharyngeal branch of the vagus
Palatinus	Shorten and depress the palate	Pharyngeal branch of the vagus
Palatopharyngeus	Shorten and depress the palate	Pharyngeal branch of the vagus

## DORSAL DISPLACEMENT OF THE SOFT PALATE

**Definition** Dorsal displacement of the soft palate (DDSP) results in an upper airway expiratory obstruction at exercise. It is a common cause of poor performance in racehorses and has a prevalence of 10% to 20%.<sup>14,15,148,149</sup> Most affected horses make a loud, vibratory respiratory noise, known as *choking down*,<sup>150,151</sup> although a proportion are silent during displacement.<sup>13,151</sup> Endoscopic examination of the upper airway at rest is a poor predictor of DDSP.<sup>152</sup> A definitive diagnosis is made, during high speed treadmill examination, if the caudal border of the soft palate is seen dorsal to the epiglottis for more than 8 seconds.<sup>153</sup>

**Anatomy** The horse is an obligate intranasal breather, and the epiglottis is usually positioned dorsal to the caudal border of the soft palate. A common analogy is a *button through a buttonhole*.<sup>154</sup> The anatomy of this area is complex. The larynx is suspended from the pterous part of the temporal bone by a chain of paired hyoid bones, the stylohyoid, ceratohyoid, single basihyoid bone, and thyrohyoid, which articulates with the rostral aspect of the thyroid cartilage. The strap muscles (sternohyoid, sternothyroid, and omohyoid) contract during exercise and pull the larynx caudally. Similarly, the genioglossus, geniohyoid, and styloglossus muscles (through their direct or indirect attachments to the hyoid apparatus) pull the larynx rostrally.<sup>155,156</sup> The tone of the soft palate is determined by four pairs of muscles. The innervation and function of these muscles is shown in Table 9-2. The stylopharyngeus muscle is innervated by the glossopharyngeal nerve and tenses the dorsal wall of the nasopharynx.<sup>157</sup>

**Etiology** The etiologic factors of DDSP are not completely understood and can be divided into intrinsic and extrinsic causes. Intrinsic dysfunctions are seen with decreased tone in muscles of the palate. Dysfunction of the palatinus and palatopharyngeus muscles results in DDSP.<sup>147</sup> This cause is closely linked to PLH in young horses because the pharyngeal branch of the vagus nerve runs through the floor of the guttural pouch, which is also the roof of the pharynx. Transection of the tensor veli palatini tendon alone destabilizes the rostral aspect of the soft palate, leading to inspiratory airway obstruction but not DDSP.<sup>158</sup> Dysfunction of the caudal stylopharyngeus muscle destabilizes the nasopharynx but does not cause DDSP.<sup>157</sup>

Extrinsic causes are related to the musculature that controls the position of the larynx and hyoid apparatus. Transection of the paired thyrohyoid muscles produces DDSP<sup>159</sup> presumably because these muscles, innervated by the hypoglossal nerve, prevent caudal retraction of the larynx at exercise. Partial resection of the sternothyroid and sternohyoid tendons produces an inspiratory airway obstruction but not DDSP.<sup>160</sup>

Investigation targeting the role of the rostral hyoid muscles (geniohyoid, stylohyoid, and styloglossus) in horses are lacking, but, in humans at least, these muscles are critical to pharyngeal stability.<sup>161,162</sup> Indirectly, tongue-tie devices, which are designed to prevent caudal retraction of the hyoid apparatus at exercise, have been shown to prevent DDSP in some horses.<sup>163</sup>

In addition to these neuromuscular dysfunctions, structural abnormalities such as masses or granulomas associated with the epiglottic cartilage or the soft palate can induce DDSP.<sup>148</sup>

**Treatment** Surgical techniques aimed at preventing caudal retraction of the larynx, such as strap muscle resection and the Llewellyn procedure (transection of the tendon of insertion of the sternothyroid muscle), are associated with success rates ranging between 58% to 73%.<sup>151,164,165</sup> Treatments aimed at intrinsic causes include staphylectomy<sup>165</sup> and soft tissue stiffening techniques such as rostral palatoplasty.<sup>166</sup> Conservative management of DDSP, incorporating rest, improvement of fitness, use of a tongue tie, or any combination, has also been reported, with a success rate of up to 61%.<sup>163,167</sup> A case-control study demonstrated that composite surgery including staphylectomy, sternothyrohyoideus myectomy, and ventriculocorpectomy produced increased race earnings in 60% of horses compared with 40% in controls.<sup>150</sup>

Surgical advancement of the larynx (laryngeal tie-forward procedure) demonstrated a success rate of 80% to 82% in racehorses.<sup>168</sup> The proposed mechanism of this procedure is that it replaces the action of the thyrohyoid muscles and prevents ventral descent and caudal retraction of the larynx during exercise. This procedure is well described elsewhere.<sup>168</sup> Horses undergoing this procedure are as likely to race postoperatively as matched controls. The procedure restores race earnings to preoperative baseline levels and to those of matched controls.

In addition, an external device (Cornell Collar, Vet-Aire, Inc., Ithaca, NY) that applies forward and upward pressure to the hyoid apparatus and incorporates a figure-8 noseband also prevents experimentally induced DDSP during strenuous exercise.<sup>169</sup>

## RECURRENT LARYNGEAL NEUROPATHY

**Definition and Epidemiology** Recurrent laryngeal neuropathy is a major cause of poor performance in racehorses and affects 1.6% to 8% of Thoroughbreds.<sup>170-173</sup> The prevalence in draft horses is nearly 42%,<sup>174</sup> and the risk of RLN increases with increasing height in Belgians and Percherons but not in Clydesdales.<sup>174</sup> Horses as young as 6 months may be affected.<sup>175</sup> The condition produces an inspiratory noise at exercise, which has been described as both *roaring* and *sawing*. The term *recurrent laryngeal neuropathy* is preferred to idiopathic laryngeal hemiplegia.<sup>176</sup>

**Diagnosis** A diagnosis can be made in most horses based on a resting endoscopic examination of the arytenoid cartilages. Some confusion has arisen from different grading systems used to diagnose the degree of arytenoid dysfunction present at this examination. A recent meeting of investigators

TABLE 9-3

### Grading System for Laryngeal Function Performed in the Standing Unsedated Horse<sup>176</sup>

Grade	Description
I	All arytenoid cartilage movements are synchronous and symmetrical, and full arytenoid abduction can be achieved and maintained.
II	Arytenoid cartilage movements are asynchronous at times, but full arytenoid abduction can be achieved and maintained.
III	Arytenoid cartilage movements are asynchronous or asymmetrical (or both). Full arytenoid cartilage abduction <i>cannot</i> be achieved and maintained.
IV	Immobility of the arytenoid cartilage and vocal fold is complete.

Grades II and III contain several subgrades. Readers are referred to the monograph for further information.

TABLE 9-4

### Grading System for Laryngeal Function Performed During Treadmill Endoscopy<sup>177</sup>

Grade	Description
A	Full abduction of the arytenoid cartilages during inspiration
B	Partial abduction of the left arytenoid cartilage (between full abduction and the resting position)
C	Abduction less than resting position, including collapse into the contralateral half of the rima glottidis during inspiration

reached consensus on a four-level grading system (Table 9-3), and this system should now be used.<sup>176</sup> This resting grading system is most useful in its ability to predict arytenoid function at high-speed exercise. Arytenoid position at exercise is shown in Table 9-4.<sup>177</sup>

All grade 1 horses are normal (grade A) at exercise, and all grade 4 horses show dynamic collapse (grade C).<sup>178</sup> During exercise, 4% of grade 3 horses are normal (grade A), 19% are grade B, and 77% grade C.<sup>179</sup> For grade 2 horses, 4% are grade B or C at exercise.<sup>178</sup> Recently, a technique for examining the lateral cricoarytenoid muscle using ultrasound has been described, and this technique is a good predictor of arytenoid function at exercise.<sup>180,181</sup> It is especially useful if a high-speed treadmill examination cannot be performed.

**Anatomy and Etiology** The left recurrent laryngeal nerve curves medially around the aortic arch during development and is approximately 1 m long.<sup>182</sup> In contrast, the right recurrent laryngeal nerve courses around the right subclavian artery and is approximately 25% shorter.<sup>182</sup> The high prevalence of chronic demyelinating peripheral neuropathy in the left recurrent laryngeal nerve has been attributed to its length.<sup>183,184</sup> The myelin loss is most severe distally<sup>185,186</sup> and is associated with axonal loss.<sup>187,188</sup> RLN results in progressive atrophy of

the left dorsal cricoarytenoid muscle and associated loss of arytenoid cartilage abduction.<sup>183,185,188</sup> The right recurrent laryngeal nerve is rarely affected, although direct trauma to the nerve can induce dysfunction.

During exercise, arytenoid dysfunction narrows the rima glottis and increases inspiratory impedance and noise.<sup>189,190</sup> This circumstance, in turn, results in airflow limitation and increased driving pressure during inhalation, leading to severe exercise-induced hypoxemia and decreased performance.<sup>189,191-193</sup>

**Treatment** The current gold standard for treatment of RLN in horses is prosthetic laryngoplasty, with or without vocal cordectomy or ventriculectomy.<sup>194-197</sup> This technique involves the placement of a nonabsorbable suture to create arytenoid abduction. One limitation of this technique is the frequent and significant loss of abduction of the arytenoid cartilage seen in the immediate postsurgical period.<sup>197,198</sup> This loss of abduction leads to a reduction in cross-sectional area of the rima glottidis and the return of exercise intolerance and abnormal respiratory noise.<sup>197-199</sup> Loss of abduction may also contribute to the modest postoperative success rate of 48% to 68% observed in racehorses.<sup>194,195,200-203</sup> A much higher success rate (73% to 91%) is reported in horses performing at submaximal exercise.<sup>204</sup>

In draft breeds, the degree of abduction required at laryngoplasty is lower than that for a racehorse, given that the goal is to prevent dynamic collapse of the arytenoid rather than to achieve a normal cross-sectional area of the rima glottidis. Some clinicians recommend vocal cordectomy alone for draft breeds. For racehorses and nonracehorses, the major complications are exercise intolerance, respiratory noise, and coughing.<sup>195,196,203</sup>

Restoration of physiologic function through reinnervation and nerve-muscle pedicle transplant techniques has also produced positive results,<sup>205-207</sup> although a delay of several months occurs before any improvement in arytenoid function is seen.

Partial arytenoidectomy is associated with a fair prognosis for the treatment of RLN in horses<sup>200,208</sup> and is not generally recommended as a first-line surgical option.

## EPIGLOTTIC ENTRAPMENT

**Definition and Epidemiology** The aryepiglottic fold is the mucous membrane that extends from the lateral aspect of the arytenoid cartilages to the ventrolateral aspect of the epiglottis, where it blends with the subepiglottic mucosa and the glossoepiglottic fold. In epiglottic entrapment, this membrane envelopes the free border of the epiglottis.<sup>209</sup> Billowing of the entrapping membranes during respiration decreases the cross-sectional area of the pharynx and effectively obstructs the airflow, particularly during expiration.

The cause of epiglottic entrapment is not understood completely. In most cases, the epiglottic cartilage and associated soft tissues appear normal. In occasional cases, congenital epiglottic hypoplasia or inflammation of the upper respiratory tract structures appears to contribute to entrapment. Epiglottic entrapment is responsible for 1% to 3% of upper airway obstructive problems in horses.<sup>15,173</sup>

**Clinical Signs** Most horses exhibit exercise intolerance and respiratory stertor. Horses may occasionally cough during exercise or while eating.

**Diagnosis** Diagnosis is based on endoscopic examination. The membrane obscures the normal serrated margin of

the epiglottis and its dorsal vasculature. In contrast to dorsal displacement of the soft palate, the shape of the epiglottis can still be seen. Ulceration of the free margin of the fold and erosion of the entrapped epiglottis may be apparent.<sup>210</sup>

**Treatment** Entrapment requires surgical correction. Several different approaches have been used and include transoral<sup>209,211-213</sup> or transnasal<sup>214</sup> axial division with a hooked bistoury and transendoscopic division with a laser.<sup>215-217</sup> The prognosis is good after surgery, although reentrapment and DDSP may occur after surgery.<sup>209,213,217</sup>

## ARYTENOID CHONDRITIS

**Definition and Epidemiology** Arytenoid chondritis is a condition affecting the corniculate process of the arytenoid cartilage or its mucosal surface and may produce an abnormal enlargement of the arytenoid cartilages caused by chronic inflammation,<sup>218,219</sup> a mucosal ulceration of the vocal process,<sup>220</sup> and the formation of intralaryngeal granulation tissue.<sup>221,222</sup>

The condition is most commonly diagnosed in young racehorses between 2 and 4 years of age<sup>223</sup> and is more prevalent in North America, Australia, and New Zealand than in Europe.<sup>208,218,220-224</sup> Although the prevalence of the condition in North American horses has not been defined, its prevalence in Australian and New Zealand yearling Thoroughbreds (at sales) has been estimated at 0.21% to 0.6%.<sup>220,223</sup> In nonracehorses, arytenoid chondritis is more common in older animals.<sup>221</sup>

**Cause** The cause of arytenoid chondritis is not fully understood. The proposed etiologic factor is ascending infection and inflammation of the underlying cartilage after mucosal injury.<sup>220,225</sup> Affected arytenoid cartilage is thickened and laminated with fibrous connective tissue. Intraluminal granulation and sinus tracts are seen in some cases. The condition is typically unilateral, though often secondary contact damage (*kissing lesion*) occurs to the contralateral cartilage.

**Diagnosis** Diagnosis is made based on endoscopic examination. Mildly affected horses retain arytenoid mobility yet have ulcerations of the body of the affected cartilage or granulomata that project into the laryngeal lumen. In more advanced cases, the affected arytenoid cartilage is immobile and deviated medially. Laryngeal ultrasound may be useful for identifying concurrent abscessation.<sup>180</sup> Radiographs may reveal excessive mineralization of laryngeal cartilages.

**Clinical Signs** Clinical signs include exercise intolerance and inspiratory stridor during exercise. In severe bilateral cases, the reduction in rima glottidis cross-sectional area may be obstructive.

**Treatment** Mild cases of arytenoid chondritis may be treated with systemic antibiotics and application (20 ml every 12 hours) of a throat spray. The latter consists of 1 g nitrofurazone in 250 ml dimethyl sulfoxide, 500 ml water, 250 ml 99% glycerine, and 25 ml dexamethasone.

In moderate to severe cases, or if throat spray is not effective, a partial arytenoidectomy should be performed to remove the affected cartilage.<sup>200,208</sup> This procedure involves resection of the laryngeal ventricle, vocal fold, and arytenoid cartilage (excluding the muscular process) and the rostral strip of the corniculate cartilage and is associated with a fair prognosis for return to racing.<sup>208</sup> Intraluminal granulation tissue can be removed with a transendoscopic laser.<sup>222</sup> In severe bilateral cases, a tracheostomy may be required to create an effective airway.

### ROSTRAL DISPLACEMENT OF THE PALATOPHARYNGEAL ARCH

In the horse, the soft palate terminates caudally by the confluence of the caudal pillars to form the palatopharyngeal arch that covers the esophageal orifice.<sup>226</sup> In rostral displacement of the palatopharyngeal arch, this fold of tissue appears to be displaced forward, overlying the apices of the arytenoid cartilages. The condition is uncommon, with a number of small case series and individual cases being reported.<sup>14,227-230</sup> The displacement of the palatopharyngeal arch may be associated with malformation of the laryngeal cartilages and the crico-pharyngeal and cricothyroid muscles.<sup>14</sup> The condition may be present from birth. In most cases, abnormal respiratory noise and poor athletic performance are the presenting complaints. Abnormal pharyngeal conformation prevents normal deglutition, predisposing horses to develop aspiration pneumonia. In severe cases, horses may exhibit dysphagia, nasal discharge of food material, and persistent coughing.<sup>229,231</sup> The diagnosis is based on the clinical signs and history and confirmed with endoscopic examination. The rostrally displaced palatopharyngeal arch obscures the normal view of the apices of the arytenoid cartilages. Rostral displacement of the palatopharyngeal arch represents a major deformation of the laryngeal structures and is associated with a guarded prognosis. Resection of the arch by conventional surgery or laser surgery has not enabled successful athletic performance.<sup>227</sup>

### NASOPHARYNGEAL CICATRIX

This condition is almost exclusively seen in horses on pasture in eastern and southern Texas, with occasional reports from Mississippi, Louisiana, and Florida.<sup>210,232</sup> The cause of the condition is unknown, but an environmental allergen may lead to nasopharyngeal inflammation with subsequent scarring and web formation and with reduction in the cross-sectional area of the rima glottidis<sup>210,232</sup> (Figure 9-12). Horses housed inside do not appear to be affected. Clinical signs include exercise intolerance and stridor. The arytenoid cartilages are involved in more than 70% of cases.<sup>233</sup> Horses should be removed from pasture and have antiinflammatory treatment initiated as soon as the diagnosis is made. If airway obstruction is present then a permanent tracheostomy should be performed.<sup>233</sup> This technique is associated with a high number of horses (89%) returning to their previous level of use.

### STREPTOCOCCUS EQUI SUBSP. EQUI INFECTIONS (STRANGLES)

**Causes** *Streptococcus equi* subsp. *equi*, a gram-positive  $\beta$ -hemolytic bacterium of the Lancefield group C, is the causative agent of strangles, a highly contagious disease of Equidae. The disease was recognized in the thirteenth century and occurs worldwide.<sup>234</sup> Multilocus enzyme electrophoresis studies have confirmed a close genetic relationship of *S. equi* subsp. *equi* and *S. equi* subsp. *zooepidemicus*, indicating that the former is a clone derived from the more genetically diverse *S. equi* subsp. *zooepidemicus*.<sup>235</sup> This finding has led to the recommendation that *S. equi* subsp. *equi* be reclassified as a biovar of *S. equi* subsp. *zooepidemicus*.<sup>236</sup> Although isolates of these two organisms show greater than 92% DNA homology, immunity is species specific; immunization with *S. equi* subsp. *zooepidemicus* does not protect against challenge by *S. equi* subsp. *equi*.

*S. equi* subsp. *equi* (hereafter termed *S. equi*) is not a normal inhabitant of the equine upper respiratory tract and does

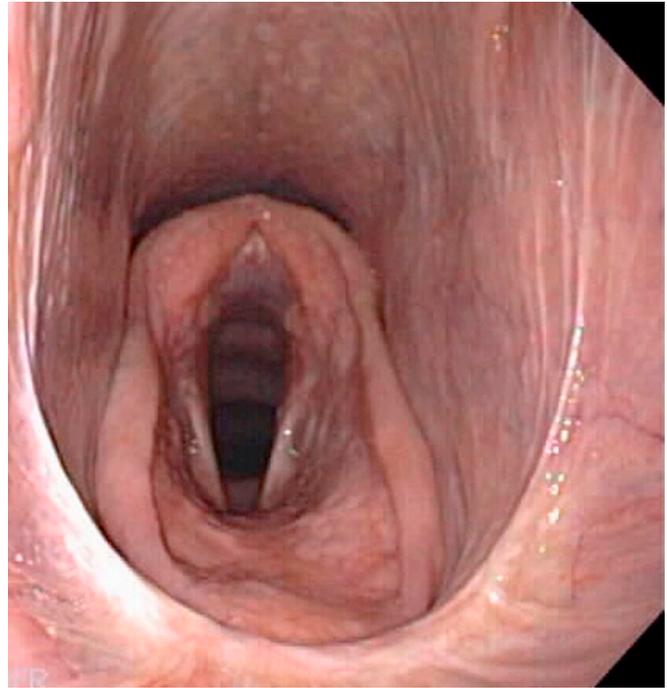

FIGURE 9-12 Nasopharyngeal cicatrix.

not require prior viral infections for successful colonization and infection.<sup>237</sup> Based on morphologic features of the bacterial colony, three strains of the organism occur that differ in virulence. The typical and highly virulent encapsulated *S. equi* strains produce golden, honey-colored mucoid colonies on blood agar. Atypical *S. equi* colonies exhibit a matte appearance within 24 hours of incubation. Nonencapsulated colonies are glossy, dry, and small.<sup>238</sup> Differences in the hyaluronic acid content of the capsule are responsible for the morphologically distinctive features of *S. equi* colonies.

Laboratory diagnosis of Lancefield group C streptococci (*S. equi*, *S. zooepidemicus*, *S. equisimilis*) is traditionally based on fermentation patterns of lactose, sorbitol, and trehalose. Typical *S. equi* isolates fail to ferment any of these sugars, whereas atypical *S. equi* isolates may ferment lactose or trehalose but not sorbitol.<sup>239</sup> In some laboratories, polymerase chain reaction (PCR) confirms the isolate to be *S. equi*.<sup>240</sup> Ideally, PCR should be performed using primers based on the nucleotide sequence of the gene encoding the *S. equi* M-like (SeM) protein.<sup>241</sup>

**Epidemiology** The infection occurs primarily in horses 1 to 5 years of age but is not restricted to this age group. Foals up to 3 months of age born from immune mares are known to be resistant to the development of strangles.<sup>242</sup> Thus infection in foals typically develops after weaning. In susceptible equine populations, morbidity is nearly 100%, whereas mortality is low (up to 10%).<sup>243</sup> Once having been infected, approximately 75% of the horses are immune to the organism for greater than 5 years.<sup>244,245</sup> However, 25% of these horses become susceptible to reinfection within months, which may represent a failure to produce or maintain an adequate level of the appropriate mucosal and systemic antibodies.<sup>245</sup> In one study of young horses that had been affected with clinical strangles as foals, researchers found that 83 were resistant to co-mingling exposure 6 months later.<sup>246</sup> Unfortunately, immunity is not

lifelong. Epidemiologic studies report attack rates in horses greater than 3 years of age of 18%, 29%, and 35%.<sup>243,247,248</sup>

The organism is transmitted (1) via direct contact with nasal or ocular secretions or lymph node discharges from infected horses or (2) via exposure to fomites such as contaminated equipment, pails, halters, leads, brushes, clothing, horse vans, or stalls. Recent additions to a stable are most often the cause of a strangles outbreak because a recovering horse—one that is free of clinical signs—may shed the organism for several weeks. In closed herds, epidemics have been attributed to exposure of horses to asymptomatic chronic carriers of the organism. Such horses harbor the organism in the guttural pouches for periods as long as 39 months in the absence of clinical signs. Other sites of long-term carriage of *S. equi* include the paranasal sinuses.<sup>249</sup> The reason why the carrier state develops in certain horses is unknown. Waller (2007) suggested that incomplete drainage of the guttural pouches or sinuses (e.g., residual empyema or even chondroid formation) continuously stimulates an immune response that produces a modified humoral immunity profile that is distinct from that of a noncarrier. This hypothesis remains to be verified. Regardless of the mechanism, subclinical persistent carriage of *S. equi* is necessary for maintaining this infection between outbreaks.<sup>250</sup>

Controlled field studies that have documented the survivability of *S. equi* in the environment have not been conducted.<sup>251</sup> Although Jorm<sup>252</sup> found that *S. equi* survived for 63 days on wood at temperatures of 2° C and for 48 days on glass or wood at temperatures of 20° C, the effects of other competing bacteria (and their secreted bacteriocins) were not considered. The organism is susceptible to a 1:200 dilution of phenol and disinfectants such as povidone-iodine, chlorhexidine, and glutaraldehyde kill the organism within 90 minutes.

*S. equi* is traditionally thought to infect only Equidae. However, a fatal pneumonia attributed to the organism was reported in a dromedary camel.<sup>253</sup> In the literature on human beings, descriptions of *S. equi* bacteremia and meningitis exist, but infections in human beings are considered rare.<sup>254</sup>

**Pathogenesis** After infective droplets are inhaled or ingested, the organism adheres to the epithelial cells of the buccal and nasal mucosa of the horse. The mechanism or mechanisms involved in bacterial adherence is currently unknown<sup>245</sup> but may involve exposed bacterial surface proteins such as SzPSe, Se73.0, and Se51.9.<sup>251</sup> Within hours of adhesion, the organism has translocated below the mucosa and gained access to the local lymphatics and lymph nodes, where replication occurs extracellularly.<sup>234</sup> Complement-derived chemotactic factors generated after interaction of C1 with bacterial peptidoglycan attract large numbers of neutrophils that contribute to the lymphadenitis and abscess formation.<sup>245</sup> Spread of the organism to sites other than the upper respiratory tract lymphoid tissue may occur by hematogenous or lymphatic pathways. In experimental infections of *S. equi*, the organisms can be cultured from the blood 6 to 12 days after intranasal inoculation.<sup>255</sup>

Numerous virulence factors of *S. equi* contribute to its pathogenicity, a few of which include the hyaluronic acid capsule, the SeM protein, an antiphagocytic protein (Se18.9), a leukocidal toxin (streptolysin S-like [SLS] toxin), and cell membrane lipoproteins.<sup>241,256-258</sup> Synthesis of the hyaluronic acid capsule is controlled by the *has* operon, which consists of *hasA* (encodes hyaluronate synthase), *hasB* (encodes UDP-glucose dehydrogenase), and *hasC* (encodes UDP-glucose

pyrophosphorylase). The capsule is antiphagocytic, ultimately reducing the number of bacteria that are subsequently ingested and killed. The capsule, by virtue of its negative charge and hydrophilicity, also produces a localized reducing environment that protects the activity of oxygen-labile proteases and toxins (SLS). Finally, the capsule is required for the activity of SeM. In nonencapsulated strains of *S. equi*, SeM aggregate and fail to achieve the three-dimensional structure required for their function.<sup>245</sup> Although nonencapsulated strains of *S. equi* are able to colonize the surface of the upper respiratory tract and stimulate production of serum antibody, they are unable to induce detectable pathologic changes in the retropharyngeal and mandibular lymph nodes.<sup>259</sup> The second virulence factor, the SeM protein, is a 58-kDa cell wall antigen that is also antiphagocytic. At its N-terminal end, SeM binds to fibrinogen, at its central region, to IgG. In doing so, it masks the C3b binding surface on the bacterial cell wall and inhibits the alternative C3 and classical C5 convertase.<sup>245</sup> Sequencing of the SeM gene between codons 38 and 143 from 142 *S. equi* strains has identified 43 alleles of SeM with each allele characteristic of a particular outbreak in a geographic location.<sup>260</sup> Thus SeM sequence analysis can be used to complement epidemiologic investigations of strangles outbreaks. The loss of SeM expression leads to a loss of virulence but not to a decrease in the infectivity of the organism. Another M-like protein of *S. equi*, SzPSe, exhibits antigenic cross reactivity with the M-like proteins of *S. zooepidemicus*, but its contribution to the virulence of *S. equi* is unknown.<sup>235</sup> Recently, a protein unique to *S. equi*, Se18.9, was found to also possess antiphagocytic properties.<sup>258</sup> The net effect of Se18.9 is to decrease deposition of C3 (and hence opsonic C3b) on the bacterial surface, reducing phagocytosis. SLS protein is thought to represent a fourth virulence factor by its cytotoxic properties. It damages host macrophages and neutrophils enabling immune evasion, as well as access to released essential nutrients.<sup>241</sup> A fifth virulence factor resides in the lipoprotein components of the *S. equi* cell membrane. When mutants of a specific lipoprotein are synthesized (PrtM) and the organisms are administered to susceptible ponies, clinical signs are markedly attenuated (0 of 5 infected ponies developed signs compared to controls). These data suggest that this lipoprotein is an important virulence factor and might become targeted for vaccine development.<sup>257</sup> Additional factors that contribute to the pathogenicity of *S. equi* include extracellular proteins or exotoxins that are mitogenic for peripheral blood mononuclear cells.<sup>261</sup> These mitogenic factors (SePE-H, SePE-I, SePE-K, and SePE-L) bind simultaneously to class II major histocompatibility complex (MHC) molecules on antigen presenting cells and to the T-cell receptor of T cells to induce nonspecific T cell stimulation, proliferation, and cytokine release. As a result, an acute phase response ensues characterized by release of interleukin-1 (IL-1), tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ), and IL-6 from mononuclear cells that contribute to the production of fever, malaise, neutrophilia, and hyperfibrinogenemia.<sup>245,261</sup>

Humoral immune responses to many of these virulence factors are apparent in infected horses. During the initial stages of infection, serum IgG to the SeM protein is induced, followed by the appearance of IgA and IgG to SeM on the mucosal surfaces.<sup>262</sup> During convalescence, strong IgG responses appear to SeM, as well as to other surface exposed proteins (Se44.2, Se46.8, Se45.5, Se42.0).<sup>245</sup>

**Clinical Signs** The incubation period ranges between 2 to 6 days. In typical cases, horses are febrile (103° F or higher), exhibit malaise, and develop a serous nasal discharge that

becomes mucopurulent. Ocular and nasal mucosal membranes become hyperemic, and a mucopurulent ocular discharge may ensue. Mandibular and retropharyngeal lymph nodes are initially firm but become fluctuant before rupturing 7 to 10 days after the onset of signs. Retropharyngeal lymph nodes may rupture into the guttural pouches, causing neuropathy (dysphagia), empyema, and chondroid formation. Lymphadenopathy, one of the major signs of *S. equi* infections, may be asymmetrical and may become so severe that dysphagia, stridor, and respiratory distress ensue. Swelling of the throatlatch area or of Viborg's triangle may be apparent and palpation of this area may elicit pain. The affected horse may stand with its neck stretched out and be reluctant to swallow. A soft moist cough may be heard. The average course of the syndrome is 23 days.<sup>237</sup> In atypical *S. equi* infections, a mild inflammation of the upper respiratory tract occurs and is characterized by a slight nasal discharge, cough, and fever. Abscessation of the lymph nodes occurs only in a small number of the cases.<sup>238,239,263</sup> In the majority of horses, clinical signs resolve and bacterial shedding ceases by 4 to 6 weeks. In an estimated 10% of affected horses, continued intermittent shedding of *S. equi* may occur for several additional weeks.

**Clinical Pathology** A marked neutrophilic leukocytosis, hyperfibrinogenemia, hyperglobulinemia, and anemia of chronic infection are found in typical strangles cases. In cases complicated by concurrent pneumonia (aspiration), a left shift and the presence of neutrophils with toxic signs may be noted. In horses with purpura hemorrhagic, moderate to marked elevations in muscle enzymes occur.

**Diagnosis** The diagnosis is usually based on clinical signs and the isolation (culture) or detection (via PCR) of *S. equi* from a lymph node, a nasopharyngeal swab, nasal washings, or lavage fluid from the guttural pouches. Nasal shedding of *S. equi* occurs 2 to 3 days after the onset of fever and usually persists for several weeks. Thus culture of acutely affected horses may initially be negative.<sup>251</sup> Nasal washes appear to be more effective than nasopharyngeal swabs in detecting small numbers of *S. equi* because a greater surface area is inherently sampled. The wash is accomplished by instilling 50 ml of warm sterile saline into the nasal cavity via a 15-cm soft rubber tubing that has been inserted to the level of the medial canthus. Fluid is collected and centrifuged, and the pellet is cultured. Guttural pouch lavage is best performed endoscopically, allowing inspection of the medial and lateral compartments for evidence of lymphadenopathy, empyema, or (in more chronic infections) chondroid formation. For the lavage, 30 to 50 ml of sterile saline is instilled through the biopsy chamber and gently aspirated for culture or PCR or both. When endoscopy is not feasible, a guttural pouch lavage may yet be possible by advancing a Chambers catheter blindly into the guttural pouch of the sedated horse and lavaging the compartments. Finally, blood cultures may become positive for *S. equi* on days 6 to 12 after infection.<sup>255</sup> The PCR assay, based on the DNA sequence for SeM, is used in conjunction with bacterial culture in diagnostic workups. PCR is more sensitive than bacterial culture and can detect SeM DNA for weeks in guttural pouch lavages after the disappearance of live organisms.<sup>264</sup> It is useful in detecting asymptomatic carriers, in establishing *S. equi* infection status before or after transport or commingling, and in establishing success of treatment.<sup>251</sup>

Serologic diagnosis of *S. equi* infections entails measurement of SeM-specific antibody and can be helpful in detecting

horses that have been exposed to *S. equi* or that have developed untoward sequelae as a result of infection. For example, a titer of more than 1:12,800 is highly supportive of a diagnosis of purpura hemorrhagica or of metastatic strangles.<sup>251</sup> Serologic testing can also be helpful in determining the need for vaccination or in identifying horses that may be hyperresponders and predisposed to the development of purpura hemorrhagica (SeM-specific antibodies > 1:1600). An enzyme-linked immunosorbent assay (ELISA) based on SeM-specific antibodies is commercially available (IDEXX Laboratories) but may not reliably detect subclinical carriers because of the overlap in the breakpoints between normal and convalescent horses.<sup>250</sup>

As previously stated, endoscopic examination of the guttural pouches for evidence of lymphadenopathy, empyema, or chondroids can be helpful in the diagnosis of *S. equi* infections. It can also aid in the identification of asymptomatic carriers, given that endoscopic abnormalities are often still present in these horses.<sup>249</sup> However, the absence of visible pathologic signs in one asymptomatic carrier emphasizes the need to still obtain samples for concurrent culture and PCR assay.<sup>264,265</sup>

**Treatment** Differences of opinion are marked as to whether or not to use antibiotics in horses with strangles.<sup>251</sup> Treatment is a function of the stage of the disease, and the general recommendations listed here are those included in the American College of Veterinary Internal Medicine (ACVIM) Consensus Statement developed by Sweeney, Timoney, Newton, et al.<sup>251</sup> The reader is referred to this excellent review. In treating horses with *S. equi*, penicillin is the drug of choice, although the organism is sensitive to oxytetracycline and the potentiated sulfonamides.<sup>234,249</sup>

The treatment plan is as follows:

1. For horses exhibiting early clinical signs of infection (fever, depression) in the absence of lymph node abscessation, penicillin G therapy for 3 to 5 days can arrest the progression of the disease. One should isolate the horses during their treatment protocol. Treated horses are likely to remain susceptible to infection because sufficient bacterial antigen to elicit a protective immune response may not have been produced as a result of treatment. No evidence has been found that the use of antibiotics during this stage will promote the development of metastatic strangles.<sup>266</sup>
2. For alert and otherwise healthy horses exhibiting lymph node abscessation, administration of penicillin slows the progression of lymph node abscessation and is generally contraindicated. Hot-packing the area or areas promotes maturation of the abscess. Once achieved, the clinician should lance the abscess and flush it with a 3% to 5% povidone-iodine solution and, if desirable, then institute antibiotic therapy. Horses may benefit from phenylbutazone or flunixin meglumine administration, which will reduce fever, lessen pharyngeal discomfort associated with the lymphadenitis, and improve their demeanor. The horses should be treated in isolation.
3. Horses that are systemically ill or that develop complications such as dysphagia, aspiration pneumonia, or respiratory distress require supportive care in addition to high levels of intravenous penicillin and other antimicrobials effective against gram negative organisms (aminoglycosides) or anaerobes (metronidazole). Horses may also require intravenous fluid therapy, a tracheostomy, nonsteroidal antiinflammatory drugs, and feeding via a nasogastric tube.

**Sequelae** The overall complication rate in horses with strangles is estimated to be 20%; most frequently, complications result from metastasis of the organism to other organ systems with the formation of purulent foci.<sup>267</sup> Complications include the following:

1. *Internal abscessation of the mesentery or of parenchymatous organs.* The causes of internal abscessation are not known,<sup>268</sup> and no evidence currently exists to suggest that the initiation of antimicrobial therapy predisposes the horse to the formation of internal abscessation.<sup>266</sup> Furthermore, internal abscesses have formed in the absence of prior antimicrobial treatment, making this risk factor unlikely.<sup>269</sup> The prevalence of metastatic abscessation is low, with estimates of 28% based on outbreaks on two farms.<sup>269</sup>

The horse with metastatic strangles may have a history of intermittent colic, periodic pyrexia, anorexia, depression, and weight loss. The clinician should direct diagnostic techniques, including rectal palpation, abdominocentesis, ultrasonography, CT (foal, miniature horse, or pony), and nuclear scintigraphy,<sup>270</sup> at determining the location of the abscess. In a review of 10 horses with internal abdominal abscesses caused by *S. equi*, abdominal ultrasonography (transabdominal or transectal or both) was useful in detecting circular encapsulated hypoechoic masses of either homogenous or mixed echogenicity in seven of the horses.<sup>271</sup> Internal abscessation can be difficult to differentiate from abdominal neoplasms because both processes may induce similar abnormalities in the peritoneal fluid (leukocytosis and hyperproteinemia). Differentiation between the two processes may not be possible unless exfoliated neoplastic cells are identified.<sup>272</sup> Culture of the peritoneal fluid in horses with *S. equi* internal abdominal abscesses rarely yields positive (diagnostic) microbial isolates.<sup>271</sup>

Hematologic and serum biochemical abnormalities in horses with internal abscessation include (1) anemia, (2) neutrophilic and monocytic leukocytosis, (3) thrombocytosis, (4) hyperfibrinogenemia, (5) hyperglobulinemia and hypocalcemia, and (6) hypocalcemia.<sup>268,271,272</sup> However, these changes are not unique to internal abscessation and may be found in horses with intraabdominal neoplasms.<sup>271,272</sup> However, detecting an elevated SeM specific titer (>1:3200) is supportive evidence of metastatic strangles.<sup>271</sup> Once one confirms the diagnosis, long-term antimicrobial therapy is indicated and may be required for several months.

In the report of Pusterla et al. (2007), 7 of 10 horses with abdominal abscesses received a protracted course of antimicrobials (mean duration of 72 days) that initially consisted of a beta-lactam antimicrobial (ceftiofur, ampicillin) followed by chloramphenicol, trimethoprim sulfamethoxazole, or rifampin. Clinical signs, rectal palpation, repeated abdominocentesis, and multiple complete blood counts (CBCs) were used to monitor the progress of therapy. Nevertheless, survival rate was reported to be 40%.<sup>271</sup>

2. *Purpura hemorrhagica.* This aseptic necrotizing vasculitis may occur after reexposure to *S. equi* by natural infection or after vaccination. The prevalence of this disorder after natural outbreaks is not known. In a retrospective study of 53 horses diagnosed with purpura hemorrhagica at a university teaching hospital,<sup>273</sup> 17 horses had confirmed exposure or infection with *S. equi*, and 5 had been vaccinated with SeM protein. In horses with *S. equi*-associated purpura, IgA titers to the SeM and to nonspecific proteins in the *S. equi* culture supernatant (SC-P) are significantly greater than those titers found in horses with uncomplicated

strangles.<sup>274</sup> The isolation of immune complexes consisting of IgA and M-like proteins in the sera of horses with purpura hemorrhagica has led to the suggestion that this isotype is involved in the development of purpura.<sup>274,275</sup> The immunologic basis for the increase in serum IgA levels is not known, but possible explanations include uncontrolled expansion of B cell populations that produce IgA against antigens of *S. equi*; failure of IgA removal mechanisms because of hepatic dysfunction; delayed, defective, or suppressed production of IgG or neutralization; or excess utilization of IgG. In the horse, purpura hemorrhagica has been likened to Henoch-Schönlein purpura, an immune complex-mediated disease of human beings.<sup>275</sup>

The clinical signs of purpura vary and range from a mild transient reaction to a severe and fatal form. Horses with purpura develop pitting edema of the limbs, head, and trunk and petechiation and ecchymoses of the mucous membranes. The vasculitis may cause skin sloughing or affect other sites, such as the gastrointestinal tract, lungs, and muscles. Death may ensue as a result of pneumonia, cardiac arrhythmias, renal failure, gastrointestinal disorders, or severe muscle infarcts.

Confirmation of the diagnosis is by skin biopsy specimen characterized as a leukocytoclastic vasculitis, isolation of the organism, or demonstration of elevated IgA titers to *S. equi* and IgG SeM titers of greater than 1:3200.

Treatment entails administration of intravenous penicillin (20,000 IU/kg four times daily), dexamethasone (0.1 mg/kg intravenously or intramuscularly), intravenous fluids, and antiinflammatory drugs. Treatment may be necessary for more than 7 days. Clinical recovery occurs as the source of the antigen is removed and as the immune response is suppressed. Coincidental with recovery is the production of IgG to *S. equi* antigens.<sup>274</sup>

3. *Guttural pouch empyema and chondroid formation* (see the previous discussion).
4. *Septicemia and the development of infectious arthritis and pneumonia.* These conditions warrant a poor prognosis.<sup>276</sup>
5. *Retropharyngeal abscessation.* This circumstance may cause the horse to develop respiratory distress or dysphagia (or both) and coughing. Endoscopy demonstrates collapse of the nasopharynx, deviation of the larynx, or drainage of purulent material into the nasopharynx when external pressure is applied to the parotid region.<sup>277</sup> Radiographs demonstrate a soft tissue density in the retropharyngeal area, thickening of the roof of the pharynx, reduction in the diameter of the pharyngeal airway, and distortion or compression of the guttural pouches, pharynx, and trachea.<sup>278</sup> Ultrasound of the region—caudal to the mandible, dorsal to the trachea, and between the linguofacial vein and maxillary vein—is used to determine the size and position of the retropharyngeal lymph nodes.<sup>279</sup> The retropharyngeal abscess may rupture into the pharynx and cause a secondary pneumonia (dysphagia) or may rupture dorsally into the guttural pouches.<sup>267,277,278</sup>

De Clercq and colleagues described an ultrasound-guided percutaneous technique for draining abscessed retropharyngeal lymph nodes that, when combined with local and systemic antimicrobial therapy, resolved clinical signs in four horses. When the purulent exudate was too viscous to be aspirated, surgical excision of the abscessed lymph node was performed.<sup>279</sup>

6. *Laryngeal hemiplegia*. This condition occurs when abscessed lymph nodes encroach on the recurrent laryngeal nerve.<sup>280</sup>
7. *Tracheal compression after abscessation of the cranial mediastinal lymph nodes has been reported*. The horse may show respiratory distress or exhibit stertorous breathing. Laryngeal hemiplegia may be an additional complication if the abscess compressing the trachea involves the recurrent laryngeal nerves.<sup>280</sup>
8. *Endocarditis, myocarditis, or cardiac conduction abnormalities*.
9. *Agalactia in periparturient mares*.
10. *Central nervous system abnormalities, including abscess formation and meningoencephalomyelitis*.<sup>269,281,282</sup> Clinical signs depend on the location of the abscess; but for those affecting the cerebrum, one may note circling, altered behavior, blindness, depression, and inappetence. In a report of four cases of brain abscesses, MRI localized the lesion, and a T2-weighted image revealed the abscess surrounded by a hyperintense rim. Additionally, the MRI demonstrated retropharyngeal lymphadenopathy and hyperintense areas within the sinuses.<sup>269</sup> Treatment was not attempted, and culture of the abscesses at postmortem confirmed *S. equi* as the etiologic agent. In a case of *S. equi* meningoencephalomyelitis in a foal, cerebral spinal fluid (CSF) analysis demonstrated an elevated total nucleated cell count and total protein concentration, as well as the presence of gram-positive cocci. *S. equi* infection was confirmed by PCR assay on the CSF.<sup>282</sup>
11. *Myopathies*. Several types of muscle disorders associated with *S. equi* infection have been described. One potentially fatal form is characterized by a vasculitis and infarction of skeletal muscles. In addition to muscle swelling and gait stiffness, horses may exhibit colic and unrelenting pain, necessitating euthanasia. Laboratory data often reveals neutrophilia with a left shift, hyperproteinemia, and hypoalbuminemia. Serum creatine kinase and aspartate transferase activities are markedly increased as a result of muscle inflammation and necrosis. Postmortem examination reveals muscle infarctions, as well as infarcts in the skin, gastrointestinal tract, pancreas, and lungs that are compatible with purpura hemorrhagica. Prognosis is guarded, and horses require treatment with intravenous fluids, antimicrobials, and corticosteroids.<sup>283</sup>

A second type of muscle disorder characterized by acute severe rhabdomyolysis without evidence of infarction or atrophy has been described in Quarter Horses exposed to *S. equi*.<sup>284</sup> Affected horses exhibit stiff gaits, muscle swelling, and recumbency. They also have elevations in neutrophils, fibrinogen, serum creatine kinase, and aspartate aminotransferase. However, on necropsy, pallor to the affected muscles (semimembranosus, semitendinosus, sublumbar, and gluteal muscles) is seen, with no evidence of infarction or muscle atrophy. *S. equi* can be isolated from affected muscles. Horses should be treated with penicillin and dexamethasone.<sup>285</sup>

**Control Measures during an Outbreak** The clinician should recommend that the following be implemented to reduce transmission of *S. equi* during an outbreak<sup>251,286</sup>:

1. Prevent spread of infection to horses on other premises and to new arrivals immediately by stopping all movement of horses on and off the premises.
2. Identify symptomatic and asymptomatic carriers by sampling nasopharyngeal or guttural pouch regions at weekly

intervals and testing for *S. equi* by culture and PCR. Endoscopy of the guttural pouches to facilitate lavage and to inspect the compartments for evidence of abnormalities should be performed.

3. Isolate infectious horses from those screened negative for *S. equi*. Cordon off the isolation area, and have infectious horses looked after by a dedicated staff wearing protective clothing and footwear. Disinfect stalls, aisles, and equipment and water troughs (at least daily).
4. Once clinical signs have disappeared, perform at least three consecutive swabs or lavages for *S. equi* culture coupled with endoscopic examination of the guttural pouches to confirm that horses are noninfectious.
5. Manure and waste feed from infectious animals should be composted in an isolated location. Pastures used to hold infectious animals should be rested for 4 weeks.

**Prevention** Vaccines currently available include a protein-rich acid- and enzyme-extract product that is administered parenterally (e.g., Strepvax II) and attenuated live *S. equi* products that are administered intranasally (Pinnacle I.N.) or, in Europe, submucosally in the upper lip (Equilis StrepE). None of the vaccines guarantee prevention of strangles in vaccinated horses.

Parenteral (killed) vaccines induce strong serum bactericidal activity, but these antibodies are not necessarily protective because mucosal immunity plays a significant role in the resistance to infection.<sup>287</sup> For naïve horses and foals, two to three doses of the vaccine are administered at 2-week intervals and then boosted annually. Horses with high SeM titers should not be vaccinated.

In contrast to parenteral vaccination, mucosal immunization induces a combination of systemic and local responses that produce a greater variety of immunoglobulin isotypes and specificities that more closely mimic those induced by natural disease. Based on manufacturer's comments, approximately 40% of horses that have been vaccinated with the intranasal product before *S. equi* challenge develop clinical signs of the disease when challenged as compared with 60% of nonvaccinated controls that have been similarly challenged. Although intranasal vaccines are expected to produce fewer adverse reactions than parenteral vaccines, lethargy, inappetence, fever, lymphadenopathy, lymph node abscessation, purpura hemorrhagica, and intramuscular abscesses have occurred after vaccination.<sup>245</sup>

Submucosal vaccines have also been associated with the production of adverse reactions, including neck and mandibular lymph node abscesses.<sup>288</sup> In instances of suspected adverse vaccinal reactions, genetic typing of the isolate is required to confirm that coinfection of a wild type *S. equi* is not responsible for the problem. Attenuated live vaccines should be administered only to healthy afebrile animals free of nasal discharges. For the intranasal vaccine, it is recommended that two doses at 2-week intervals followed by an annual booster be administered. Foals may be vaccinated at 1 to 2 months of age, but vaccination may cause mandibular abscessation. For the submucosal vaccine that is available in Europe, two doses (0.2 ml) of the vaccine are injected at 4-week intervals in healthy horses older than 4 months. Because the duration of immunity by the submucosal vaccine is limited, it is recommended that high-risk horses receive a booster every 3 months, although boosting of horses vaccinated up to 6 months previously in the setting of an outbreak has been shown to improve clinical outcome and extends the usefulness of the vaccine.<sup>250</sup>

One should not administer intranasal (or submucosal) vaccines concurrently with other parenteral injections because of the risk of abscess formation at the site of the intramuscular injection. One should wash one's hands thoroughly after vaccination. Use of the vaccine during an outbreak remains controversial and should be restricted to select horses that are healthy and have not been exposed to horses infected with *S. equi*. Vaccination of horses with an SeM titer of more than 1:1600 may be associated with the development of purpura hemorrhagica. During vaccination, effective immune response still requires 7 to 10 days to develop. Thus protection may not be provided quickly enough during outbreaks. None of the vaccines provide cross-protection against *S. zooepidemicus* infections.

**General Control Measures** Whenever feasible, new additions to a farm should be isolated from the resident population for a minimum of 4 weeks. Horses should be monitored twice daily for evidence of fever spikes and examined for evidence of nasal discharge and lymph node enlargement. If possible, new additions to the herd while in isolation should be screened (via PCR) for *S. equi*. This assessment may require lavage of the guttural pouches to ensure that asymptomatic carriers have not been introduced to the facility. Measures should be implemented to prevent animal or personnel contact between the new additions and resident horses.

In a recent commentary, Prescott and Timoney (2007) suggested that strangles has all of the characteristics of an infection that should and could be eradicated.<sup>289</sup> These features include (1) infection limited to equids, (2) poor survival in the environment, (3) little to no antigenic variability, (4) availability of a PCR test to detect presence of organism, (5) low prevalence of a carrier state that could be eliminated by local treatment of the guttural pouches, and (6) existence of moderately effective vaccines that could be combined with eradication program. The envisioned eradication program entails making strangles a reportable disease (with agreed outbreak investigation procedures and published findings) and having each horse be issued a health passport that records exposure to strangles (or other infectious disease outbreaks) that could be used to institute movement controls and more rigorous import-export regulations, including providing results of a recent culture or PCR assay on the health passport.

## VIRAL INFECTIONS

Viruses of known pathogenicity to the horse (or donkey) that are associated with respiratory tract disease include equine influenza virus (EIV), EHV1, EHV2, EHV4, EHV5, asinine herpesvirus 4 (AHV4), AHV5, equine arteritis virus (EAV), equine rhinitis viruses A (ERAV), equine rhinitis virus B1, 2, and 3 (ERBV1, ERBV2, ERBV3), equine adenoviruses 1 and 2, Hendra virus, and African horse sickness virus.

### EQUINE INFLUENZA

**Causes** The influenza viruses are enveloped viruses with a segmented, single-strand RNA genome belonging to the family Orthomyxoviridae. Based on the internal nucleoproteins and matrix antigens, influenza viruses are classified as types A, B, or C. Types B and C infect only human beings, but type A infects many different species, including human beings, horses, swine, dogs, and fowl.<sup>287</sup> Type A is classified further into subtypes based on the surface antigens, the hemagglutinin (H, which is involved in binding of the virus to the host cell)

and neuraminidase (N, which controls release of virus from infected host cells). Two subtypes of equine influenza are recognized as infectious for the horse: subtypes H7N7 and H3N8. Subtype H7N7 was first isolated in Prague in 1956 and has been called equine-1 influenza (A/equine/Prague/56). Subtype 1 is thought to have disappeared from horses worldwide because an isolate has not been confirmed since 1980. Subtype H3N8 was first isolated in Miami in 1963 (prototype) and was designated as equine-2 influenza (A/equine/Miami/63). Several variants of subtype 2 (antigenic drift) were identified and included A/equine/Fontainebleau/79, A/equine/Kentucky/81, A/equine/Saskatoon/90, and A/equine/Newmarket 2 (N2/93), among others.<sup>290-292</sup>

Recent studies of the H3N8 subtype have demonstrated that in the early 1990s, strains diverged into two distinct lineages designated as Eurasian and American (A/eq/Newmarket/1/93-like). In contrast, the oldest H3N8 strains circulating in the 1960s through the 1980s (Miami/63-like, A/eq/Fontainebleau/79-like) apparently became extinct.<sup>293</sup> Results from field observations indicate that the two lineages are sufficiently different that representatives of both lineages should be included in equine influenza vaccines.<sup>294</sup> Compared with the human influenza virus, EIV is relatively stable antigenically, not experiencing major antigenic shifts. This stability has been postulated to result from the shorter lifespan of horses relative to human beings and the lower mutation pressure placed on the EIVs because of low specific antibody titers.<sup>295</sup>

**Epidemiology** Equine influenza virus, as with the human influenza virus, is highly contagious and is transmitted through the air. It most commonly affects 2- and 3-year-old horses and may be the most common cause of respiratory illness in racehorses. Some racetrack facilities experience influenza outbreaks two to three times within a racing season.<sup>291,292,296</sup> This phenomenon may reflect poor ventilation systems (closed sheds), lack of adequate immunization protocols, and rapid transmission of the virus from exercise ponies to racehorses.<sup>291</sup> Recent outbreaks in Japan and Australia during the summer of 2007 have raised questions about the failure of quarantine and vaccination to control the spread of disease, especially given the increased air transport of Thoroughbred stallions between the Northern and Southern hemispheres. Specifically, rapid air transport enables horses to arrive within 48 hours of departure, a time that is within the incubation period for influenza.

Although experimental infection of human beings with EIV (subtype 2) is possible, natural infections do not occur.<sup>295</sup> Interspecies transmission of influenza A2 was recently reported in Greyhound dogs, some of which eventually died of hemorrhagic pneumonia.<sup>297</sup> Interspecies transmission of viruses depends on several factors, one of which is ecology. It is unclear what association the dogs that developed influenza had with horses and whether infection resulted from aerosol transmission or from consumption of untreated meat (including lungs) from an infected horse.<sup>298</sup> A second factor that facilitates interspecies transmission is the presence of appropriate viral receptors (sialic acid linkages) in the host respiratory tract epithelium that are recognized by the viral hemagglutinin (H). When compared with equine influenza, canine isolates had undergone four amino acid modifications in the H antigen, and these changes are postulated to facilitate attachment of the virus to the canine epithelium.<sup>297</sup> Third, for successful interspecies transmission, the virus must be able to

replicate efficiently within the cells of the new host for continued propagation and transmission. It is possible that recent equine H3N8 influenza strains have enhanced virulence and their transmission to dogs are now just being recognized.<sup>298</sup>

The reservoir of EIV between epizootics remains unknown. Some researchers speculate that the virus is maintained in the horse population itself and that asymptomatic carriers shed virus when stressed. Alternatively, the virus may be harbored in other species such as birds, which are asymptomatic but shed the virus in their feces.<sup>295</sup>

**Pathogenesis** The incubation period for equine influenza is 1 to 3 days. The virus infects and replicates primarily in respiratory epithelial cells of the upper respiratory tract with minimal pulmonary involvement. Healthy respiratory tract epithelium is ciliated and contains mucus that forms a protective layer over the cell surface. The mucus normally acts as a mechanical barrier between air and tissue and contains antibody and protein substances that deter the attachment of viral particles to the epithelium.<sup>299</sup> Neuraminidase activity of the viral particles alters the efficiency of the mucociliary apparatus, allowing the virions to attach via hemagglutinin antigens to the sialic acid moieties of the epithelial cells. The epithelial cell internalizes the bound virus and surrounds it with an endosome. However, in the mildly acidic conditions of the mature endosome, the H antigen protein becomes activated and promotes fusion of the viral and cellular membranes, leading to release of the nucleocapsid into the cytoplasm.<sup>300</sup> Release of replicated virions from the epithelial cell is controlled by the neuraminidase glycoproteins, enabling the cycle to continue.<sup>301</sup> Cell necrosis and patchy areas of desquamation follow viral replication within the respiratory tract epithelium. Exposure of irritant receptors causes hypersecretion of submucosal serous glands and further damage to the mucociliary apparatus. Inflammation leads to massive lymphocyte infiltration and edema. Recovery of the normal epithelial architecture can require more than 6 weeks.<sup>302</sup>

Humoral and cellular immunity are important in providing protection against viral disease, and the hemagglutinin and neuraminidase molecules are the main targets of the humoral immune responses against influenza. Thus small antigenic changes in the epitopes of these molecules enable the virus to evade the protective humoral immune responses of the host. IgA blocks viral penetration but is not cidal; certain IgG isotypes, IgGa and IgGb, opsonize the virus particles and enhance phagocytosis.<sup>303</sup> After natural infection, complete clinical and virologic immunity against reinfection with an homologous strain persists for at least 32 weeks, and partial protection is still evident after 1 year.<sup>301</sup> Exposure to the A2 subtype does not protect against infection with the A1 subtype, and vice versa.

**Clinical Signs** Clinical signs of influenza appear 3 to 5 days after exposure to the virus. Severity of signs is related to the strain of the virus and the immune status of the individual.<sup>301</sup> Horses exhibit a sudden onset of fever (103° to 105° F), which may be biphasic; a serous or mucopurulent nasal discharge (or both); anorexia; depression; and a dry, deep cough. Some horses exhibit myalgia, myositis, and limb edema and are thus reluctant to move.<sup>295</sup> A mild form of azoturia (myoglobinuria) occurs in some cases. One may find mandibular lymphadenopathy, as well as endoscopic evidence of pharyngitis and tracheitis. Bronchitis with minimal changes in lung sounds (wheezing) may occur. The severity of lower airway disease appears to be dependent on prior exposure (vaccination).<sup>304</sup>

From experimental studies, inoculation with A/equine-1 produces a milder (subclinical) syndrome unless the animal is stressed before infection, whereas A/equine-2 usually generates the typical clinical signs. The course of the infection usually lasts 2 to 10 days in uncomplicated cases. Exercise exacerbates the clinical signs.<sup>305</sup> Secondary bacterial infections may occur, and donkeys and mules appear to have greater susceptibility to secondary infections than do horses.<sup>306</sup> Horses remain infectious for 3 to 6 days after the last signs of illness. In young foals and in donkeys or mules, influenza infections can be severe, producing signs of viral interstitial pneumonia and respiratory distress that may lead to death within 48 hours.<sup>307,308</sup> (See the later discussion on interstitial pneumonia.)

**Clinical Pathology** Horses may initially exhibit lymphopenia followed by monocytosis.

**Diagnosis** The clinician may diagnose equine influenza by the following methods:

1. *Detection of the virus.* Based on studies of influenza outbreaks, viral culture and isolation alone from nasopharyngeal swabs appears to be the least-sensitive method for diagnosing influenza,<sup>291</sup> probably because the chances of viral isolation are greatest when samples are collected within the first 24 hours.<sup>296</sup> A stall-side assay (Directigen Flu-A test, Becton Dickinson, Franklin Lakes, N.J.) allows rapid detection of influenza antigen and an immediate diagnosis.<sup>302</sup> PCR detection of viral nucleotides obtained from nasopharyngeal swabs enables a diagnosis of influenza infections within 48 hours of sample submission. In a natural outbreak of influenza in 11 horses at a riding school, a diagnosis was confirmed by viral isolation in five horses and by ELISA and by Directigen assay in five and seven horses, respectively, and by PCR in nine horses.<sup>309</sup> In testing horses for import quarantine, the Directigen or PCR should prove extremely useful in detecting impending or prior infections.
2. *Serologic testing.* Several diagnostic methods for detecting influenza virus antibodies in the horse are available and include complement fixation, hemagglutination inhibition, single radial hemolysis, viral neutralization, and enzyme immunoassay.<sup>310</sup> Acute and convalescent serum samples are needed to establish a definitive diagnosis, and although viral neutralizing antibodies may be detectable within a week of infection, up to 28 days may pass before a rise in hemagglutination titers is detected.<sup>295</sup> Serologic testing has been considered to be a sensitive method for diagnosing influenza outbreaks, although in one epidemic, approximately 24% of horses with clinical signs of influenza failed to seroconvert.<sup>291</sup>
3. *Pulmonary imaging.* In both experimental and clinical infections of influenza, pulmonary abnormalities can develop, although whether these infections result directly from the viral or from secondary bacterial infections is uncertain. The primary ultrasonographic alterations include mild lung consolidation and peripheral pulmonary irregularities and the absence of pleural effusion.<sup>304,305</sup> Thoracic radiographs, especially of foals with equine influenza, demonstrate an interstitial pattern. (See also the later discussion on interstitial pneumonia.)

**Treatment** Neuraminidase inhibitors such as oseltamivir phosphate and zanamivir have been used in human medicine for the treatment of influenza and have recently been investigated for use in equine medicine.<sup>311,312</sup> After oral administration, the phosphate salt of oseltamivir is absorbed and

undergoes hepatic metabolism to the active drug oseltamivir carboxylate. When evaluated in vitro, both drugs (oseltamivir carboxylate and zanamivir) inhibited the plaque-forming abilities of 12 equine influenza viral isolates tested.<sup>311</sup> In a small experimental challenge study, prophylactic treatment of horses with oseltamivir phosphate (2 mg/kg orally once daily) 24 hours before influenza challenge and continuing for 5 additional days, shortened the duration of pyrexia and viral shedding compared with the control group.<sup>312</sup> Administration of oseltamivir phosphate (2 mg/kg orally twice) approximately 2 days after influenza challenge (when horses were pyrexia) also reduced the magnitude of pyrexia and the duration of viral shedding relative to controls. Based on pharmacokinetic studies (2 mg/kg orally),<sup>313</sup> the investigators recommended that the dosing interval for oseltamivir should be less than 10 hours to maintain viricidal plasma levels of the drug. Because of its poor bioavailability, zanamivir is administered as an inhalant in human medicine. No studies have been conducted investigating the efficacy of inhaled zanamivir in horses.

In the absence of a readily available and economically feasible source of neuraminidase inhibitors, treatment of affected horses is symptomatic with the primary objectives being to maintain adequate hydration and to prevent undue stresses. Nonsteroidal antiinflammatory drugs may be indicated to reduce the fever, eliminate the myalgia, and improve the appetite. The risk is that the owner will return the horse to strenuous exercise before the horse has rested a sufficient time. Horses that suffer severe infections may be unfit for competition for 50 to 100 days after infection. During the infection, frequent examinations of the respiratory tract are indicated to detect the development of secondary complications such as pneumonia, pleuropneumonia, and myocarditis.

**Prevention** Regular vaccination significantly reduces the population at risk. In fact, the suggestion has been made that at least 70% of the equine population (horses, ponies, and donkeys) should be vaccinated to prevent epidemics of influenza.<sup>314</sup> Dead and live vaccines are commercially available. The former include products containing killed whole virus (either A2 alone or with A1), subunit proteins (purified H or N proteins), and DNA plasmids. Inactivated whole influenza or subunit vaccines are typically administered intramuscularly (primary and secondary booster are required for naïve animals) and induce a humoral immune response characterized by serum antibodies that are able to neutralize the virus. However, the antibody response is short lived, and infection may occur in the case of low antibody concentrations or when a significant mismatch exists between the vaccine strain and the infecting strain of influenza.<sup>301</sup> In one study, the use of a killed vaccine reduced neither the rate of respiratory tract disease nor the severity of clinical scores compared with nonvaccinates.<sup>315</sup> The failure of vaccines to prevent infection is commonly known as *vaccine breakdown* and is most commonly reported in young racehorses. It has been attributed to variable vaccine potency, poor response to vaccination, antigenic drift, or a combination of these factors. This vaccine failure may also be a function of the number of boosters a horse receives before infection and of the strain of A2 contained within the vaccine. The transmission of influenza infection may be facilitated by vaccination that successfully attenuates the clinical signs but fails to prevent viral shedding.<sup>316</sup>

DNA vaccination is typically administered at mucosal sites or in the skin. However, based on experimental studies,<sup>317,318</sup> this approach requires multiple injections, reducing its field

applicability; DNA vaccination can result in the in vivo expression of antigenic proteins that stimulate both humoral and cellular immune responses. A DNA vaccine for equine influenza is currently not commercially available.

The live influenza vaccines are products that contain the virus-based vector product or the temperature-sensitive (Ts) or cold-adapted virus. A live recombinant vaccine is commercially available in Europe (ProteqFlu, Merial Animal Health, Ltd). It contains a canarypox virus to express equine influenza hemagglutinin genes derived from both American (Kentucky/94) and Eurasian (Newmarket/2/93) strains. Thus far, the vaccine has shown promise in reducing clinical signs and nearly completely suppressing viral shedding in vaccinated ponies that were challenged with influenza. The vaccine induces both humoral and cellular immune responses.<sup>294,319-321</sup> The manufacturer's recommendation is to administer a series of three intramuscular injections beginning when the horse is 5 to 6 months of age, repeated 4 to 6 weeks later, and again 5 months after the first injection. Annual boosters are administered.

A second type of live commercially available influenza vaccine contains a cold-adapted, Ts virus that was derived from the wild-type A/eq/Kentucky/1/91 (H3N8) strain. After a single intranasal immunization, ponies were fully protected from clinical signs of disease when challenged with the parental influenza virus 5 weeks later.<sup>301,322,323</sup> Only 20% of vaccinates shed virus when challenged 5 weeks after the vaccination. Little data are available concerning the performance of the virus-based vector or modified-live vaccines during influenza outbreaks.

Vaccinating foals with killed, subunit, or attenuated virus vaccines may be ineffective because of interference by maternally derived antibodies.<sup>301,324,325</sup> Although the use of virus-based vectors for foals could circumvent the neutralizing effect of maternal antibody on vaccine efficacy, a complete understanding of the maturation of the foal's cell-mediated immune response is lacking. Thus most vaccination protocols are focused on enhancing maternal antibody production and providing secondary passive protection of the foal.

Some undesirable side effects of vaccination occur, including fever, depression, pain, swelling at the vaccination site, and muscular stiffness, but these adverse effects usually resolve within 1 or 2 days.<sup>296</sup>

**Sequelae** Secondary bacterial pneumonia and pleuropneumonia are potential complications that may follow viral respiratory diseases in horses that have not been rested adequately before being returned to training or that have undergone other potentially stressful events such as long trailer rides. Myocarditis, pericarditis, and cardiac arrhythmias are other possible sequelae to influenza infections. Interestingly, during an influenza outbreak in the United Kingdom in 2003, two unvaccinated Thoroughbred horses were purported to develop neurologic signs—ataxia, dog-sitting, and leaning. Postmortem examination attributed the neurologic deficits to an influenza-associated encephalopathy or encephalitis. However, this complication seems relatively rare.<sup>326</sup>

## EQUINE HERPESVIRUSES

The Herpesviridae family of viruses contains a significant number of pathogens that have been grouped into alpha-, beta-, and gamma-herpesvirus subfamilies based on morphologic, biologic, and genomic characterizations.<sup>327</sup> The hallmark of these enveloped DNA viruses is their ability to establish lifelong infections achieved by a state of latency from which

the virus may reactivate from time to time with recurrence of infections and transmission to other susceptible hosts.<sup>328</sup> In Equidae, several pathogenic herpesviruses in the alpha and gamma subfamilies have been identified.<sup>329</sup> In horses these include three alpha-herpesviruses, EHV1, EHV3, and EHV4, and two gamma-herpesviruses, EHV2 and EHV5. Note that EHV4, formerly called EHV1 subtype 2, serologically cross-reacts with EHV1 but is genetically distinct from that virus.<sup>330</sup> Similarly, EHV2 and EHV5 also cross-react with each other but are genetically distinct.

In donkeys, six herpesviruses have been identified thus far. AsHV1, an alpha-herpesvirus, was isolated from a donkey foal with vesicular lesions on its muzzle. The dam had similar lesions on the external genitalia and udder. This virus is related to, but genetically distinct from, EHV3. AsHV2 was isolated from the blood of a healthy donkey. Another herpesvirus, AsHV3, was isolated from donkeys after treatment with steroids. AsHV3 has the greatest genetic similarity to EHV1, suggesting that AsHV3 is a member of the alpha-herpesvirus subfamily. When experimentally inoculated with AsHV3, donkeys develop afebrile rhinitis. Three additional gamma-herpesviruses, AsHV4, AsHV5, and AsHV6, have been detected in lung tissues of donkeys dying from acute interstitial pneumonia.<sup>327,331</sup> (See the later discussion on interstitial pneumonia.) However, to date, virus isolation of AsHV4, AsHV5, or AsHV6 has not been successful despite repeated inoculation attempts on a variety of primary and continuous cell lines.<sup>332</sup>

#### EQUINE HERPESVIRUS TYPES 1 AND 4

**Causes** Both viruses have a double-stranded DNA genome of 145 to 150 kbp that, based on sequence analysis, contains 76 unique genes for either virus.<sup>333</sup> The degree of DNA sequence homology between EHV1 and EHV4 varies between 55% and 84%; the degree of amino acid sequence identity varies between 55% and 96%.<sup>334</sup>

Although the host range of EHV1 was once considered to be restricted to the horse, EHV1 has been isolated from cattle, fallow deer, antelopes, alpacas, llamas, and camels.<sup>335-337</sup> In cattle at least, genomic analysis of the herpesvirus isolates failed to demonstrate any specific mutations that permitted interspecies transmission.<sup>338</sup> EHV1, in addition to causing respiratory disease, causes abortions, neonatal deaths, and myeloencephalitis. In horses that develop neurologic signs, the majority of the EHV1 isolates exhibit a single nucleotide polymorphism within the gene encoding the viral DNA polymerase (open reading frame 30).<sup>339</sup>

EHV4 is associated predominantly with respiratory disease in young horses, although the virus has been isolated from older horses exhibiting signs of acute febrile respiratory disease.<sup>340</sup> EHV4 only sporadically causes neurologic disease, abortion, or neonatal deaths.<sup>341-344</sup> In a study conducted by Van Maanen and colleagues (2000), 4% of 254 abortions were caused by EHV4.<sup>345</sup>

**Epidemiology** EHV1 and EHV4 may persist within a herd because of recrudescence of latent infections during periods of stress or immunosuppression. Dexamethasone or cyclophosphamide administration is a reliable reactivation stimulus for viral shedding in experimental studies.<sup>346</sup> For several years, the site of viral persistence was unknown. However, in a study of 40 abattoir horses, EHV1 and EHV4 were detectable by PCR methods in the bronchial lymph nodes of 88% of the horses examined. Of the trigeminal ganglia examined in nine of the horses, one was found to contain only EHV1, four

had detectable EHV4 in the ganglia, and three had evidence of EHV1 and EHV4.<sup>347</sup> EHV2 also was isolated from all of the horses examined, leading some researchers to speculate that EHV2 activates the promoter gene of EHV1, although this has not been proven.<sup>348</sup> In addition to the clinical trials, experimental studies of EHV1 and EHV4 also have provided data supporting the fact that lymphoid and neural tissues are sites of viral latency.<sup>346,348</sup> Interestingly, in an investigation of a respiratory disease outbreak in young foals (7 to 17 months of age) attributed to EHV4, Pusterla, Leutenegger, Wilson, et al. (2005) were unable to demonstrate that EHV4 had established latency in the nasal mucosa or peripheral blood leukocytes within 28 days after developing of clinical signs.<sup>349</sup>

Some studies demonstrate that foals are infected during the first 5 weeks after birth and that horizontal spread continues up to and even after the time of weaning.<sup>350-352</sup> In a recent study of weaning foals with clinical signs of respiratory disease, EHV1 was not detected by PCR in the nasopharyngeal swabs from any of the foals, and EHV4 was identified in the nasopharyngeal swabs in two foals with respiratory disease.<sup>353</sup> Using diagnostic detection tools of seroconversion and viral isolation (nasopharyngeal swabs), Dynon, Black, Ficorilli, et al. (2007) investigated the prevalence of EHV1 and EHV4 in 20 Thoroughbred or Standardbred racehorses with acute febrile respiratory disease. In 3 of the 20 horses (ages 3, 4, and 6 years), EHV4 was diagnosed concurrently by viral isolation, PCR, and increasing antibody titers.<sup>340</sup> The fact that EHV4 was not detected in the other 17 clinically ill horses suggested to the investigators that EHV4 was not simply present in the nasal cavity as a consequence of a highly contaminated environment. For this same sample population, Dynon and colleagues found no evidence of EHV1 infection using either viral isolation techniques or serologic data. In another study, the prevalence of EHV1 was evaluated in a Thoroughbred breeding and racehorse training farm that historically had experienced abortions caused by EHV1. Despite numerous samplings of the asymptomatic horses (broodmares, foals, stallions, and racehorses) over the 9-month study period, EHV1 was detected only in the nasal secretions from 3 of 75 horses.<sup>352</sup> It was not detected (by PCR) in the whole blood samples from any of the horses.

Immunity to EHV1 or EHV4 is short lived (3 to 5 months); thus most horses are reinfected during their breeding or racing careers. Reexposure usually results in mild or inapparent infections, except in the case of broodmares in which reinfection may lead to abortion in the last trimester. Immunity after abortion is generally of longer duration, and in the field, repeat abortions rarely occur in the same mares. No clear relationship exists between gestational age or the level of virus-neutralizing antibody and the incidence of virus-induced abortion.<sup>354</sup> Perinatal disease characterized by weakness and respiratory distress is usually evident within 18 to 24 hours of birth, with foals dying within 24 to 72 hours.<sup>355</sup>

**Pathogenesis** Infection by EHV1 occurs via inhalation of the virus or contact with infected tissues (e.g., fetus, placenta). The virus is delicate and does not survive in the environment; thus close contact appears to be important for transmission.<sup>355</sup> Kydd, Smith, Hannant, et al.<sup>356</sup> have suggested that EHV1 enters the upper respiratory tract and, in the absence of mucosal antibody, immediately infects the epithelial lining of the nasopharynx and tonsils. Based on *in vitro* data, researchers thought that EHV1 attaches to the cell via the viral glycoproteins gB and gC.<sup>357</sup> After attachment, an interaction

between a putative receptor enables fusion between the envelope of the virion and the cellular membrane. In vitro data also demonstrate that EHV1 can enter the cell by a second nonclassical endocytotic pathway. Both pathways require activation of an intracellular kinase, ROCK1, a potential site for therapeutic interventions. Once membrane fusion is completed, the capsid is released into the cytoplasm and transported to the nucleus. Subsequent events depend on whether EHV1 becomes a productive or limited infection. Productive infection results in the intercellular spread of EHV1 through susceptible cells (including leukocytes) in the stroma until the vascular or lymphatic endothelium becomes infected. Thereafter, infection spreads via leukocyte adhesion to the infected endothelium, leading to the development of cell-associated viremia. As a result of viremia and of inhalation of viral particles, the virus disseminates to the lower respiratory tract. In a limited infection, infected cells are phagocytized, and viral antigens are processed and presented to lymphocytes in mucosal lymphoid nodules or lymph nodes. The studies of Burrell<sup>144</sup> and Sutton, Viel, Carman, et al.<sup>358</sup> have demonstrated lower respiratory tract involvement in which hyperemia and mucous accumulations develop 2 to 12 weeks after the initial infection. EHV1 also has a tropism for lymphocytes and is reported to cause immunosuppression. Other clinical signs, such as abortion and neurologic disease, are a sequelae of the cell-associated viremia in which the virus is inaccessible to antibodies.<sup>333</sup>

Modes of transmission of EHV1 other than through the respiratory route have been investigated. Viral DNA has been isolated from semen collected from clinically normal stallions that were experimentally infected. However, venereal spread resulting in infection of susceptible mares has not yet been proven.<sup>359</sup> In another experimental investigation, 8-day-old equine embryos were inoculated for 24 hours with EHV1 before being washed 10 times according to guidelines established by the International Embryo Transfer Society. The investigators detected viral DNA (via PCR) and found evidence of cytopathic effects in 7 of the 10 embryos, suggesting a potential risk for transmission of EHV1 to recipient mares.<sup>360</sup>

The pathogenesis of EHV4 has not been investigated completely by experimental transmission studies but may be similar to that of EHV1. For example, EHV4 can multiply in the epithelia of the nasal cavities, pharynx, trachea, and bronchioli, with subsequent spread to the regional lymph nodes.<sup>333</sup> In contrast to EHV1, EHV4 generally does not cause viremia, and hence abortions and neurologic disease are rare.<sup>361</sup>

**Clinical Signs** EHV1 and EHV4 produce similar respiratory-related signs, but for either virus, mild or subclinical infections are common. Clinical signs of rhinopneumonitis appear 1 to 3 days after infection and are indistinguishable from influenza. Horses are febrile and exhibit a cough and a serous nasal discharge, which may become mucopurulent with secondary bacterial infections. Horses develop rhinitis, pharyngitis, and tracheitis detectable endoscopically. A severe disseminated EHV1 infection that caused fever, depression, respiratory distress, and eventual death has been described in yearlings and 2-year-old horses.<sup>362,363</sup> This form is characterized by vasculitis, hemorrhage, and edema in the lung and has been attributed to a pulmonary vasculotropic form of EHV1. Perinatal disease characterized by weakness and respiratory distress is usually evident within 18 to 24 hours of birth, with foals dying within 24 to 72 hours.<sup>355</sup> With EHV4 infections, researchers believe that during the 6- to 8-month

period after weaning, the majority of foals experience repeated infections with EHV4. The majority of such infections may go unnoticed.<sup>345</sup>

**Clinical Pathology** An epidemiologic survey by Mason, Watkins, McNie, et al.<sup>364</sup> during an outbreak of EHV1 infection on a racetrack in Hong Kong documented a monocytosis in infected horses (>500 cells/ $\mu$ l) during the first 5 days of clinically apparent infections. In experimental infections of EHV1, a decrease in neutrophils and monocytes occurs on day 3 after infection, but the absolute values of both cell types remain within normal limits.<sup>358</sup>

### Diagnosis

1. *Viral isolation.* The virus has been recovered from peripheral blood mononuclear cells for up to 2 weeks after the infection or from nasopharyngeal swabs that have been collected in viral transport media. However, nasopharyngeal swabs should be obtained in the early febrile phase of the disease and transported to the laboratory as soon as possible in a sterile, cold-transport medium.<sup>333</sup> Viral isolation in cell culture is limited by time constraints and the need to confirm viral identity by immunostaining or PCR. In contrast, direct PCR on clinical materials is rapid and enables distinction between EHV1 and EHV4.<sup>365</sup> Recent work reveals poor sensitivity of a real-time PCR assay in detecting EHV1 DNA in buffy coat leukocytes.<sup>366</sup> A PCR assay of materials obtained from nasopharyngeal swabs is more sensitive.<sup>352</sup> However, because of the short duration of nasal shedding, viral DNA may not be detected, and thus diagnosis should also be supported by serologic assessment. A PCR has been developed that can distinguish between neuropathogenic and nonneuropathogenic strains of EHV1.<sup>367</sup>
2. *Serologic diagnosis* is via virus neutralization, immunosay, complement fixation, or a radial immunodiffusion enzyme assay that detects antibodies against EHV1. A fourfold change in antibody titer is suggestive of infection.<sup>368</sup> A commercially available ELISA (Svanovir, Svanova Biotech AB, Uppsala, Sweden) based on the structural differences of the viral glycoprotein G of EHV1 and EHV4 distinguishes between antibodies against these two viruses.<sup>352</sup>
3. *Postmortem examination* of foals that died from EHV1 or EHV4 infection revealed interstitial pneumonia, pleural and peritoneal effusions, hypoplasia of the thymus and spleen, focal necrosis of the liver, and viral inclusion bodies within the hepatic parenchyma. Similar pathologic findings are observed in aborted fetuses. Immunohistochemistry, in situ hybridization, and PCR can be used on tissues to establish the diagnosis of EHV1.

**Treatment** Data available from experimental or clinical trials using antiviral drugs (nucleoside analogs) for the treatment of equine herpesvirus infections are limited. The key protein target for many of the antiviral compounds is the virus-encoded DNA polymerase. The activity of the second-generation nucleoside analogs such as acyclovir, valacyclovir (its prodrug), or ganciclovir is dependent on the drug being phosphorylated by the viral thymidine kinase. During latent infections, the virus does not express genes encoding for viral proteins (thymidine kinase, DNA polymerase), thus latent virus is unaffected by any of the conventional nucleoside analogs.<sup>328</sup> Nevertheless, in human medicine, routine use of these antivirals can suppress recurrent infections in patients for periods up to 10 years.

In a recent investigation, the *in vitro* activity of six nucleoside analogs in reducing plaque number or plaque size associated with EHV1-infected cells was examined.<sup>369</sup> The investigators used three different abortigenic and three neuropathic strains of EHV1. They found that the ED<sub>50</sub> (defined as the 50% effective concentration for inhibition of plaque formation) of ganciclovir was less than that of acyclovir and that no differences in susceptibility of the six different EHV1 strains to these two drugs existed. Based on their studies, the researchers in the investigation suggested that an effective concentration for ganciclovir was 0.1 µg/ml and that of acyclovir was at least 2.0 µg/ml. Given that ganciclovir would be quite expensive to use clinically in the horse, it was more likely that acyclovir would be used. Indeed, during outbreaks of EHV1 involving neurologic disease or neonatal deaths, acyclovir has been administered at doses ranging between 8 to 16 mg/kg orally three times daily to 20 mg/kg orally three times daily.<sup>370,371</sup> The efficacy of acyclovir in treating respiratory diseases has not been demonstrated, and its poor bioavailability (3%) when given orally<sup>372</sup> may preclude it from achieving the requisite viricidal plasma levels (>2 µg/ml). Even when administered intravenously at 10 mg/kg,<sup>373</sup> the *in vitro* data suggest that the drug would have to be given either as a constant infusion or as a single treatment eight times a day to achieve plasma concentrations between 1.7 and 3.0 µg/ml.<sup>369</sup> In humans, the major reported adverse effect of parenteral administration of acyclovir is renal toxicity caused by precipitation of the acyclovir crystals in the renal tubules when maximal solubility is exceeded.<sup>374</sup>

Because of its improved bioavailability, interest in the acyclovir prodrug valacyclovir has prompted recent pharmacokinetic investigations. Garré, Shebany, Gryspeerdt, et al. (2007) reported that when valacyclovir was administered to horses at 20 mg/kg, its bioavailability was much improved, as compared with acyclovir (26%). However, plasma concentrations were maintained above the EC<sub>50</sub> value for only 1.5 to 2.0 hours. Based on computer modeling, the investigators suggested dosing valacyclovir at 40 mg/kg orally three times daily in an effort (1) to maintain plasma concentrations greater than 1.7 µg/ml during the entire treatment interval and (2) to exceed plasma concentrations of 3.0 µg/ml during 30% of the treatment interval.<sup>374</sup> One potential drawback of acyclovir (or valacyclovir) is the development of viral resistance in strains lacking thymidine kinase, although this circumstance, to date, has not been realized.

Another antiviral drug, (s)-1-[(3-hydroxy-2-phosphonyl methoxyl)-propyl] cytosine (HPMPC), has been shown to be efficacious when given before EHV1 challenge in naïve foals but has not been used clinically in North America.<sup>375</sup>

Because evidence of immunosuppression during herpetic infections exists, the clinician may consider administering broad-spectrum antimicrobials for 7 to 10 days to affected horses. In addition, horses should be rested for 4 to 6 weeks before exercise training commences.

**Management Recommendations during an Outbreak**  
During an outbreak of EHV1, measures should be implemented to reduce the potential sequelae, such as abortion and neurologic disease. Affected animals should be isolated, and no horse should be permitted to leave the property or track until 3 weeks after recovering from the last clinical sign.<sup>333</sup> Stalls should be cleaned thoroughly of contaminated materials and then disinfected.

**Prevention** Commercially available vaccines include two single-component inactivated (killed) vaccines that are marketed for the prevention of EHV1-induced abortions in pregnant mares and respiratory infections (Pneumabort K, Fort Dodge Animal Health; Prodigy, Intervet Inc.). Three intramuscular doses are recommended for primary immunization followed by an annual booster. Multicomponent inactivated vaccines include products such as Prestige (Intervet Inc.) or Calvenza (Boehringer Ingelheim) that contain both EHV1 and EHV4 or Fluvac Innovator (Fort Dodge Animal Health) that contains influenza A1 and A2 with EHV1 and EHV4. A modified-live product (Rhinomune, Pfizer Animal Health) is also commercially available, although it is not recommended for use in pregnant mares. None of the products provides complete protection against clinical disease.

On the premises with confirmed clinical EHV1 infections, booster vaccination of horses that are likely to have been exposed to EHV1 is not recommended. Booster vaccinating nonexposed horses and horses that would come onto the premises is rational. This approach assumes that vaccination induces an anamnestic and not a primary response. The question of whether vaccination during an outbreak could induce nasal shedding (and thus preclude identification of clinically infected horses during an outbreak) was investigated. In a pilot study, 14 horses were vaccinated with either a killed product (Pneumabort K + 1b) or a modified-live product (Rhinomune). The investigators found that EHV1 DNA was not detected by PCR in nasopharyngeal swabs or in whole blood samples obtained from horses at 1-week intervals for 4 weeks after the vaccination.<sup>376</sup> These results suggested that in healthy unstressed horses, one should not detect vaccine DNA or reactivated latent EHV1 DNA after the vaccination.

A recent product that has been marketed to prevent EHV1 or EHV4 (or both) infections during disease outbreaks or during times in which the horse is stressed is Zylexis (Pfizer Animal Health), an inactivated *Parapox ovis* virus was purported to have immunomodulator activity. The manufacturer's recommendation are to administer the preparation to healthy horses 4 months of age or older via a series of three intramuscular injections given on days 0, 2, and 9. No scientific data establishing the efficacy of Zylexis have been published by independent groups.

## EQUINE HERPESVIRUS 2

EHV2 is a slowly replicating virus, often known as *equine cytomegalovirus*. It is believed to establish latency in B-lymphocytes but can be found in lymphoid and neural tissue.<sup>377</sup>

**Epidemiology** EHV2 is endemic in horse populations tested worldwide with approximately 90% of horses tested being seropositive.<sup>378,379</sup> Because the prevalence of seropositivity and the magnitude of these titers are not different between healthy and diseased horses, opinions vary as to the true pathogenicity of EHV2.<sup>142,380</sup> In surveys of healthy adult horses, viral DNA can be recovered from the peripheral blood leukocytes in the majority of animals, with frequencies ranging between 68% to 71%<sup>381</sup> to 89%.<sup>332</sup> The virus has been isolated from nasopharyngeal swabs obtained in young racehorses with PLH, implicating EHV2 in the development of this condition.<sup>144</sup> The suggestion has been made that most foals are exposed to EHV2 at 2 to 3 months of age and shed the virus for 2 to 6 months until a humoral antibody response develops and eventually is associated with low viral recovery.<sup>380</sup> EHV2 has been isolated from 2- to 3-month-old foals during outbreaks

of pneumonia in Hungary, Japan, Australia, New Zealand, and the United States.<sup>380,382-385</sup> In a longitudinal study of 27 foals in a Hungarian stable that experienced respiratory disease outbreaks, peripheral blood leukocytes and nasopharyngeal swabs were obtained from young foals until they reached 23 weeks of age.<sup>381</sup> By 6 weeks of age, 93% of the nasopharyngeal swabs were positive for EHV2 DNA, and by 8 weeks, 100% of the peripheral blood leukocytes were positive for EHV2 DNA. In some investigations of respiratory disease outbreaks in foals, EHV2 was the sole infectious agent isolated from the respiratory tract, whereas in other outbreaks, bacterial agents—*S. zooepidemicus* and *Rhodococcus equi*—complicated the pneumonia.<sup>384</sup> This finding has led some researchers to speculate that if the foals are stressed or infected with a large dose of the virus during a period in which maternal antibodies are waning, then the virus may invade the cells of the immune system and cause further immunosuppression. Blakeslee, Olsen, McAllister, et al.<sup>142</sup> reported a dose-related immunosuppression after in vitro infection of lymphocytes with EHV2, and this effect has been documented in vivo using a rabbit model.

**Pathogenesis** After natural exposure, EHV2 is recoverable from nasal and nasopharyngeal swabs; from the kidney, bone marrow, spleen, mammary gland, salivary gland, vagina, tracheal mucus, neural tissue; and from the cornea and conjunctiva.<sup>378,386</sup> Leukocytes and lymph nodes draining the respiratory tract are major reservoirs of EHV2 DNA.<sup>378</sup>

**Clinical Signs** In foals that are experimentally infected with EHV2, pharyngitis and lymphoid hyperplasia develop, implicating the EHV2 as a causative agent of chronic lymphoid hyperplasia in young horses.<sup>142</sup> However, the role of EHV2 in the natural production of pharyngitis or lymphoid hyperplasia remains uncertain. The role of EHV2 in causing keratoconjunctivitis also remains equivocal, with clinical investigations both supporting<sup>387</sup> and refuting its involvement.<sup>379</sup>

**Diagnosis** EHV2 diagnosis depends on isolation of the virus, serologic evidence of an active viral infection, and the presence of clinical signs. EHV2 is highly cell associated but more slowly cytopathic than the equine alpha-herpesviruses. Its slow growth in culture may hinder its recognition if alpha-herpesviruses are present, increasing the time required for laboratory diagnosis.<sup>353</sup> Diagnosis is aided by PCR methods.

**Treatment** Treatment is symptomatic. Efficacy of antiviral agents has not been examined in EHV2 infections.

**Prevention** No commercial vaccine is available.

## EQUINE HERPESVIRUS 5

**Causes** Originally classified as EHV2, examination of restriction endonuclease profiles of some slowly growing equine herpesviruses eventually led to its identification as a separate DNA virus in the gamma-herpesvirus subfamily.

**Epidemiology** The initial isolates of EHV5 were obtained from peripheral blood leukocytes and nasal swabs from Australian horses,<sup>388</sup> but the virus has been subsequently identified in horses in Switzerland, Germany, New Zealand, and the United States.<sup>381,389,390</sup> In a longitudinal study of mares and their foals that were monitored from birth to 6 months of age, latent EHV5 infections were detected in the peripheral blood mononuclear cells of 88% of the foals at 6 months of age. The presence of the virus was not associated with respiratory disease in that study.<sup>390</sup>

**Pathogenesis** Little is known about the natural course of disease in horses infected with EHV5. The initial isolates of EHV5 were from horses with upper respiratory tract disease

and, similar to EHV2, has been implicated in the production of lymphadenopathy, immune suppression, malaise, and respiratory tract disease.<sup>391</sup>

**Clinical Signs** In a retrospective study of 24 horses with clinical signs and radiographic evidence of interstitial lung disease, EHV5 was detected by PCR in 79% of the paraffin-fixed lung samples obtained from these horses.<sup>392</sup> However, causality between EHV5 and multinodular interstitial lung disease remains to be established because EHV5 can be isolated from peripheral blood mononuclear cells (PBMCs) or nasal swabs of 24% to 33% of healthy horses.<sup>381,389</sup>

**Diagnosis** The diagnosis is confirmed by viral isolation and identification of the virus by PCR. Serologic tests are problematic because EHV2 and EHV5 share considerable cross-reactivity in ELISA and radioimmunoprecipitation because of common epitopes.<sup>391</sup>

**Treatment** Treatment is supportive if indicated. (See the later section on interstitial pneumonia.)

**Prevention** No vaccine is currently available.

## EQUINE VIRAL ARTERITIS

**Causes** Equine arteritis virus (EAV), an enveloped single-stranded RNA virus, is a member of the family Arteriviridae (genus *Arterivirus*, order Nidovirales). EAV is genetically similar to corona viruses (also a member of Arteriviridae) but has a dissimilar viral structure and complement-fixing antigen.<sup>393</sup> The virus contains six envelope proteins (E, GP2b, GP3, GP4, GP5, and M) and a nucleocapsid protein (N). The major neutralization determinants of EAV are expressed by GP5, and although considerable variation in the sequence of this protein exists in field strains of the virus, only one serotype of EAV (the Bucyrus strain) has been found.<sup>394</sup> All strains of EAV evaluated thus far are neutralized by polyclonal antiserum raised against this highly virulent Bucyrus strain.<sup>395</sup> The virus, which has a worldwide distribution, may cause sporadic and sudden death in foals, abortion in mares, and mild or subclinical infections in adult horses.<sup>393</sup>

**Epidemiology** Before the 1984 epizootic of equine viral arteritis (EVA) in Kentucky, little attention was paid to this virus.<sup>396</sup> Most infections were assumed to be transmitted by inhalation until the important role of venereal transmission was demonstrated in those outbreaks. The virus is maintained in the equine population by long-term and short-term stallion carriers. The duration of the carrier status ranges between several weeks to years. Testosterone is essential for maintenance of persistence because long-term infections do not occur in colts exposed to the virus before the onset of peripubertal development or in mares.<sup>396-398</sup> During the carrier state, the virus is present solely in the reproductive tract, principally in the ampulla of the vas deferens. In the carrier stallion, genetic and antigenic variation (diversity of viral isolates) is generated in the course of persistence.<sup>395</sup> Primary exposure to the virus is presumed to be via the venereal route. Susceptible mares bred to carrier stallions almost always become infected with EAV. Viral shedding into the respiratory tract allows secondary horizontal transmission of the virus to occur. The latter type of transmission (aerosol or fomites) would be more typical of that occurring in young racehorses at training facilities. The mode of transmission to neonatal foals is not known and might entail both transplacental infection during late gestation or inhalation during or after the birth.<sup>399,400</sup>

In addition to the outbreak in Kentucky in 1984, several other outbreaks have been reported in North America, Europe,

Australia, New Zealand, and South Africa.<sup>395</sup> A significant difference in seropositivity to EAV exists not only between countries, but also among the horse breeds within a given country. Approximately 84% of Standardbreds and 93% of Austrian Warmblood stallions have circulating antibodies to EAV, whereas less than 5% of Thoroughbred and less than 1% of Quarter Horses are seropositive.<sup>401</sup> No evidence has been found of any breed-specific variation in susceptibility to EAV infection or in establishment of the carrier state, thus the number of actively shedding carrier stallions likely determines the prevalence of EAV infection in the individual horse breeds.<sup>395</sup> The virulence of the strains of EAV associated with individual horse breeds may not be constant, and those shed by carrier Standardbred stallions are often very highly attenuated and cause minimal if any disease in susceptible horses (regardless of breed).<sup>395</sup>

**Pathogenesis** After intranasal challenge (aerosolization), the virus invades the respiratory tract epithelium and the alveolar macrophages. By 72 hours after infection, replicating viruses are detectable in the bronchopulmonary lymph nodes, endothelium, and circulating macrophages. With venereal transmission (by natural cover or by artificial insemination), the virus can be isolated from swabs of the rectal and vaginal mucosa during the febrile periods. Dissemination of the virus by hematogenous routes allows infection of mesenteric lymph nodes; spleen; liver; kidneys; nasopharyngeal, pleural, and peritoneal fluid; and urine.<sup>396</sup> By 6 to 8 days after infection, the virus has localized within the endothelium and medial myocytes of blood vessels, where it causes a necrotizing arteritis, a panvasculitis.<sup>393</sup> Thus the clinical manifestations of EVA reflect vascular injury with increased permeability and leakage of fluid.<sup>395</sup> The vascular lesion may be caused by a direct cytopathic effect of the virus on the endothelium and medial myocytes, from the effects of anoxia or thrombosis induced by cell damage, or from virus-induced macrophage-derived vasoactive and inflammatory cytokines.<sup>395</sup> In neonatal foals, the virus, by virtue of its ability to cause lymphoid depletion in the spleen and lymph nodes, enhances the neonate's susceptibility to secondary bacterial infections.<sup>400</sup>

**Clinical Signs** The vast majority of EAV infections in equids (horses, donkeys, and mules) are inapparent or subclinical, but occasional outbreaks of EVA occur that are characterized by persistent infections in stallions, influenza-like illness in adult horses (with nasal and ocular discharge), abortion in pregnant mares, and fatal interstitial pneumonia and enteritis in neonatal foals.<sup>395</sup> The variation in clinical signs may be a function of host factors, such as age and immune status, and virus factors, including the virulence, the amount of infective virus, and the route of infection.<sup>402</sup> Thus very young, very old, debilitated, or immunosuppressed horses are predisposed to severe EVA. The incubation period ranges between 3 to 14 days (6 to 8 days if transmitted venereally). In the acute disease, horses are febrile (105° F) for 1 to 5 days, anorectic, depressed, and may cough. They may exhibit a serous nasal discharge, congestion of the nasal mucosa, mandibular lymphadenopathy, conjunctivitis, lacrimation, and, less frequently, corneal opacification. Edema of the sheath, scrotum, ventral midline, limbs, and eyelids occurs secondary to the vasculitis. Other signs may include respiratory distress, stiffness, soreness, diarrhea, icterus, skin rash on the neck, and papular eruptions on the inside of the upper lip. Most adult horses recover uneventfully; mortality rarely, if ever, occurs in natural outbreaks of EVA. Note that the highly virulent horse-adapted

Bucyrus strain of EAV, which does cause high mortality in healthy adult horses, is not representative of field strains of the virus and is best regarded as a laboratory strain.<sup>395</sup>

Abortions occur between 10 to 34 days after exposure (during the third to tenth months of gestation), but the mechanism is not known. Abortion can occur with or without preceding clinical evidence of infection.<sup>403</sup> EVA has not been associated with teratologic abnormalities in fetuses or foals.

Neonates may die suddenly or develop severe respiratory distress followed by death.<sup>396,399</sup> In such cases, the dam of the affected foal may be completely asymptomatic.<sup>393,400</sup>

**Clinical Pathology** Infection causes leukopenia, lymphopenia, and thrombocytopenia.

**Diagnosis** In North America, EVA is a reportable disease. Although the virus may persist in the buffy coat for up to 36 days after infection, viral isolation can be difficult.<sup>402</sup> Samples to be submitted for viral isolation include citrated blood samples, nasopharyngeal and conjunctival swabs, vaginal swabs, and semen from an infected stallion.<sup>404</sup> PCR enhances viral detection and specificity, but the serum should also be submitted for detection of antibodies. Virus neutralization, complement fixation, immunodiffusion, and immunofluorescence are techniques used to demonstrate changes in antibody titers. A fourfold or greater rise in titer or a change in status from seronegative to seropositive may indicate a recent infection. Postmortem examinations of aborted fetuses demonstrate edema, excessive pleural fluid, and petechiation on the mucosal surfaces of the respiratory and gastrointestinal tracts, but focal necrosis of the liver or intranuclear inclusions are not features of the disease.<sup>394</sup> Foals that die acutely of EVA exhibit interstitial pneumonia characterized by a predominant macrophage infiltrate, hyaline membrane formation, and vasculitis of the small muscular arteries.<sup>400</sup> Infective virus particles or viral antigen can be identified by immunofluorescence in the small muscular arteries of the lung, kidney, spleen, thymus, and heart.

**Treatment** Treatment is symptomatic with the primary objectives being to keep the horse well hydrated and to provide analgesics (nonsteroidal antiinflammatory drugs) as needed. Fever in stallions can lead to sperm damage and temporary infertility; thus one should administer nonsteroidal antiinflammatory drugs. The horses should be isolated for 3 to 4 weeks to minimize the chances of transmission.

**Prevention** EAV infections are readily prevented through serologic and virologic screening of horses coupled with sound management practices that include appropriate quarantine and strategic vaccination.<sup>395</sup> Vaccination of seronegative stallions with a commercially available modified-live vaccine (ARVAC, Fort Dodge Animal Health) is credited with preventing the establishment of carrier states in the stallion or with further increases in the carrier state during the 1984 epizootic in Kentucky. (A modified-live vaccine is licensed for use in the United States and in Canada, whereas a killed vaccine [Artervac; Fort Dodge Animal Health] is available in the United Kingdom, Ireland, France, Denmark, and Hungary.<sup>405</sup>) For example, in the Kentucky outbreak, stallions were bred only to mares that were vaccinated or were seropositive from previous natural exposure to EVA. After vaccination, clinical immunity was found to develop rapidly and to last for 1 to 3 years.<sup>396</sup> Some vaccinates develop mild febrile reactions and transient lymphopenia, and the vaccine virus can be sporadically isolated from the buffy coat for 7 days (but occasionally up to 32 days). Thus mares should be vaccinated 3 to 4 weeks

before breeding to an EAV carrier stallion and isolated.<sup>403</sup> Vaccinated stallions do not shed the virus in either semen or urine. Thus vaccination of prepubertal colts prevents them from becoming persistently infected carriers and is central to any effective control program. Vaccination is not recommended for pregnant mares or for foals younger than 6 weeks. Fetal infections have been documented after murine leukemia virus (MLV) vaccination of pregnant mares.<sup>405</sup> Passively derived antibodies to EAV decrease to undetectable amounts by 8 months postpartum for foals born to seropositive mares. Vaccination should be effective at this time if necessary.<sup>406</sup> Although the current MLV vaccine is effective, a recombinant subunit vaccine coexpressing the two major envelope proteins of EAV (GP5 and M) that experimentally has been shown to effectively induce neutralizing antibodies and protective immunization, may find commercial success.<sup>405</sup>

## EQUINE RHINITIS VIRUSES

**Causes** Formerly termed *equine rhinoviruses*, at least four serotypes of equine rhinitis viruses have been identified to date. These viruses have been isolated from horses in the United Kingdom, mainland Europe, the United States, Australia, and Japan. Serotype 1, formerly called equine rhinovirus 1, has been renamed equine rhinitis A virus (ERAV) and is now reclassified as a member of the genus *Aphthovirus*, family Picornaviridae. The reclassification is based on (1) the homology of the nucleotide sequence of the ERAV genome with that of foot-and-mouth disease virus, (2) the physicochemical properties of ERAV, and (3) the production of viremia and persistent nasal, urine, and fecal shedding after ERAV infection.<sup>407</sup> Serotype 2, formerly called equine rhinovirus 2, has been renamed equine rhinitis B virus 1 (ERBV1) and has been reclassified to the genus *Erbovirus* (from **e**quine **r**hinitis **B** virus), family Picornaviridae.<sup>408</sup> A third serotype, formerly designated P313/75 or equine rhinovirus 3 has also been assigned to the genus *Erbovirus*. It is now called equine rhinitis B virus 2 (ERBV2).<sup>409</sup> A fourth antigenically distinct, acid-stable equine picornavirus has also been assigned to the genus *Erbovirus* and is called equine rhinitis B virus 3 (ERBV3).<sup>410,411</sup> This virus had been originally classified with the ERBV1 isolates and exhibits weak serologic cross-reactivity with antibodies against ERBV1.<sup>411</sup>

**Clinical Signs** Infection of horses with ERAV causes acute fever, nasal discharge, coughing, anorexia, pharyngitis, laryngitis, and mandibular lymphadenitis.<sup>412,413</sup> Infection produces moderate increases in the neutrophil-to-lymphocyte ratios (from 50:49 in healthy horses to 57:43 in infected horses) and in plasma fibrinogen.<sup>413</sup> The importance of ERAV as a cause of respiratory disease has not been recognized previously because clinical signs may be mild and because viral isolation is difficult.<sup>414</sup> The incubation period is 3 to 8 days, with shedding of viral particles from pharyngeal secretions, urine, and feces being a feature of the infection. Young horses are infected more commonly than older horses. For example, the prevalence of serum neutralizing titers in 24-month-old Thoroughbreds just entering a training facility had increased from 18% to 63% when sampled 7 months later.<sup>415</sup> Other studies have found prevalence rates of neutralizing antibodies to ERAV to range between 73% to 90%.<sup>413,416</sup> ERAV has also been isolated from horses without clinical evidence of respiratory disease.<sup>415</sup> Equine rhinovirus A has a broad host range that includes rabbits, guinea pigs, monkeys, and human beings, although the virus does not seem to spread horizontally in each of these

species. Intranasal inoculation of a human volunteer with ERAV resulted in severe pharyngitis, lymphadenitis, fever, and viremia.<sup>412</sup> Experimental and epidemiologic evidence of ERAV infection of human beings exists. High antibody titers were found in the sera of 3 of 12 stable workers, whereas no ERAV antibody was found in the sera of 159 non-stable workers.<sup>417</sup> In a serologic survey of 137 samples obtained from mixed-practice veterinarians, only 3% were seropositive for ERAV, suggesting that the risk of infection is low.<sup>416</sup> One can diagnose ERAV infections by serologic testing (fourfold changes in titers between acute and convalescent samples) or by PCR identification of the virus in nasopharyngeal swabs.<sup>414</sup>

Equine rhinitis viruses assigned to the genus *Erbovirus* are also respiratory tract pathogens. In a survey involving horses with acute respiratory disease, researchers isolated ERBV from 30% of the horses sampled. Of the 28 horses from which the virus was recovered, a serologic diagnosis was made in only 6 horses. Researchers attributed the low diagnostic rate to the difficulty of initially collecting samples during the acute phase: Antibody levels rise rapidly from day 6 after infection and peak between days 14 and 18.<sup>418</sup> Thus, in contrast to ERAV, viral isolation may be the more successful diagnostic method. In a survey involving Australian horses, serum neutralizing antibodies against ERBV1 were detected in 77% of the 2- to 3-year-old Thoroughbred horses in training and in nearly 94% of stable horses aged 10 to 22 years.<sup>415</sup> Interestingly, approximately 4% of mixed-animal veterinarians develop serum neutralizing antibodies against ERBV1, suggesting that, similar to ERAV, humans are at low risk for becoming infected with this virus.

The clinical significance of ERBV2 (formerly P313/75) is currently uncertain. ERBV2 has been isolated from one horse with a 6-day history of intermittent fever that began 4 days after an umbilical hernia operation and castration<sup>419</sup> and from another horse with signs of acute febrile respiratory disease and high titers against ERBV2.<sup>340</sup> In the epidemiologic survey conducted by Black, Wilcox, Stevenson, et al. (2007), 89% of 2- to 3-year-old Thoroughbreds at a training facility in Australia exhibited serum neutralizing antibodies to ERBV2. This prevalence rate contrasts with that found in older stable horses of 45%.<sup>415</sup>

The fourth rhinovirus, ERBV3 (originally classified as ERVA), was initially isolated from horses with acute respiratory disease. Additional studies are required to ascertain the severity of clinical disease that occurs with ERBV3 infections, as well as the seroprevalence in equine populations. No vaccine is currently available against ERAV or ERBV1, 2, or 3.

## EQUINE ADENOVIRUSES

Two separate nonenveloped DNA viruses belonging to the family Adenoviridae have been isolated from horses and are recognized as equine adenovirus 1 (EADV1) and EADV2.<sup>420</sup>

EADV1 is endemic in most horse populations, and the belief is that most foals acquire the infection during the suckling period from the mares. Disease develops if maternal antibodies wane or if active immune responses are impaired. Susceptible foals include Arabian foals with combined immunodeficiency or Fell pony foals with an undefined immunodeficiency.<sup>421</sup> The virus replicates in the respiratory tract and can cause conjunctivitis, rhinitis, and bronchopneumonia. In one recent survey, EADV1 was detected by PCR in the nasal swabs of 40% of hospitalized foals and in 58% of healthy control foals.<sup>422</sup>

EADV2 has been isolated from the lymph nodes and feces of foals with upper respiratory tract disease and diarrhea.<sup>423,424</sup> For a more detailed description, the reader is referred to the section on foal pneumonia.

### EQUINE HENDRA VIRUS

**Cause** Originally called equine morbillivirus but later renamed equine Hendra virus (HeV), this enveloped RNA virus is a prototype of a new genus, *Henipavirus*, within the subfamily Paramyxovirinae.<sup>425</sup> HeV is a pleomorphic (spherical or filamentous) structure, the genome of which exceeds 18 kbp. The latter encodes for eight different proteins, including the cell-attachment (G) and fusion (F) proteins that protrude from the viral envelop.<sup>426</sup>

**Epidemiology** The virus was first recognized as a causative agent of severe respiratory disease in Thoroughbred racehorses in a suburb of Brisbane, Australia, called Hendra.<sup>427</sup> During the 1995 outbreak in which 13 of 20 horses died or were euthanized, two humans also became infected, one fatally. However, in a retrospective analysis of postmortem tissues, it was later determined that in 1994, HeV was the cause of death of two other horses and a person assisting with their necropsy in Mackay, a city approximately 800 kilometers from the Brisbane area. Since that time, several additional outbreaks have occurred in Australia involving fewer numbers of horses or humans. In Australia, most equine cases have been documented to occur in the spring or summer and involve horses that were housed near food or the roost trees of flying foxes. Based on testing of wildlife, flying foxes (fruit bats, *Pteropus* spp.) were subsequently shown to be the source of infection of the horses. Despite the presence of antibody to HeV in fruit bats throughout their geographic range in Australia, suggesting that infection is quite common in that species,<sup>428</sup> HeV disease in horses in Australia has thus far been uncommon and sporadic.

**Pathogenesis** Natural and experimental infection in horses suggests an incubation period of 8 to 16 days or 4 to 10 days, respectively.<sup>427,429</sup> The means by which HeV infects horses is still unknown. The virus can be isolated from the oral cavity and urine of some infected horses but not from rectal or nasal swabs.<sup>425</sup> One hypothesized route of infection is via consumption of pasture or feed contaminated with bat urine, aborted bat fetuses, or reproductive fluids.<sup>425</sup> (The birthing season of the bats is consistent with the timing of the HeV cases that were recorded in horses between August and January.) In experimental infections, horses can be infected by eating material contaminated with the virus. Transmission to horses from exposure to infected cat urine is also possible. Horse-to-horse or horse-to-human transmission has been suggested to occur by direct contact with frothy nasal discharges, urine, blood, or pleural fluids of a viremic horse. No human-to-human transmission has been reported.

In experimental infections, horses kept in stalls adjacent to an infected horse fail to become infected, suggesting that the virus is not highly contagious and that aerosol transmission is inefficient. One additional hypothesis regarding transmission of the virus from bats to horses involves the Australian paralysis tick *Ixodes holocyclus*. This tick is a blood feeder that feeds both on bats and horses (as well as other mammals, including humans).<sup>430</sup>

The mode of viral attachment and cell infectivity of HeV is different from that of other paramyxoviruses. It does not engage the sialic acid-containing receptors for attachment but rather depends on the viral G protein to interact with a

cell-surface glycoprotein called ephrin-B2.<sup>426</sup> The ephrin-B2 receptors are highly concentrated on endothelial cells (hence the tropism of the virus for those cells), as well as neurons and smooth muscle cells. Fusion of the viral membrane is accomplished by the F glycoprotein. This process not only enables the virus to gain entrance into the cell but is also responsible for the formation of syncytial giant cells.<sup>426</sup> The virus replicates within the upper and lower respiratory tract epithelium and causes an interstitial pneumonia.

**Clinical Signs** Horses acutely develop signs of respiratory distress that are characterized by fever ( $>104^{\circ}$  F), depression, tachycardia, tachypnea, sweating, poor capillary refill, and abnormal lung sounds (caused by pulmonary edema). Neurologic deficits such as ataxia, head pressing, and recumbency can also occur.<sup>431</sup> The time between the onset of signs until death is usually between 1 and 3 days.<sup>425</sup> Humans die as a result of respiratory and renal failure and relapsing encephalitic disease.<sup>430</sup>

**Diagnosis** Differential diagnoses to be considered in affected horses include heart failure, acute African horse sickness, highly virulent influenza, and plant intoxications.<sup>431</sup> Serologic testing (ELISA or virus neutralization tests) can be used to detect antibody titers in affected horses (or humans). Gross abnormalities in the lungs of affected horses are highly suggestive of but not pathognomonic for the disease. Histo-pathologic findings include alveolar edema, hemorrhage, lymphatic dilation, and vasculitis of pulmonary capillaries and arterioles. Within the walls of the blood vessels are the characteristic syncytial giant cells that contain cytoplasmic inclusion bodies.<sup>425</sup> From tissues, the virus can be isolated in cell culture, visualized by electron microscopy, and confirmed by indirect immunoperoxidase test, immunofluorescence test, or PCR.

Because of the susceptibility of humans, the high virulence of the virus, and the absence of therapeutic modalities and vaccines, HeV is classified as a biosecurity level 4 pathogen and requires the highest level of caution and preparedness when working with the tissues obtained from infected animals.<sup>426</sup> Such precautions include wearing effective eye, nose, and mouth protection from fomites and aerosols, complete covering of the body with plastic overalls, and double gloving with gloves tied by adhesive tape to the cuffs of the overalls.<sup>431</sup>

**Treatment** No antiviral agent exists that is effective against Hendra virus. The outbreak of the disease in Brisbane was controlled by a stamping-out program involving slaughter of all known infected horses, quarantine of premises, controls on the movement of horses within a defined disease control zone, and serologic surveillance to determine the extent of infection.<sup>431</sup>

**Vaccination** No vaccine is available.

**Prevention** In endemic areas, one should avoid confining horses to paddocks that contain roost trees for bats. The virus is susceptible to several different disinfectants, including 3% Lysol for 3 minutes at  $20^{\circ}$  C, 1% glutaraldehyde for 10 minutes at  $20^{\circ}$  C, irradiation, or formaldehyde fumigation.

### AFRICAN HORSE SICKNESS VIRUS

**Cause** The African horse sickness virus (AHSV) is a double-stranded RNA nonenveloped member of the family Reoviridae (genus *Orbivirus*). It is morphologically similar to other orbiviruses, including bluetongue virus and equine encephalitis virus. Nine antigenically distinct serotypes of AHSV have been found: serotypes 1 to 8 are highly pathogenic for horses (90%-95% mortality rate), whereas infection with serotype

9 is associated with a mortality rate of 70%. Serotypes 1 to 8 are typically found only in restricted areas of sub-Saharan Africa, whereas type 9 is more widespread, being responsible for nearly all epidemics outside of Africa. The one exception to this report was in the 1987 to 1991 Spanish-Portuguese outbreaks resulting from infection with AHSV4.<sup>432</sup> The virus is transmitted by hematophagous arthropods, the most important being *Culicoides* spp. midges. Because of its severity and its ability to expand rapidly and without apparent warning out of its endemic areas, AHS is classified as a reportable disease by the World Organization for Animal Health, formerly known as the Office International des Epizooties (OIE).

**Epidemiology** Zebras are considered to be the natural vertebrate host and reservoir of the AHSV and thus play a role in its persistence in Africa. The single exception to this observation involves serotype 9, which is found in West Africa where zebras no longer occur.<sup>432</sup> Indeed, in the early and mid-1960s, serotype 9 spread across the Middle East (Saudi Arabia, Syria, Lebanon, Jordan, Iraq, Turkey, and Cyprus) and Central Asia (Iran, Afghanistan, Pakistan, and India) and later through North Africa into Spain. AHS was believed to have been effectively eradicated after its appearance in these regions. Then, in 1987, after the import of zebras from Namibia into Madrid, Spain again experienced an outbreak of AHS attributed to serotype 4. Unfortunately, because the climate was sufficiently moderate to permit overwintering of the virus or vector, outbreaks continued into 1991. *Culicoides imicola* is considered to be the most important field vector for AHSV, and although this biting midge is present in southern Europe (Spain, Portugal, Italy, Greece, and southern Switzerland), concern exists that with global warming and climatic change, the vector may extend its habitat to northern Europe.<sup>433,434</sup> Even more worrisome is that *Culicoides variipennis*, the North American vector of bluetongue virus, is an efficient laboratory vector of AHSV,<sup>435</sup> suggesting that should viremic equids gain entrance into North America, transmission of the virus could occur.

Although AHSV typically affects equids, dogs are experimentally susceptible to infection via ingestion of infected horse meat. This route is not considered to be an important means of transmission of the virus to susceptible equids.

**Pathogenesis** Once the virus gains entry into the host, it replicates in the regional lymph nodes before being spread hematogenously to most organs and tissues in the body. In the lungs, spleen, lymphoid tissues, and in certain endothelial cells, a secondary viral replication phase ensues. The incubation period from inoculation to secondary viremic phase is approximately 9 days.<sup>432</sup>

**Clinical Signs** Clinical signs arise as a result of increased capillary permeability and secondary circulatory impairment leading to serous effusion and hemorrhage in various tissues and organs. Four clinical syndromes of AHS infection have been identified (listed in order of decreasing severity): pulmonary or acute form, mixed form (cardiopulmonary), cardiac or subacute form, and the mild (horse sickness fever) form.<sup>436</sup> In the acute form, horses initially develop a fever (up to 107° F) and severe respiratory distress characterized by tachypnea, base-wide stance, extended neck, nostril flaring, and coughing. Frothy white and, occasionally, blood-tinged fluid may be evident at the nostrils. The course of the disease is usually 4 to 5 days. The mortality rate for this form is 95%. In the cardiac or subacute form, horses exhibit fever (104° F) and subcutaneous edema in the supraorbital fossa, head, neck, and chest regions. The conjunctiva may be congested, petechial

hemorrhages may be evident, and the horse may develop signs of colic. Mortality rates may exceed 50%. The mixed form, the most common syndrome, represents a combination of the two syndromes, with death occurring within 3 to 6 days of fever. Mortality rates are 70% for this form. The AHS fever form typically affects mules, donkeys, zebras, and partially immune horses and is characterized by a mild to moderate fever and the development of edema in the supraorbital fossa. Affected animals recover.

**Diagnosis** Differential diagnoses include EVA, purpura hemorrhagica, equine infectious anemia, and babesiosis (early stages). Lesions are not pathognomonic for AHS, thus viral isolation or identification confirms the diagnosis. Samples of whole blood collected in an anticoagulant (preferably ethylenediaminetetraacetic acid) during the febrile phase or of pulmonary, lymphoid, or splenic tissues collected at postmortem enable viral isolation. AHSV can be detected in tissues by PCR or by ELISA.<sup>432</sup>

**Treatment** Specific therapy for this viral infection is not available, and treatment of individual affected horses is supportive and symptomatic. (See respiratory distress section later in this text.)

**Prevention** This noncontagious disease is spread by bites of infected midges, *Culicoides* spp. Control should be directed at restricting import of infected animals, slaughter of viremic animals to prevent them from serving as a source of the virus, reducing vector access to susceptible animals (by stabling), and implementing vector control by eliminating breeding sites of *Culicoides* and applying insecticides in and around stables and directly to equids.<sup>432,437</sup>

Polyvalent-attenuated vaccines (containing serotypes 1, 2, 4 and 2, 6, 7, 8) are available in Africa, where most animals are vaccinated twice in the first and second years of life and annually thereafter. A monovalent-attenuated vaccine containing serotype 9 is available for use in West Africa and outside of sub-Saharan Africa. The live vaccines are not recommended for use in pregnant mares.

## TRACHEAL DISORDERS

**Definition** Tracheal disorders are not common in the horse. Tracheitis often accompanies viral upper respiratory tract diseases (see viral infections) and is characterized by areas of hyperemia and epithelial desquamation on endoscopy. Tracheitis may also develop after smoke inhalation or barn fires. Tracheal perforation or rupture can occur as a result of trauma. Tracheal compression may result from extraluminal masses such as streptococcal abscesses or neoplasms such as lymphosarcoma or lipoma. Intraluminal obstructions may follow fibrotic stricture formation secondary to trauma, tracheostomy, or pressure necrosis from inflated cuffs of endotracheal tubes or may be caused by granulomatous reactions within the trachea.<sup>438</sup> Foreign bodies, such as twigs, may be inhaled.<sup>439</sup> Tracheal collapse may occur as a congenital defect in miniature horses and ponies.<sup>440</sup>

**Clinical Signs** Clinical signs of tracheal disorders include subcutaneous emphysema and harsh tracheal sounds. Tracheal perforation can lead to pneumomediastinum and pneumothorax. Horses with viral infections or with tracheitis secondary to fires may have chronic and persistent coughing, bilateral nasal discharge, and a foul odor. Mild manipulation of the trachea may induce paroxysmal coughing.

**Diagnosis** A thorough physical examination or endoscopic evaluation of the trachea will identify these disorders.

Radiographs may aid in the visualization of foreign bodies, as well as in the detection of a concomitant pneumonia, pneumomediastinum, or pneumothorax.

**Treatment** Treatment is directed toward the primary cause. Primary inflammation after viral infection is not treated unless a persistent fever and a secondary bacterial tracheitis and pneumonia develop (see later discussion). In horses with tracheitis and pneumonitis secondary to smoke inhalation, a tracheostomy may be indicated to circumvent swollen soft tissues of the nasopharynx and to aid in the removal of casts and airway debris in the large airways. Foreign bodies may be retrieved by endoscopy snare but may require a tracheotomy to retrieve them if the endoscope is not long enough. In the adult horse, a 2-m endoscope is necessary to reach the level of the carina located at the fifth to sixth intercostal space. Extraluminal masses require careful drainage or excision, with the potential for spread of infection into the mediastinum. Minor tracheal tears usually resolve within 48 hours and may be managed conservatively. Large tears should be managed surgically with débridement and repair of the defect. If complete rupture occurs between tracheal rings or trauma is extensive, then tracheal resection and anastomosis is indicated.<sup>441,442</sup> Rupture of the trachea may require a temporary tracheotomy distal to the rupture to ensure patency of airflow. Broad-spectrum antimicrobial therapy may be indicated, especially if the mucociliary clearance mechanism is compromised. Complications such as subcutaneous emphysema, cellulitis, and pneumomediastinum usually resolve over 2 weeks. Horses with tracheal defects have a poor to guarded prognosis for return to athletic potential.

### EMERGENCY TRACHEOSTOMY

An emergency tracheotomy may be necessary in horses with acute airway obstruction of any origin. Common indications include arytenoid chondritis, strangles, and anaphylactic reactions. The procedure is most readily performed in the standing horse. A site on the ventral midline at the junction of the proximal and middle third of the neck is selected and the trachea palpated between the paired sternothyroid muscles. If time allows, the area is prepared for surgery, and the skin and subcutaneous tissues are infiltrated along the midline with local anesthetic. A 10-cm skin incision is made along the midline. The subcutaneous tissue and paired sternothyroid muscles are separated bluntly until the trachea can be seen. A curved hemostat is placed on the midline and used to retract the musculature laterally to the left. A stab incision is made into the trachea between two tracheal rings and extended to the tracheal midline. This procedure is repeated on the right side so that the incisions connect. It is important to reflect the muscles and to avoid extending each incision beyond the midline to prevent inadvertent transection of the common carotid artery or jugular vein. Removing a tracheal ring is not necessary for this emergency procedure.

A tracheostomy tube is placed in the incision to provide an airway. Two types of tubes are in common use. The older style metal tracheostomy tube is inserted in two pieces, locks, and is self-retaining. This tube has the advantage of not occluding the trachea if its lumen becomes blocked. The other type of tube is made of a synthetic material (commonly silicon) and has an inflatable cuff. The tube should be inserted with the lumen down (toward the lungs) and secured with umbilical tape to skin sutures and around the neck. The cuff should not be inflated because doing so will occupy the space around the

tube and lead to airway obstruction should the tube's lumen become occluded with inflammatory exudate. Barrier cream should be placed below the surgical site to prevent serum scaling of the skin.

## ☞ NORMAL LUNG

### ANATOMY

The lungs of the horse differ from those of other domestic species in that they lack deep interlobar fissures and distinct lung lobes. Superficially, however, the left lung consists of a cranial and caudal lobe, whereas the right lung contains a cranial, an intermediate, and a caudal lobe.<sup>443</sup> The intrathoracic trachea bifurcates into the right and left mainstem bronchi at the level of the fifth or sixth intercostal space and enters the hilum of each lung. At its division from the trachea, the right bronchus assumes a straighter, more horizontal position relative to the left bronchus, a configuration that may predispose the horse to develop right-sided pulmonary disorders. Each bronchus divides into lobar, segmental, and subsegmental bronchi with the eventual formation of bronchioles. In the distal part of the bronchial tree, the terminal bronchioles lead into poorly developed respiratory bronchioles or open directly into alveolar ducts.<sup>443,444</sup> The tracheobronchial lining consists of tall columnar, pseudostratified epithelium interspersed with serous and goblet cells. The goblet cells and the underlying submucosal mucous glands function to produce mucus consisting of an outer gel and an inner sol layer.<sup>445</sup> Mucus serves to prevent epithelial dehydration, contains protective factors that guard against infectious agents, and is an integral part of the mucociliary apparatus. The rapid beating of the cilia moves mucus and any particulate matter to the pharynx to be swallowed. Approximately 90% of material deposited on the mucinous layer is cleared within 1 hour.

Ciliated cells decrease in frequency with successive divisions of the airways so that at the level of the bronchioles the epithelium is composed predominantly of low ciliated and taller nonciliated Clara cells.<sup>446</sup> Glands are also absent at this level. The bronchiolar epithelium becomes contiguous with that of the alveoli, which are characterized by two distinct cell types. Type I pneumocytes cover most of the alveolar surface with thin cytoplasmic extensions 0.2 to 0.5  $\mu\text{m}$  thick.<sup>445</sup> Type II cells are considered to be stem cells, replacing the type I cells when damaged. Type II cells are cuboidal and contain the characteristic lamellar cytoplasmic inclusions thought to contain surfactant components. Surfactant is a complex mixture of phospholipids, surfactant-specific proteins (SP-A, -B, -C, and -D), and neutral lipids that functions to lower alveolar surface tension (SP-B, SP-C) and to enhance innate immune defenses (SP-A, SP-D). Age-related differences in the phospholipid components of surfactant exist. The concentrations of phosphatidylglycerol (a marker of lung maturity) are significantly lower in the bronchoalveolar lavage fluid (BALF) of term foals as compared with adult horses.<sup>447</sup>

Lymphocytes are scattered throughout the pulmonary epithelium, are associated with the bronchioles and bronchi, and occur in discrete nodules or patches.<sup>448</sup> These cells, along with alveolar macrophages, provide an integral component of the pulmonary immune surveillance system. Macrophages are derived from blood monocytes via the interstitium and are cleared continuously from the alveoli. They are the predominant cell type recovered from the bronchoalveolar lavage

in normal horses (see Table 9-1). Pulmonary interstitial macrophages are able to ingest particles introduced within the pulmonary circulation rapidly.<sup>449</sup> The ability of these macrophages to localize antigenic particles within the pulmonary vasculature may predispose the equine lung to development of acute pulmonary inflammation (e.g., during endotoxemia).

Additional cells within the lung parenchyma include subepithelial and free mast cells. These cells bear IgE on their cell surface and release biogenic amines in response to specific antigen stimulation. They appear to be important in the pathogenesis of several equine pulmonary disorders, including anaphylaxis and lungworm infections.

Tracheobronchial secretions consist of substances secreted from mucous and serous glands, as well as serum transudates. The principal component of the secretions is water, with approximately equal amounts of protein, carbohydrate, lipid, and inorganic material. Contained within the protein fraction of the tracheobronchial secretions are albumin, IgA, IgG (the predominant immunoglobulin in the lower lung), lysozyme, lactoferrin, haptoglobin, transferrin, and complement components.<sup>445</sup>

## VASCULAR SUPPLY

The lung has two sources of blood flow. The major source of blood is the pulmonary circulation, a low-pressure, low-resistance system that serves primarily to deliver blood to the alveoli for participation in gas exchange and secondarily to provide nutrients to the alveolar constituents. The distribution of the pulmonary arterial flow to the various lung regions depends largely on mechanical forces: gravity and pulmonary arterial, pulmonary venous, and alveolar pressures.<sup>450</sup> In the standing horse, a vertical perfusion gradient of the lung has been demonstrated,<sup>451</sup> the most dorsal part of the equine lung being less well perfused than the ventral dependent regions. The distribution of pulmonary blood flow is also influenced by vasoactive compounds such as catecholamines, histamine, and eicosanoids and by changes in alveolar oxygen and carbon dioxide. Alterations in pulmonary vascular resistance may help match ventilation with perfusion and optimize gas exchange.

The bronchial circulation, the second source of blood flow to the lungs, provides nutrient support to the lymphatics and vascular and airway components. Bronchial circulation provides arterial blood to the pleural surface and anastomotic connections with the alveolar capillary bed derived from the pulmonary circulation.<sup>444</sup> The magnitude of the anastomotic flow depends on the relative pressure in the bronchial and pulmonary microvasculature and on the alveolar pressure. Thus, in the dorsal part of the lung where pulmonary arterial flow is poor, blood flow from the bronchial circulation may be favored.<sup>452</sup> The degree of anastomotic bronchial blood flow through the alveolar capillaries increases with systemic arterial hypoxemia and alveolar hypoxia.<sup>450</sup> The bronchial circulation undergoes hypertrophy (angiogenesis) in response to inflammatory pulmonary diseases such as chronic bronchitis, bronchiolitis, and bronchiectasis.

## INNERVATION

The autonomic nervous system supplies innervation to the pulmonary structures. This nervous system influences (1) airway smooth-muscle tone, (2) secretion of mucus from the

submucosal glands, (3) transport of fluid across the airway epithelium, (4) permeability and blood flow in the bronchial circulation, and (5) release of mediators from mast cells and other inflammatory cells.<sup>453</sup> In the horse, the autonomic nervous system can be classified functionally into three categories: (1) parasympathetic, (2) sympathetic, and (3) nonadrenergic noncholinergic (NANC) pathways.<sup>454</sup> The vagus nerve is an integral component of the parasympathetic and NANC systems. The vagus nerve not only contains the efferent fibers of these pathways, which help alter airway resistance, lung volume, and compliance, but also contains the afferent fibers, the central input of which regulates the pattern of breathing. Stimulation of the parasympathetic fibers within the vagus nerve (i.e., the efferent limb) releases acetylcholine from the postganglionic fibers and combines with the muscarinic receptors of the airway smooth muscle to cause bronchoconstriction. Nonetheless, because atropinization (antagonism of muscarinic receptors) does not normally change airway resistance, the parasympathetic system appears to exert little influence on resting airway tone in the healthy horse.<sup>455</sup> However, vagal efferents are important in reflex bronchoconstriction during pulmonary disease.

As described previously, the vagus nerve also contains afferent nerve fibers that transmit information detected by three types of pulmonary mechanoreceptors: (1) the slowly adapting receptors, (2) the rapidly adapting receptors, and (3) the nonmyelinated C fibers. The receptors relay information to the central respiratory neurons located within the ventral medulla and pons. Changes in breathing depth and frequency occur in response to mechanical deformations or chemical stimulation of these receptors. Thus these receptors mediate the tachypneic breathing pattern that occurs in response to inhalation of irritant substances. Stimulation of these receptors also influences airway smooth-muscle tone,<sup>456</sup> inducing reflex bronchoconstriction in response to inhaled irritants.

In the lung,  $\alpha$ - and  $\beta$ -adrenergic receptors mediate sympathomimetic effects. Postsynaptic fibers course from the sympathetic ganglion to airway smooth muscle where released norepinephrine interacts with  $\alpha$ - and  $\beta$ -receptors. Postganglionic sympathetic fibers also innervate the parasympathetic ganglia. The released norepinephrine inhibits cholinergic neurotransmission.<sup>454</sup> However, numerous  $\beta_2$ -adrenergic receptors are distributed throughout the pulmonary parenchyma that lack innervation by the sympathetic fibers. Circulating catecholamines are probably important in activating these receptors and in causing subsequent bronchodilation. Interestingly,  $\beta_2$ -adrenergic stimulation does not alter airway diameter in the healthy horse<sup>457</sup> but does increase airway caliber in horses with recurrent airway disease.  $\beta$ -Agonists also promote ion transport and water secretion across human airway epithelium (in vitro) and may cause similar effects in vivo in the horse. This effect would benefit mucociliary clearance by increasing the sol component of the mucus. In addition,  $\beta$ -agonists stimulate surfactant secretion by type II pneumocytes, inhibit antigen-induced mast cell degranulation, and modulate cholinergic neural transmission.<sup>453</sup> Such effects remain to be demonstrated in the horse, however.

$\alpha$ -Adrenergic receptors also exist in the equine lung, but their stimulation induces bronchoconstriction only in horses with reactive airway obstruction and not in normal horses.<sup>458</sup> This finding suggests that, in health, these receptors are probably unimportant in the regulation of bronchomotor tone.

An additional autonomic pathway, the NANC inhibitory system, has been demonstrated in the equine lung, and its fibers course within the vagus nerve.<sup>454</sup> Although the mediators involved in neural transmission have not been identified definitively, some researchers speculate that vasoactive intestinal peptide or peptide histidine isoleucine or both may be the neurotransmitters.<sup>459</sup> Stimulation of this pathway causes a 50% reduction in smooth-muscle tone, thus exerting a vasodilating effect.<sup>460</sup> Interestingly, horses with recurrent airway disease appear to lack NANC innervation in the bronchioles, and this dysfunction may contribute to the airway hyperactivity observed.<sup>454</sup>

## LYMPH DRAINAGE

Lymph drainage from the lung is accomplished by (1) the deep lymphatics, which begin at the level of the alveolar ducts and run with the conducting airway and arteries toward the hilar lymph nodes, and (2) the superficial lymphatics, which drain the visceral pleura through a plexus converging on the hilum.<sup>445</sup>

## PULMONARY PHYSIOLOGY

The major function of the lung is gas exchange: diffusion of oxygen and elimination of carbon dioxide. During eupnea, an adult horse breathes at a frequency of approximately 12 breaths per minute and a tidal volume near 6.5 L, which represents a total minute ventilation of 77 L/min, or more than 100,000 L/day. During this same period, the resting horse consumes approximately 2.1 L/min of oxygen (3000 L/day) and produces approximately 1.7 L/min of carbon dioxide (2400 L/day).<sup>67</sup> Thus the lung provides an important means by which normal arterial oxygen and carbon dioxide tensions and arterial pH are maintained. In the absence of lung disease, pulmonary arterial oxygenation ( $PAO_2$ ) depends on the inspired fraction of oxygen (normally 0.21) and the effective level of alveolar ventilation, which is approximated by a version of the alveolar gas equation:

$$PAO_2 = PIO_2 - (PACO_2/R)$$

where  $PAO_2$  is the alveolar oxygen tension,  $PIO_2$  is the inspired oxygen tension,  $PACO_2$  is the alveolar carbon dioxide tension, and  $R$  is the respiratory exchange quotient (the ratio of carbon dioxide production to oxygen consumption). Because an admixture of venous blood with the pulmonary arterial circulation occurs, alveolar oxygen tension exceeds arterial oxygen tension by approximately 10 mm Hg.

In the absence of alterations in inspired oxygen tensions, arterial hypoxemia ( $PAO_2 < 85$  mm Hg) may result from basically four processes, including (1) hypoventilation, (2) diffusion impairment, (3)  $(\dot{V}/\dot{Q})$  inequality, and (4) right-to-left shunts.<sup>461</sup>

Alveolar and thus arterial carbon dioxide levels depend on the rate of carbon dioxide elimination relative to its production, given by the following equation:

$$PACO_2 = \dot{V}CO_2/\dot{V}A$$

where  $\dot{V}CO_2$  is the rate of  $CO_2$  production and  $\dot{V}A$  is alveolar ventilation. Hypoventilation is defined as inadequate  $CO_2$  elimination relative to production, resulting in an elevated

$PACO_2$  (hypercapnia, hypercarbia). Hypoventilation can result from a variety of abnormalities. A convenient diagnostic approach follows the control of breathing from (1) the respiratory center in the medulla, (2) the efferent nerves (phrenic), (3) the bellows (diaphragm and chest wall muscles), (4) the pleural space, and (5) the airways. Some situations in which hypoventilation may develop include (1) drug administration (barbiturates, diazepam, xylazine); (2) diseases of the brainstem after infection (encephalitis), trauma, hemorrhage, or neoplasia; (3) diseases of the respiratory muscles, including botulism, trauma, or fatigue; (4) pleuritis and space-occupying lesions; and (5) choke and upper airway obstruction.

In patients suffering from hypoventilation, arterial oxygenation improves with oxygen administration (by increasing inspired oxygen tension), but the most efficacious mode of correcting the hypercapnia and consequent hypoxemia is by mechanical ventilation. Diffusion impairment occurs when time is inadequate for equilibration of alveolar oxygen tensions with pulmonary capillary oxygen tensions. Under normal resting conditions, equilibration of oxygen tensions occurs within 0.25 seconds, approximately one third of the contact time of the blood in the pulmonary circulation.<sup>461</sup> Some evidence suggests that in the exercising horse, the arterial hypoxemia that normally develops at high exercise intensities is caused in part by the decrease in time available for oxygen diffusion.<sup>462,463</sup> During rest, diffusion impairment is unlikely to occur. Arterial hypoxemia caused by diffusion impairment can be corrected by administration of supplemental oxygen.

Inequalities are the primary cause of arterial hypoxemia and occur when alveolar ventilation and pulmonary blood flow are mismatched despite the existence of several reflexes that normally tend to prevent this problem. For example, a fall in the  $(\dot{V}/\dot{Q})$  ratio causes alveolar hypoxia, which induces pulmonary vasoconstriction and decreases perfusion to that lung region. (However, this reflex also increases pulmonary vascular resistance and thus the work of the right side of the heart.) A second reflex is hypocapnic bronchoconstriction. When the  $(\dot{V}/\dot{Q})$  ratio increases, regional ventilation of those lung units is reduced by smooth-muscle constriction.  $(\dot{V}/\dot{Q})$  inequalities interfere with oxygen and carbon dioxide transfer such that hypoxemia and hypercapnia may ensue. Usually the consequent hypercapnia increases chemoreceptor drive and thus increases alveolar ventilation, which restores normocapnia. However, because of the shape of the oxyhemoglobin dissociation curve, the increase in oxygen tension in the normal alveoli caused by the hyperventilation does not significantly increase the oxygen content of the blood coming from these units. Several factors can exacerbate the hypoxemia of  $(\dot{V}/\dot{Q})$  inequalities, including hypoventilation (sedation) and decrements in cardiac output (mechanical ventilation with positive end-expiratory pressure).  $(\dot{V}/\dot{Q})$  inequalities respond to oxygen therapy, although this may lead to increases in arterial carbon dioxide tension by (1) a reduction of the chemoreceptor (hypoxic) drive, (2) an increase in  $(\dot{V}/\dot{Q})$  inequalities, and (3) a shift in the carboxyhemoglobin dissociation curve to the right, decreasing its affinity for carbon dioxide.<sup>464</sup> Mechanical ventilation may be indicated in severe  $(\dot{V}/\dot{Q})$  inequalities if hypercapnia is progressive.

Passage of blood through abnormal cardiovascular communications (atrial septal defects, ventricular septal defects, patent ductus arteriosus) or through pulmonary capillaries within the walls of atelectatic or fluid-filled alveoli causes

shunts and consequent hypoxemia. Such defects may be considered as one extreme of ( $\dot{V}/\dot{Q}$ ) inequality ( $\dot{V}/\dot{Q} = 0$ ) and are resistant to correction by oxygen therapy.<sup>464</sup> In shunts caused by pulmonary disease, mechanical ventilation and positive end-expiratory pressure increase end-expiratory lung volume and thus the alveolar surface area available for gas exchange. The incremental increase in end-expiratory lung volume may also help redistribute the excessive extravascular lung water from the alveoli to the interstitium.

## METABOLIC FUNCTIONS

The entire cardiac output passes through the pulmonary circulation, thus providing an ideal means by which hormones and drugs may be metabolized to inactive compounds. Indeed, relative to the hepatic blood flow (approximately 25% of the cardiac output), the contribution of the lungs to the total body clearance of drugs or xenobiotics may be significant. The lung contains hydrolytic enzymes that cleave peptides such as bradykinin and angiotensin I, thus serving to inactivate (bradykinin) or to bioactivate (angiotensin) compounds. The enzymatic activity responsible is concentrated within the caveolae of the pulmonary capillary endothelium or in pouchings in the plasma membranes of these cells.<sup>465</sup> Other pulmonary enzymes exist that are capable of cleaving phosphate groups from nucleotides (adenosine triphosphate, adenosine diphosphate, and adenosine monophosphate), of oxidizing steroid hormones (testosterone), of inactivating prostaglandins E and F, and of metabolizing biogenic amines such as 5-hydroxytryptamine, norepinephrine, and tyramine.<sup>450,465,466</sup>

## DEFENSE AGAINST INFECTION

The sterile environment of the lung results from several mechanisms, including the mucociliary apparatus, which clears particulate debris from the lung at a rate of approximately 17 mm/min,<sup>56</sup> vagally mediated reflexes, which serve to initiate coughing and concomitant bronchoconstriction, and lung surfactant proteins, SP-A and SP-D, that act as collections against a large number of pathogens.<sup>447,467</sup> However, the predominant line of defense against noxious agents and bacteria are the alveolar macrophages and dendritic cells of the distal airways and alveoli. Recent investigations have shown depression in alveolar macrophage function after exercise or long transport.<sup>468,469</sup> Viral infections also depress macrophage function. Helping to maintain immunosurveillance and the sterile pulmonary environment are polymorphonuclear cells that respond to chemotactic stimuli and lymphocytes.

## DISORDERS OF THE LOWER RESPIRATORY TRACT

Disorders of the lower respiratory tract are common in horses of all ages. Presenting signs and symptoms vary with these disorders and may include exercise intolerance, cough, nasal discharge, fever, respiratory distress, increased respiratory rate or effort, or generalized depression, inappetence, and weight loss. Careful clinical examination that includes auscultation while rebreathing often confirms the anatomic site of the problem. Ancillary diagnostic testing such as bronchoalveolar lavage, transtracheal wash, thoracic ultrasound,

or thoracic radiography are often indicated to confirm a suspected diagnosis.

## BACTERIAL PNEUMONIA

### CAUSES

Normally the lungs contain only small numbers of bacteria (colony-forming units) that are considered to be transient contaminants in the process of being removed by clearance mechanisms.<sup>470</sup> When pulmonary defense mechanisms are overwhelmed, aspirated bacteria from the oropharynx may proliferate and cause pneumonia. The most common gram-positive bacteria involved are *Streptococcus equi* subsp. *zooepidemicus* ( $\beta$ -hemolytic), *Staphylococcus aureus*, and *S. pneumoniae* ( $\alpha$ -hemolytic). The most frequent gram-negative isolates are *Pasteurella* and *Actinobacillus* spp., *Escherichia coli*, *Klebsiella pneumoniae*, and *Bordetella bronchiseptica*.<sup>40,41,471-474</sup> *Pseudomonas* sp. is rarely a cause of equine pneumonia, and its isolation from tracheobronchial aspirates suggests environmental contamination of equipment (endoscope). *Nocardia* organisms also have been isolated from horses with pulmonary infections, but these are rare and appear to require significant derangements of host defense mechanisms.<sup>475</sup> The anaerobic bacteria most commonly isolated are *Bacteroides fragilis*, *Peptostreptococcus anaerobius*, and *Fusobacterium* spp. Polymicrobial infections are not uncommon in cases of equine pneumonia and may represent a synergy between aerobic or facultatively anaerobic and anaerobic bacteria. Mechanisms of synergy may involve protection from phagocytosis and intracellular killing, production of essential growth factors, and lowering of local oxygen concentrations.<sup>472</sup>

### PATHOGENESIS

Bacterial pneumonia may develop after viral infections, athletic events (races), trailer rides, and general anesthesia. It occurs in horses that are overcrowded, maintained on poor nutrition, or exposed to inclement weather. Laryngeal and pharyngeal dysfunction may predispose the horse to develop pneumonia by aspiration of oropharyngeal bacteria. Such predisposition occurs in horses (1) with primary neuropathies of the ninth and tenth cranial nerves (e.g., equine protozoal myeloencephalitis, botulism, *S. equi* infections, guttural pouch mycoses, neoplasia), (2) with primary myopathies of the pharyngeal, laryngeal, or esophageal musculature (e.g., vitamin E and selenium deficiency, megaesophagus), (3) after laryngeal surgery, or (4) with esophageal obstructions (choke). The pathogenic mechanisms described subsequently apply to the development of lung abscesses and pleuropneumonia.

Viral-induced modifications of respiratory tract defenses include (1) enhanced susceptibility to bacterial attachment and colonization after damage to the epithelial cells, (2) diminished mucociliary clearance and physical translocation of bacterial particles deposited on the bronchial ciliated epithelium, and (3) decreased surfactant levels and collapse of the airways because of viral destruction of alveolar type II cells.<sup>476</sup> The ensuing anaerobic environment predisposes the area to macrophage dysfunction. In addition, the alveolar exudate that accompanies viral pneumonitis may provide a nutrient medium for multiplication of aspirated bacteria.

During high-intensity exercise, the horse may aspirate track debris and oropharyngeal secretions. This, coupled with exercise-induced pulmonary hemorrhage, which provides a nutrient source, predisposes the horse to developing pneumonia.<sup>477</sup>

An exercise-associated increase in bacterial contaminants of the lower respiratory tract has been demonstrated experimentally. Strenuously exercised horses exhibit a tenfold and a 100-fold increase, respectively, in the number of aerobic and anaerobic bacteria isolated from transtracheal aspirates relative to preexercise samples.<sup>478</sup> The bacterial contamination, along with exercise-associated increases in bronchoalveolar cortisol concentrations, decreased pulmonary alveolar macrophage viability, and impaired phagocytic function, enables bacteria to proliferate and cause pneumonia.<sup>468,469,477,479,480</sup>

Transportation remains one of the most common causes of pneumonia and pleuropneumonia in the horse because physically restraining the head of the horse and preventing postural drainage enhances bacterial colonization of the lower respiratory tract.<sup>477,481</sup> Inflammation and increased numbers of bacteria are found in the transtracheal aspirates of horses within 6 to 12 hours of confinement with the head elevated.<sup>482</sup> Furthermore, although the stress response of horses during transport contributes to immunosuppression and enhanced susceptibility to pneumonia, the increase in serum cortisol levels are greater when horses are cross-tied compared with when left unrestricted in the box during transport.<sup>483</sup> Another hypothesis is that dehydration, associated with reduced fluid consumption before or during transportation, reduces mucociliary clearance and contributes to bacterial proliferation. Neither the prophylactic administration of antibiotics nor the intermittent release from the confined head posture reliably reduces tracheal bacterial numbers or prevents the accumulation of purulent tracheobronchial secretions in horses confined with their heads elevated.<sup>481,482</sup>

Horses undergoing general anesthesia may develop pneumonia when endotracheal intubation introduces oropharyngeal contaminants to the lower respiratory tract. Anesthesia may compromise mucociliary clearance and cause compression atelectasis and vascular congestion that results in regional ischemia and necrosis of lung regions. This circumstance provides local conditions suitable for bacterial multiplication.<sup>477</sup> In addition, excessive extension and flexion of the neck (e.g., during myelography) with secondary movement of the endotracheal tube may cause tracheal erosions that impair mucociliary clearance and predispose the horse to developing pleuropneumonia.<sup>484</sup>

### CLINICAL SIGNS

In the early stages of bacterial pneumonia, clinical signs may not be obvious, being limited to a gurgling sound of exudates in the trachea, fever, or depression. As pneumonia progresses, horses may exhibit intermittent fever, tachypnea or respiratory distress, nasal discharge, coughing, inappetence, exercise intolerance, and weight loss. Nasal discharge is usually mucopurulent but may be hemorrhagic in some cases.<sup>472</sup> Epistaxis may be the result of bacterial hemolysin production (*Actinobacillus equuli*) or ischemic necrosis of lung tissue.<sup>485</sup> Auscultation of the thorax reveals increased harsh breath sounds dorsally, crackles, wheezes, and dullness of respiratory sounds ventrally. Manipulation of the trachea or larynx may induce a cough. Halitosis and a foul-smelling nasal discharge suggest an anaerobic infection. Mandibular lymphadenopathy may be apparent in aspiration pneumonia associated with strangles or with viral infections.

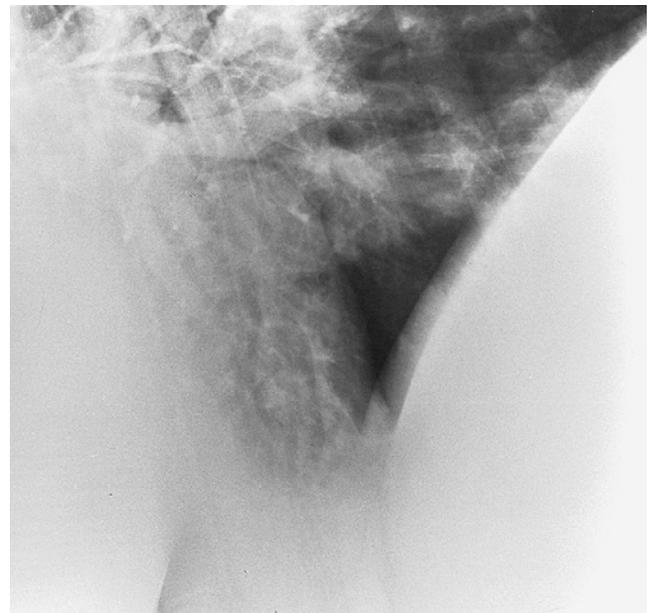

### DIAGNOSIS

Clinical signs and history aid in the diagnosis. Clinical pathologic data consistent with bacterial pneumonia include leukocytosis caused by absolute neutrophilia with or without a left

shift. Neutropenia may be evident if gram-negative organisms are involved. Hyperfibrinogenemia (>500 mg/dl), hyperglobulinemia, hypoalbuminemia, and anemia of chronic inflammation are compatible with the diagnosis of chronic bacterial pneumonia. Endoscopic evaluation of the upper respiratory tract may demonstrate a defect in laryngeal or pharyngeal function if this is the inciting cause. One may observe a mucopurulent exudate with or without traces of blood by endoscopy in the lower respiratory tract. Thoracic radiographs demonstrate a radiopacity in the anteroventral thorax and a loss of clarity in the lung fields caudal to the heart. Air bronchograms are occasionally found in the adult horse with bacterial pneumonia (Figure 9-13). Ultrasound may demonstrate consolidation of ventral lung lobes and extension of the pneumonia to the pleural surfaces as evident by the presence of comet tails. Tracheobronchial aspirates yield degenerative neutrophils, damaged epithelial cells, and microorganisms. The presence of squamous epithelial cells supports a diagnosis of aspiration pneumonia, provided that the tracheal catheter was not misplaced in the pharynx during sampling. The clinician should perform aerobic and anaerobic cultures on the tracheal aspirates.

### TREATMENT

The clinician should direct treatment at the causative organism, but in the absence of culture and sensitivity results, one should administer broad-spectrum antimicrobials. Appropriate therapy might include intravenous aqueous sodium or potassium penicillin and an aminoglycoside or third-generation cephalosporin (Table 9-5). The aminoglycosides are efficacious against most gram-negative aerobes, but they lack efficacy against anaerobes. However, metronidazole is effective against most anaerobes, including the penicillin-resistant *B. fragilis* and is routinely included in the treatment protocol.

**FIGURE 9-13** Two-year-old Thoroughbred with pneumonia. A patchy area of pulmonary consolidation is notable in the ventral dependent portion of the lung silhouetting the heart and diaphragm. (Courtesy D. S. Biller, Manhattan, Kan., 1991.)

TABLE 9-5

Antimicrobials and Other Drugs	
Antimicrobial	Dose
Amikacin	16-18 mg/kg, IV, q 24 h
Ampicillin sodium	11-22 mg/kg, IV or IM, q 6-8 h
Ceftiofur	2.2 mg/kg, IV or IM, q 12 h
Chloramphenicol	50 mg/kg, PO, q 6 h
Doxycycline	10 mg/kg, PO, q 12 h
Enrofloxacin	7.5 mg/kg, PO or IV, q 24 h
	5.0 mg/kg, PO or IV, q 12 h
Gentamicin	4.4-6.6 mg/kg, IV or IM, q 24 h
Metronidazole	15-25 mg/kg, PO, q 6-8 h
Oxytetracycline	6.6 mg/kg, IV, q 12-24 h
Potassium penicillin G	22,000 IU/kg, IV q 6 h
Procaine penicillin G	22,000 IU/kg, IM, q 12 h
Rifampin	5-10 mg/kg, PO, q 12 h
Sodium penicillin G	22,000 IU/kg, IV, q 6 h
Trimethoprim-sulfonamide	15-20 mg/kg, PO or IV, q 12 h
Other Agents Used	
Acetylcysteine	10-20 ml 20% solution (nebulized)
Albuterol	360-720 µg via inhalation
Clenbuterol	0.7-0.8 µg/kg, PO, q 12 h or nebulized
Fenoterol	1-2 mg via inhalation
Ipratropium bromide	2-3 µg/kg (nebulized)
Salmeterol	0.5-1 µg/kg via inhalation
Fluticasone	2-4 µg/kg via inhalation

*IM*, Intramuscularly; *IV*, intravenously; *PO*, orally; *q*, every.

Depending on the culture and sensitivity results, one may also administer potentiated sulfonamides. The clinician should use aminoglycosides judiciously in animals that have renal compromise or are dehydrated. (See the section on treatment for parapneumonic effusions.) Antimicrobial therapy may also be administered by nebulization. In general, one third of the calculated systemic dose of the antimicrobial (ceftiofur, gentamicin, marbofloxacin) is administered via an ultrasonic nebulizer two or three times daily.<sup>486,487</sup> With the nebulizate, one may also add 5 mg albuterol to enhance bronchodilation and 10 ml 20% acetylcysteine.

With gram negative infections and the potential for endotoxemia, small doses of flunixin meglumine (0.25 mg/kg three times daily) may be given to inhibit arachidonic acid metabolism. Other treatment modalities that have been advocated include prophylactic measures against laminitis. The goal of supportive care should be to minimize stress and ensure adequate ventilation and hydration. Ideally, horses should be bedded on paper or on other materials free of dusts or molds and should be fed forages of excellent quality. One should also direct attention to correcting the primary cause of the pneumonia. Depending on the chronicity of the pneumonia, one should note clinical improvement in 48 to 72 hours. The prognosis can be excellent if the pneumonia is treated aggressively, but the clinician should forewarn the owner of potential complications (see the following discussion). The clinician

should administer treatment for 2 to 6 weeks, depending on the extent of the pneumonia and the underlying inciting cause. (See the section on treatment for parapneumonic effusions.)

Preventive measures that help deter the development of pneumonia include (1) adequate immunization protocols with vaccination against EIV, EHV1, and EHV4 every 4 to 6 months (in the performance horse); (2) the minimization of stressors such as long van rides in which the head is restrained constantly; and (3) the use of management or husbandry methods that minimize dust or noxious gas accumulations within the stall, prevent exposure to inclement weather, and provide adequate nutrition for the horse.

## LUNG ABSCESSSES

### CAUSES

In foals younger than 6 months, *R. equi* and *S. equi* subsp. *zooepeidemicus* are the most common bacterial isolates recovered.<sup>488</sup> In adult horses, *Streptococcus* and *Actinobacillus* species are the most common gram-positive and gram-negative organisms implicated in the development of pulmonary abscesses.<sup>488-490</sup> This discussion addresses predominantly lung abscesses in the adult horse.

### PATHOGENESIS

Lung abscesses may develop as a consequence of inhaling bacterial organisms resident to the oropharynx or contaminating the environment (*R. equi*). The abscess may develop as a consequence of a focal pneumonia or may be a component of pleuropneumonia complex. (See discussion elsewhere in this chapter.) Racehorses may be at an increased risk for developing lung abscesses when bacteria proliferate in the blood in the airways and alveoli after episodes of EIPH. The regional location of lung abscesses in these cases supports this hypothesis.<sup>490</sup>

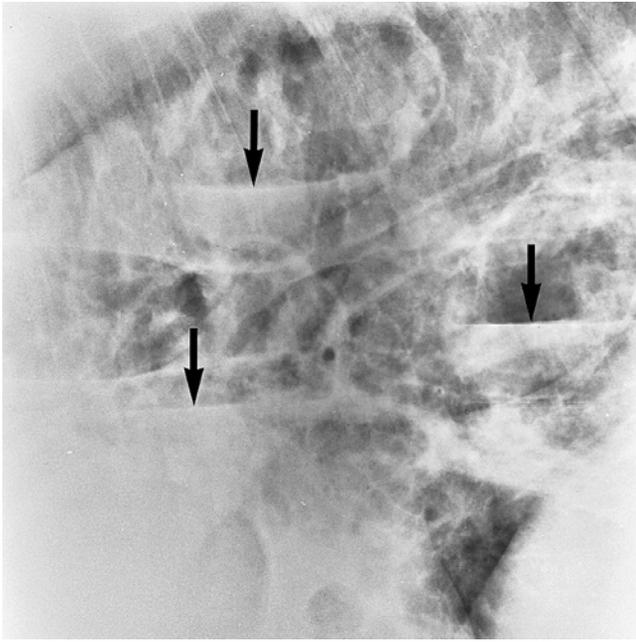

### CLINICAL SIGNS

Clinical signs may vary, but most horses have periods of pyrexia, inappetence, lethargy, mild tachycardia, and respiratory-related signs ranging from tachypnea to distress.<sup>489,490</sup> Other signs that may be evident include cough, purulent nasal discharge, thoracic pain, epistaxis, and halitosis.

### DIAGNOSIS

The adult horse may have a history of transport, strenuous exercise, surgery, prior pneumonia, or administration of medications. In most cases, evidence of an infection is found on the CBC and serum chemistry panel: mature neutrophilia, hyperfibrinogenemia, hyperglobulinemia, and anemia. Radiography and ultrasound are useful imaging modalities, and one may use them concurrently to detect lung abscesses (Figures 9-14 and 9-15). Pulmonary abscesses appear on ultrasonography as encapsulated cavitated areas filled with fluid or echogenic (white) material. Cardiac structures or an air-filled lung may overlie an abscess, obscuring its detection. In one study, two thirds of the abscesses were located in the caudodorsal lung field, whereas the remaining abscesses were located in the caudoventral region.<sup>490</sup>

Transtracheal aspirates or percutaneous aspirates of lung abscesses adhered to the body wall may help the clinician decide the choice of antimicrobials. One should culture isolates under aerobic and anaerobic conditions.

**FIGURE 9-14** Nine-year-old saddle horse. Multiple cavitating pulmonary abscesses are present within the lungs. Arrows indicate air-fluid interfaces within the abscesses. (Courtesy D. S. Biller, Manhattan, Kan., 1991.)

### TREATMENT

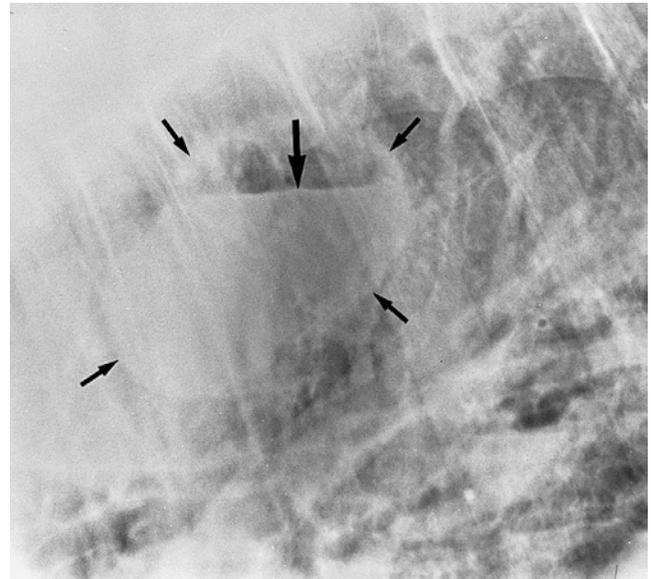

Long-term antimicrobial therapy (8 to 10 weeks) along with prolonged periods of rest (5 to 6 months) before resuming strenuous exercise is recommended. (See the section on treatment for pneumonia and parapneumonic effusions for specific antimicrobial recommendations.) In human beings receiving antimicrobial treatment for pulmonary abscesses, an 80% reduction in the size of abscess cavities less than 3 cm in diameter usually occurs within 1 month of appropriate therapy.<sup>491</sup> Furthermore, 70% of cavitory lesions in human cases of lung abscessation resolve completely by 3 months.<sup>492</sup> For lung abscesses unresponsive to therapy, the clinician should consider drainage via a thorotomy or thoracoscopy.<sup>493</sup>

The prognosis for resumption of athleticism is good if treatment is initiated early. In one study, 23 of 25 Standardbreds and 13 of 20 Thoroughbreds raced after the diagnosis and treatment of a lung abscess with no significant effect on race performance.<sup>490</sup>

### PARAPNEUMONIC EFFUSIONS AND SEPTIC PLEURITIS

#### CAUSES

Between two thirds and three quarters of cases of septic pleuritis arise as an extension of pneumonia or pulmonary abscessation.<sup>494-496</sup> Septic pleuritis also may occur in horses with thoracic trauma, esophageal rupture, or penetration of the esophagus or stomach by a foreign body.<sup>477,497-499</sup> The aerobic or facultatively anaerobic organisms most often isolated from horses with pleuropneumonia are bacterial species that normally reside in the oropharyngeal cavities: *Streptococcus* spp.,

**FIGURE 9-15** A large air-capped pulmonary abscess. Small arrows indicate an abscess; large arrow indicates the air-fluid interface. (Courtesy D. S. Biller, Manhattan, Kan., 1991.)

*Pasteurella* and *Actinobacillus* spp., *E. coli*, and *Enterobacter* spp. Anaerobic organisms frequently isolated include *Bacteroides* spp., *Peptostreptococcus* spp., *Fusobacterium* spp., and *Clostridium* spp.<sup>499-501</sup>

#### EPIDEMIOLOGY

Risk factors for the development of pleuropneumonia are the same as those associated with pneumonia (see the previous discussion) and include long-distance transport, strenuous exercise, viral respiratory tract disease, surgery, dysphagia, general anesthesia, and systemic illness (enteritis). These conditions may enhance aspiration of oropharyngeal organisms or impair clearance of such organisms.<sup>477,495,502</sup>

#### PATHOGENESIS

The causative factors of equine pleuropneumonia are those that suppress the pulmonary defense mechanisms and allow bacterial contamination of the lower respiratory tract to progress to pneumonia or abscess formation. The subsequent extension of the infectious process into the pleural space causes pleuritis. The distribution of the pulmonary lesions—cranioventral with the right cranial and middle lung lobes more severely afflicted—is consistent with inhalation or aspiration of bacteria rather than infection from a hematogenous spread. Fluid accumulates within the pleural cavity as the parenchymal inflammation increases the permeability of the capillaries in the overlying visceral pleura, causing an outpouring of protein and cells. Bacteria may also invade the pleural fluid. (See previous discussion of pneumonia.)

#### CLINICAL SIGNS

Depending on the chronicity of disease, clinical signs may vary and may be confused with signs of colic or rhabdomyolysis. In the acute stages, horses are febrile and lethargic, have a slight nasal discharge, and exhibit a guarded cough, shallow breathing pattern, and painful, stilted gait.<sup>501</sup> The right hemithorax

is affected more often than the left, presumably because of the more direct route of the right mainstem bronchus.<sup>477</sup> Thoracic auscultation may be abnormal, as evidenced by pleural friction rubs and ventral dullness. In severe acute cases, the horse may exhibit nostril flaring; tachycardia; jugular pulsations; toxic mucous membranes; a guarded soft, moist cough; and a serosanguineous fetid nasal discharge. In chronic cases of pleuropneumonia (duration longer than 2 weeks), horses may have bouts of intermittent fever and exhibit weight loss and substernal and limb edema.

## DIAGNOSIS

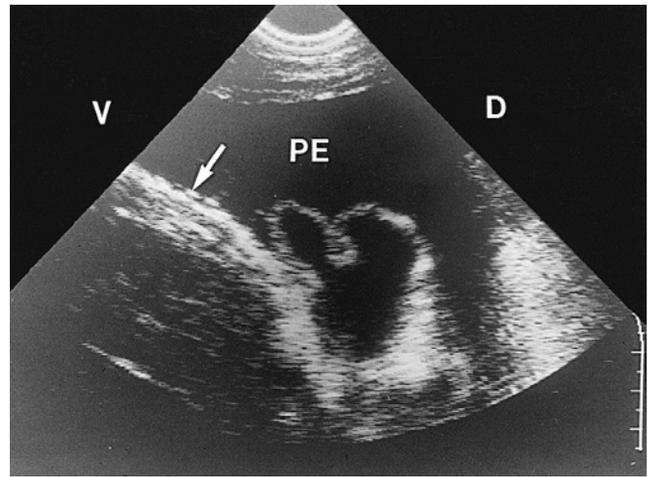

The diagnosis is based on historical information, clinical examination, imaging results, and microbiologic and cytologic analysis of tracheal and pleural fluid aspirates. On auscultation of the thorax, one may hear vesicular sounds only dorsally, with an absence of lung sounds ventrally. One may hear bronchial or tracheal sounds if lung consolidation exists. Cardiac sounds radiate over a wider area of the lung field than normal, a finding distinct from clinical cases of pericarditis. On percussion of the chest, the clinician may elicit a painful response (pleurodynia) and detect an area of dullness or decreased resonance ventrally.

Laboratory assessment may reveal a normal or toxemic leukogram and chemistry findings in acute cases. In chronic cases, one may find anemia, neutrophilia, hyperfibrinogenemia, and hyperproteinemia.

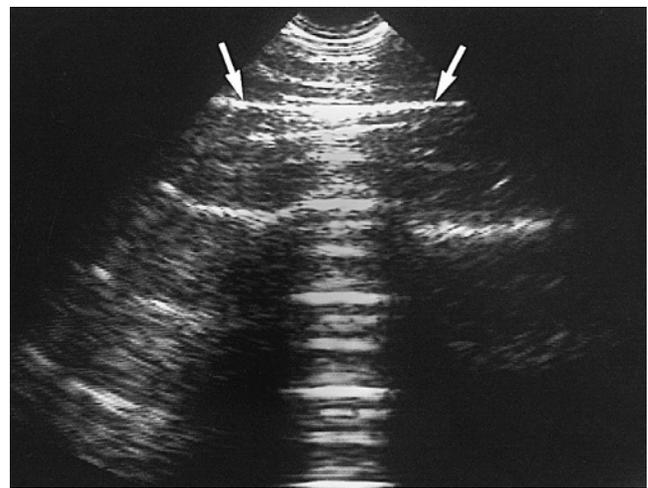

Ultrasound is the diagnostic technique of choice in horses with suspected pleuropneumonia or pleural effusion. Using a 3.5- to 5-MHz transducer (sector scanner or linear probe), one can detect free or loculated fluid, pleural thickening, pulmonary and mediastinal abscesses, pulmonary consolidation, inundation of airways with fluid, fibrinous adhesions, and concurrent pericarditis. Pleural fluid may displace the lungs axially and dorsally. The fluid may appear anechoic or hypoechoic, depending on the relative cellularity.<sup>501</sup> Free gas echoes within the pleural fluid may reflect (1) the presence of anaerobic organisms,<sup>48</sup> (2) the presence of air introduced during a thoracocentesis, or (3) the presence of air introduced by a bronchopleural fistula. Ultrasonography enables accurate placement of the catheter during thoracocentesis and ensures productive yields during placement of a chest drain (Figures 9-16 to 9-18). Ultrasound examination fails to demonstrate deep parenchymal lesions if the overlying lung is normally aerated.

Thoracic radiography also remains a useful technique for evaluating horses with pleuropneumonia, permitting detection of a pneumothorax or an abscess located deep in aerated lung tissue. Pneumothorax may develop after transtracheal aspiration, thoracocentesis, thoracic drainage, or pleuroscopy. Pneumothorax may also develop as a sequela to gas-producing organisms in the pleural cavity or to air leaks from bronchopleural fistulae.<sup>477</sup> Although radiographs may detect pulmonary abscesses, they may fail to detect lesions obscured by the cardiac silhouette.

Thoracocentesis of both sides of the chest is indicated if one notes fluid bilaterally. Not only is thoracocentesis diagnostic and prognostic, it may also be a therapeutic life-saving procedure in horses with severe respiratory distress.<sup>503</sup> In healthy horses, the fenestrated caudal mediastinum allows communication of the fluid between the two sides of the chest. In horses with pleuropneumonia, fibrin may close mediastinal fenestrations, allowing for differences to develop in the pleural

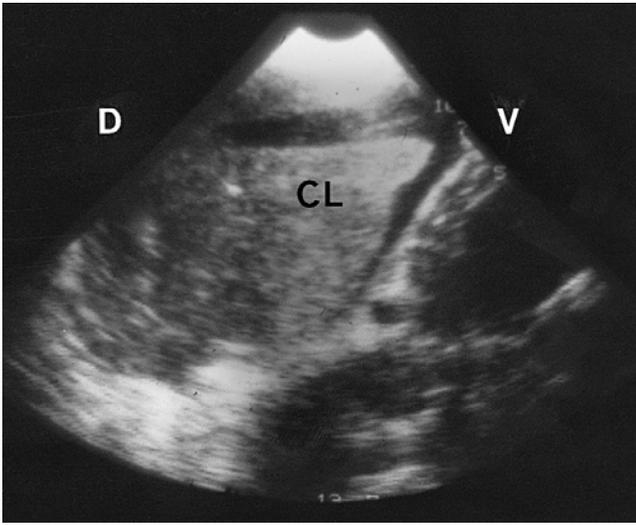

**FIGURE 9-16** Ultrasound of pleural effusion. Anechoic (black) area represents pleural effusion (PE). The echogenic (white) tortuous fibrin strand is attached to the parietal pleura of the diaphragm. V, Ventral; D, dorsal; arrow, diaphragm. (Courtesy D. S. Biller, Manhattan, Kan., 1991.)

**FIGURE 9-17** Normal thoracic ultrasound demonstrates a highly echogenic interface (arrows) between the chest wall and normal lung. A reverberation artifact is notable deep to the chest wall–lung interface. (Courtesy D. S. Biller, Manhattan, Kan., 1991.)

fluid of the two hemithoraces. The clinician should submit fluid for cytologic examination and for aerobic and anaerobic culture. Pleural fluid in healthy horses contains fewer than 10,000 cells/ $\mu$ l, approximately 60% of which are neutrophils, and has a total protein of less than 2.5 g/dl. In cases of pleuropneumonia, pleural fluid white blood cell counts and protein are elevated and glucose levels may be low (<40 mg/dl). The fluid may have a foul odor if anaerobes are contributing to the infection, but the absence of an odor should not preclude the possibility of an anaerobic component.

The clinician should always obtain a tracheobronchial aspirate to recover the inciting bacterial agents and to examine tracheobronchial secretions cytologically (Gram stain, cell types). One should submit aspirates for aerobic and anaerobic culture and Gram staining to provide guidance on

**FIGURE 9-18** Ultrasound of ventrally consolidated lung (CL) surrounded by a small amount of pleural effusion. V, Ventral; D, dorsal. (Courtesy D. S. Biller, Manhattan, Kan., 1991.)

antimicrobial selection. During the course of the disease, one may obtain multiple tracheobronchial aspirates to identify new or resistant bacterial organisms.

One can use thoracoscopy, performed in standing sedated horses or in horses under general anesthesia, in acute and chronic cases of pleuropneumonia (1) for guided placement of drains into abscesses and loculated pleural effusions, (2) for assessment of the extent and progression of pleural disease, and (3) for the evaluation of therapeutic responses and the efficacy of pleural lavage or drainage.<sup>75</sup>

## TREATMENT

For horses with pleuropneumonia, the aims of treatment are (1) to remove excessive pleural fluid, (2) to administer systemic antimicrobials to inhibit bacterial growth, (3) to provide antiinflammatory and analgesic drugs that deter the development of secondary complications, and (4) to provide supportive care.

Under ultrasound guidance, one can remove pleural fluid aseptically through the seventh or eighth intercostal spaces at a locale dorsal to the costochondral junction using a 24- to 32-Fr chest tube. One may remove as much as 30 to 50 L. If blood discoloration of the pleural fluid is caused by the underlying disease, the fluid remains blood-tinged throughout the drainage.<sup>503</sup>

The clinician should place indwelling chest tubes (1) if large volumes of foul-smelling fluid with microorganisms are obtained, (2) if the pleural fluid has a pH less than 7.2 or a glucose concentration less than 40 mg/dl, or (3) if the horse responds poorly to intermittent drainage.<sup>496-503</sup> To the end of the indwelling chest tube one should attach a Heimlich valve or a nonlubricated condom with its tip snipped off. Complications of chest tube placement include pneumothorax; lung laceration; hemothorax; cardiac arrhythmias; bowel, liver, or heart puncture; and localized swelling.<sup>503</sup>

Appropriate antimicrobial therapy is based on the results of the culture and sensitivity. Pending microbiologic test results, one should administer broad-spectrum intravenous antibiotics in most cases of pleuropneumonia because the

infections are polymicrobial. Penicillin is one of the drugs of choice because it is efficacious against *Streptococcus* spp., *Staphylococcus* spp., and many anaerobes. Metronidazole is added routinely to the penicillin to broaden bactericidal activity against anaerobes, especially *B. fragilis*. Aminoglycosides lack efficacy against anaerobic bacteria and have poor penetration into respiratory tract secretions but still are administered with penicillin. Third-generation cephalosporins such as ceftiofur sodium, with activity against gram-negative aerobes and facultative anaerobes, showed excellent efficacy in the treatment of spontaneous clinical and posttransport pneumonia associated with *S. zooepidemicus*, *Actinobacillus* spp., and *Pasteurella* spp.<sup>504</sup>

Depending on the clinical response of the horse, 10 to 14 days after the onset of initial therapy, the clinician usually replaces parenteral antimicrobials with oral antibiotics. Chloramphenicol, a bacteriostatic drug, has excellent broad-spectrum activity against gram-negative, gram-positive, and anaerobic bacteria and can be given orally. (One must use caution when handling the drug.) Enrofloxacin, a fluoroquinolone, has excellent antibacterial action against aerobic gram-negative bacteria, many gram-positive bacteria, and mycoplasma bacteria but has limited activity against *Streptococcus* spp. and anaerobes.<sup>505</sup> Concentrations of the enrofloxacin in lung tissue are similar to those in serum.<sup>506</sup> Erythromycin and rifampin attain good concentrations in the lung and pleural fluid and within phagocytic cells, but rifampin is expensive and erythromycin may induce a fatal colitis, precluding their use in adult horses.<sup>507</sup> Antimicrobials may also be nebulized (see previous discussion on pneumonia).

Antimicrobial therapy should continue for 2 to 4 months until the horse is gaining weight, hematologic and serum chemistry values have normalized, and no evidence of respiratory tract disease exists. One should implement limited exercise (hand walking) and avoid stressing the horse. One should reevaluate refractory cases using the techniques of ultrasonography, thoracocentesis, or transtracheal aspiration to determine if drug resistance has developed, if additional pathogens are involved, or if untoward sequelae have occurred (see the following discussion).

In refractory cases, drainage of pulmonary or mediastinal abscesses or mechanical débridement of fibrinous material (decortication) may become necessary. One should consider initially attempting drainage using a large-bore chest tube (24 Fr) directed through the chest wall and then the capsular wall of the abscess followed by suction of the abscess contents. Lavage of the contents of the abscess may improve removal of the purulent material. One should take care to prevent spillage of the contents into the pleural cavity. For removal of fibrinopurulent material or necrotic lung segments, a standing thoracotomy may provide necessary access.<sup>508</sup> After removing accessible exudates and fibrin manually, one lavages the chest cavity with a warm 1% Betadine solution, packs it with a large lap sponge, and covers it with a self-adhering dressing and pad. One must lavage the pleural cavity daily. Fistulae formation is a common sequela in these clinical cases, but this does not preclude horses from returning to racing or breeding careers.

Nonsteroidal antiinflammatory drugs (flunixin meglumin, 0.25 to 0.50 mg/kg intravenously two to three times daily) provide analgesia, increase appetite, increase the comfort of the horse, and decrease the inflammatory response.

Many horses with pleuropneumonia benefit from the administration of intravenous fluids for the first 48 to 72 hours, until the horse is comfortable enough to resume drinking and the danger of endotoxemia has lessened. Nasal insufflation of oxygen (10 to 15 L/min) may be indicated if the horse is hypoxemic or in respiratory distress. One may achieve bronchodilation using inhaled or nebulized albuterol (600 to 720 µg three to four times daily). Because gram negative organisms are often involved in pleuropneumonia cases, one should implement prophylactic measures against laminitis.

### PROGNOSIS

A favorable response most often relates to early identification and aggressive treatment of pleuropneumonia. Survival rates<sup>495,509</sup> of horses treated for acute pleuropneumonia range between 49% to 98%. The prognosis deteriorates with the increased duration of the illness because of involvement of anaerobic bacteria and the development of complicating factors such as pleural adhesions, pulmonary necrosis, cranial mediastinal abscesses, bronchopleural fistulae, constrictive pericarditis, and laminitis.<sup>509,510</sup> In a recent study, 61% of Thoroughbreds treated for pleuropneumonia raced after recovery, with 56% winning at least one race.<sup>511</sup>

### COMPLICATIONS

Long-term medical treatment of pleuropneumonia may induce complications such as venous phlebitis or thrombosis (from intravenous catheter placement), cellulitis or pneumothorax after thoracocentesis, diarrhea resulting from antimicrobial and antiinflammatory therapy or endotoxemia, and laminitis. With minor changes in the therapeutic approaches, many of these complications resolve and do not impede the eventual return to health of the horse. The more complicated sequelae of infectious pleuropneumonia have been described in detail by Byars, Dainis, Seltzer, et al.<sup>512</sup> and Byars and Becht.<sup>513</sup> In a survey involving 153 horses brought to their veterinary hospital over a 4-year period with pleuropneumonia, the investigators detailed the development of cranial thoracic masses (7.2%), bronchopleural fistulae (6.5%), pericarditis (2.6%), and laminitis (1.3%).

One should suspect cranial thoracic masses when horses exhibit tachycardia, jugular distention, forelimb extension (pointing), and caudal displacement of the heart. One can confirm the presence of empyema, loculations, or encapsulated abscesses cranial to the heart by ultrasonography. In most cases, medical therapy is effective at reducing the abscess, and thus one should elect this conservative approach initially. Additional therapeutic modalities include the administration of a diuretic (furosemide) and a chronotropic agent (digitalis) to improve cardiac performance. However, refractory cases may require ultrasound-guided drainage of the abscess performed under short-term anesthesia (xylazine-ketamine combination).

Bronchopleural fistulae develop when necrotic pulmonary tissue sloughs, providing a direct communication of the airways with the pleural cavity. One confirms the diagnosis by visualization of the airways after pleuroscopy or by the intratracheal appearance of contrast media injected into the pleural cavity. Bronchopleural fistulae may close eventually as the pulmonary tissue adheres to the chest wall or as the airways close. In persistent cases, surgical removal of the affected tissue and closure of the airway may be indicated by thoracoscopy.

## PLEURAL EFFUSION

### CAUSES

Accumulation of fluid within the pleural space most often results from imbalances in Starling's law of fluid fluxes. As described previously, pleural effusions in the horse most commonly occur with bacterial pneumonia or lung abscesses.<sup>514</sup> (See the section on treatment for parapneumonic effusions.) Pleural effusions also may accompany a significant number of thoracic neoplasms such as fibrosarcoma, gastric or esophageal squamous cell carcinoma, hepatoblastoma, hemangiosarcoma, melanoma, mesothelioma, and metastatic mammary or ovarian adenocarcinoma, but they are most commonly associated with lymphoma.<sup>515-524</sup> Pleural effusion also develops in a significant number of other conditions, including thoracic trauma; pericarditis; peritonitis; viral, mycoplasmal, and fungal infections; congestive heart failure; liver disease; diaphragmatic herniation; hypoproteinemia; equine infectious anemia; pulmonary granulomata; and damage of the thoracic duct.<sup>496,525-527</sup>

### PATHOGENESIS

Pleural fluid is the interstitial fluid of the parietal pleura. A pressure gradient driving its formation exists because the parietal pleura is supplied by the systemic circulation and because the pressure of the pleural space is more negative than that of the subpleural interstitium.<sup>528</sup> Pleural liquid and protein exit the pleural space via the parietal pleural stomata. Fluid production in the pleural space increases if any of the following occurs: (1) an elevation of the hydrostatic pressure gradient (congestive heart failure, portal hypertension); (2) a decrease in the colloid osmotic pressures (hypoproteinemia); (3) an increased permeability of the capillary vessels (infection, malignancy, inflammation); or (4) a decreased removal of fluid because of impaired lymphatic drainage or obstruction (neoplasia) or infiltration of the pleura or parenchyma (neoplasia).<sup>529,530</sup> Excessive amounts of peritoneal fluid may accumulate in the pleural cavity as the fluid moves through diaphragmatic defects or through diaphragmatic lymphatics.<sup>528</sup>

### DIAGNOSIS

A physical and rectal examination, CBC and chemistry panel, cardiac evaluation, thoracic and abdominal ultrasound, and abdominocentesis may be helpful in determining the cause of the pleural effusion. When one suspects infectious agents, one should perform a transtracheal aspirate. One should also obtain a Coggins test and measure titers against *Coccidioides immitis*, *C. neoformans*, and *Mycoplasma felis*, depending on the nature of the effusion and the geographic location of the affected horse.

Cytologic and microbiologic evaluation of the pleural fluid (and pulmonary nodules or masses) may help identify neoplastic cells or fungal elements. Transudates, fluid with a total protein less than 2.5 g/dl, and few cells are usually associated with congestive heart failure, liver fibrosis, hypoalbuminemia, or early neoplastic processes. Modified transudates have low nucleated cell counts (<10,000 cells/µl) and moderate to high protein levels (>2.5 g/dl) and can be found in many disorders, including neoplasia. Exudates have nucleated cell counts exceeding 10,000 cells/µl and total protein levels greater than 3.0 g/dl and are found in infections and intraabdominal diseases.<sup>514</sup> One can distinguish septic effusions from nonseptic effusions by biochemical analysis of pleural fluid aspirates. For

example, fluid that has a pH less than 7.2, a glucose concentration less than 40 mg/dl, and a lactate dehydrogenase concentration greater than 1000 IU/L has been suggested to indicate septic effusions. Chylous effusions, which are milky white to pale pink, have triglyceride concentrations exceeding that of simultaneously measured serum.<sup>514</sup>

## TREATMENT

Treatment is aimed at the primary cause, but neoplastic conditions and pleural effusions associated with an end-stage organ failure carry a poor prognosis. Therapeutic thoracocentesis is indicated in malignant effusions when horses are experiencing breathing difficulties. Chest tube drainage and chemical pleurodesis, thoracoscopy with talc poudrage, or tunneled pleural catheters may be palliative approaches to reduce respiratory-related signs. The clinician should consider these procedures if (1) significant improvement in the status of the horse occurs with pleural fluid evacuation and (2) reexpansion of the lung is achieved once fluid is removed.
