# DISORDERS OF THE SKIN

## CHAPTER 13

*Christine A. Rees\**

### 🌀 BASIC STRUCTURE AND FUNCTION OF THE SKIN

The skin is the largest and one of the most important organ systems within the body. Without skin a human being or animal would die. The functions of the skin are:

1. An enclosing barrier that prevents water, electrolytes, and macromolecules from being lost and provides internal support for various organs within the body
2. A storage reservoir for vitamins, fats, carbohydrates, electrolytes, water, proteins, and other materials
3. A protective barrier against chemicals and physical factors such as heat, cold, microbiologic organisms, and ultraviolet light (melanocytes)
4. A sensory organ for heat, cold, touch, pain, pressure, and itch
5. A regulator of body temperature through the hair coat
6. A regulator of blood pressure by changes in peripheral vasculature
7. A producer of keratinized structures such as hair, hooves, horn, and the uppermost layer of the epidermis
8. A secretory and excretory organ for apocrine and sebaceous glands that includes antimicrobial factors
9. A provider of flexibility, elasticity, or toughness to allow for shape and form
10. An immunosurveillance organ through keratinocytes, lymphocytes, and Langerhans cells
11. An indicator of general health (e.g., icteric skin can indicate hepatic dysfunction)<sup>1</sup>

### 🌀 GROSS ANATOMY

#### SKIN

Skin thickness varies between 1 to 5 mm depending on the body location. The skin thickness is greatest at the dorsum and the proximal extremities and gets thinner ventrally and distally down the extremities. Skin is thickest on the forehead, dorsal

neck, dorsal thorax, and base of the tail. The skin is thinnest on the ears and in the axillary, inguinal, and perianal areas.<sup>2,3</sup>

The skin consists of two main layers: the epidermis and dermis. The epidermis consists of the basal, spinous, granular, clear, and horny layers. Each layer has different types of cells and differs in function. The basal layer consists of a single column of cells that are attached to the basement membrane. Typical basal keratinocytes have an oval nucleus, prominent nucleolus or nucleoli, and little heterochromatin. The basal keratinocytes contain melanosomes; various metabolic and synthesizing organelles such as mitochondria, lysosomes, rough endoplasmic reticula, and Golgi complexes; and cytoskeletal structures such as keratin intermediate filaments, microfilaments, and microtubules. Structures such as desmosomes and hemidesmosomes that help form the attachment and help to shape the basal layer are also present.<sup>4,5</sup>

The spinous layer of the epidermis comprises two to four layers. The cells become progressively differentiated as they move outward toward the skin surface. The spinous layer cells first appear polyhedral and then become more flattened as they develop and move outward. The spinous cells contain cellular organelles and keratin filaments. The cells of the uppermost one to two layers of the granular layer contain small, oval, membrane-bound organelles (300 nm) with alternating lamellae called lamellar granules (membrane-coating granules, keratinosomes, Odland bodies) formed in the Golgi region. They contain polar lipids such as phospholipids, glycosphingolipids, free sterols, and so-called probarrier lipids and hydrolytic enzymes that convert the probarrier lipids into stacks of neutral lipid-rich lamellae that assemble in the intercellular space, coat the surfaces of the cornified cells, and provide a barrier to the permeation of the skin. The spinous cells have abundant desmosomes that consist of adhesion plaques and submembranous plaques involved in cell cohesion.<sup>4,5</sup>

The granular layer consists of highly differentiated cells that are flattened polyhedrons with keratohyalin granules. In this layer of the skin, dephosphorylation and proteinolysis activate filaggrin, which cross-links and bundles with keratin filaments into large macrofilaments. Filaggrin is broken down in the stratum corneum to free amino acids important for the proper hydration of the epidermis. Lamellar granules present in the granular layer aggregate beneath the plasma membrane and fuse with it, opening a channel for the release of granule

\*The editors acknowledge and appreciate the contributions of Karen A. Moriello, Douglas J. DeBoer, and Susan D. Semrad, former authors of this chapter. Their work has been incorporated into this edition.

contents such as polysaccharides, glycoproteins, acid hydrolases, acid lipase, and probarrier lipids into the intercellular spaces. After release, polar lipids are remodeled into hydrophobic, neutral, lipid-rich lamellae that form an effective barrier. A dense layer of highly cross-linked proteins is deposited inside the inner leaflet of the membrane. Together with the membrane, this boundary is called the cornified cell envelope, a rigid structure that resists degradation and is rich in glutamyl-lysine isopeptide cross-links. At the uppermost aspect of this layer, substances such as keratins, filaggrin, and the cornified cell envelope are passed on to the cornified cell layer.<sup>4,5</sup>

The cornified layer contains the largest and most numerous cells of any zone in the epidermis. Cells are large, flattened, and polyhedral; overlap with the margins; and associate through interlocking ridges and modified desmosomes. The contents of the cell are limited primarily to disulfide-bonded keratin filaments, highly cross-linked bundles of macrofilaments, and filaggrin. The compact organization of the proteins becomes looser toward the outer epidermal surface. The breakdown of filaggrin to its constituent amino acids in the outer cell layers accounts for the greater water-holding capacity of the cells and the more diffuse organization of the filaments. Uricanic acid is degraded from filaggrin with histidase and absorbs ultraviolet light. Therefore uricanic acid is important in ultraviolet light protection. The pyrrolidone carboxylic acid derived from glutamine is hygroscopic and helps to keep the skin hydrated even in a dry environment. The preserved trilaminar plasma membrane outside the cornified cell envelope becomes discontinuous and desquamates toward the upper portion of the cornified layer so that the envelope serves as the real cell membrane.<sup>4,5</sup>

The dermis contains a variety of cells that are essential for the skin to function normally. The dermis contains cellular elements such as fibroblasts, macrophages, histiocytes, eosinophils, and mast cells in the fibrous matrix and nonfibrous matrix. The fibrous matrix consists of collagen and elastic fibers. The nonfibrous matrix consists of glycosaminoglycans and proteoglycans. The blood vessels, nerves, lymphatics, hair, and sebaceous and apocrine glands are found within the dermis. The sebaceous and apocrine glands in the horse are larger and more numerous compared with those in other large animal species.<sup>4,5</sup>

The area that separates the epidermis from the dermis is known as the basement membrane zone. This layer of the skin functions as a scaffold for organization (important for growth and differentiation of keratinocytes) and repair (speeds up reepithelization), acts to regulate selective permeability by only allowing passage of molecules of the correct charge and molecular size, provides a physical intercellular barrier (tumor containment), and links epithelia to their underlying matrices. The basement membrane consists of structures such as tonofilaments, hemidesmosomes, laminin, fibronectin, proteins such as collagen, laminin-like molecules such as entactin and nidogen, anionic glycosaminoglycans such as heparin sulfate, anchoring fibrils, oxytalan filaments, elaunin fibers, microthread-like filamentous threadwork, and large glycoproteins such as fibrillin.<sup>5</sup>

## HAIR

The hair tends to cycle in a specific manner. Initially, hairs are in the growing or anagen phase, progressing through an intermediate or catagen phase into a resting or telogen phase

(Figure 13-1). The time period that hairs are in the catagen phase is short, and finding hairs in this stage of the cycle is difficult using a trichogram (plucking hairs and looking at them under the microscope). A variety of conditions including temperature, photoperiod, genetics, and hormones can affect the hair cycle.<sup>1,6</sup>

The hair follicles are located within the dermis and are associated with sebaceous and apocrine glands. Hairs are important in thermoregulation, protection of the skin from external factors, and as an ornament to attract other animals. The types of hairs found in equine skin are simple primary hairs. Horse hairs tend not to shed at once. Instead their hair sheds in patches or in a mosaic pattern.<sup>1</sup>

Ambient temperature affects the texture of the hairs. In warm temperatures the hair coat comprises thick, medullated hairs. Piloerection of hairs occurs to aid in cooling the body. In contrast, in cold temperatures the coat comprises longer, finer, and poorly medullated fibers. This type of hair coat provides more insulation from cold. The hairs of the fetlock, mane, and tail do not shed as do the other hairs on the horse.<sup>1</sup>

## ADDITIONAL SKIN-RELATED STRUCTURES

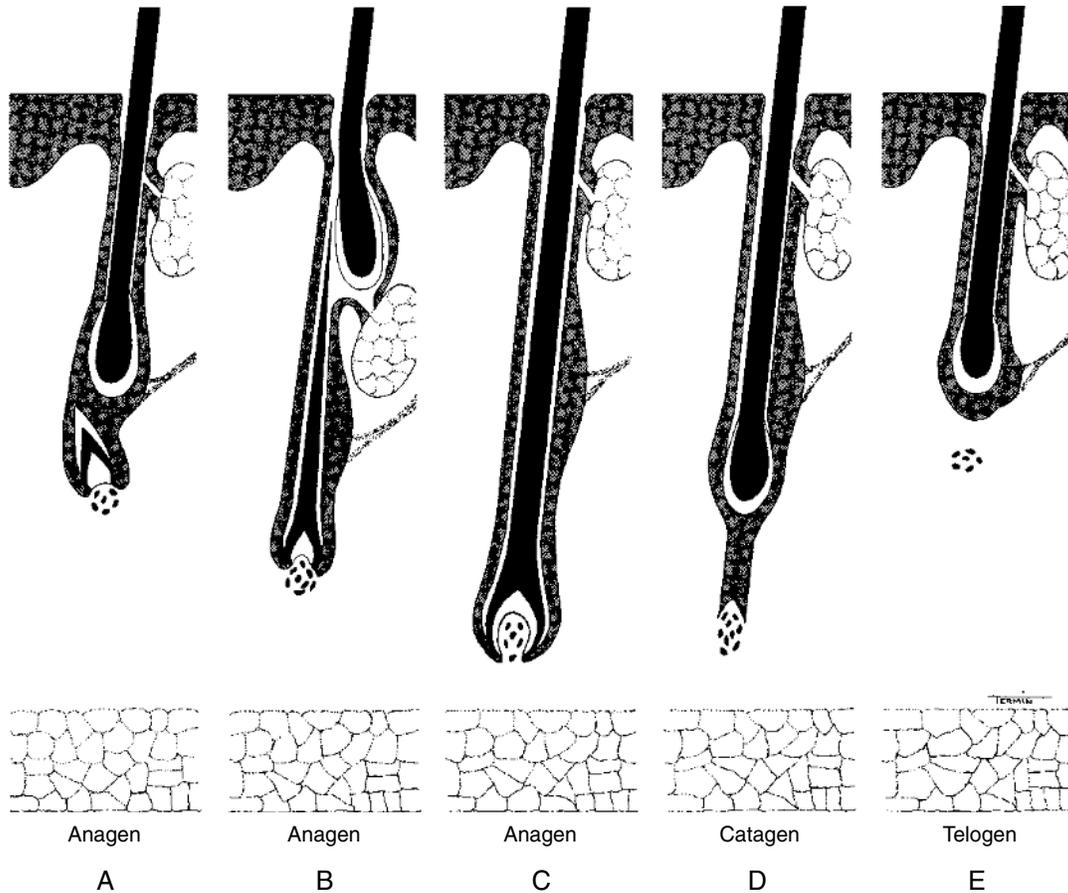

The horse and other Equidae have skin structures unique to these species, including the ergot, chestnut, and hoof. The ergot is a small mass of cornified tissue located in a tuft of hair on the flexor surface of the fetlock. The ergot is a vestige of the second and fourth digits of extinct Equidae. The chestnut refers to a mass of horny tissue on the medial surface of the radius and is believed to be a vestige of the first digit. The hoof is the horny covering over the distal end of the third digit. The hoof includes the frog, important for shock absorption and stimulation of blood flow to the foot, and other components that provide a firm structure to facilitate motion.

## ☞ HISTORY

A patient history of the horse can provide the clinician with useful clues to help determine the underlying cause of a dermatologic problem. Figure 13-2 is an example of a form with different types of dermatologic questions. For example, most allergies produce the clinical sign of pruritus. The owner may notice the horse rubbing, scratching, licking, or chewing, or physical examination may reveal evidence of pruritus (i.e., broken hairs and excoriations). Pruritus does not confirm a diagnosis of allergic disease. Other conditions such as parasitic infestation or secondary bacterial or fungal skin infection may be pruritic. These differential diagnoses may be ruled out by performing the diagnostic tests discussed later in this chapter.

Insect allergies and atopy frequently recur seasonally. However, in the warm climates of the United States, some horses may have year-round or nonseasonal pruritus with insect allergies or atopy. The practitioner should also include food allergy on the list of differential diagnoses for horses with nonseasonal pruritus.

Questions concerning whether other horses in the stabling or pasture facility have dermatologic lesions may be important. Similarly, knowing if grooming aids (brushes, combs, etc.) are used on more than one horse is important. Pruritus that affects multiple animals may indicate the possibility of a parasitic or infectious process.

**FIGURE 13-1** Phases in the life cycle of a hair. **A**, Anagen begins with the renewal of the intimate relationship between the papilla and the undifferentiated cells that partially enclose it. **B**, As anagen proceeds, matrix cells generate a new hair that pushes upward toward the surface and in the process dislodges the old club hair. **C**, Mature anagen hair follicle consists of infundibular, isthmus, and inferior segments. **D**, During catagen, the entire inferior segment of the follicle shrivels upward as a thin cord of epithelial cells and is followed upward by the papilla. **E**, During telogen, the club hair rests in its cornified sac at the level of the hair erector muscle. (From Moschella SL, Herley HJ: *Dermatology*, ed 3, Philadelphia, 1992, WB Saunders.)

Response to previous therapy is another useful historical clue. The practitioner should determine the dose and frequency of medication administration. If the appropriate drug or drug dose is not used, then the patient may not respond.

Other factors to consider include feed, stabling environment, and supplements or other medications (e.g., wormers, sprays, shampoos) used regularly. If any of these factors changed before the development of the dermatologic lesions, then the change may be related to the problem in the horse.

## ☞ PHYSICAL EXAMINATION

The examiner should consider the type of skin lesions and lesion distribution when performing a physical examination on the equine patient with dermatologic disease. Pustules and vesicles are fragile skin lesions that are not found easily and are most common in bacterial or autoimmune skin diseases. Pustules and vesicles are considered primary lesions. Other examples of primary lesions include papules, wheals or hives, erythema, and nodules. Secondary lesions commonly

observed in horses may include scale, crusts, excoriations, fistulae, ulcers, necrosis, hyperpigmentation, hypopigmentation, lichenification, hyperhidrosis, and scars.

The location of lesions is important because certain dermatologic conditions tend to occur on certain areas of the body. This tendency is especially true with parasitic hypersensitivity reactions because certain parasites have a predilection for certain areas of the body.<sup>7</sup> For example, pinworms tend to cause intense pruritus of the tailhead, and black flies tend to have a predilection for the head, ears, and ventral abdomen. More detailed information concerning insect feeding preferences is covered in the insect hypersensitivity section. The horse should be examined for evidence of external parasites such as ticks or flies.

The clinician should always perform a thorough physical examination, including determining the temperature, heart rate, and respiratory rate. If abnormalities in any of these parameters exist, then the horse may have a systemic disease or more than one medical problem. For the health of the animal, exploring and treating all possible medical problems is important.

**EQUINE DERMATOLOGY HISTORY FORM**

## COMMON CAUSES OF PRURITIC DERMATOSES

Pruritus is the sensation to rub, lick, scratch, or chew.<sup>8</sup> Horses most commonly rub the skin and hair coat when they are pruritic (Figure 13-3). Clinical evidence that a horse is pruritic may include the presence of broken hairs, excoriations, hemorrhagic crust, alopecia, lichenification (thickening of the skin), and hyperpigmentation. Lichenification and hyperpigmentation occur most commonly after chronic inflammation and pruritus.

Conditions that tend to be pruritic include parasite infestations such as lice, mites, ticks, *Onchocerca* spp., *Habronema* spp., and pinworms or allergic reactions such as insect hypersensitivity, food allergy, contact allergy, and atopy. Occasionally, pruritus occurs with bacterial or fungal infections.

### PARASITIC SKIN DISEASES

#### LICE (PEDICULOSIS)

Two types of lice may be found on horses. Biting lice feed on epidermal debris, whereas sucking lice feed on blood and lymph. *Haematopinus asini*, the sucking louse of horses, most commonly infests the mane and tail and the hairs behind the

fetlock and pastern. The biting louse, *Damalinea equi*, tends to feed on the dorsolateral trunk.

Lice are host-specific and complete their entire life cycle on the host. Female lice attach their eggs to hairs. In cool, moist environments, lice can live for 2 to 3 weeks; they live only a few days off of the host. Lice infestations are transmitted by direct or indirect contact. Brushes, combs, and tack serve as fomites for transmission of lice. Adult horses may act as asymptomatic reservoirs for infection.

Lice infestations can occur year round, but they are more common in the winter in northern climates. Cooler skin and hair coat temperatures are more favorable for development of eggs within the female, oviposition, and egg development.<sup>9</sup> Skin temperatures on the legs of horses, with the possible exception of Draft-breed horses, are too cold for louse development.

Lice infestation has no age, breed, or sex predilection in horses. Affected horses tend to be restless and have a poor appetite. They have a dry, dull hair coat with patchy areas of hair loss and excoriation. The coat may appear moist and have a sour or mousy odor. Skin fasciculation may be the only evidence of early infestations in foals. Some horses may be asymptomatic carriers that are identified only when foals or other susceptible animals become infested. Heavy infestations of sucking lice may cause anemia or severe debilitation.

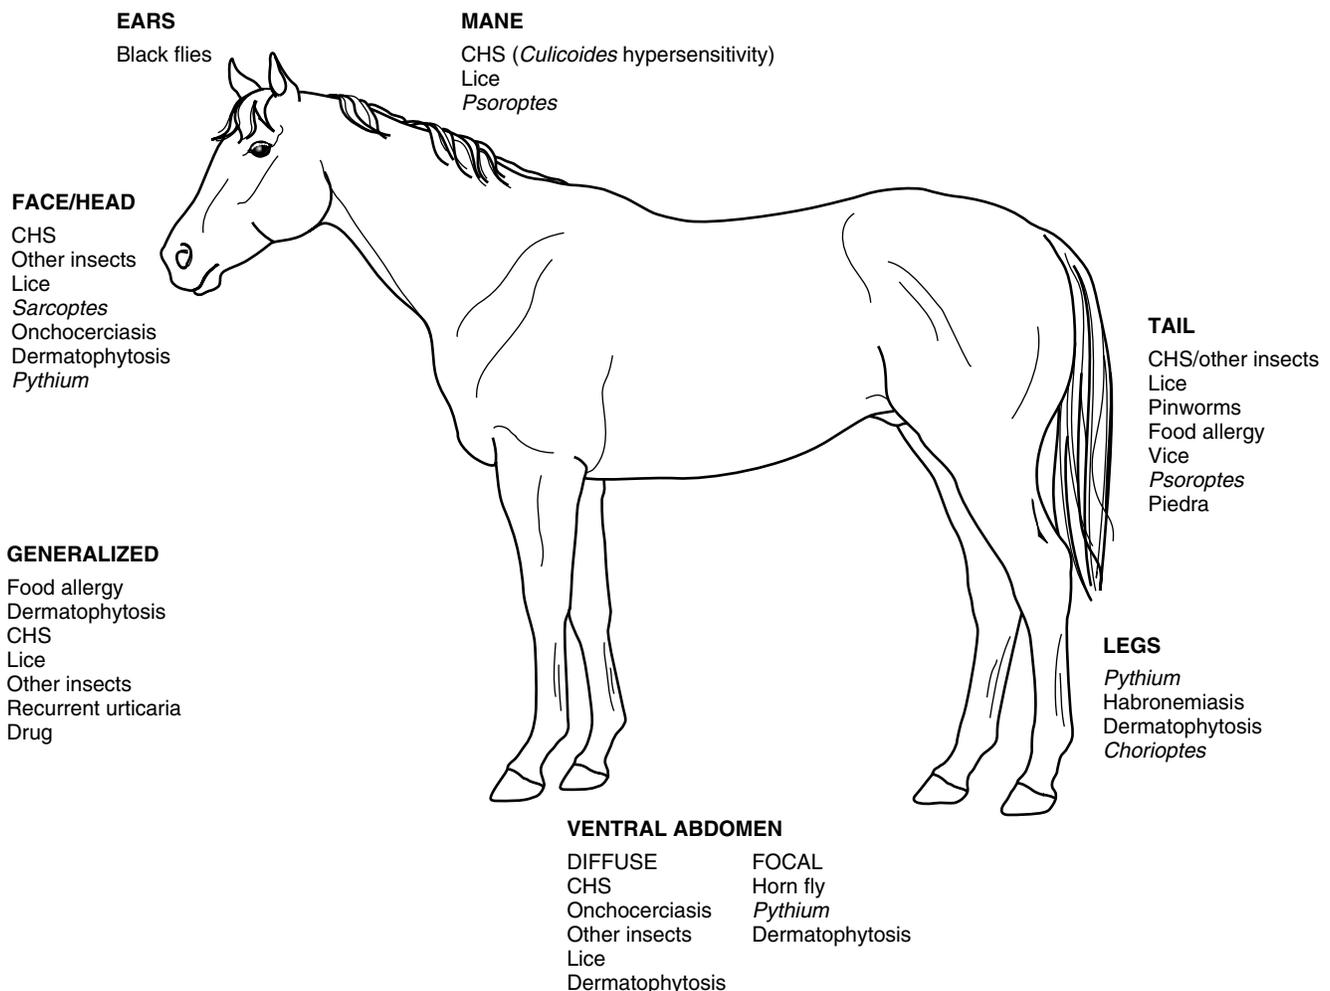

FIGURE 13-3 Regional pruritus: differential diagnosis of pruritic skin diseases.

The diagnosis of lice infestations is made by demonstration of adults or eggs or both on the hairs. Sometimes, lice cannot be visualized easily in direct light. In these circumstances the veterinarian may need to comb the hair coat with a fine-toothed comb to find the lice. Skin biopsies may reveal a nonspecific superficial perivascular eosinophilic dermatitis with or without intraepidermal microabscesses.<sup>1</sup>

When managing a lice infestation, the veterinarian should treat all animals on the premises. Ivermectin at 200 µg/kg orally every 2 weeks for three treatments is effective for treating sucking lice. Biting lice do not respond to ivermectin treatment, and thus one should treat affected horses with other medications, such as dips. Common types of dip may be used to treat sucking and biting lice infestations include lime sulfur, pyrethrins, methoxychlor, malathion, coumaphos, crotoxyphos, pyrethroids, lindane, permethrin, selenium sulfide, imidacloprid, phoxim, and fipronil.<sup>10-12</sup> Lime sulfur and pyrethrin dips have fewer associated adverse reactions in horses than do other dip treatments. All products should be used according to label directions. None of these treatments affect lice eggs, and two to three repeat applications of the dip are recommended at 2-week intervals. For optimal efficacy, one should treat the whole body of the horse when applying the dips. Other precautions include cleaning and disinfecting all tack and grooming supplies (brushes and combs), decontaminating the stabling area using a commercial premise spray used to kill fleas because lice may survive for days to weeks in the environment, and, although reinfestation is difficult to prevent, treating animals returning from shows, breeding farms, or training facilities prophylactically.

## MITES (MANGE)

A variety of mites may infest horses. *Sarcoptes scabiei* var. *equi* (scabies, head mange), *Chorioptes equi* (leg mange), *Psoroptes equi* (body mange), *Pyemotes tritici* (straw itch mite), and *Trombicula* and *Eutrombicula* species (chiggers) are species associated with equine pruritic skin disease.<sup>7</sup> The pruritus accompanying a mite infestation results from a combination of mechanical irritation and hypersensitivity to the mite and by-products of the mite (i.e., feces).<sup>13</sup> The primary skin lesion from a mite infestation is a maculopapular eruption. These skin lesions are often difficult to find with chronic infestations.

***Sarcoptes scabiei*** In the United States, *S. scabiei* infestations in horses are a reportable disease.<sup>7</sup> This mite is highly contagious and infests horses and transiently infests human beings (self-limiting disease) in contact with parasitized horses. This parasite is capable of surviving off the host for up to 3 weeks, and transmission of scabies by fomites or in the environment is possible. Scabies mites burrow in the superficial epidermis and lay their eggs. In early infestations, mites are found in highest concentration around the head and neck. These mites seem to prefer the ears on horses. As disease progresses, mites usually spread over the entire body. A scabies infestation in a horse results in intense pruritus and generalized scaling and crusting with excoriations and lichenification. A secondary skin infection may result from the pruritus. One may elicit the itch-scratch reflex by scratching the horse over the withers, causing the horse to tuck its nose close to its chest and make smacking noises and exaggerated lip movements. This reflex suggests scabies but is not diagnostic, and one may elicit the reflex in some normal horses.<sup>14</sup> The scabies mite is circular with short legs, a terminal anus, and long

unjointed pedicles. Unfortunately, as in other species, the scabies mites are difficult to find on skin scrapings. Therefore a negative skin scraping does not ensure that the horse does not have scabies.

Ivermectin at a dose of 200 µg/kg orally is effective for treating horses with scabies. As in other species, the practitioner should repeat ivermectin treatment at 2-week intervals for a total of two to three treatments. Within 2 weeks the eggs hatch and new adult mites are present. Topical treatments such as lime sulfur dip, lindane, coumaphos, diazinon, malathion, or toxaphene also have been used. The practitioner should dip horses every 7 to 10 days for three to six treatments, treat all horses in contact with the infested horse, and decontaminate fomites (e.g., tack, brushes) and the environment.

***Chorioptes equi*** *Chorioptes equi* mites are host-specific and do not parasitize human beings (Figure 13-4). Unlike the scabies mite, infestation with *C. equi* is not a reportable condition. *C. equi* mites spend their entire life cycle on the host feeding on epidermal debris. Preferred feeding sites include the distal limbs and perineum. Infested horses exhibit intense pruritus with stomping of feet and rubbing of the perineal area. Skin lesions include alopecia, erythema, and crusting of the pasterns, fetlocks, or perineum. Draft-breed horses or other horses with feathered fetlocks are predisposed to *C. equi*. The mite tends to be more common in the winter months. *C. equi* should be included in the list of differential diagnoses for horses with pastern dermatitis or greasy heel. Treatment of this mite is the same as for *S. scabiei*. However, ivermectin-resistant *C. equi* mites have been reported, and topical dip therapy may be indicated if the horse does not respond to oral therapy. If

FIGURE 13-4 *Chorioptes* mite.

a topical medication is used, clipping the hair around the fetlocks and pasterns to ensure optimal contact of the dip with the skin and mites is advisable.

**Psoroptee equi** *Psoroptes equi* mite infestations are a reportable condition in horses in the United States. *P. equi* mites are highly contagious to other horses but do not infest human beings. These mites do not burrow but live on the skin surface. They are biting mites that feed on serum and cellular components. Transmission of *P. equi* mites is by direct contact and exposure to fomites. Mite infestations tend to begin on the forelock, mane, and tail and spread to the trunk. These mites have been known to infest the ear canal and cause otitis externa. Affected horses typically show head shaking or rubbing. As with many other mites, pruritus results in alopecia, papule, oozing crusts, excoriations, and ulcers on the skin. The intensity of pruritus varies. History and clinical signs suggest the diagnosis of *P. equi* mange. Skin scrapings are required to diagnose this condition definitively. *P. equi* has an oval body with segmented pedicles. Treatment for *P. equi* infection is similar to that described for sarcoptic mange.

**Trombiculidiasis** Trombiculidiasis (chiggers, red bugs, harvest mites) is caused by an infestation with larvae of free-living adult mites (genus *Eutrombicula* or *Neotrombicula*). Larvae are most prevalent in grasses, forests, or swamps in late summer and fall. Small rodents are the natural host. Pathognomonic skin lesions are papules or wheals with a small orange or red dot (trombiculid larvae) in the center. Trombiculidiasis is seasonal, but the seasonality varies with genus and species. *Eutrombicula alfreddugesi* is active in the late spring and peaks midsummer, whereas *Neotrombicula autumnalis* is most active from the late summer to midautumn.<sup>10</sup> Larvae feed on the host in the late afternoon and early evening. Areas of the body most commonly infested are the face, muzzle, distal limbs, ventral thorax, and abdomen. The diagnosis is based on observation of the distinctive lesion with the larvae approximately 0.2 to 0.4 mm in size, oval in shape with six legs, in the center of the skin lesion. Trombiculidiasis is a self-limiting disease. Some horses are uncomfortable with this mite infestation and should be treated. Recommended treatments include lime sulfur dip, permethrin, pyrethrin, cypermethrin, and phoxim sprays or dips as a one-time treatment in association with prednisolone at a dose of 0.5 mg/kg orally for 3 to 5 days.

**Pyemotes tritici** *Pyemotes tritici* (straw itch mite) normally parasitizes the larvae of grain insects. Occasionally this mite parasitizes human beings and horses.<sup>15</sup> Infestation in horses occurs from contaminated hay fed in overhead racks. The mite produces a maculopapular crusted eruption on the head, neck, and trunk that is only occasionally pruritic. The diagnosis is based on history and clinical examination. This disease is self-limiting, and the owner should remove contaminated forage or feed the horse from the ground until all contaminated forage has been consumed. Infestations from fomites or hay fed on the ground have not been reported.

**Dermanyssus gallinae** The nymphs and adults of the poultry mite, *Dermanyssus gallinae*, will occasionally parasitize the horse. This mite feeds at night. The adults are oval, 0.6 to 1 mm long with eight long legs. The color of the mites is white, gray, or black. However, after the poultry mite consumes a blood meal the color turns to red.

This mite causes pruritic papules and crust of the head and legs of horses. Skin scrapings and tape preparations at night yield the best chance of obtaining the mite. Routine mite treatments that were discussed previously are also beneficial for

treating this mite. However, with the poultry mite, one needs to treat the environment and remove the bird nests from the stable or eliminate the horse's contact with poultry.<sup>10</sup>

**Demodicosis** Demodicosis is a rare equine skin condition. Two species of *Demodex* can infest horses (i.e., *D. equi* and *D. caballi*), and each affects different areas of the body. *D. equi* affects the body, whereas *D. caballi* prefers the eyelids and muzzle. Clinically these horses have one or more alopecic or scaling areas of the body. The most common areas of the body affected in horses with demodex are the face, neck, and sometimes shoulders. The diagnosis is based on skin scrapings. Demodex mites are easily found on skin scrapings. Several different treatment options exist for treating equine demodex. Treatment with 2% trichlorfon topically every other day has been used with success. Daily ivermectin or doramectin has also been used with some success. Amitraz is contraindicated because this drug causes colic in horses. Regardless of the treatment used, one needs to identify and treat the underlying cause for the demodicosis. The most common underlying causes for equine demodicosis are chronic glucocorticoid use and equine Cushing's disease (pituitary pars intermedia dysfunction).<sup>10,12</sup>

**General Comments** Regardless of the type of mite present on the horse, skin scrapings should be part of the diagnostic workup. With the exception of lice and trombiculid larvae that can be seen with the naked eye, one can diagnose mite infestations best by microscopic examination of skin scraping samples.

## TICKS

Ticks are an important ectoparasite in the horse because of their potential role in disease transmission, including a variety of viral, protozoal, rickettsial, and bacterial infections. Tick infestations are most common in the spring and summer.

Argasid ticks lay eggs in cracks and crevices in the environment, and immature ticks infect hosts after hatching. Larvae and nymphs suck blood and lymph and then drop off to develop into adults. These ticks infest barns, sheds, and other areas where animals are found. In horses, *Otobius megnini* (spinose ear tick) tends to infest the ears and ear canal. Clinical signs of infestation include otitis externa, head tilt, head shaking, ear rubbing, and occasionally aural hematomas.

*Dermacentor*, *Ixodes*, and *Amblyomma* species are the most common ixodid ticks of horses. These ticks are found outdoors and have complicated life cycles in which all stages of the life cycle are parasitic. The severity of clinical signs depends on the density of the infestation and whether the horse develops a hypersensitivity reaction to the bites. Infestations occur most commonly on the ears, face, neck, groin, distal limbs, and tail. Early lesions consist of papular to pustular eruptions that rapidly develop into crusts, erosions, ulcers, and hair loss. Hypersensitivity reactions may be local or general. Local responses appear as nodules that develop at the site of the tick bite. Although the pathogenesis is unknown, cutaneous basophil hypersensitivity is believed to be involved.<sup>16</sup> Systemic reactions are characterized by whole-body urticaria or multifocal urticarial plaques. In Australia, a hypersensitivity reaction to *Boophilus microplus* has been observed in sensitized horses.<sup>17</sup> Intense pruritus, papules, and wheals develop as soon as 30 minutes after ticks begin to feed.

A definitive diagnosis is made by observation of ticks attached to the horse or in the ear canal. Treatment aims at

FIGURE 13-5 Ventral midline dermatitis caused by onchocerciasis.

killing ticks on the horse. The practitioner should apply pyrethrin or pyrethroid sponge-on dips to the body of the horse, taking extra care to soak skinfold areas. Usually, only one treatment is necessary unless reinfestation occurs. Resistance to insecticides can occur rapidly, and knowledge of local resistance patterns is important. Infestations of *O. megnini* require mechanical removal of as many ticks as possible. One part rotenone and three parts mineral oil applied twice weekly is an effective otic parasiticide for horses. The author has used a commercially available pyrethrin otic preparation (Otomite Plus, Vibac, Fort Worth, Tex.) for small animals in horse ears with success. Ivermectin also has been shown to be effective in treating ticks at a dose of 200 µg/kg orally.

**Onchocerciasis** Onchocerciasis is a nonseasonal skin disease of the horse caused by the parasite *Onchocerca cervicalis*. This nematode lives in the ligamentum nuchae and produces microfilariae that migrate to the skin and are ingested by the intermediate host, *Culicoides* species. Microfilarial populations in the skin vary, and the highest concentrations occur in the dermis of the face, neck, and ventral midline, especially the umbilicus (Figure 13-5).<sup>18</sup> Microfilarial populations vary seasonally and are highest in the spring, which interestingly is the peak season for the *Culicoides* vector.<sup>19</sup> Microfilariae are more superficial in the dermis during the spring and summer months. Clinical signs of onchocerciasis are believed to be caused by an idiosyncratic hypersensitivity reaction to one or more microfilarial antigens because many horses that have circulating microfilariae do not have any gross skin or ocular lesions.<sup>20</sup> Whether the reaction is directed only at dying or dead microfilariae is unknown.

Onchocerciasis has no breed or sex predilection and usually affects horses 4 years of age and older. Clinical signs are nonseasonal but may be worse in the spring and summer, most likely because of the added irritation from the vector. Lesions may occur on the face and neck, on the ventral chest and abdomen, or in all these areas.<sup>21,22</sup> Early lesions begin as a thinning hair coat. As the disease progresses, lesions may vary from focal to generalized areas of alopecia, scaling, crusting, and plaques. Affected areas may be severely excoriated, ulcerated, oozing, and lichenified. Annular lesions in the center of the forehead suggest the disease (Figure 13-6). Leukoderma usually develops at the site of lesions and is irreversible. Ocular lesions include sclerosing keratitis, vitiligo of the bulbar

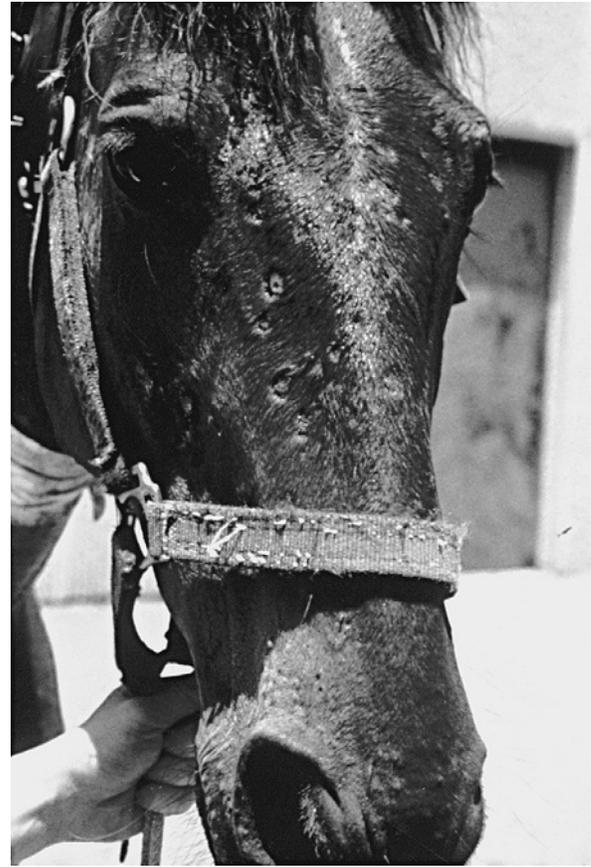

FIGURE 13-6 Equine onchocerciasis.

conjunctiva, white nodules in the pigmented conjunctiva, uveitis, and a crescent-shaped patch of depigmentation bordering the optic disk.<sup>23</sup>

The practitioner may make a presumptive diagnosis of onchocerciasis by demonstrating the microfilariae in the skin of animals with compatible historical and clinical findings. Skin scrapings and direct blood smears are often negative. One can demonstrate microfilariae most reliably with a mince preparation or via histologic examination of skin from a biopsy specimen.<sup>22</sup> Mince preparations require a 4- or 6-mm punch specimen of tissue obtained from the ventral abdomen. One places the tissue specimen in a Petri dish with a small amount of physiologic saline, minces it with a scalpel blade or razor, and incubates it at room temperature for 30 to 60 minutes. The specimen can then be examined microscopically for evidence of the rapid motion of the microfilariae. Skin biopsies reveal a superficial perivascular eosinophilic dermatitis. Often, microfilariae are visible in the superficial dermis.<sup>7</sup>

Ivermectin at a dose of 200 µg/kg orally is the treatment of choice.<sup>7,21,24</sup> A single dose often produces remission of clinical signs within 2 to 3 weeks. However, some horses require two to three monthly treatments before clinical signs resolve. Approximately 25% of horses have an adverse reaction, such as ventral midline edema or pruritus, which occurs 1 to 10 days after treatment. In rare cases, severe umbilical and eyelid edema and fever may occur. In confirmed cases of onchocerciasis, one should perform a thorough ocular examination to look for any signs of eye disease associated with onchocerciasis. Anecdotal reports suggest treatment may precipitate an episode of uveitis.

Prednisolone at a dose of 0.5 mg/kg orally may be necessary in the first week of treatment to prevent exacerbation of skin and ocular lesions as a result of massive destruction of microfilariae but is not routinely recommended. Indications include the development of ventral midline edema, pruritus, and fever. None of the currently available anthelmintics kill adult parasites in the ligamenta nuchae, and affected individuals require periodic retreatment with ivermectin when clinical signs recur. The prevalence of cutaneous onchocerciasis has decreased significantly with the advent of routine dewormings with ivermectin.

**Habronemiasis** Cutaneous habronemiasis is a common nodular skin disease caused by three species of nematodes: *Habronema muscae*, *H. majus* (*H. microstoma*), and *Draschia megastoma* (*H. megastoma*). The housefly is an intermediate host for *H. muscae* and *D. megastoma*, whereas the stable fly is the intermediate host for *H. microstoma*. The normal life cycle for these parasites is similar. Adult nematodes live in the stomach and produce larvae. Larvae are passed in the feces and ingested by maggots of the foregoing intermediate hosts. The intermediate host deposits infective larvae near the mouth of the horse, which swallows them. Cutaneous habronemiasis occurs when intermediate hosts deposit infective larvae on skin, open wounds, or chronically wet areas.

A horse with cutaneous habronemiasis has ulcerative nodules in the spring and summer that partially or completely regress in the winter. A recent study suggests that Arabians, gray horses, and horses with diluted color (i.e., palomino, buckskin, dun) may be predisposed to developing cutaneous habronemiasis.<sup>25</sup> Interestingly, in this same study, Thoroughbred horses were the most underrepresented breed of horse for cutaneous habronemiasis. No breed, sex, or age predilection exists. Some horses may be predisposed to cutaneous habronemiasis, exhibiting clinical signs each year, whereas other horses on the same premises never develop this condition.

Skin lesions of habronemiasis occur most commonly on the legs, urethral process of the penis, prepuce, medial canthus of the eye, or any area of trauma to the skin. Other areas that may be infected include the conjunctival sac, the lacrimal duct, and the third eyelid. Single or multiple nodules may be present. In most cases, pruritus is present, presumably due to a hypersensitivity reaction to the parasite. The intensity of pruritus may vary from mild to severe. In severe cases in which ocular lesions are present the horse can suffer from photophobia, epiphora, and chemosis. Dysuria can occur when lesions affect the urethral process.

Lesions often are ulcerated and appear similar to exuberant granulation tissue. Yellow granules approximately 1 mm in diameter may be present.<sup>26,27</sup> Microscopic examination of these granules does not reveal branching hyphae such as one frequently observes with granules from pythiosis or zygomycosis lesions.

Differential diagnoses for cutaneous habronemiasis include bacterial granuloma, fungal granuloma, pythiosis, exuberant granulation tissue, squamous cell carcinoma, and equine sarcoid. *Habronema* spp. may be present concurrently with other dermatologic conditions, and biopsy is important for a complete and definitive diagnosis.

The diagnosis is based on history, physical examination, cytologic examination, and biopsy of lesions. Cytologic examination of exudate sometimes reveals the presence of nematode larvae. These larvae are large (3 mm by 60  $\mu$ m), with a spiny tail, and are usually motile. Skin biopsies reveal a

nodular to diffuse granulomatous dermatitis with large numbers of mast cells and eosinophils. Foci of coagulation necrosis are characteristic.<sup>28,29</sup> Sometimes this area of necrosis contains cross-sections of larvae.

Treatment of cutaneous habronemiasis should include control of the associated hypersensitivity reaction and elimination of the parasite. Treating horses with ivermectin alone is not always effective. The author and co-workers examined 14 horses between 1988 and 1998 that had been treated with ivermectin in the preceding month and had intralesional habronema larvae present on biopsy. Similarly, 5 of 31 horses treated with ivermectin for habronemiasis required an additional treatment 2 to 4 weeks later.<sup>30</sup> One may treat the hypersensitivity reaction with systemic corticosteroids such as prednisolone at a dosage of 1 mg/kg once daily for 10 to 14 days with a gradual decrease over an additional 2-week period. Corticosteroids and dimethyl sulfoxide (DMSO) are often combined with fenthion, thiabendazole, ronnel, or trichlorfon in a variety of topical preparations for treatment of habronemiasis.<sup>29</sup> Some more common topical lesional medications include (1) 1 oz dexamethasone (2 mg/ml) in 1 oz 90% DMSO and 1 oz 20% fenthion; (2) 3 oz 90% DMSO in 15 ml dexamethasone (2 mg/ml), 40 ml nitrofurazone solution, and 1 oz trichlorfon powder; and (3) 30 ml 20% fenthion,  $\frac{1}{4}$  lb petrolatum (heated), 10 mg triamcinolone acetonide powder, and 90 ml 90% DMSO. Ivermectin is sometimes used concurrently with these topical medications. Unfortunately, fenthion is no longer commercially available in the United States. Another systemic medication besides ivermectin that has been used to treat habronemiasis is moxidectin at 400  $\mu$ g/kg. This drug is active against *Habronema* spp. in the stomach. A more recent study suggested that topical triamcinolone ointment or a preparation containing 50 mg dexamethasone, 500 g nitrofuraxone, 60 g of 90% DMSO solution, and 1.4 g of ivermectin paste may be an effective alternative treatment for equine cutaneous habronemiasis. With these treatments the skin lesions healed within 7 to 42 days with a mean of 19.3 days in 25 out of 26 horses.<sup>25</sup>

The practitioner may treat conjunctival habronemiasis with topical echthiophate drops three times a day to kill larvae in combination with an ophthalmic ointment that contains dexamethasone and an antibiotic. Other ocular treatments include neomycin, polymyxin B, and dexamethasone applied three to four times daily to the ocular lesions until healed. If corneal ulcers are present, then this triple antibiotic preparation without the steroid is used until the ulcer is healed. After the corneal ulcer is healed, an ophthalmic dexamethasone ointment is used. Most ocular lesions heal within 5 to 18 days, with a mean of 8.2 days.<sup>25</sup>

Fly control is an essential part of treatment. Oil-based fly sprays tend to last longer than water-based fly sprays. Products that contain permethrin are effective.

Prognosis for horses with habronemiasis is good with appropriate and timely treatment. The veterinarian should warn the owner that habronemiasis may recur in subsequent years. Fly control is essential to preventing recurrence. Regular collection and stacking of manure will also help with preventing recurrence.

**Pinworms** Equine pinworms, *Oxyuris equi*, cause intense anal pruritus. Adult pinworms are found in the colon. The female worm migrates down the gastrointestinal tract and deposits eggs around the anus. These eggs are cemented to the skin with a thick, sticky, yellow-gray substance. Horses develop perianal pruritus as a result of this sticky substance, which

contains the eggs. In severe infestations, horses may develop vague abdominal discomfort. This abdominal discomfort results directly from inflammation of the cecal and colonic mucosa in response to third- and fourth-stage pinworm larvae.<sup>31</sup>

Eggs develop to the infective stage within a 4- to 5-day period. At this time the cement substance cracks and dries and then detaches from the skin as flakes. These flakes contain a large number of eggs that adhere to walls, buckets, and other objects in the environment.

Because ova of *O. equi* are not often observed on routine fecal flotation, a diagnosis of pinworms is based on clinical signs and identification of pinworm eggs on cellophane tape preparations. A piece of clear adhesive tape is pressed to the skin around the anus. One removes the tape and places it on a slide for microscopic examination for oval ova with an operculum or plug at one end.

*O. equi* infection is treated easily with a variety of anthelmintic agents. Anecdotal reports exist of occasional resistance to ivermectin and pyrantel; these horses respond to treatment with fenbendazole. One may treat the horse once with fenbendazole and remove it from the environment for 1 month. (Pinworms can survive in the environment under ideal conditions for up to 1 month.) Alternatively, one may treat horses with fenbendazole three times at 2- to 3-week intervals.

## ☞ ALLERGIES

### INSECT HYPERSENSITIVITY

Insect hypersensitivity is a common cause of skin disease in the horse. Mosquitoes and species of *Culicoides* (biting midges, “sweet itch”), *Simulium* (black flies), *Tabanus* (horse flies), *Chrysops* (deer flies), *Stomoxys calcitrans* (stable flies), *Haematobia* (horn flies), *Musca* (houseflies), bees, and wasps cause skin lesions in horses.<sup>7</sup>

Insect hypersensitivity reactions are seasonal in colder climates, can be nonseasonal in warmer climates, and may affect any age, sex, or breed of horse. This dermatologic condition may have an inherited component, but specifics of these claims have not been verified. The distribution of skin lesions varies and may depend on the type of insect involved. Certain insects have preferred feeding sites.<sup>7,32</sup> The black fly tends to feed on the head, ears, and ventral abdomen. Black flies may produce a generalized pattern of ventral midline edema. Stable flies prefer feeding on the lower legs but also have been known to feed on the ventral abdomen, chest, and back. The location for *Culicoides* spp. feeding is species dependent. Classically, *Culicoides* spp. feed on the dorsal surface of the horse (especially the mane and tail areas), face, and ears (Figure 13-7). In Florida, some *Culicoides* spp. prefer feeding on the lower legs, ventral trunk, and neck. Horn flies feed on the ventrum around the umbilicus (Figure 13-8). Mosquitoes prefer feeding on the lateral aspects of the body.

A few insects bite anywhere on the body and do not prefer a specific location. Examples include deer flies, horse flies, houseflies, bees, and wasps.

Some insects require a specific environment to propagate. Knowledge of these requirements may be helpful in establishing insect control programs. *Culicoides* spp. and mosquitoes prefer freestanding stagnant water for propagation. In contrast, black flies prefer moving water such as a stream, brook, or river. Horn flies are obligate parasites of cattle that require fresh cattle feces for reproduction. Several species of insects, including stable flies and houseflies, prefer decaying vegetation or manure for

FIGURE 13-7 Two-year-old horse with *Culicoides* hypersensitivity.

FIGURE 13-8 Alopecia with some crusting around the umbilicus on a horse with horn fly infestation.

reproduction. They tend to be a bigger problem when sanitation practices at the stabling facility are problematic.

The time of day that an insect prefers to feed also differs between species. Horseflies, stable flies, black flies, and horn flies are usually active during the daylight hours. More specifically, black flies feed in the morning and late afternoon. Mosquitoes and most *Culicoides* spp. are active at night. Mosquitoes are most active at dusk and the first 2 hours after sunset. If the time of feeding is known for the potential offending insect, then the horse may be stalled during peak feeding hours to limit exposure.

Types of dermatologic lesions seen with equine insect hypersensitivity include pruritus, alopecia, excoriations, and lichenification. A generalized papular-crusted eruption also may occur.

The diagnosis of insect hypersensitivity is based on a compatible history, physical findings, and elimination of other causes of pruritus in the horse. Skin scrapings show no abnormalities. Skin biopsies may reveal the presence of a superficial

or deep perivascular eosinophilic dermatitis with epidermal spongiosis (intercellular edema of the epidermis), necrosis, and collagen degeneration. Intradermal skin testing is useful for diagnosing insect hypersensitivity.<sup>21</sup> Some insect allergens are inconsistently available (e.g., *Culicoides* spp.), and purchase of insect allergens for the nonspecialist veterinarian may be cost prohibitive. Fortunately, therapy and environmental control measures are similar for most biting and flying insects, and therefore confirming the diagnosis by intradermal skin testing may not be crucial.

Treatment of insect hypersensitivity involves insect control and judicious use of glucocorticoids.<sup>21</sup> Boxes 13-1 to 13-3 summarize recommendations. Ideally, owners should stable horses during the target peak feeding period for insects and should screen windows with a small-meshed screen and spray with a residual parasiticide. If possible, bedding areas for flies (e.g., standing water, manure) should be eliminated. Spraying horses with residual insecticides (e.g., pyrethrins or pyrethroids) is useful, and sprays containing permethrin and pyproxifen (Knock-Out Spray, Vibrac, Fort Worth, Tex.) are

effective for treating horses with *Culicoides* spp. hypersensitivity. Anecdotal reports suggest that weekly application of fipronil (Frontline, Merial, Iselin, N.J.) may be useful for treating horses with *Culicoides* spp. hypersensitivity. Avon Skin So Soft bath oil (Avon Products, Inc., New York, N.Y.) mixed in equal volumes with water has been used to repel insects in horses. However, this product with should be used with care because contact dermatitis has been reported. One should follow label recommendations with changes depending on the response of the individual horse. Cattle tags impregnated with insecticide may be helpful if attached to manes, tails, or halters.

Anecdotal reports suggest the importance of applying repellents and insecticide sprays to the horse when the skin is cool and dry, which may minimize development of sensitivity reactions to products by limiting percutaneous absorption. Many horses are sensitive to petroleum-based products and develop erythematous skin and hair loss in areas where the insecticide, fly wipe, or bath oil has been applied to the skin. If a horse has a history of this type of reaction, performing an open patch test with any new product before applying the spray over the entire body is advisable. The practitioner applies a small amount of the test substance to an area of skin and observes the site for 72 hours for signs of erythema, swelling,

#### BOX 13-1

### PRIMARY MANAGEMENT STRATEGIES FOR COMMON EQUINE PESTS

#### 1. Stabling

Tabanids: diurnal and crepuscular periods  
Black flies: diurnal and crepuscular periods  
Biting midges: under fans; nocturnal and crepuscular periods

#### 2. Exclusion devices

Black flies: ear nets  
Houseflies: facemasks  
Face flies: facemasks

#### 3. Hay and manure management

Stable flies: particularly hay in pastures  
Houseflies: general sanitation

#### 4. Cattle management

Horn flies: control pest on natural host  
Face flies: undisturbed cattle manure requisite for larval development

#### 5. Water management

Mosquitoes: only certain species  
Biting midges: only certain species

#### 6. Source identification and removal

Straw itch: normally infested hay  
Blister beetle: normally products containing alfalfa

#### 7. Restricted grazing or movement

Chiggers: erratic distribution in spring or fall  
Ticks: mowing and understory control also helpful  
Tabanids: allow horses to escape from wooded areas  
Poultry pests (sticktight fleas and lice): separate horses from poultry

From Robinson NE, editor: *Current therapy in equine medicine*, ed 6, St. Louis, 2009, Saunders.

## PESTICIDES RECOMMENDED FOR EXTERNAL PARASITE CONTROL ON HORSES\*

### Residual Insecticides

#### Pyrethroids

Cypermethrin  
Fenvalerate  
Permethrin  
Resmethrin  
Tetramethrin  
S-Bioallethrin  
Sumethrin

#### Organophosphates

Coumaphos  
Dichlorvos  
Malathion  
Tetrachlorvinphos

### Organochlorines

Lindane  
Methoxychlor

### Other Compounds

#### Repellents

MGK 326 *di-N-propyl isocinchomeronate*  
Stabilene: *butoxy polypropylene glycol*

#### Botanicals

Pyrethrins (also insecticidal)  
Synergists  
Piperonyl butoxide 5-((2-(2-butoxyethoxy) ethoxy)methyl)-  
6-propyl; 1,3-benzodioxole  
MGK 264 *N-octyl bicycloheptene dicarboximide*

From Robinson NE, editor: *Current therapy in equine medicine*, ed 6, Philadelphia, 2009, Saunders.

\*Categories may overlap; for example, some pyrethrins are also insecticidal, and some pyrethroids are repellent. William B. Warner and Roger O. Drummond assisted in compiling this list.

and hair loss. Fly masks or fly sheets are useful adjunct therapy for control of insects.

In many cases, insect control alone is insufficient to alleviate discomfort and clinical signs. Hydroxyzine hydrochloride may be beneficial in some horses with insect hypersensitivity when administered orally at a dose of 200 to 500 mg every 8 to 12 hours.<sup>33</sup> This drug also has been useful in managing insect-induced urticaria. Side effects associated with hydroxyzine in horses include sedation or hyperactivity. If the horse does not respond after hydroxyzine administration, one may try systemic corticosteroids. The recommended dosage for prednisolone is 1 mg/kg orally administered daily until the pruritus is relieved (usually 1 to 2 weeks); the dose is then tapered to the lowest effective every-other-day dose.

Anecdotal reports suggest that a DMSO derivative, methylsulfonyl methane, may be effective as an aid to relieve pruritus associated with equine insect hypersensitivity. This medication is available as a powder to be sprinkled on food and should be used according to label directions.

Fatty acids have been recommended for control of pruritus associated with insect hypersensitivity.<sup>21,33</sup> The effectiveness of this therapy may depend on dose and fatty acid source. One study in Florida used flaxseed oil in horses with *Culicoides* spp. hypersensitivity and found no benefit in decreasing pruritus.<sup>34</sup> A study in Canada demonstrated that flaxseed meal was beneficial in treating pruritus in horses with *Culicoides* spp. hypersensitivity.<sup>35</sup> These apparently disparate results may be explained by geographic factors or the source of flaxseed.

## FOOD ALLERGY

Documented cases of feed-related hypersensitivity are rare in horses, and most information on this condition is based on anecdotal reports. Food hypersensitivity refers to an immune-mediated adverse reaction to a feedstuff unrelated to any physiologic effect of the feed. The pathogenesis of dietary hypersensitivity in horses is understood poorly but is believed to involve type I, type II, and type IV hypersensitivity reactions.

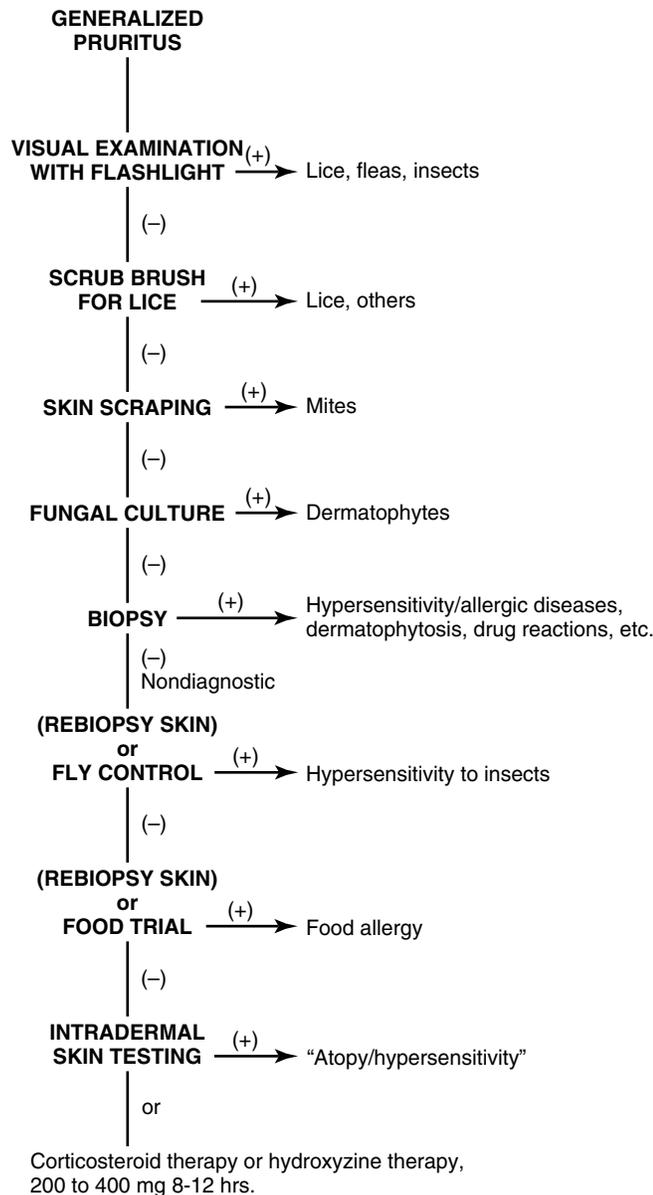

The skin, respiratory tract, and gastrointestinal tract may be affected. The most commonly incriminated foods include potatoes, malt, beet pulp, buckwheat, fish meal, wheat, alfalfa, red and white clover, St. John's wort, chicory, glucose, barley, bran, oats, and tonics.<sup>34</sup>

Dermatologic manifestations of food allergy include generalized pruritus with or without papules, urticaria, and pruritus ani. Flatulence, loose stools, heaves, or asthma may accompany skin lesions.

The diagnosis is made by eliminating the more common causes of pruritus in horses and by positive response to a food elimination trial (Figure 13-9). Hypoallergenic diets are individualized for each patient, and obtaining a thorough dietary history from the owner is critical. One must identify any change in the diet (vitamin supplements, grains, hays). A practical approach is to start by eliminating any supplements and concentrates from the diet. The trial should not include dusty feedstuffs because some horses can develop inhalant allergy to feedstuffs. The horse should be fed oats and grass hay for 4 to 8 weeks and observed whether a decrease in pruritus occurs. In the South, coastal Bermuda grass hay tends to be less allergenic than other types of hay. If the horse is notably less pruritic, one should reinstitute the previous diet to confirm that the pruritus is caused by a food allergy and that improvement was not coincidental. If food allergy is present, pruritus will return, and one should reinstitute the hypoallergenic diet until clinical signs subside. The offending substance is identified by reintroducing one dietary item at a time each week and observing the horse for recurrence of clinical signs.

## CONTACT ALLERGY

True contact allergies are rare in horses, perhaps in part because the hair coat acts as a protective barrier. Irritant contact reactions are more common (see the following discussion). Contact allergies, when they occur, are type IV hypersensitivity reactions. Potential allergens are usually small molecules that penetrate the skin, bind to dermal collagen or carrier proteins,

**FIGURE 13-9** Flowchart for diagnosis of equine pruritic skin diseases.

and are taken up by antigen-presenting cells (Langerhans cells) in the dermis. On re-exposure, an inflammatory response occurs that results in skin disease. Development of allergic contact reactions usually takes months to years.

Contact reactions most likely are related to pasture plants, changes in bedding material, insect repellents, topical medication, and tack items.<sup>1,36</sup> Parasiticides and bath oils applied as insect repellents are the most commonly identified causes of contact allergy. Repeated application of chemicals to the coat of sweating horses may lead to development of a contact allergy by compromising the protective barrier of the skin.

Clinical signs of contact allergy vary and depend on the duration of the allergic reaction. Erythema, swelling, oozing, pain, or pruritus develops within 2 to 3 days of application of the offending substance. If untreated, lesions often progress over weeks or months to alopecia, lichenification, and crusting. The distribution of the lesions may suggest the cause: legs

(plants, bedding), face and muzzle (plants, bedding), face and trunk (tack), and face, ear, neck, and trunk (insect repellents).<sup>1</sup>

A definitive diagnosis is based on provocative exposure or patch testing. Provocative exposure requires avoiding the suspect substance for 10 days or until lesions resolve, re-exposing the horse to the substance, and noting recurrence of lesions or clinical signs over the next 7 to 10 days.<sup>1</sup> Provocative testing does not distinguish between an irritant reaction and an allergic reaction but does identify the offending substance. Patch testing requires the application of the suspect substance to an area of the skin for 48 to 72 hours. Plant material, bedding, or other particulate matter does not adhere well to the skin and is tested best under an occlusive dressing (closed patch test). For each test substance, one clips a 3-cm<sup>2</sup> area of hair on the thorax or dorsum, applies a small amount of the suspect substance to the skin, and covers the site with a gauze sponge bandage for 48 to 72 hours. A control site should also be bandaged. On removing the bandages, the area is assessed for erythema, swelling, induration, pain, and exudation. Biopsies of the control should be obtained and the site or sites tested for histologic confirmation of the diagnosis. One may apply liquid substances to the skin daily and avoid using an occlusive bandage.

Successful treatment requires accurate identification of the offending substance and avoidance. If identification is not possible, one may prescribe short-term systemic corticosteroid therapy and mild cleansing shampoos.

## ☞ ATOPY

Atopy is an inherited dermatologic or respiratory condition in horses. Horses with atopy develop sensitizing antibodies, immunoglobulin E, to offending allergens. Allergens that have been implicated in this problem include molds, grasses, trees, fabrics, and dust. One or more of these allergens may be involved in an individual horse.<sup>37</sup>

Sensitizing antibodies cross-link mast cells, triggering release of inflammatory mediators with resultant inflammation in the affected target organ (i.e., skin or respiratory tract). In skin, pruritus is the end result.<sup>33,37</sup>

Arabian and Thoroughbred horses appear to be predisposed to develop atopy.<sup>33</sup> This breed predisposition suggests equine atopy may be an inherited condition. In one report a stallion and five of his offspring had atopy-induced urticaria.<sup>38</sup> A more recent California study further substantiates the idea that equine atopy is inherited.<sup>39</sup> According to this report, Thoroughbreds accounted for 25% of the horses with atopy. Interestingly, male horses were twice as likely to develop atopy when compared with female horses. The exact mode of inheritance and importance of this more recent sex difference is not known.

Atopy in horses is characterized as a seasonal to nonseasonal pruritic skin disease. Several types of skin lesions are observable, including alopecia, excoriations, crusts, scales, erythema, and hives (urticaria).<sup>40</sup> Urticaria is not always pruritic in horses. A tentative diagnosis of atopy can be made after eliminating other causes of pruritus and on positive response to exogenous corticosteroids.

The most effective way to confirm a diagnosis of equine atopy is by intradermal skin testing. One sedates the horse with xylazine at 0.05 mg/kg intravenously and clips a rectangular area on the lateral aspect of the neck. One then injects allergens known to cause allergic problems in a particular

geographic area intradermally and denotes each site of allergen injection on the skin by a dot made with permanent marker. The practitioner reads the test at specific time intervals after injection—15 minutes, 30 minutes, 4 to 6 hours, and 24 hours—then compares the negative (sterile saline) and positive (histamine 1:100,000 weight to volume) control reactions to reactions of the various allergens. The negative control is assigned an arbitrary grade of 0 and the positive control a grade of 4. One considers size of the wheal, firmness, redness, and shape when grading individual allergen reactions. Reactions greater than or equal to 2 are considered potentially significant. The history, clinical signs, and pollination times must be considered in the final determination of whether individual reactions are significant.

Certain allergens tend to cause many false-positive reactions, including alfalfa, corn, corn smut, grain dust, grain smut, black ants, mosquitoes, fire ants, *Rhizopus* spp., *Penicillium* spp., sheep wool epithelium, English plantain, red mulberry, black willow, mesquite, and dock sorrel. If a reaction occurs with one of these allergens and is inconsistent with the history and physical examination findings, it is probably an irritant reaction.

Horses with laminitis tend to have hyperresponsive immune systems and may be more likely to have false-positive skin test reactions than normal horses.<sup>41</sup> If the horse has had laminitis, skin test results should be interpreted with care.

Drugs such as corticosteroids, antihistamines, fatty acids, and those that affect vasodilation such as acepromazine may interfere with skin test results and cause false-negative reactions. To prevent this situation from occurring, one should observe drug withdrawal times. Exact withdrawal times are extrapolated from small animal medicine and applied to horses. Administering long-acting injectable corticosteroids should be avoided for 3 months before skin testing, oral or injectable dexamethasone for at least 1 month before skin testing, and antihistamines for 7 to 10 days before testing. A withdrawal time of 7 days is recommended for acepromazine.

Serum allergy testing has been recommended for diagnosis of atopy in horses. However, recent studies question the validity of this test. One study compared test results of three different serum allergy tests with intradermal skin test results in the same animal.<sup>42</sup> None of the three serum allergy tests reliably detected allergen hypersensitivity compared with results of the intradermal skin test. Serum allergy tests were not as sensitive as intradermal skin tests. At this time, in human and veterinary medicine, intradermal skin testing is considered the gold standard for confirming a diagnosis of atopy.<sup>37</sup>

Treatment of atopy should include hyposensitization whenever possible. The offending allergens are administered at a set amount and time to the horse. Many horses are treated with a maintenance schedule of 1 ml of a 20,000 protein nitrogen unit aqueous solution administered subcutaneously every 3 weeks. The exact mechanism of action for hyposensitization therapy is not known. Human beings with allergies tend to have a higher proportion of type 1 T helper cells compared with type 2 T helper cells.<sup>43</sup> After hyposensitization therapy the T helper cell populations shift toward normal. Other theories suggest that blocking antibodies are produced with hyposensitization. Regardless of the exact mechanism of action, hyposensitization therapy has been effective in human beings for more than 30 years.<sup>44</sup> The percentage of horses that respond to therapy varies and is thought to be similar to that in small animal medicine (59% to 86% effective).<sup>44,45</sup> Hyposensitization

therapy may take 1 to 12 months (average 3 to 6 months) before it starts to work. One may use corticosteroids, antihistamines, and fatty acids in the period between initiation of hyposensitization therapy and expected response.

Corticosteroids are a mainstay of therapy for allergies but have been associated with a variety of adverse effects, including polyuria, polydipsia, increased susceptibility to infection, mood changes, elevations in liver enzymes, and laminitis.<sup>46</sup> The most commonly used corticosteroids in equine dermatology are prednisolone and dexamethasone. The dosage for prednisolone for treating atopy is 0.5 to 1.5 mg/kg daily as an induction dose (usually 4 to 14 days) tapered to 0.2 to 0.5 mg/kg every 48 hours for maintenance or 200 to 400 mg/500-kg horse every 24 hours. Prednisone is absorbed poorly from the intestine of many horses after oral administration and should not be used. The recommended dosage for dexamethasone is 0.04 to 0.2 mg/kg administered orally, intramuscularly, or intravenously every 24 to 48 hours for 4 to 7 days, decreasing to a maintenance dose of 0.01 to 0.02 mg/kg every 48 hours. Another dosage for dexamethasone for treating atopy is 0.05 to 0.1 mg/kg every 24 hours either oral or injected intramuscularly or intravenously. Although the injectable dexamethasone has been used orally, the bioavailability of the injectable form of dexamethasone orally is only 60% to 70% of the injectable route. A tablet form for dexamethasone is available and appears to be effective.<sup>39</sup> Several antihistamines have been recommended for treating equine atopy.<sup>39</sup> Hydroxyzine is recommended at 200 to 400 mg orally, regardless of body mass, every 12 hours orally, 1.5 mg/kg orally every 8 to 12 hours, or 200 to 500 mg/500 kg orally every 8 to 12 hours. Other antihistamines that have been used include chlorpheniramine maleate (0.26 mg/kg every 12 hours orally), diphenhydramine (0.75 to 1 mg/kg every 12 hours orally), doxepin hydrochloride (300 to 400 mg every 12 hours or 0.5 to 0.75 mg/kg every 12 hours or 300 to 600 mg/500-kg horse orally every 12 hours), and pyrillamine maleate (0.8 to 1.32 mg/kg intravenously, intramuscularly, or subcutaneously; may be repeated in 6 to 12 hours if needed). The author has used all of these medications in horses and believes that hydroxyzine and chlorpheniramine maleate work most consistently in horses. Side effects associated with antihistamine use include sedation and behavior changes.

Fatty acids can act synergistically with steroids and antihistamines to decrease inflammation.  $\Omega$ -3 and  $\Omega$ -6 fatty acids seem to be most beneficial. They shift products of the arachidonic acid cascade from more inflammatory to less inflammatory mediators.<sup>47</sup>

Many fatty acid supplements are currently available, including Derm Caps ES (DVM Pharmaceuticals, Miami, Fla.), Derm Caps 100 (DVM Pharmaceuticals), Glänzen 3 (Horse Tech, Lawrence, Iowa), and Platinum Performance (Platinum Performance, Inc., Buellton, Calif.). The first two products are available as a capsule or liquid, whereas the last product is a powder to be sprinkled on food.

Dosage varies according to the fatty acid product used. The dosage for Derm Caps ES is five capsules every 12 hours; the dosage for Derm Caps 100 is two to three capsules every 12 hours. The dosage for the Glänzen 3 is 2- to 6-oz powder sprinkled on the food per day (not to exceed 6 oz per day). This product also contains biotin and other vitamins and minerals. The Platinum Performance is used according to label directions.

Topical treatments may be a useful adjunct therapy for horses with atopy. Various shampoos, lotions, and sprays

marketed for use in small animals may be of benefit in horses. Antipruritic ingredients may include oatmeal, aloe, pramoxine, and hydrocortisone. Combination products may be most effective. The author prefers the Relief products marketed by DVM Pharmaceuticals of Miami, Florida, that contain oatmeal and pramoxine. These products may be used daily or weekly.

## ☞ CUTANEOUS DRUG REACTIONS

Cutaneous drug reactions in horses are rare and can mimic any known skin disease. Drug reactions are believed to involve type I, II, III, or IV hypersensitivity reactions. Any therapeutic agent administered by any route may cause a drug reaction. The most commonly incriminated drugs are penicillin, streptomycin, oxytetracycline, neomycin, chloramphenicol, sulfonamides, phenothiazines, phenylbutazone, guaifenesin, aspirin, and glucocorticoids. Clinical signs vary, and pruritus may or may not be present. Urticaria is a commonly observed skin reaction. Less commonly, mucocutaneous ulceration or vesiculation may be present.

The diagnosis of a drug reaction depends on an accurate medication history. Skin biopsies may be helpful in supporting a clinical diagnosis. The most commonly reported patterns of inflammation are perivascular dermatitis and intraepidermal or subepidermal vesicular dermatitis.<sup>1</sup> One can confirm the diagnosis by provocative challenge, but this may lead to anaphylaxis or death and therefore is not recommended.

Treatment requires removal of the offending drug, symptomatic therapy, and avoiding related compounds. Drugs reactions, in general, do not respond well to glucocorticoids. A drug reaction usually subsides within 2 to 3 weeks but may last for months.

## ☞ CAUSES OF PRURITUS: CRUSTING AND EXFOLIATIVE DERMATOSES

Dermatophytosis and bacterial skin infections may cause pruritus in horses. They are recognized more commonly in the field as crusting or exfoliative dermatoses.

### COMMON CAUSES OF SCALING AND CRUSTING DERMATOSES

Exfoliative dermatoses in horses have a wide range of causes. Historical and physical findings are important in differentiating these diseases. To make a diagnosis in difficult cases

may require skin scrapings, fungal cultures, bacterial cultures, mince preparations of crusts for cytologic examination of dermatophilosis, and skin biopsies. If cost constraints are present the most useful diagnostic test is a carefully obtained skin biopsy. Not scrubbing or preparing the skin in any way before obtaining skin biopsy specimens is critical. In addition, one should take extreme care to collect the crust when obtaining a skin biopsy from a horse with exfoliative skin disease. In many instances, one obtains the causative agent or evidence of a definitive diagnosis from histopathologic examination of the crust. Figure 13-10 shows a simplified approach to the diagnosis of exfoliative dermatoses.

## INFECTIOUS CAUSES OF EXFOLIATION

### DERMATOPHILOSIS (RAIN SCALD)

Dermatophilosis is a bacterial skin disease of horses and other large animals caused by the gram-positive, facultative anaerobic actinomycete *Dermatophilus congolensis*. The normal habitat of the organism is unknown, but the organism is thought to exist in a quiescent state on carrier animals until conditions are optimal for proliferation.<sup>48</sup> Whether carrier animals act as reservoirs of infection for other animals is unknown. However, one recent report suggests that dermatophilosis in horses can be zoonotic. In this report, a young girl riding a horse that had dermatophilosis contracted the bacteria and needed to be treated for this infection.<sup>49</sup>

The development of lesions depends on chronic moisture and skin damage.<sup>1,48</sup> The organism cannot penetrate intact healthy skin, and moisture is required for release of zoospores. The skin can be damaged from chronic maceration caused by moisture, biting flies, vegetation, or underlying pruritic skin diseases. Chronic moisture is more conducive to the growth of the organism than intermittent but heavy rainfall. When these two prerequisites (moisture and trauma) are met, the organism multiplies. Moisture induces release of infective, motile, flagellated zoospores. These organisms are attracted to low concentrations of carbon dioxide and repelled by high concentrations of carbon dioxide. As the organism multiplies and inflammatory cells migrate into the area the carbon dioxide concentration in the skin increases and zoospores migrate toward the surface of the skin in search of a more suitable environment. The organism again multiplies and numbers increase. This cycle repeats until layering, crusting, and matting of the hair coat results. Zoospores remain viable in crusts at ambient temperatures of 28° to 31° C for up to 42 months.<sup>48</sup>

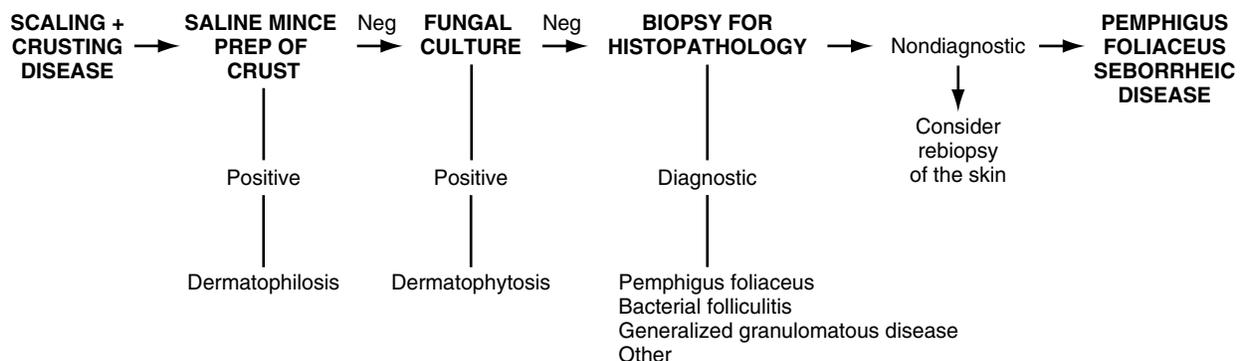

FIGURE 13-10 Flowchart for diagnosis of equine scaling and crusting diseases.

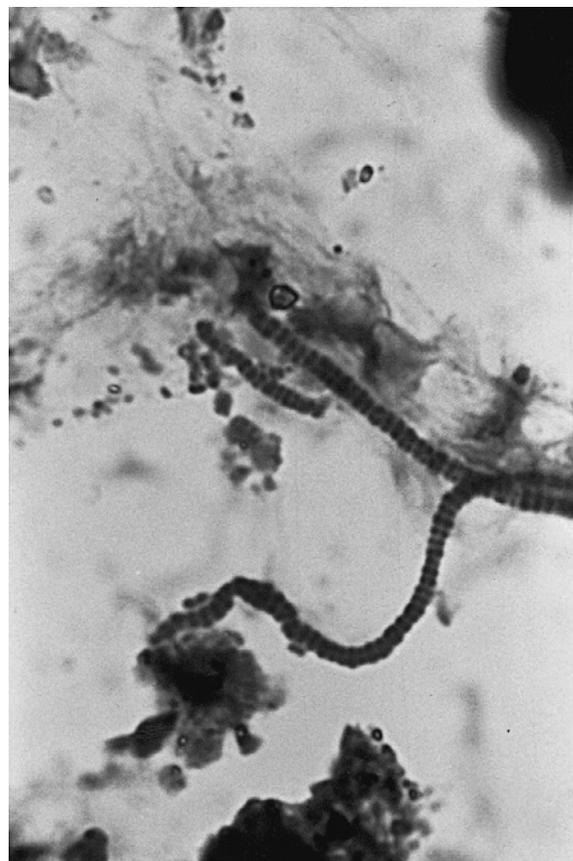

Clinical signs of dermatophilosis can develop within 24 hours. The disease has a follicular orientation, and lesions appear as crusted, moist mats of hair that can resemble small paintbrushes. Under fresh crusts, the skin is soft, exudative, and yellow-tinged. Exudative crusted lesions tend to occur on the back, gluteal area, face, neck, and distal extremities (Figure 13-11). Lesions on the limbs may cause pain, swelling, and erythema, especially in white or lightly pigmented areas. Racehorses or horses in training commonly develop abrasions on the cranial surface of the hindlegs. These lesions are prime sites for infection. Severely affected horses may be febrile, depressed, lethargic, and anorectic and have a regional lymphadenopathy.

Dermatophilosis is diagnosed by demonstration of the organism by cytologic examination of the crust or by histologic examination of a skin biopsy specimen. Dermatophilosis preparations can be made from dried or fresh crusts or from direct smears of exudate. Dried crusts are finely minced in a few drops of sterile saline, allowing the preparation to dry for 45 minutes and then staining it. A fast Giemsa, Diff Quik, or Gram stain can be used for direct smears or dried mince preparations. The organism is visualized best under 1000 $\times$  oil immersion and appears as fine-branching multiseptate hyphae with transverse and longitudinally arranged cocci (railroad track appearance; Figure 13-12). When a skin biopsy is collected from a horse with suspected dermatophilosis, submitting a specimen with the crust attached to the skin or hairs is important. Key histologic findings include folliculitis, intraepidermal pustules, intradermal edema, and alternating layers of parakeratotic (epidermal cells with retained nuclei) and orthokeratotic (keratinized epidermal cells without nuclei) hyperkeratosis with leukocyte debris.<sup>44</sup> The organism is often found only in crusts.

**FIGURE 13-11** Horse with matting of coat caused by dermatophilosis.

The practitioner may treat horses with mild infections with topical therapy alone. One should gently soak and remove crusts using a mild antibacterial shampoo such as chlorhexidine or benzoyl peroxide. Some horses for which this treatment is difficult or painful may require sedation. One should dry the horse with towels and apply a topical antibacterial sponge-on dip (chlorhexidine 1:32 dilution of 2% stock solution or lime sulfur 1:32 dilution of stock solution). Another option is a commercially prepared chlorhexidine 2% lotion (Resi-Chlor, Vibrac, Fort Worth, Tex.). This formulation is a leave-on product with residual properties. Daily shampoo therapy should continue for 5 to 7 days until healing is evident then twice weekly until all lesions have resolved. Horses with lesions on the muzzle may benefit from a topical cream with or without corticosteroids. Severely affected animals may benefit greatly from systemic antibiotics, such as procaine penicillin at 22,000 IU/kg intramuscularly twice daily for 5 to 7 days. Trimethoprim sulfa (TMS) at 10 to 15 mg/kg orally twice daily for 5 to 7 days also may be effective. In either case, one should eliminate exposure to excessive moisture and skin trauma. However, some cases of dermatophilosis do not appear to be responsive to TMS. In these cases, doxycycline at a dose of 10 mg/kg every 12 hours with food has been used and appears to be effective. In vivo sensitivity results suggest that doxycycline is a reasonable option for refractory cases of dermatophilosis.<sup>50</sup>

**FIGURE 13-12** Microscopic appearance of *Dermatophilus congolensis*.

### DERMATOPHYTOSIS (RINGWORM)

Dermatophytosis is the most common contagious skin disease in the horse. *Trichophyton equinum*, *T. mentagrophytes*, *Microsporum gypseum*, and *M. canis* are the most frequent isolates.<sup>51</sup> The infection is self-limiting but may affect the function of the horse seriously and is of zoonotic importance.

Dermatophytes are transmitted by direct contact with an infected host or by indirect contact with contaminated fomites or the environment. Illness, poor nutrition, overcrowding, age (young or old immunosuppressed individuals), and stress predispose horses to infection. Chronic moisture from sweating or the environment damages the protective barrier of the skin, enhancing the opportunity for infection. When fungal spores contact the hair coat, the spores may be removed mechanically, may be unable to compete with the normal flora of the skin, or may remain on the coat in a dormant state until conditions are optimal for infection. Dermatophytes invade keratin of the epidermis and hair with the aid of enzymes that are allergenic to the host. Dermatophytosis is considered a biologic contact dermatitis.<sup>51</sup> The incubation period is usually several weeks. During this time, fungi invade the epidermal keratin, hair follicles, and the hair shaft itself. The epidermis responds to the intruder by increasing epidermal cell turnover in an effort to remove the fungi mechanically. Clinically the response is scaling. Hair shaft integrity is compromised, and hairs fall out or are fractured easily, resulting in areas of alopecia characteristic of the disease. Infection is eliminated from a particular hair on shedding or as it enters the telogen stage, or the dermatophyte elicits an inflammatory response.

Clinical signs of dermatophytosis, including pain and pruritus, vary. The infection is follicular in distribution, and early lesions often begin as a papular eruption with erect hairs (Figure 13-13). Urticarial eruption may occur 24 to 72 hours before the owner notices the papules.<sup>52</sup> Lesions rapidly progress to crusted papules that spread circumferentially. The classic lesion is a circular patch of alopecia with stubby hairs on the margin and variable amounts of scaling (Figure 13-14). Erythema and hyperpigmentation may be present. In rare instances, dermatophytosis may cause generalized scaling without significant hair loss. If the dermatophytosis causes follicular rupture, nodules, and ulcers, or a kerion reaction

(inflammatory dermatophyte infection that may resemble an abscess) may develop. Lesions are most common in areas where tack contacts the skin but may be limited to the posterior pastern. Rarely, dermatophytes can cause coronary band disease.<sup>53</sup>

The diagnosis is made by demonstration and identification of the organism. Wood's lamp examinations are not useful for logistic reasons and, more importantly, because few cases of equine dermatophytosis are caused by *M. canis*. Direct examination of hair and scale is useful but requires special training. The most reliable tests are fungal culture and skin biopsy. The details of superficial fungal culture techniques have been reviewed elsewhere.<sup>1,27</sup> One should collect hairs for culture from the periphery of a newly developing lesion. Avoiding areas that may have been treated previously is critical. One should wipe the area gently with an alcohol swab before collecting hair samples to minimize growth of contaminants, should pluck hairs in the direction of growth, and transport them to the laboratory or clinic in a paper envelope for inoculation on dermatophyte test medium or Sab-Duets plates (Bacti-Labs, Mountain View, Calif.), the commercial fungal culture media preferred by most veterinary dermatologists. Each plate contains Sabouraud's glucose medium and dermatophyte test medium. Using both media plates greatly enhances the culturing of suspect organisms. *Trichophyton* spp. isolation improves if a few drops of B vitamin complex is added to the surface of the media and the plate is incubated at 37° C. Because *T. equinum* is supposed to be one of the more common equine dermatophytes, one should add the B vitamin complex to all equine fungal cultures. One should select skin biopsy sites with care and should not scrub or wipe the area before sampling. Early lesions with crusts are ideal. Histologic findings include folliculitis, perifolliculitis, and furunculosis; superficial perivascular dermatitis with ortho- or parakeratosis; and intraepidermal vesicular or pustular dermatitis. Septate fungal hyphae and oval spores may be present in the superficial keratin or hair follicle.<sup>1</sup>

Dermatophytosis is a self-limiting disease, and most cases heal spontaneously within 1 to 6 months. Treatment is strongly advised to minimize contagion to other animals and human beings. In horses, antifungal shampoos and sponge-on dips are the treatment of choice. The author has found the most effective topical treatment combination to be weekly

**FIGURE 13-13** Dermatophytosis. The papular eruption on the advancing edge of lesions is notable.

**FIGURE 13-14** Classic signs of dermatophytosis (ringworm).

bathing with a shampoo that contains 2% miconazole followed by a lime sulfur dip (Lym-Dyp; DVM Pharmaceuticals, Miami, Fla.), or lime sulfur dip (DermPet, Potomac, Md.) for 4 to 8 weeks. Another alternative is a miconazole and chlorhexidine shampoo (Malaseb; DVM Pharmaceuticals) followed by a miconazole and chlorhexidine rinse (Malaseb rinse, DVM Pharmaceuticals, Miami, FL). A less-expensive topical alternative that has been used is a dilute bleach solution (1:10 in water). This bleach solution is messy, odiferous, and staining. Systemic antifungal drugs, such as griseofulvin (50 mg/kg orally once daily or 100 mg/kg once daily for 7 to 10 days) or itraconazole (5 to 10 mg/kg orally once daily) are effective but expensive. Alternatively, intravenous injections of 20% sodium iodine or 250 ml/500-kg horse every 7 days for one to two treatments has also been used. This treatment is contraindicated in pregnant mares given that sodium iodine systemically has been shown to induce abortion.<sup>53</sup> In instances in which treating an infected herd is necessary or desirable, itraconazole at 5 to 10 mg/kg orally once daily for 15 days aborts the infection. Concurrent topical therapy with lime sulfur is necessary.

Elimination of dermatophytosis from single or multiple horse barns requires elimination of the organism from infected hosts and decontamination of the environment. Box 13-4 summarizes one approach to treatment. Commercial antifungal vaccines for equine dermatophytosis are not available in the United States. Autogenous vaccines are not recommended at this time because of lack of information on their efficacy and potential for serious adverse effects, including sterile abscesses, hypersensitivity reactions, generalized anaphylaxis, and death.

### BACTERIAL INFECTIONS

Bacterial folliculitis in horses is caused most commonly by *Staphylococcus* spp. *Streptococcus* spp. infections also may occur. Infections most frequently occur in the summer when heat, moisture, increased insect populations, and increased use of the horse act in concert as predisposing factors.

The pathogenesis of bacterial folliculitis in the horse is similar to that in other animals. The causative agents are normally found on the host; when the natural protective barrier of the skin is compromised, bacteria invade and multiply within hair follicles. Infection results in inflammation, destruction of the hair follicle, and shedding of the hair. As the infection spreads, lesions enlarge. If hair follicles rupture, furunculosis and deep pyoderma may result.

Clinically, bacterial folliculitis may be indistinguishable from dermatophytosis. Bacterial lesions are much more likely to be painful and are only rarely pruritic. Infection is most common in the saddle and tack area but may be limited to the pastern area. Deep pyoderma of the tail base also occurs.

The definitive diagnosis is made best by cytologic examination, bacterial culture, and skin biopsy. Differentiating bacterial folliculitis from dermatophytosis is important. Skin biopsy reveals varying degrees of folliculitis, intraepidermal pustules, and perivascular inflammation. Neutrophils are the primary inflammatory cell. Keratinocytes often show intracellular edema; parakeratosis and orthokeratosis are common in the crust. Special stains often reveal bacteria within the crusts and hair follicles.

Treatment depends on severity of the clinical signs. Mild infections may be self-limiting but benefit from topical therapy. Severe cases require daily topical antibacterial shampoos

#### BOX 13-4

### TREATMENT OF EQUINE DERMATOPHYTOSIS (RINGWORM, FUNGUS) IN MULTIPLE HORSES

In the treatment of ringworm or superficial fungal infections of the skin, one must accomplish three things:

1. Kill the fungus on the animal to stop progression of the disease.
2. Kill the fungus on the animal to prevent spread to other animals, human beings, and the environment.
3. Decontaminate the environment.

The following suggestions have been helpful when treating outbreaks in the multiple-horse barn. Fungal infections may take 6 to 8 weeks to heal completely.

1. Isolate all affected horses from normal horses.
2. Treat the barn by cleaning out all bedding and spraying stalls and exposed surfaces with 1:10 dilution of household bleach.
3. Treat all affected horses daily with lime sulfur sponge-on preparations (4 oz/gal) for 7 days and then once weekly. Treating the entire body of each horse, not just the affected areas, is vital. One should allow sponge-on preparations to dry on the horse and should not bathe horses between treatments.
4. Use individual brushes and tack for each horse. Disinfect brushes and tack frequently. Do not transfer equipment between horses.
5. Blankets should be disinfected with household bleach twice weekly or more often. Not using blankets or sheets is best to prevent enhancing the spread of the lesions.
6. Ideally, the persons who handle affected horses should not handle normal horses. If this precaution is not possible, one should handle normal horses first and then affected horses. Washing thoroughly between animals with a chlorhexidine scrub is important.
7. Ringworm is contagious to other animals and human beings; handlers should be careful to wash thoroughly and report the development of any lesions. If possible, handlers should wear gloves when handling affected horses.
8. Ideally, horses affected with ringworm should be rested from training or riding until lesions are gone. Continued riding or training may contribute to skin microtrauma and spread of infection.

Modified from client education handouts used at the College of Veterinary Medicine, University of Florida, and the School of Veterinary Medicine, University of Wisconsin.

with benzoyl peroxide or chlorhexidine and oral antibiotics. Ideally, systemic antibiotic therapy should be based on results of culture and sensitivity testing, but procaine penicillin at 22,000 IU/kg intramuscularly every 12 hours until resolution of clinical signs is usually effective.<sup>1</sup> A minimum of 10 to 14 days of therapy is recommended.

## NUTRITIONAL CAUSES OF EXFOLIATION

Nutritional deficiencies are rare in horses, and much of this information has been extrapolated from work in other species or experimentally induced deficiencies.

### PROTEIN

Protein deficiency may occur in horses with fever, dysphagia, burns, proteinuria, liver disease, gastrointestinal diseases, or any disease in which metabolic demand increases and production of protein decreases. The skin uses 25% to 30% of the daily protein intake for hair production and maintenance of the epidermis,<sup>54</sup> a requirement that may increase fivefold in disease states. In experimental deficiencies created in ruminants and laboratory animals, protein-deficient animals develop dry, dull, brittle, thin hair. Prolonged shedding also occurs.<sup>1</sup> Presumably, horses with protein-deficient diets would exhibit similar clinical signs.

### ZINC

Naturally occurring zinc deficiencies have not been reported in horses. Classically this deficiency appears as crusting skin disease. Experimentally induced zinc deficiencies in foals resulted in alopecia, dense scaling on the lower limb that progressed to the trunk, inappetence, decreased growth rate, and decreased tissue and serum zinc concentrations.<sup>1</sup> The definitive diagnosis is made by observing histologic lesions compatible with zinc deficiency (diffuse epidermal and follicular parakeratosis) and response to oral supplementation with zinc sulfate at 10 mg/kg once daily. A significant response usually occurs within 2 to 3 weeks, and therapy may or may not be lifelong.

### IODINE

Suspected iodism caused by excessive supplementation therapeutically or in feeds has been reported in horses.<sup>55</sup> Noncutaneous signs include cough, lacrimation, nasal discharge, and joint pain. Severe dry seborrhea with or without dorsal alopecia is also present. No treatment is necessary, and horses recover spontaneously on removal of the source of excess iodine.

## PARASITIC CAUSES OF EXFOLIATION

Insect hypersensitivities (discussed earlier) are the most common parasitic cause of exfoliation in horses. The major differentiating feature is the presence of pruritus, lack of a circumferentially spreading lesion, and the absence of pain. Skin biopsy findings of superficial or deep eosinophilic perivascular dermatitis with or without collagen degeneration suggest insect hypersensitivity.

## IMMUNOLOGIC CAUSES OF EXFOLIATION: PEMPHIGUS FOLIACEUS

Pemphigus foliaceus (PF) is a rare autoimmune skin disease that results in severe crusting and matting of the hair coat. An autoantibody against the glycocalyx of keratinocytes results in the release and activation of keratinocyte proteolytic enzymes into the intercellular space. The glycocalyx is hydrolyzed and intercellular cohesion is lost, leading to acantholysis.<sup>56</sup>

Pemphigus foliaceus has no age or sex predilection. Previous reports suggest that Appaloosa horses appear to be predisposed to developing PF.<sup>57</sup> However, a recent California study suggests that no breed predisposition is involved for horses

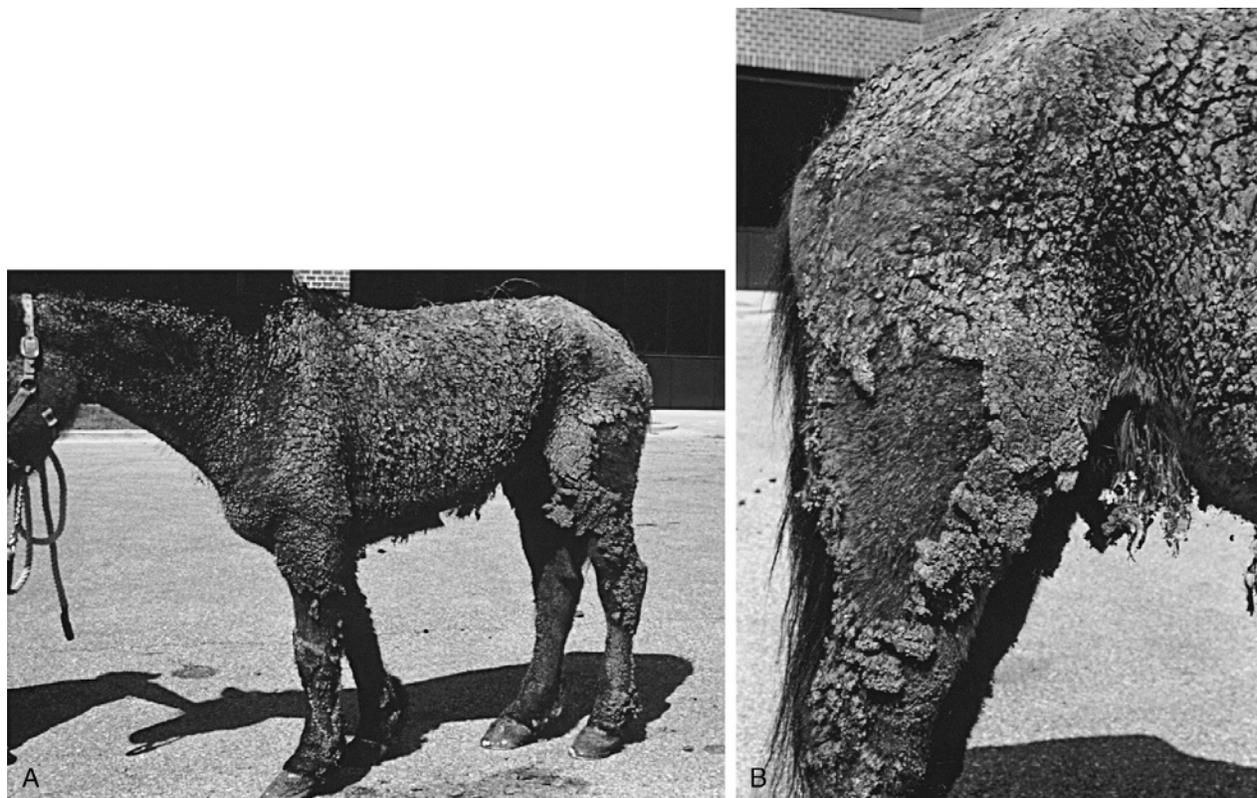

developing PF. Interestingly, this same study found a statistically significant number of horses developed PF between September and February.<sup>58</sup> The occurrence of seasonality being associated with the development of PF has suggested that an insect hypersensitivity (especially black flies or *Simuliidae* spp.) may play an important role. Another interesting finding was the development of a drug induced PF in one horse treated with trimethoprim sulfa. In humans, thiol group or sulfur molecule has been shown to trigger PF. The sulfa drugs and their metabolites bind to cell membranes as haptens to change conformation of cell-surface antigens. This change causes an inadequate cell adhesion and results in acantholysis.<sup>59,60</sup>

Lesions usually begin on the face and limbs and may take weeks or months before becoming generalized. In some horses the disease affects only the coronary band. One rarely observes the primary lesion, a subcorneal pustule, because of the hair coat of the horse. The most common clinical presentation is severe matting and crusting of the coat with oozing of serum from the skin (Figure 13-15). Most horses are depressed and show signs of systemic illness. Swelling and pain of the distal extremities, in addition to lameness, are common. Pruritus and pain on the trunk, ventral edema, and regional or generalized lymphadenopathy vary. The California PF study found that the most common early clinical sign was edema of the distal legs and ventral abdomen. In the past, the edema was thought to be caused by hypoproteinemia.<sup>58</sup> However, none of the horses with edema also had hypoproteinemia.

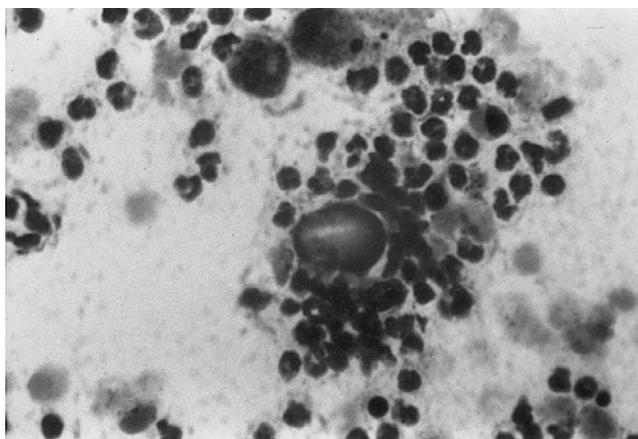

The definitive diagnosis is made by routine histologic examination of a skin biopsy specimen. Submitting a skin biopsy with intact crusts attached to the underlying skin or hairs is critical. Histologically, PF is characterized by intragranular to subcorneal acantholysis. One often observes layered rafts of acantholytic cells within crusts interspersed among neutrophils.<sup>52</sup> According to one study, approximately one third of the horses with PF will have a predominance of eosinophils in the inflammatory infiltrate.<sup>57</sup> Direct immunofluorescence is unreliable but, if positive, reveals diffuse intercellular fluorescence. One may make a tentative diagnosis of PF based on impression smears of the content of intact pustules or the underside of exudative crusts (Figure 13-16). Rafts of deeply basophilic acantholytic cells and nondegenerate neutrophils are highly suggestive of this disease.

Treatment recommendations vary depending on the age of onset for the PF. PF in horses less than 1 year of age is usually self-limiting. Spontaneous remission is common in foals, and they often do not require long-term therapy. Because treatment is difficult and often unrewarding in adults, many owners elect euthanasia.

When the owner elects to treat the horse, remission and control of the disease is induced with prednisolone at 1 mg/kg orally every 12 hours until no new lesions develop, which usually occurs within 7 to 10 days, at which point alternate-day therapy continues at the same dose. A recommended immunosuppressive dose for dexamethasone is 0.05 to 0.1 mg/kg/day or 20 to 40 mg per horse per day. Chrysotherapy (gold salts) has been used in horses but is expensive.<sup>21,62</sup> One administers two doses of aurothioglucose (Solganal; Schering Corp., Kenilworth, N.J.) 1 week apart intramuscularly, 20 and 40 mg, respectively. If no adverse effects (stomatitis, urticaria, sloughing of skin, blood dyscrasia) are observed, then one begins weekly therapy at 1 mg/kg intramuscularly until observing a response (6 to 12 weeks). Maintenance therapy is tailored to the individual animal, which may involve biweekly or monthly

**FIGURE 13-15** A, Pemphigus foliaceus in a horse. B, Skin with significant crusting.

**FIGURE 13-16** Cytologic appearance of a touch preparation from a lesion of pemphigus. Rounded cells (acanthocytes) are notable.

therapy. Complete remission of clinical signs may not be possible to achieve even with combination therapy. The most common adverse effects of aurothioglucose therapy in human beings, dogs, and cats are immune-mediated thrombocytopenia and proteinuria. Presumably, these effects could occur in the horse. Weekly monitoring of a complete blood count and urinalysis is recommended for the first month and then monthly if no abnormalities are observed. Aurothioglucose is no longer commercially available. Antedoctal reports suggest that a different gold salt, gold sodium thiomalate (Myochryline: Merck and Co., White house Station, NJ) may be used in place of the aurothioglucose. The dose and contraindications

appear to be the same for both drugs. Azathioprine has also been used as a steroid sparing drug to treat equine PF. The dose for azathioprine is 1 mg/kg/day orally for 14 days then every other day or 2.2 mg/kg every other day orally.

The survival rate for PF-treated horses is reported to be 46% (20 horses total in study). Therefore a guarded prognosis should be given to owners who have horses diagnosed with PF.<sup>58</sup>

### IRRITANT CONTACT DERMATITIS

Irritant contact dermatitis is fairly common in horses. This reaction differs from allergic contact dermatitis because the offending substance invariably causes a reaction if left in contact with the skin; prior sensitization is not needed.

The mechanism of irritant contact reaction depends on the causative chemical, but moisture and tissue maceration are important predisposing factors. Common irritating substances include feces, urine, wound secretions, caustic substances, crude oil, diesel oil, turpentine, blisters, leg sweats, improperly used insecticides, fly wipes, concentrated disinfectants, irritating plants, and soiled bedding.<sup>1</sup>

No age, sex, or breed predilection exists for irritant contact dermatitis.<sup>1,21,63</sup> Direct contact with the offending substance is required for irritant reactions to occur. Acute lesions are often erythematous, vesiculated, erosive or ulcerated, and painful. As the condition continues, necrosis, crusting, scaling, and hair loss occur. Leukoderma and leukotrichia are common and may be permanent. Pruritus and pain vary.

The diagnosis is determined from the history, clinical signs, and inspection of the environment of the horse. Provocative testing is useful in identifying and confirming the causative agent, as long as the risk is minimal to the horse.

Histologic examination of skin reveals necrosis, spongiotic vesicles, and ulceration.

Treatment requires identification and removal of the offending substance. One should wash affected areas daily with copious amounts of water and apply topical 0.5% chlorhexidine soaks. Astringent topical solutions, for example, aluminum acetate (Domeboro, available as an over-the-counter preparation), may be beneficial but often cause pain or delay wound healing. Topical antimicrobial creams free of corticosteroids may promote healing. Healing is usually rapid once the irritant is removed.

### ALLERGIC CONTACT DERMATITIS

Allergic contact dermatitis has been discussed. An important note is that allergic contact dermatitis may cause scaling and crusting in addition to pruritus. Lesions are usually distributed in a pattern that reflects the offending substance.

### PHOTODERMATITIS

Photodermatitis is caused directly by sunburn or indirectly by photoallergy or photosensitization.

#### SUNBURN

Sunburn is a phototoxic reaction caused by excessive exposure to ultraviolet B light. Horses with white or light skin or hair are at risk. Affected areas become erythematous and scaly. If sunburn is severe, necrosis and exudation may occur. The diagnosis is based on history and clinical signs. Topical glucocorticoid creams alleviate pain, but excessive use has the potential to cause minor adverse effects (depigmentation, failure, or slowing of hair regrowth) or possibly serious adverse effects (laminitis) because these drugs are absorbed systemically. Stabling horses during periods of intense sunlight and application of water-repellent sunscreens may be helpful.

#### PHOTOALLERGY

Photoallergy is believed to be caused by contact with a chemical or plant (species unknown) and ultraviolet light. The condition is observed most commonly on white muzzles and extremities of horses housed on pasture containing clover, particularly alsike clover. Erythema, vesicles, and crusts develop. The diagnosis is determined by clinical findings. If one cannot identify the offending substance and remove it from the environment, then horses should be stabled during daylight, if possible, to minimize exposure to the offending substance.

#### PHOTOSENSITIZATION

Photosensitization may develop as a result of hepatogenous photosensitization, aberrant pigmentation formation, or ingestion, injection, or topical application of a primary photodynamic agent.<sup>1,4</sup> Examples of plants known to cause primary photosensitization in horses include St. John's wort, buckwheat, perennial rye grass, and burr trefoil. Chemicals that may cause primary photosensitization include phenothiazine, thiazide, acriflavine, rose bengal, methylene blue, sulfonamides, and tetracyclines. Plants, fungi, infection, neoplasms, and certain chemicals have been associated with hepatogenous photosensitization in horses. Plants that may cause equine hepatogenous photosensitization are burning bush or fireweed, ngaio tree, rape or kale, heliotrope, ragworts, tarweed or fiddleneck, and *Crotalaria* (rattleweed). Fungi that

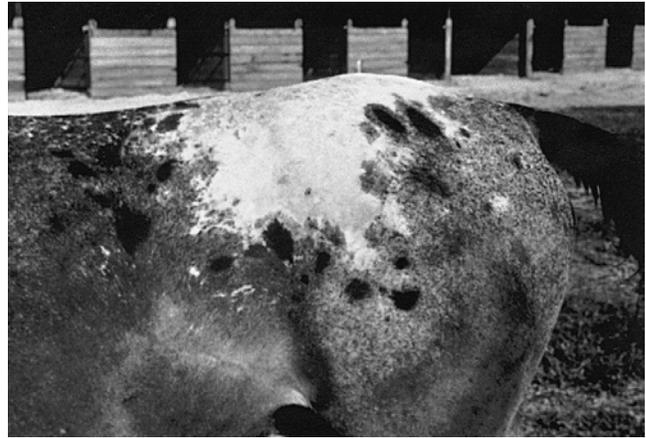

FIGURE 13-17 Horse with photosensitization.

can induce hepatogenous photosensitization in horses include blue-green algae and *Phomopsis leptostromiformis* (on lupins). A detailed discussion on the pathogenesis of liver disease and its association with cutaneous photosensitization is included elsewhere in this text.

Regardless of the source of the photodynamic agent, the pathophysiologic nature of skin disease is similar. Photodynamic agents are deposited in the skin and absorb energy when exposed to sunlight. These molecules are elevated to a high-energy state and, in the presence of oxygen, produce free radicals that damage cell membranes. Lysosomes and other organelles release hydrolytic enzymes and other mediators of inflammation.

Lesions are most common in white or lightly pigmented areas but have been observed to extend into dark-colored areas.<sup>1</sup> Eyelids, lips, face, perineum, and coronary bands are commonly affected. Usually an acute onset of erythema, edema, pruritus, and pain occurs. Vesicles and bullae may develop (Figure 13-17). Necrosis, ulceration, and crusting often occur.

The diagnosis is based on clinical signs, history, and laboratory tests. One should perform liver function tests regardless of whether the horse is showing clinical signs of hepatic disease.

Treatment requires identification of the underlying cause. Prognosis varies in horses with liver disease. Therapy requires removal of the offending substance, avoidance of sunlight, and topical or systemic glucocorticoids.<sup>1</sup>

### SEBORRHEA AND LOCALIZED DISORDERS OF KERATINIZATION AS CAUSES OF SCALING AND CRUSTING

#### SEBORRHEA

Seborrhea is a descriptive term for excessive scaling and crusting. The condition may or may not result from excessive sebum production. Most seborrheic skin conditions are secondary, resulting from dermatophytosis, dermatophilosis, or parasitic or bacterial skin diseases. The natural response of the skin to insult is proliferation as a mechanism by which to remove an offending organism or as a result of inflammation. Primary seborrhea is a disorder of keratinization in which epidermal cell turnover time and basal cell proliferation increase. Genetic factors may control these mechanisms. Secondary

seborrhea, the most common form of seborrhea, can occur in any inflammatory, infectious, or parasitic disease.

Idiopathic or primary seborrhea in horses may be generalized or localized to the tail and mane. No age, sex, or breed predilection exists. Generalized seborrhea appears clinically as diffuse matting of the coat. The texture of the coat may be oily and thick; adherent crusts may be removed easily. Oily or dry scales are present at the base of the hairs. Lesions are usually generalized and involve the face and legs (Figure 13-18). The animal is odoriferous and is not usually pruritic. Seborrhea of the mane and tail is common and characterized by crusts or scales attached to the bases of hairs. Pain and inflammation are generally absent.

Primary seborrhea is a diagnosis of exclusion. Severe generalized seborrhea must be differentiated from PF. One should perform skin scrapings, fungal cultures, dermatophilosis preparations, and skin biopsies on all suspected cases. Skin biopsies may help in determining whether primary or secondary seborrhea is present.<sup>64</sup> In early cases of generalized equine seborrhea involving little secondary inflammation, skin biopsy findings strongly suggest a primary keratinization disorder. The noncornified epidermis is not hyperplastic (thickened), but a significant orthokeratotic hyperkeratosis is attached to an epidermis of normal thickness. The superficial dermis shows only a noncornified epidermis, suggesting a keratinization defect. In horses with secondary inflammation or in which the seborrheic condition is more long standing, one may not interpret the biopsy findings as easily. The cornified epidermis is acanthotic (thickened) with significant orthokeratosis or parakeratotic hyperkeratosis. Superficial perivascular inflammation is often present in the superficial dermis.

Treatment of seborrhea involves eliminating the predisposing cause. Primary seborrhea is usually incurable, and management is symptomatic with topical therapy. The owner can usually manage a seborrheic condition satisfactorily with antiseborrheic shampoos. The owner should wash the horse with a cleansing shampoo before using a medicated shampoo. This treatment removes excess dirt and scale, improves efficacy of the medicated shampoo, and decreases the amount of medicated shampoo needed, minimizing potential for a contact reaction. The owner may use several brands of shampoo before finding a suitable shampoo for an individual patient. In general, dry seborrhea responds best to sulfur-based shampoos and oily seborrhea to tar-based shampoos. Benzoyl peroxide shampoos

FIGURE 13-18 Horse with primary seborrhea.

also work well in cases of oily seborrhea. Antiseborrheic shampoos formulated for small animals work well for horses but may be expensive. The owner should avoid human shampoos because these products are often more expensive than veterinary products and lather excessively, making rinsing difficult. Owners should allow the antiseborrheic shampoo to contact the coat for 10 to 15 minutes before rinsing. Thoroughly rinsing the horse is important, especially in the axillary and inguinal region, because shampoo residues irritate the skin. Initially, owners may need to shampoo the horse daily for 1 to 2 weeks. After the coat of the horse is normal, the owner may decrease shampooing to twice a week but must realize that therapy is lifelong. If shampoo therapy dries the coat and worsens dry seborrhea, then the owner may use a moisturizing spray or lotion.

### CANNON KERATOSIS

Cannon keratosis is an idiopathic skin disease characterized by the presence of plaques and patches of hyperkeratosis on the cranial aspect of the rear cannon bones.<sup>1,21</sup> This disorder of keratinization is uncommon and does not appear to have any recognized age, breed, or sex predilection. Clinically, well-circumscribed plaques of tightly adherent crusts and scales with or without alopecia develop over the cranial surface of the rear cannon bones. The lesions are not pruritic.

The diagnosis is usually made by clinical examination and confirmed by skin biopsy. Differentiating cannon keratosis from dermatophilosis and dermatophytosis is important. Treatment consists of antiseborrheic shampoos. Topical glucocorticoids may be useful. Topical vitamin A cream (tretinoin [Rein-A cream 0.1%; Ortho Pharmaceutical Corp., Raritan, N.J.]) may be beneficial in removing crusts and plaques.

### LINEAR KERATOSIS

Linear keratosis is an uncommon idiopathic disorder of keratinization.<sup>1,21</sup> The disease appears to be heritable, especially in Quarter Horses. Lesions develop between 1 and 5 years of age. One or more painless, nonpruritic unilateral, vertically oriented bands of alopecia and hyperkeratosis develop on the neck or lateral thorax. Lesions vary in size, ranging between 0.25 to 3.5 cm in width and 5 to 70 cm in length. Early lesions may begin as coalescing groups of papules. Lesions are not painful or pruritic.

The diagnosis usually is based on clinical signs alone. Skin biopsy reveals regular, irregular, or papillated epidermal hyperplasia with significant compact orthokeratotic hyperkeratosis.<sup>64</sup> Superficial perivascular dermatitis may or may not be present. If the linear keratosis does not interfere with the function of the horse, no treatment is necessary; surgical excision of small lesions may be curative. Topical vitamin A cream or salicylic cream may be useful in nonsurgical cases. These agents are keratolytic and may decrease the height, width, or thickness of the keratosis, allowing the horse to be used. Owners should not breed affected animals.

### IDIOPATHIC CAUSES OF SCALING AND CRUSTING

#### EQUINE EXFOLIATIVE EOSINOPHILIC DERMATITIS AND STOMATITIS

Equine exfoliative eosinophilic dermatitis and stomatitis is an idiopathic disease of horses characterized by ulcerative stomatitis, severe wasting, significant exfoliation, and eosinophil

infiltration of the skin.<sup>1,21,65</sup> The disease is also called multisystemic eosinophilic epitheliotrophic disease. No age, sex, or breed predilection exists, but lesions tend to occur more commonly in the winter than other times of the year.

Early lesions begin as scaling, crusting, exudation, and fissuring at the coronary band. Oral ulcers are usually present at this stage. Over several weeks a generalized exfoliative dermatosis develops. Hairs are epilated easily, and alopecia with multifocal areas of ulceration and exudation develops. The horse may be pruritic. Affected horses without ulcerative stomatitis have a good appetite and may even be ravenous but exhibit rapid, severe weight loss. Some horses have concurrent protein-losing enteropathy or malabsorption syndrome.

The definitive diagnosis is based on the history, physical examination, and skin biopsy. Ruling out PF and bullous pemphigoid is important. The chronic wasting nature of the disease and multisystemic signs are key to making a diagnosis. Laboratory features include hypoalbuminemia, hypoproteinemia, impaired small intestinal carbohydrate absorption, and increased activities of gamma-glutamyltransferase, serum alkaline phosphatase, and bile duct isoenzymes. A superficial and deep eosinophilic and lymphoplasmacytic dermatitis with irregular epidermal hyperplasia is present.<sup>65,66</sup> Exocytosis of eosinophils and lymphocytes and necrosis of keratinocytes occurs.<sup>1,65,66</sup> Perivascular collagen degeneration, lymphoid nodules, and a lichenoid inflammatory infiltrate may be present. Eosinophilic infiltrates of the pancreas, salivary glands, oral cavity, and gastrointestinal tract are common. Peripheral eosinophilia is usually absent.

Two horses have responded to dexamethasone at 0.2 mg/kg intramuscularly for the first 5 days, followed by prednisolone at 0.5 mg/kg orally every 12 hours for 7 days, and then 1.0 mg/kg every 24 hours for a week, followed by alternate-day therapy.<sup>1,65,66</sup> However, most horses respond poorly to systemic glucocorticoids, and the prognosis is grave. A single horse with this disease showed a partial response to hydroxyurea and dexamethasone therapy.<sup>67</sup>

### GENERALIZED GRANULOMATOUS DERMATITIS (EQUINE SARCOIDOSIS)

Generalized granulomatous disease is a rare idiopathic skin disease characterized by exfoliation, severe wasting, and granulomatous inflammation of multiple organ systems.<sup>21,68</sup> This disease has also been called equine sarcoidosis because it resembles sarcoidosis of human beings. One should avoid using this term because of possible confusion with sarcoid tumors. The cause of the disease is unknown. The disease may represent an abnormal host reaction to an infectious agent or allergen<sup>21</sup> or a nonmalignant neoplastic proliferation of cells.

No breed, age, or sex predilection exists for this condition. The skin disease begins as scaling, crusting, and alopecia on the face, limbs, and trunk (Figure 13-19). Clinical signs rapidly become generalized. Occasionally the disease is focal or multifocal in distribution.<sup>21</sup> Peripheral lymphadenopathy may develop concurrently with weight loss, muscle wasting, anorexia, exercise intolerance, and fever.

The definitive diagnosis is made by skin biopsy.<sup>21</sup> Perifollicular and middermal noncaseating granulomatous dermatitis occurs frequently with multinucleated giant cells. Neutrophils, lymphocytes, and plasma cells are present in small numbers. Granulomata are present in the superficial portion of the dermis. Granulomatous infiltrates also occur in other organs, including the lymph nodes, lung, gastrointestinal organs,

liver, and spleen. A complete blood count reveals leukocytosis, increased fibrinogen, and hyperglobulinemia. Anemia caused by chronic infection may be present.

The prognosis is grave, and no treatment exists. Horses are usually euthanized within several months. Large doses of prednisolone (2 mg/kg orally every 24 hours) may be beneficial in the early stage of the disease. Occasionally, spontaneous remission may occur.

## ☞ DISEASES CHARACTERIZED BY PAPULES AND NODULES

Many diseases are associated with single or multiple nodules in the skin of horses. Making a definitive diagnosis based on history and clinical signs alone is almost impossible. The most useful and cost-effective diagnostic test is a skin biopsy. Figure 13-20 illustrates a diagnostic algorithm for equine nodular skin disease.

### INFECTIOUS CAUSES OF NODULES

#### BACTERIAL GRANULOMATA (BOTRYOMYCOSIS)

*Botryo-* is a prefix that means “grapelike.” Horses affected with botryomycosis have clusters of nodular, grapelike lesions. Many species of bacteria have been associated with bacterial granulomata in horses; however, the most commonly isolated organism for equine bacterial granulomata is *Staphylococcus* spp.

Bacterial granulomata begin as traumatic injuries to the skin during which an infectious organism is inoculated into the dermis. A granulomatous reaction develops because the organism is capable of eliciting a response from the host, but the host is only able to contain the infection and not eradicate it. Bacterial granulomata develop in areas of previous trauma and are common on the limbs and scrotum. Poorly circumscribed, firm, draining lesions may or may not be painful. The center of the lesion may be ulcerated. In some cases, variable numbers of white to yellow pieces of particulate matter resembling grains of sand (tissue grains) may be present in the exudate.<sup>68</sup>

Confirmation of the diagnosis is made by skin biopsy, and identification of the causative organism is confirmed by bacterial or fungal culture. Histologic examination of a skin biopsy

**FIGURE 13-19** Horse with generalized granulomatous dermatitis. (Courtesy A. A. Stannard, University of California at Davis.)

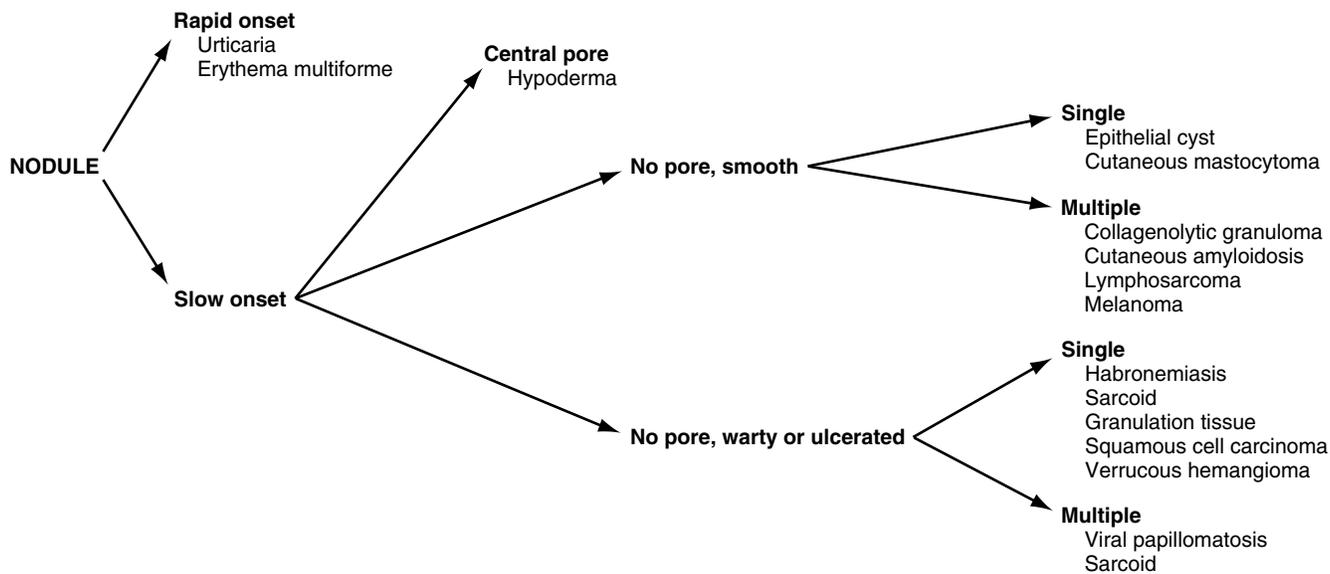

FIGURE 13-20 Flowchart for equine nodular dermatitis.

reveals nodular to diffuse pyogranulomatous inflammation with or without tissue grains. One may observe bacteria.

Surgical excision or radical debulking followed by long-term antibiotic therapy based on culture and sensitivity has been the most successful treatment for bacterial granulomata.<sup>27,68</sup> Organisms may be difficult to isolate from biopsy tissue samples, and submission of large wedges of tissue obtained at the time of surgery is recommended. If possible, tissue should be obtained to submit for aerobic, anaerobic, and deep fungal culture from the deepest portion of the lesion to increase the likelihood of isolating an infectious agent.

### CORYNEBACTERIAL INFECTIONS

*Corynebacterium* spp. are gram-positive pleomorphic rods that are associated with two clinical syndromes in horses: abscesses and ulcerative lymphangitis.<sup>27,48,69</sup>

**Abscesses** Corynebacterial abscesses occur frequently in the horse in the western United States. Lesions tend to be seasonal, occurring most commonly during the summer and fall concurrent with peak fly season, especially in dry dusty conditions. The organism is believed to be transmitted by flies, particularly horn flies. For unknown reasons, fly bites are susceptible to infection.

Lesions develop slowly and may be single or multiple. The pectoral and ventral abdominal areas are affected most commonly. These abscesses drain a creamy to caseous material that may be whitish to greenish. Pitting edema, ventral midline dermatitis, depression, fever, and lameness may be present. The course of the disease may be chronic, and recurrent internal abscesses are frequent.

The diagnosis is based on the season and the appearance of the abscess and exudate. Because identifying the organism on cytologic examination of exudate may be difficult, a culture is always recommended.

Treatment is protracted and is complicated by the limited response of the organism to systemic antibiotics. The veterinarian should allow the abscess to mature and then surgically

incise and drain it.<sup>27</sup> Systemic antibiotic use before abscess rupture may be followed by recurrence of the abscess on discontinuation of the drug. If drainage cannot be accomplished, large doses of procaine penicillin (50,000 IU/kg intramuscularly every 12 hours) for up to 6 months may be curative.<sup>27,48,68,69</sup> Toxoids and bacterins have not been useful.

**Ulcerative Lymphangitis** Ulcerative lymphangitis is an infection of the cutaneous lymphatics caused most commonly by *Corynebacterium pseudotuberculosis*. Infection is believed to begin by wound contamination. The disease occurs infrequently today.

No age, sex, or breed predilection exists. Lesions usually develop on the hindlimbs, especially at the fetlocks. Hard to fluctuant chains of nodules that abscess, ulcerate, and drain occur most commonly. Old lesions heal within 1 to 2 weeks, but new lesions develop.<sup>1</sup> The affected limb may be swollen and painful, and the horse may be depressed. Regional lymphatics appear corded. In chronic cases, permanent thickening of the tissue surrounding the regional lymphatics is common.

The diagnosis is based on the appearance of the lesion and identification of the organism. Direct smears of the exudate stained with a fast Giemsa or Gram stain and a culture and sensitivity usually confirm the diagnosis.

The practitioner must initiate treatment rapidly to prevent permanent debilitation and disfigurement. In early cases, hydrotherapy, exercise, surgical drainage, and large doses of procaine penicillin (20,000 to 80,000 IU/kg intramuscularly every 12 hours) for at least 30 days after clinical normalcy may be curative.<sup>68</sup> Nonsteroidal anti-inflammatory drugs may be beneficial. If the area becomes fibrotic and joint motion is restricted, then the prognosis is poor.

### MYCETOMATA

Mycetomata (Table 13-1) are chronic subcutaneous infections characterized by swelling, draining tracts, and tissue granules. Filamentous bacteria or eumycetic fungi (fungi that inhabit

TABLE 13-1

Fungal Diseases of Horses		
Disease	Common Causative Agents	Clinical Signs
<b>SUPERFICIAL INFECTIONS</b>		
Dermatophytosis	<i>Microsporum</i> and <i>Trichophyton</i> spp.	Circular patches or hair loss, crusting and scaling, urticaria, papules
Piedra	<i>Piedraia</i> spp. or <i>Trichosporon beigellii</i>	Black or white filamentous nodules on hair shaft
<b>INTERMEDIATE INFECTIONS</b>		
Sporotrichosis	<i>Sporothrix schenckii</i>	Papules and nodules occur along lymphatics; nodules may ulcerate, become thickened, and drain a thick brown-to red-colored exudate
Phaeohyphomycosis (chronic, subcutaneous fungal infection caused by pigmented opportunistic fungi)	<i>Hormodendrum</i> , <i>Drechslera</i> , <i>Phialophora</i> , <i>Curvularia</i> , <i>Cladosporium</i>	Single or multiple nodules; lesions may be grossly or microscopically pigmented, nonpruritic, nonpainful, and cool to the touch
Mycetoma (chronic subcutaneous infection)	Filamentous bacterial organisms and opportunistic fungi	Single or multiple nodular lesions are present; ulcerated, draining tracts are common; mycetomata discharge tissue grains in contrast to phaeohyphomycosis, which does not

the soil or vegetation) may cause mycetomata. The most common fungal organisms that cause mycetomata in horses are *Curvularia geniculata* and *Pseudallescheria boydii*. The most common bacteria isolated from equine mycetomata are *Actinobacillus* spp., *Nocardia* spp., and *Actinomyces* spp. Regardless of causative agent the organism usually gains entrance to the body through traumatic inoculation. As with other granulomatous reactions the body is able to recognize the intruder and isolate it but not to eliminate it.

Single or multiple nodules of varying sizes can occur almost anywhere on the body of the horse. The nodules often are pigmented and ulcerated and may discharge tissue grains (small sandlike particles). The tissue grains are believed to be masses of hyphae from the organism. Gross examination of the cut surface often reveals dark-brown pigment or granules scattered in yellow to pink tissue.

Distinguishing clinically among bacterial or fungal mycetomata or any number of other causes of lumps in the skin is impossible. A definitive diagnosis requires an excisional or wedge biopsy of a lesion. Histologic examination shows diffuse to nodular pyogranulomatous to granulomatous inflammation surrounding septate branching hyphae. Tissue grains are often visible microscopically. The hyphae contained in tissue grains or tissue may be pigmented or nonpigmented. Fungi are cultured best from tissue grains and, occasionally, exudate. If possible, surgical excision is curative.<sup>27</sup> Antibiotic therapy is usually ineffective, especially for fungal mycetomata.

### PHAEOHYPHOMYCOSIS

Phaeohyphomycosis (see Table 13-1), sometimes known as chromomycosis, is a chronic subcutaneous and occasionally systemic infection caused by pigmented opportunistic fungi, such as *Hormodendrum*, *Drechslera*, *Phialophora*, *Curvularia*, and *Cladosporium* species. Many of the organisms that cause fungal mycetomata can cause phaeohyphomycosis. The distinguishing difference is the lack of tissue grains. Pigmented fungi

(dematiaceous fungi) causing this disease are soil and vegetative saprophytes that gain entrance into the body via a wound or abrasion. The body is not able to eliminate the organism, which proliferates in tissues. Immunosuppression may be a predisposing factor.

Lesions appear anywhere on the body and may be single or multiple. Some lesions are pigmented deeply on gross examination, or pigmentation is only a microscopic feature. Nodules vary in size and are cool, nonpainful, and nonpruritic. Regional granulomatous dermatitis may be present.

The definitive diagnosis is made by histologic examination of an excised nodule. Skin biopsy reveals suppurative to granulomatous dermatitis with pigmented septate hyphae. Observation of pigmented septate hyphae in the skin indicates opportunistic invasion of the tissue. Fungal culture of tissue samples is necessary to identify the organism. An important note is that growth of these organisms is slow, often requiring weeks, and a reference laboratory is able to culture the organism best.

Excision is the only effective treatment but may be impractical when numerous lesions are present. These organisms are not susceptible to commonly used systemic or topical antifungal agents. However, the author has treated an affected dog successfully with itraconazole. The recommended dosage is 3 mg/kg orally every 12 hours for 1 month beyond when the skin appears normal (usually 4 to 12 months). Ketoconazole therapy is not recommended in the horse because of poor bioavailability after oral administration. Even when the solution is acidified with hydrochloric acid, bioavailability is approximately 23%.

### SPOROTRICHOSIS

Sporotrichosis (see Table 13-1) is a fungal disease caused by *Sporothrix schenckii*, a dimorphic aerobic fungus. The organism is a soil and plant saprophyte that lives in decaying vegetation and gains entrance via traumatic inoculation, especially from puncture wounds.

In horses the cutaneous lymphatic form is most common.<sup>70,71</sup> Early lesions begin as papules that may exude a seropurulent material. Nodules are most common on the thigh or proximal foreleg and chest. If the immune system does not eliminate the organism, hard subcutaneous nodules develop along the lymphatics draining the area. The lymphatics become corded and drain thick, brown to red exudate. Regional lymph nodes are not involved. Occasionally, only a solitary nodule develops. The disease rarely becomes systemic.

The definitive diagnosis is determined by demonstration of the organism via cytologic examination of exudate, culture of tissue or exudate, or skin biopsy. The organism appears as a cigar-shaped yeast in macrophages and neutrophils on Giemsa-stained smears. Histologic examination of tissue reveals nodular to diffuse, suppurative to granulomatous dermatitis. Intraepidermal microabscesses may be visible. The yeast is rarely seen in tissue sections. The number of organisms present in the tissue may vary, and repeat cultures are often necessary.

Sodium iodide (20% solution) has been successful for treating sporotrichosis in horses.<sup>21,71</sup> A loading dose of 20 to 40 mg/kg is administered intravenously for 2 to 5 days, followed by once daily oral therapy (20 to 40 mg/kg) until all clinical lesions are gone. One should administer therapy for at least 3 weeks after lesions disappear. Sodium iodide may be given orally via syringe or mixed in sweet feed. Topical hot packs of 20% sodium iodide may be used on open wounds. Iodism (see the previous discussion) may develop and may require temporary discontinuation of therapy. Iodines cause abortion and should not be used in pregnant mares.<sup>21</sup>

### PYTHIOSIS (PHYCOMYCOSIS, FLORIDA LEECHES, GULF COAST FUNGUS, AND SWAMP CANCER)

Pythiosis is caused by an aquatic fungus, *Pythium insidiosum*, common in the Gulf Coast region of the United States, South America, and Australia. This organism is a plant parasite that normally lives on aquatic vegetation or organic debris. Damaged animal tissue is chemotactic for the organism, and the fungus probably gains entrance into animal tissue via wounds in prolonged contact with contaminated water.<sup>72</sup>

The disease commonly affects ventral body areas, including legs, abdomen, and chest (Figure 13-21), and also may involve nasal tissue. Wire cuts, puncture wounds, and ventral midline dermatitis caused by horn flies or *Culicoides* gnats are prime locations. Early signs of fungal invasion include single or multiple minute foci of necrosis that progress rapidly into circular, ulcerative, granulomatous masses with serosanguinous discharges. These masses are intensely pruritic and are often hemorrhagic from self-trauma. Thick, sticky material exudes from the wound. This discharge often contains “kunkers,” hard, gritty, white to yellow masses that develop in tissue tracts and are considered a hallmark of this disease. These granules branch macroscopically, distinguishing them from granules observed in other skin diseases. Kunkers are composed of fungal hyphae, host exudate, and protein. Lameness, regional lymph node involvement, anemia, and hypoproteinemia are common noncutaneous findings. Anemia and hypoproteinemia develop after blood loss and serum exudation from the mass. Occasionally the disease may become systemic. The disease is not a known zoonosis,

FIGURE 13-21 Horse with bilateral pythiosis on the legs.

but protective latex gloves should be worn when examining patients.

Pythiosis is difficult to differentiate from habronemiasis, exuberant granulation tissue, bacterial granulomata, and invasive squamous cell carcinoma. A definitive diagnosis requires biopsy, culture, and cytologic examination of exudate and kunkers. One should submit tissue specimens and kunkers for histologic examination. Common findings include pyogranulomatous inflammation with large numbers of eosinophils. If hyphae are visible, they are 2.6 to 6.4  $\mu\text{m}$  in diameter, thick-walled, and irregular.<sup>1</sup> Pythiosis can be grown on fungal culture medium and requires incubation in a vegetable extract agar. A laboratory familiar with appropriate isolation techniques is able best to culture it. One should collect kunkers, wash them in sterile saline, and embed them deeply in the media. Occasionally, the disease can be diagnosed by cytologic inspection of the kunkers. One macerates and minces small kunkers with a scalpel, places the material on hydroxide, and stains it with India ink. Hyphae appear as black, broad, thick-walled branching structures. Recent advances in enzyme-linked immunosorbent assays and molecular techniques offer a better potential for organism detection and identification.<sup>73</sup>

The prognosis is poor because treatment is difficult. With early diagnosis, surgical excision may be possible. However, relapses are common, and repeated excision may be required. One should monitor surgical sites closely for evidence of recurrence manifesting as focal areas of edema in the granulation tissue with dark hemorrhagic patches 1 to 5 mm in diameter and serosanguinous discharge.

Systemic antifungal drugs are not effective in treating this disease.<sup>72,74</sup> Systemic amphotericin B (Fungizone IV; Bristol-Myers Squibb, New Brunswick, N.J.) combined with

topical amphotericin B may be curative in rare, isolated cases. Amphotericin B is administered at a dose of 0.3 mg/kg in 5% dextrose intravenously daily until reaching a total dose of 350 mg. One then administers this dose on alternate days until the horse is cured. In addition, one treats lesions topically with gauze dressing soaked in an amphotericin B and DMSO solution (50 mg amphotericin B, 10 ml sterile water, and 10 ml DMSO). One may also inject amphotericin B into the lesions. Amphotericin B is nephrotoxic, and serum creatinine and serum urea nitrogen concentrations and hydration should be monitored daily. Immunotherapy with phenolized, ultrasonicated proportion from fungal culture is reportedly curative if administered early in the course of the disease. In a small number of cases, vaccine administration resulted in a decrease in the size of the lesion. This therapy may be of benefit if used preoperatively to enhance complete removal of the infected tissue. Unfortunately the vaccine is not commercially available. Because of the cost of medical or surgical therapy the risks of treatment, and because of the high probability that excision is incomplete, owners often elect euthanasia.

### PARASITIC CAUSES OF NODULES

A variety of parasites may infest equine skin and cause cutaneous nodules. Some of the more common causes of parasitic nodules in the horse are warbles, cutaneous habronemiasis, and ticks. The last two have been discussed previously and are not covered in this section.

Warbles occasionally occur in horses and are caused by a larval stage of *Hypoderma bovis* and *Hypoderma lineatum*. In horses, larvae do not usually complete their life cycle.<sup>24</sup> Horses that develop infestation are usually pastured or housed with cattle. Adult flies lay eggs on the hairs, and larvae migrate toward the skin surface and eventually penetrate the skin. Once in the body of the host, the larvae migrate to reach the subcutaneous tissues of the neck and trunk. A swelling develops at the site of the larvae, which eventually becomes perforated as a breathing pore is formed. Nodules are visible most commonly over the withers, and almost all develop a breathing pore. The nodules are often painful. Spontaneous rupture may cause anaphylaxis.<sup>24</sup> Occasionally, aberrant migration causes neurologic signs.

The presence of dorsal swelling or a nodule with a breathing pore is diagnostic. The major differential consideration is collagenolytic granuloma; however, these nodules lack a breathing pore. Hypodermiasis is treated by gently enlarging the breathing pore surgically and removing the grub, removing the entire nodule surgically, or allowing the grub to fall out spontaneously. In areas of high occurrence, one may use pour-on insecticides as a preventative. Horses should be treated at the same time of year as affected cattle are treated in the area.

### URTICARIA

Urticaria is a nodular skin disease of horses characterized by wheals, edema, and often pruritus (Figure 13-22) and most commonly is caused by a type I hypersensitivity reaction. However, urticaria may also result from nonimmunologic factors such as pressure, sunlight, heat, exercise, stress, and drugs. Prerace stress, insect or arthropod bites, bacterial infections, topical parasiticides, systemic drugs (penicillin, phenylbutazone, aspirin, guaifenesin, phenothiazine, quinidine,

**FIGURE 13-22** Urticaria in a horse following administration of penicillin.

streptomycin, oxytetracycline), feedstuffs, soaps, leather conditioners, vaccines, snake bites, inhalants, and plants can cause urticaria in horses. In the author's experience, urticaria is a common manifestation of insect hypersensitivity and atopy. Mosquito swarmings commonly result in urticaria.

No age, sex, or breed predilection exists for urticaria. Lesions may develop rapidly or slowly and may be localized or generalized. Lesions are raised, cool to the touch, pit when depressed, and may or may not exude serum or blood. Pruritus varies. In rare instances, lesions may coalesce to form bizarre patterns.

Although urticaria is usually recognizable, its cause can be difficult to identify. The cause of an acute urticaria episode (<6 weeks in duration) is much more likely to be identified than the cause of a chronic episode (>6 weeks in duration). A detailed history is critical. Important questions to answer are listed in Box 13-5.

In cases in which lesions are bizarre in appearance, chronic, or exudative, one should perform a skin biopsy to rule out other causes of nodular disease. Typical histologic findings for urticaria include vasodilation, edema in the dermis, and mild to moderate eosinophilic perivascular inflammation. Complete blood cell counts and serum chemistry profiles are rarely useful. Before beginning expensive or involved diagnostic testing, one should be sure to rule out the possibility of allergic reactions to shampoos, tack cleaners, soaps, and so forth. All horses with chronic urticaria should undergo a food trial, be moved to a new environment for 5 to 7 days, and undergo a program of insect control before being referred for intradermal skin testing. Intradermal skin testing is the best method for identifying the cause of allergic inhalant dermatitis. Horses should not receive antihistamines or tranquilizers for 1 week or corticosteroids for 4 weeks before intradermal skin testing.

Treatment is aimed at eliminating the underlying cause, if possible. Hydroxyzine at 200 to 400 mg orally every 12 hours is effective in eliminating urticarial swellings in most horses with acute or chronic urticaria.<sup>35</sup> Transient sedation of several days may occur with this drug. If the horse is nonresponsive to hydroxyzine, prednisolone at 1 mg/kg or dexamethasone at 0.02 to 0.1 mg/kg orally, intravenously, or intramuscularly may be beneficial on a short-term (<1 week) basis.

## BOX 13-5

## QUESTIONS USED TO DIAGNOSE URTICARIA

1. Is this a corticosteroid-responsive urticaria? A positive answer would indicate an allergic cause such as atopy, insect hypersensitivity, or food allergy.
2. Does the development of the lesion correlate with the administration of systemic drugs or the application of topical medications? A positive answer would suggest a drug reaction.
3. Does the application of fly repellent aggravate or alleviate the urticaria? Worsening of the urticaria suggests an allergic contact reaction, whereas alleviation suggests an insect hypersensitivity.
4. Do the lesions resolve with stabling the horse for 24 to 48 hours or moving to a new environment? A positive answer would suggest an environmental cause of the urticaria (molds, inhaled dust from bedding, hay, feedstuffs, feathers from roosting birds).
5. Do lesions improve if the horse is moved off pasture? A positive answer would suggest plant antigen as a cause of the urticaria.
6. Do the lesions improve if the feed is changed? Improvement in clinical signs suggests an ingested allergen or inhaled allergen from feedstuffs.

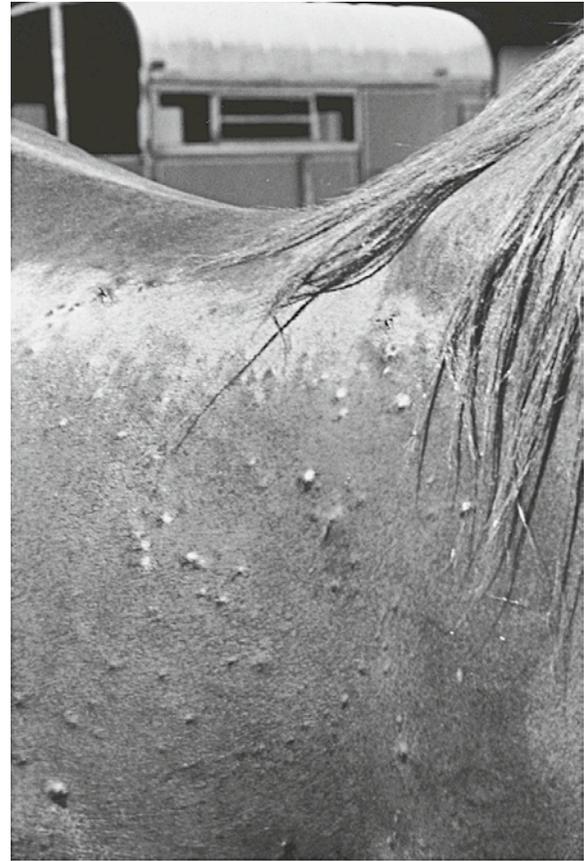

FIGURE 13-23 Horse with multiple eosinophilic granuloma.

## IDIOPATHIC INFLAMMATORY CAUSES OF NODULES

### EOSINOPHILIC COLLAGENOLYTIC GRANULOMA (NODULAR COLLAGENOLYTIC GRANULOMA AND NODULAR NECROBIOSIS)

Eosinophilic collagenolytic granuloma are a frequent cause of nodules in the skin of horses. The exact cause of these lesions is unknown, but they may result from a hypersensitivity reaction to insect bites.<sup>1</sup> Lesions, however, have been reported to develop spontaneously or as a result of trauma, suggesting multiple causes.<sup>75</sup> Regional variability in the occurrence of lesions has been noted.

These lesions have no sex, breed, or age predilection but occur most commonly in warmer months. They may be single or multiple and vary greatly in size (0.5 to 10 cm in diameter). The nodules may occur anywhere on the body but are most common on the neck, withers, and dorsal trunk (Figure 13-23). Individual lesions are rounded, well circumscribed, firm, haired, nonpainful, and nonpruritic. Owners of horses with seasonal problems have reported that early lesions are often soft and fluctuant and develop into firm masses over weeks to months. If lesions are under the saddle, then the horse may exhibit pain.

The definitive diagnosis is made by skin biopsy. Histologic examination of tissue reveals multifocal areas of collagen degeneration surrounded by granulomatous eosinophilic inflammation. Chronic lesions may have significant dystrophic mineralization.<sup>64</sup>

Solitary lesions that do not cause the horse discomfort require no treatment. Problem lesions respond to excision

or sublesional injections of triamcinolone acetonide (3 to 5 mg per lesion) or methylprednisolone acetate (5 to 10 mg per lesion).<sup>1</sup> One should inject no more than 20 mg per horse of triamcinolone acetonide because of the danger of laminitis. Horses with multiple lesions may be treated with prednisolone orally at 1 mg/kg once daily for 2 to 3 weeks. After lesions have resolved, the dose of prednisolone should be tapered and discontinued over a 5- to 10-day period. Horses with seasonal recurrences in which insect hypersensitivity is involved and documented via intradermal skin testing might benefit from hyposensitization to insects.

### EQUINE AXILLARY NODULAR NECROSIS

Equine axillary nodular necrosis is a rare idiopathic skin disease of horses. The disease is similar to equine eosinophilic granuloma with collagen degeneration, except that the lesions are localized to the axillary region.<sup>29</sup>

The condition has no known age, sex, or breed predilection. Clinically, single or multiple nodules develop unilaterally in the axillae. The nodules are painless, nonpruritic, haired, well-circumscribed firm masses that vary in size from 0.5 to 4.0 cm or greater in diameter. Multiple lesions tend to be arranged in a row.

Skin biopsy is diagnostic. Biopsy findings include pyogranulomatous, eosinophilic dermatitis with foci of coagulation necrosis. Collagen degeneration is not a common finding.

Treatment is the same as that for equine eosinophilic granuloma. Corticosteroids often do not work well, and surgical excision may be necessary. Lesions tend to recur.

**FIGURE 13-24** Horse with unilateral papular dermatitis. (Courtesy V. Fadock, University of Florida.)

### EQUINE UNILATERAL PAPULAR DERMATOSIS

Equine unilateral papular dermatitis is a rare idiopathic skin disorder of horses.<sup>76</sup> This disease has been seen in several breeds of horses but may be more common in Quarter Horses. Lesions develop in the warm months and are characterized by the unilateral development of multiple (30-300) papules and nodules on the trunk (Figure 13-24). Lesions are firm, well circumscribed, nonpainful, and nonpruritic.

The diagnosis is made by skin biopsy. Histologic examination of tissue reveals eosinophilic folliculitis and furunculosis. Spontaneous remission may occur; otherwise, prednisolone at 1 mg/kg orally once daily for 2 to 3 weeks is recommended until nodules resolve. Relapses may occur.

### NEOPLASTIC CAUSES OF NODULES

Reviewing all of the neoplastic skin conditions of horses is beyond the scope of this chapter. Only the skin tumors of horses that commonly masquerade as nodules are discussed: sarcoids, melanomas, mast cell tumors, and cutaneous lymphoma. One can diagnose some cutaneous neoplasms via exfoliative cytologic examination, but biopsy is the diagnostic test of choice.

### SARCOIDS

Sarcoids are the most common skin neoplasms in horses, accounting for up to one third of all reported tumors in horses. Sarcoids are locally invasive fibroblastic neoplasms.<sup>21,27,77-79</sup>

The cause of equine sarcoids is controversial; currently the papovavirus is believed to be involved in the development of lesions.<sup>27,76,77</sup> Polymerase chain reaction nucleotide sequences strongly suggest that equine sarcoids are caused by bovine papillomavirus types 1 and 2.<sup>78</sup> Evidence for this suggestion

**FIGURE 13-25** Fibroblastic (proliferative) sarcoid.

includes the clinical observations that lesions often develop in areas of previous trauma, lesions may spread to other areas on the same horse or to other horses, epizootics of equine sarcoid have been described, and autotransmission is possible under experimental conditions. Equine sarcoids were produced in donkeys inoculated experimentally with bovine papillomavirus. A predisposition or susceptibility also appears to play a part in the pathogenesis. Equine sarcoids occur with increased incidence in certain families, and a genetic link with specific major histocompatibility complex genes (W13 MHC class II antigen) has been demonstrated. Exposure to the virus and genetic susceptibility are probably required for a horse to develop sarcoids.

No sex or breed predilection exists, but greater than 70% of sarcoids develop in horses less than 4 years of age. They may arise spontaneously or at a site of previous trauma and may occur anywhere on the body. Sarcoids have a predilection for the head, ears, and limbs. One third of affected horses have multiple lesions.

Equine sarcoids may be classified as nodular sarcoids, fibroblastic sarcoids (Figure 13-25), verrucous sarcoids, occult or flat sarcoids (Figure 13-26), malevolent sarcoids, and mixed sarcoids. Each type of sarcoid differs clinically in its morphologic appearance and lesion location.<sup>21</sup> Nodular sarcoids are firm, raised, circular nodules that are 5 to 20 mm in diameter and tend to occur on the sheath or groin areas and the eyelids. Fibroblastic sarcoids resemble proud flesh (proliferative, fleshy, and ulcerated lesion) and are usually located around the groin, lower limbs, coronet, and eyelid. Verrucous sarcoids

**FIGURE 13-26** Flat sarcoid.

are warty and tend to occur on the face, body, and sheath or groin areas. Occult sarcoids normally appear as flat, circular, hyperkeratotic areas. Occult sarcoids may also appear as one or more small nodules 2 to 5 mm in diameter. The typical lesion location for occult sarcoids is the neck, mouth, eyes, and the medial aspects of the forearm and thigh. Malevolent sarcoids are locally invasive tumors with multiple nodules and a fibroblastic character. Some malevolent sarcoids infiltrate lymphatics and produce a cordlike appearance. Although local lymph nodes are enlarged, no evidence of sarcoid tumor has been detected within the lymph nodes themselves. Mixed sarcoids consist of sarcoid lesions that appear as a confluence of several different types of sarcoids. Mixed sarcoids contain verrucous- or occult-type tissue along with fibroblastic- or nodular-appearing tissue. This type of sarcoid is more common in long-standing sarcoid lesions or lesions that have experienced minor trauma.

A skin biopsy is the only way to diagnose an equine sarcoid definitively. Flat or small verrucous forms may become more aggressive after a biopsy. For this reason, some veterinarians are reluctant to take a biopsy sample of these lesions.

The histologic pattern observed with equine sarcoids is a fibroblastic proliferation of cells that form whorls or interlacing bundles.<sup>64</sup> The usual overall orientation of this proliferation is perpendicular to the basement membrane, but exceptions exist. The epidermis, when present, is hyperplastic with characteristic elongated rete ridges, but normal or even atrophic epidermis with significant hyperkeratosis can occur (flat sarcoids).

Several different treatments are described for managing equine sarcoids.<sup>21,79</sup> Previous experience suggests that the best treatment for occult and verrucous sarcoids is benign neglect. These types of sarcoids become more aggressive after biopsies have been performed. For fibroblastic sarcoids the treatment of choice is cryotherapy along with surgical debulking of the tumor. The inclusion of cryotherapy in the treatment regimen is associated with a lower rate of recurrence than with surgery alone (30% to 40% recurrence rate for cryosurgery versus 50% to 64% recurrence rate with traditional surgery). Adverse effects associated with cryosurgery include swelling, hyperemia, hemorrhage, necrosis, and local edema after treatment. Average healing time after cryosurgery is 2.4 months, with a range of 1 to 3.5 months. Cryotherapy usually destroys hair

follicles in the treated area, and hair regrowth is white. If cortical bone accidentally freezes, then the strength of the bone may decrease by 70%. For lesions around the eyes, recommended treatment is surgical debulking of the tumor followed by injections with bacille Calmette-Guérin (BCG) vaccine or mycobacterial cell wall products. BCG vaccine is thought to work by stimulating the immune response of the host to sarcoid cells. Mycobacterial antigens are thought to stimulate host lymphocytes and also may stimulate an increase in natural killer cells. The tumor is injected with BCG vaccine every 2 to 3 weeks for four treatments. One should pretreat horses with flunixin meglumine and prednisolone 30 minutes before using BCG vaccine to help reduce the risk of anaphylaxis.

Local radiation therapy using a variety of implants also has been recommended for treating equine sarcoids. This form of treatment is limited to smaller lesions because radiation does not effectively penetrate deeper skin lesions. Relapse rates with this form of therapy vary from 0% to 50%. Some disadvantages of radiation therapy are that the horse must be kept in a radiation-approved area, and cost may be significant if the tumor is large.

Cisplatin (Platinol; Bristol-Myers Squibb, Princeton, N.J.) in oil has recently been described as a treatment for horses with sarcoids. This treatment may be up to 100% effective but requires multiple intralesional injections. Emulsions are made of equal volumes of an aqueous solution of 1 mg cisplatin per milliliter of sesame or almond oil. A dose of 1 mg cisplatin per cubic centimeter of tumor is suggested. With denser sarcoid tumors, injecting cisplatin solution into the tumor may be difficult. Precautions recommended when using cisplatin include wearing gloves and protective clothing. One should place all material in a biohazard container after use and should use a Luer-Lok syringe and extension set to help minimize potential human exposure. Local skin reactions may occur when cisplatin contacts the skin and mucous membranes and, if this occurs, the area should be thoroughly washed with soap and water. One should avoid using cisplatin in patients with renal impairment or in breeding animals. Cisplatin is associated with teratogenic and embryotoxic reactions in mice and azoospermia and impaired spermatogenesis in human beings.

Another recently described therapy for equine sarcoids is a topical treatment known as Xxterra (Larson Laboratories, Fort Collins, Colo.).<sup>76</sup> This product contains a caustic substance and an extract of the bloodroot plant. Native Americans have used the bloodroot plant to treat a variety of conditions including warts. This product is thought to work by changing the antigenicity of the sarcoids so that the body recognizes these cells as foreign and produces antibodies against them. One applies Xxterra (while wearing gloves) to the sarcoid lesion and places a bandage over it for 4 days. If the sarcoid has not sloughed by 4 days, the treatment should be repeated. If one cannot bandage the area with the sarcoid, then the product should be applied to the sarcoid daily for 4 days or until sloughing occurs. Interestingly, when this product was applied to normal skin nothing happened, but when the product was applied to a sarcoid, the skin became inflamed and the sarcoid sloughed. An exception to this rule is pigmented skin. If freckles are present on the skin, Xxterra may react with them. Horses with mixed coat colors or Paint Horses have not had problems with this tissue reaction. Application of Xxterra to the ears may result in crinkling of the ears. If this reaction would be an unsatisfactory side effect for the owner, then a different treatment should be used. In addition, the veterinarian should

warn owners that the treated area may ooze a purulent material and become malodorous, which often occurs before the tissue sloughs.

Other therapies for equine sarcoids that have been used with success are limited in their use because of expense and availability. Examples of such treatments include radiofrequency-induced hyperthermia, carbon dioxide laser surgery, and immunotherapy using a tumor vaccine. With time, these therapeutic options may become more readily available and accepted.

Regardless of the form of therapy chosen the client needs to be aware that sarcoid tumors tend to recur. Verrucous or flat tumors are best left untreated.

### MELANOMAS

Melanomas may arise from dermal melanocytes or melanoblasts and may be benign or malignant. These tumors occur most commonly in older horses of Arabian and Percheron breeding. The relationship between development of melanomas and gray coat color is recognized widely.<sup>80</sup> Melanomas appear to occur exclusively in horses that are gray or become dapple-gray with age. Up to 80% of gray horses more than 15 years of age are estimated to have melanomas.<sup>81</sup>

Lesions may be solitary or multiple and occur most commonly on the perineum or ventral surface of the tail. Tumors are usually firm and nodular and may be hairless and ulcerated. They are almost always black. Vitiligo may precede the development of the lesions.<sup>80</sup> Three growth patterns have been described: (1) slow growth without metastasis, (2) slow growth with sudden metastasis, and (3) rapid growth and malignancy from the onset.

The diagnosis is usually based on clinical signs. Biopsy is not usually needed to confirm the diagnosis unless the lesion is bizarre in appearance.

No treatment is needed unless the melanoma interferes with function. Cimetidine (Tagamet; GlaxoSmithKline, Middlesex, United Kingdom) at 2.5 mg/kg every 8 hours has been reported to cause partial to complete regression of some melanomas. The number and size of the melanomas decreased by 50% to 90% in horses treated for 3 months. After tumors have regressed, daily maintenance therapy at 1.6 mg/kg orally once daily is recommended.<sup>82</sup>

### MASTOCYTOMA (MAST CELL TUMOR)

Mast cell tumors are uncommon in horses. Equine mast cell tumors are five times more common in males than females. Arabian Horses appear to be predisposed to developing mast cell tumors. The breed that is least predisposed to developing mast cell tumors is the Thoroughbred.<sup>1,29</sup> No age predilection exists for equine mast cell tumors.

Two distinct types of mast cell tumors in horses are a hyperplastic type and a neoplastic type. Most equine mast cell tumors are hyperplastic. Clinically, two forms of equine mast cell tumors exist.<sup>1</sup> The most common form is a single cutaneous nodule, often located on the head (Figure 13-27). Nodules range in size from 2 to 20 cm in diameter. The surface of the nodules may be normal, hairless, or ulcerated. Alternatively, mast cell tumors may cause diffuse swelling on a lower extremity, usually below the carpus or hock. The swelling is firm, and the overlying skin is normal in appearance. Radiographs of the limb commonly show multifocal areas of soft tissue mineralization.<sup>64</sup>

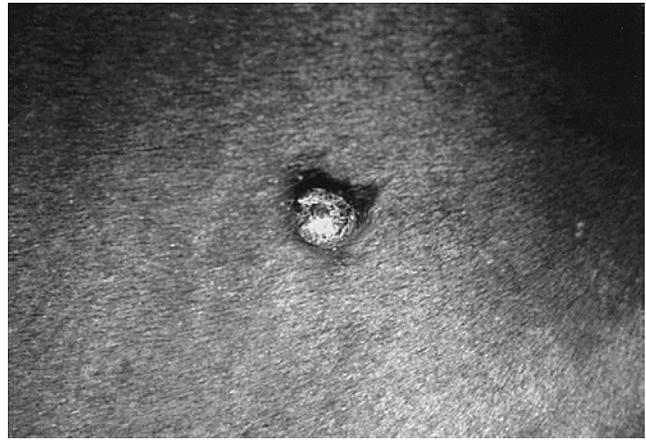

FIGURE 13-27 Hyperplastic mast cell tumor in a horse.

The diagnosis is determined by biopsy. Diffuse to nodular proliferations of mast cells occur in the dermis. Tumor cells may be well differentiated or more atypical. Tissue eosinophilia, collagen degeneration, and dystrophic mineralization occur commonly in horses.

One may treat solitary tumors by excision, with sublesional triamcinolone acetonide (5 to 10 mg per lesion), or with cryosurgery. Spontaneous remission may occur after incomplete excision or in young horses. Metastasis has not been reported.<sup>29</sup>

### CUTANEOUS LYMPHOMA

Systemic cutaneous lymphoma is discussed in detail in Chapter 14. Cutaneous lymphoma is rare in horses.<sup>75,83</sup> No age, sex, or breed predilection exists for this tumor. Lesions develop slowly or rapidly. They may occur anywhere on the body, but the trunk and neck are affected most commonly. Individual lesions may be firm or fluctuant, resembling urticaria. The overlying skin is usually normal. Involvement of internal organs may occur.

A definitive diagnosis is made by histologic examination of a skin biopsy. One should submit several representative tissue samples for examination. Histologically, lymphosarcoma is characterized by diffuse dermal and subcutaneous infiltration of malignant lymphocytes.<sup>1</sup>

If the owners want to pursue treatment, several options are available. Prednisolone at 1 mg/kg orally once daily for 7 days and then every other day has been used successfully. In addition, PEG-l-asparaginase at 10,000 IU/m<sup>2</sup> once weekly may be beneficial, although expensive. Recently, low-dose cyclophosphamide and immunization with vaccinia virus-infected autologous tumor cells was successful in inducing a 19-month remission in a 13-year old horse; however, this therapy is experimental.<sup>84</sup>

### PSEUDOLYMPHOMA

Pseudolymphomata are common in horses compared with lymphomata.<sup>1</sup> Differentiating the two diseases is important because the prognosis for pseudolymphoma is excellent.

Pseudolymphomata are nodular to papular lesions that develop in the skin as a result of chronic antigenic stimulation. The most common antigenic stimuli are believed to be insect bites and drug reactions. Lesions occur most commonly in late summer and fall and are usually solitary but may be

multiple.<sup>1,83</sup> Pseudolymphomata usually occur on the head and trunk. Individual lesions are firm, raised, and haired.

A definitive diagnosis is made by a skin biopsy. Histologic examination of tissue shows dense dermal and subcutaneous infiltration of lymphocytes, histiocytes, plasma cells, and eosinophils. Lymphoid nodules and eosinophils are present and are an important aid in the differentiation of pseudolymphoma from lymphoma.<sup>64,83</sup>

Pseudolymphomata often spontaneously regress but may be excised surgically or injected sublesionally with triamcinolone acetonide at 3 to 5 mg per lesion, not to exceed a total dose of 15 to 20 mg.<sup>83</sup>

## CONGENITAL CAUSES OF NODULES

### DERMOID CYSTS

A dermoid cyst is a tumor of developmental origin consisting of a wall of fibrous tissue lined with stratified epithelium containing hair follicles, sweat glands, sebaceous glands, nerves, or any combination of these. Dermoid cysts may be congenital or hereditary, have been reported in horses 6 months to 9 years of age, and are common in Thoroughbreds.<sup>85</sup> They occur frequently on the dorsal midline between the rump and withers. The cysts appear as soft, fluctuant swellings with normal overlying skin. The diagnosis is made by histologic examination after excision.

### ATHEROMA (FALSE NOSTRIL CYST)

An atheroma is a cyst in the false nostril. These lesions are believed to develop from hair follicle retention cysts or from displaced germ material.<sup>82</sup> Atheromata are present at birth, are usually unilateral, and enlarge with time. They are not usually noticeable until they enlarge to greater than 2 cm. The tumor is firm on palpation but is rarely painful.

The diagnosis is based on clinical signs. Treatment is not necessary unless the tumor compromises breathing or the owner is disturbed by the lesion. Surgical excision is the treatment of choice, but one must take care to remove the entire cyst, lest recurrence or chronic drainage occur.

## DISORDERS OF PIGMENTATION

Skin and hair color depend on melanin production in the skin. Melanocytes produce pigment at the dermal-epidermal junction and in the outer root sheath of the hair follicle. The ratio is one melanocyte for every 10 to 20 keratinocytes. Melanin pigments have a wide range of colors, including black-brown eumelanins, yellow-red pheomelanins, and a range of intermediate pigments. Special tyrosinase-rich organelles called melanosomes, which are found in the cytoplasm of melanocytes, produce melanin pigment. Tyrosine is converted to dopa, which is oxidized to dopaquinone. The copper-containing enzyme tyrosinase catalyzes both reactions. Subsequent intermediate products polymerize, eventually forming melanin. Melanocytes secrete or inject melanosomes into adjacent keratinocytes. Production of melanin is controlled by genetics, hormones, local keratinocytes, and Langerhans cells. Ultraviolet light, inflammation, by-products of the arachidonic acid cycle, androgens, estrogen, glucocorticoids, and thyroid hormone also may influence pigmentation.<sup>83</sup>

The number, size, type, and distribution of melanosomes determines skin and hair color. Melanosomes are responsible

for coat color, photoprotection, free radical scavenging, and heat conservation.

## CAUSES OF HYPERPIGMENTATION

Hyperpigmentation is almost always an acquired change. The skin and hair may become hyperpigmented. The usual cause of localized or patchy hyperpigmentation is chronic inflammation or irritation. Macular patches of noninflammatory hyperpigmentation, called lentigo, can occur in horses. Lentigo occurs most frequently at mucocutaneous junctions. The most important differential diagnosis for lentigo is cutaneous melanoma. A skin biopsy of the affected area is the most useful diagnostic test. Generalized hyperpigmentation of the coat or skin has not been reported; however, if observed, the condition may suggest an underlying hormonal disorder.

## CAUSES OF HYPOPIGMENTATION

Hypopigmentation is a decrease in normal melanin pigmentation. Depigmentation specifically refers to a loss of preexisting melanin. Leukoderma and leukotrichia are clinical terms used to describe the loss of color in skin and hair, respectively. Amelanosis is a total lack of melanin.

### ALBINISM AND LETHAL WHITE FOAL DISEASE

Albinism is rare in horses and is transmitted by an autosomal dominant gene. Affected animals have white skin and hair, hypopigmented irides, and photophobia. Lethal white foal disease has two forms. One form is caused by an autosomal dominant gene characterized by early embryonic death in the homozygous state. The second form results from breeding of two overo Paint Horses and is an autosomal recessive disorder. Affected foals are characterized by a white hair coat and congenital ileocolonic aganglionosis.

### LEUKODERMA

Leukoderma develops in areas of previous trauma or inflammation and may be temporary or permanent. Affected areas appear normal but depigmented. Leukoderma occurs commonly in horses with onchocerciasis, lupus erythematosus, pressure sores, ventral midline dermatitis, viral skin diseases, freezing, burns, or sun damage (Figure 13-28). Leukoderma can result from the contact of skin with chemicals that inhibit or interfere with melanogenesis, such as phenol and rubber products containing monobenzyl ether or hydroquinone.

The diagnosis is usually made by clinical signs, but elliptical biopsy of the junction of the pigmented and nonpigmented area confirms the diagnosis. Leukoderma causes no discomfort to the horse, but it may be a source of great agitation to the owner. No treatment is known.

### VITILIGO OF ARABIAN HORSES (ARABIAN FADING SYNDROME AND PINKY SYNDROME)

The term vitiligo refers to an idiopathic acquired depigmentation. Leukoderma develops in areas with no known history of previous trauma. Vitiligo can occur in any age, sex, or breed of horse but is most common in the Arabian (Figure 13-29).<sup>1</sup> Vitiligo appears to be more common in pregnant or postpartum mares, suggesting a hormonal or stress influence. In addition, the condition may be hereditary.<sup>85</sup>

With vitiligo, annular areas of depigmentation develop symmetrically on the muzzle, face, lips, and periocular areas.

FIGURE 13-28 Idiopathic leukoderma in a horse.

FIGURE 13-30 Reticulated leukotrichia in a Quarter Horse.

FIGURE 13-29 Horse with Arabian fading syndrome. Depigmented areas on the face are notable.

Depigmentation also can occur at the mucocutaneous junctions of the genital and anal area. Areas of depigmentation vary between 1 mm to 2 to 3 cm in size, and spots may become confluent at the mucocutaneous junctions. Depigmentation may wax and wane, and rarely the skin repigments completely within 1 to 2 years.

History, physical examination, and skin biopsy are diagnostic. Skin biopsy shows complete absence of epidermal melanin and lack of an inflammatory infiltrate. Success of treatment with topical glucocorticoids and vitamin-mineral supplementation (i.e., copper) is unpredictable. The practitioner should consider the condition untreatable, and owners should not breed affected animals because the condition is heritable and is considered a flaw. More practically, these areas are prone to sunburn and may predispose the horse to squamous cell carcinoma.

### LEUKOTRICHIA

Leukotrichia is an acquired loss of pigment in hairs that occurs most commonly in areas of previous trauma or inflammation. Leukotrichia may also occur at the site of previous injections of epinephrine with or without lidocaine.

Reticulated leukotrichia is an inherited disorder of Quarter Horses, Thoroughbreds, and Standardbreds<sup>1,85,86</sup> (Figure 13-30).

The condition has no sex predilection. Affected horses begin to show clinical signs as yearlings. Linear crusts in a netlike to crosshatched design develop over the dorsum from the withers to the tailhead region. Crusts are shed and after the temporary alopecia resolves, new hair growth is white. The underlying skin is normal, and leukotrichia is permanent. Leukotrichia causes no discomfort to the horse or interference with training or use of the animal. No therapy is available, and owners should not breed affected animals because leukotrichia is considered a breed flaw.

Spotted leukotrichia is a similar condition observed most commonly in Arabian Horses.<sup>1,85,86</sup> Permanent spots of leukotrichia develop over the hindquarters and trunk. Occasionally, lesions resolve spontaneously. No treatment is known, and owners should not breed affected animals because the condition is a breed flaw.

Hyperesthetic leukotrichia is a rare disease reported only in California.<sup>87</sup> Single or multiple crusts that are intensely painful characterize this disorder. Lesions develop on the dorsal midline from the withers to the tailhead. Within a few weeks, white hairs develop in the areas of crusting. The intense pain and crusting may last weeks to months. Eventually, lesions subside, but leukotrichia is permanent. Skin biopsy shows significant subepidermal and intraepidermal edema. No treatment is known, and large doses of glucocorticoids have not been of value.

### DISCOID LUPUS ERYTHEMATOSUS

Discoid lupus erythematosus is a rare skin disease in horses that is believed to be a variant of systemic lupus erythematosus. Affected horses develop areas of patchy erythema, crusting alopecia, and scaling on the face, ears, and neck.<sup>1</sup> Leukoderma and leukotrichia may be present.

The diagnostic test of choice is a skin biopsy. The skin biopsy reveals an interface dermatitis (hydropic or lichenoid or both). Focal hydropic degeneration of basal epidermal cells, pigmentary incontinence (pigment granules in the dermis or in dermal macrophages), and focal thickening of the basement membrane are important histologic features. Direct immunofluorescence testing may show a linear deposition of immunoglobulins at the basement membrane zone. This test is not reliable and is not recommended as a substitute for a routine histopathologic study.

Discoid lupus erythematosus is treated on an individual basis. Ideally the owner should stable the horse during the

hours of strong sunlight because sunlight aggravates the disease.<sup>1</sup> Topical sunscreens and topical glucocorticoids, for example, 0.1% betamethasone 17-valerate, may be beneficial. Severe or refractory cases of discoid lupus erythematosus may require immunosuppressive doses of oral prednisolone (see the section on pemphigus foliaceus).

## ☞ DISORDERS OF COLLAGEN FORMATION

Hereditary equine dermal asthenia (HERDA) and hyperelastosis cutis are defects in collagen. HERDA is an autosomal recessive trait<sup>91</sup> that occurs primarily in cutting horse strains of Quarter Horses and horses of Quarter Horse lineage (Paints and Appaloosas).<sup>4,88-90</sup> A similar condition has been described in an Arabian cross-breed, a Thoroughbred gelding, a Hanoverian foal, and a Haflinger horse. Male and female horses are affected equally. Foals are born with abnormal collagen, but the condition may take months to years before becoming clinically apparent to the owner.

Clinical signs include loose skin that is hyperextensible, hyperfragile, and easily torn and that exhibits impaired healing (Figures 13-31 and 13-32). The most common lesions in affected horses are seromas or hematomas, open wounds, sloughing skin, and loose easily tented skin that does not return to its original position. Lesions may be solitary or multiple, and the most common lesion location is the dorsal body surface. Affected horses rarely, if ever, exhibit hypermobility of the joints. Occasionally, owners complain that the horse develops hematomas and subcutaneous abscesses.

The diagnosis is based on clinical signs, physical examination, and skin biopsies. The most common histologic findings are an absent or greatly diminished deep dermal collagen layer. Other changes that may occur are thinning of the dermis and thinning, fragmented, and disordered collagen fibers. Zonal dermal separation is a distinctive histopathologic lesion associated with hyperelastosis cutis in the Quarter Horse.<sup>90</sup> The presence of tightly grouped thin and shortened collagen fibers arranged in clusters in the deep dermis is typical of HERDA.<sup>91</sup> Trichrome, acid orcein-Giemsa and immunohistochemical stains for collagen I and II showed no consistent abnormalities compared with control horses. In addition, no abnormalities were noted on electron microscopy. Therefore the diagnosis of

HERDA relies on clinical presentation and may be supported by suggestive histopathologic lesions.

No treatment for hyperelastosis cutis is available. Owners should attempt to minimize trauma to affected horses and promptly treat secondary infections. Most affected horses are euthanized because their fragile skin impairs their usefulness. Owners should remove sires and dams of affected horses from the breeding stock.

## ☞ HAIR ABNORMALITIES

Horses have simple hair follicles, which are accompanied by a sebaceous and sweat gland and an arrector pili muscle. Photoperiods and ambient temperature predominantly govern the hair cycle. Nutrition, hormone, genetics, and general well-being also may influence hair growth. Hair replacement in the horse occurs in a random pattern (mosaic) with the exception of the coarse permanent hair of the mane, tail, and fetlock.

## CHEMICAL AND PLANT CAUSES OF COAT ABNORMALITIES

### SELENIUM TOXICOSIS

Selenium is a trace mineral found in high concentrations in the Great Plains and Rocky Mountain areas of the United States. Toxicosis occurs when high levels of selenium in the soil are concentrated in selenium-concentrating plants. Interestingly, many of these plants grow selectively in selenium-rich soil and can contain up to several thousand parts per million of selenium. Selenium toxicosis may also occur when water contains 0.1 to 0.2 ppm selenium or feed contains greater than 5 ppm.<sup>1</sup> The exact mechanism of action is unknown, but selenium is believed to interfere with oxidative enzyme systems that possess sulfur-containing amino acids by displacing the sulfur groups. Selenium is substituted for sulfur in sulfur-containing amino acids. Keratinization of the hoof and hair are especially affected by the defective amino acids.

Selenium toxicosis occurs in any age, breed, or sex of animal but is most common in horses on pasture.<sup>92</sup> Early lesions begin as lameness and soreness of the coronary band and feet. The hindfeet usually are affected first. The coronary band and hoof develop cracks and separation and eventually the hoof may slough. The hair coat becomes rough, and generalized

FIGURE 13-31 Horse with severe hyperelastosis cutis.

FIGURE 13-32 Horse with mild hyperelastosis cutis.

epilation of the long hairs of the mane and tail occurs. Generalized alopecia may be visible.

A definitive diagnosis is made by history, clinical signs, and tissue analysis for selenium levels. Selenium in excess of 1 to 4 ppm from blood, 11 to 45 ppm for hair, and 8 to 20 ppm for the hoof indicates chronic toxicity. Identifying and removing the exogenous source of selenium is critical. Treatment of individual animals is frustrating because of the prolonged recovery period. Chronically affected animals have a 50% chance of recovery. A high-protein diet rich in sulfa-containing amino acids and 2 to 3 mg orally per day of DL-methionine may be beneficial. Naphthalene orally at 4 to 5 g per adult horse also may be of benefit. The horse should receive one cycle of treatment: 5 days of naphthalene, stop for 5 days, and 5 days of naphthalene treatment. Inorganic arsenic at 5 ppm in drinking water or salt with 35 to 40 ppm arsenic may protect the sulfur-containing structures of the body.<sup>92</sup>

### ARSENIC POISONING

Arsenic is commonly found in some parasiticial dips, weed and orchard sprays, insect baits, and arsenic-containing medications. Arsenic is a general tissue poison, and 1 to 5 mg/kg may be toxic to horses.<sup>21</sup> Signs of arsenic toxicosis include gastrointestinal disturbances, weight loss, and a dry, dull, easily epilated hair coat. Some horse may develop a long shaggy coat with severe seborrhea.

The diagnosis is based on history of ingestion of arsenic or an arsenic-containing compound and clinical signs. A definitive diagnosis may be difficult because the test of choice is the measurement of arsenic levels in kidney or liver (>10 ppm).<sup>1,21</sup>

Treatment of arsenic toxicity is complicated by the peracute nature of the disease. One should wash off topically absorbable arsenic and should empty the digestive tract of the horse with the aid of laxatives. Orally administered sodium thiosulfate at 50 to 75 g every 6 to 8 hours binds unabsorbed arsenic. Intravenously administered sodium thiosulfate at 25 to 30 g of a 20% solution in distilled water may counterabsorb arsenic. Dimercaprol (British AntiLewisite [BAL] in oil) is the classic antidote for arsenic toxicity and is effective if administered within hours of ingestion. Initial treatment is 5 mg/kg intramuscularly and then 3 mg/kg every 6 hours for the first day, followed by a dosage of 1 mg/kg intramuscularly every 6 hours for the next 48 hours. Intramuscular injections are painful.<sup>21</sup> One must identify the source of arsenic and eliminate it.

### MERCURY POISONING

Mercury poisoning occurs when the horse ingests feed contaminated with fungicide or absorbs or ingests mercury from counterirritants.<sup>1</sup> Affected horses may have gastrointestinal disorders, depression, anorexia, weight loss, and emaciation. Generalized alopecia with subsequent loss of mane and tail hairs is common. The diagnosis is complicated because the sample of choice is kidney tissue, where mercury is concentrated. Orally administered potassium iodide at 4 g per day for 14 days may be beneficial in treating affected horses.<sup>82</sup>

### LEUCENOSIS POISONING

Leucenosis is a toxicosis resulting from the ingestion of plants of the genus *Leucaena*.<sup>1,21</sup> In the United States, these plants are found in Hawaii. This plant contains a toxic amino acid (mimosine) that is a potent depilatory agent.

Horses with this toxicosis show a gradual loss of the mane, tail, and fetlock hairs. Severely intoxicated animals may undergo complete hair loss 7 to 14 days after exposure. Laminitis and hoof dystrophies have been reported.<sup>1,21</sup>

The diagnosis is based on history and clinical signs. One treats affected horses symptomatically after preventing further exposure to the plants. Ferrous sulfate 1% added to the feed may benefit affected horses and limit further hoof damage.<sup>1</sup>

## HAIR FOLLICLE ABNORMALITIES

### MANE AND TAIL DYSTROPHY

Mane and tail dystrophy may be congenital or acquired. Whether the condition is hereditary is unknown. Affected horses (juvenile or adult) have short, brittle, dull hairs on the mane and tail. No treatment is known, but the condition does not affect the health or function of the horse.

### BLACK AND WHITE FOLLICLE DYSTROPHY

Affected horses (juvenile and adult) have abnormal hairs growing in patches of white- or black-haired areas. These hairs are short, brittle, and dull. Affected areas may be hypotrichotic. No treatment is available.

### CURLY COAT

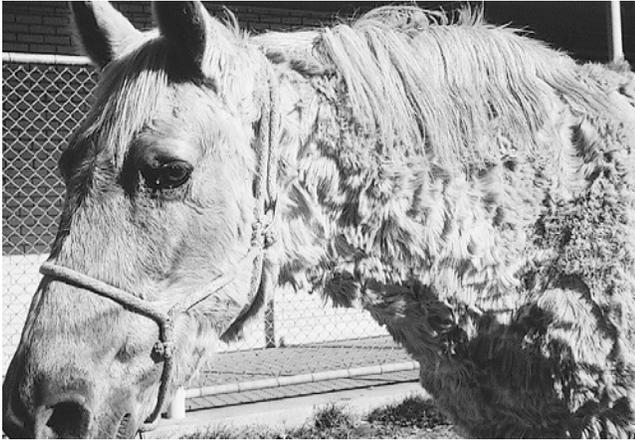

Curly coat is a hereditary condition of Percherons, Missouri Fox Trotters, and Bashkin Horse breeds that is inherited as an autosomal recessive trait. Clinically affected horses have unusually curly coats.

## ENDOCRINE CAUSES OF HAIR ABNORMALITIES

### HYPERADRENOCORTICISM

Equine hyperadrenocorticism secondary to pituitary pars intermedia dysfunction is discussed in detail in the chapter of this text on Disorders of the Endocrine System. Abnormal pituitary function results in abnormal secretion of numerous hormones.<sup>21,93</sup> Clinical signs are most common in older horses (12 to 15 years old or older),<sup>21,93,94</sup> but the condition is reported occasionally in horses 7 to 10 years of age. The first clinical sign noted by an owner is often a rapid regrowth of long hair after the shedding season or failure to shed the coat (Figure 13-33). The coat becomes shaggy, and body hairs can reach lengths of 10 to 12 cm. Interestingly, mane, tail, and fetlock hairs are unaffected. Secondary seborrhea may develop. Affected horses may be predisposed to dermatophytosis, dermatophilosis, or secondary bacterial pyoderma. Nondermatologic signs include polydipsia, polyuria, muscle wasting, lethargy, weight loss, pendulous abdomen, laminitis, and flaccid muscles. Neurologic disorders and blindness may develop.

The diagnosis is based on clinical signs and laboratory test results.<sup>94-97</sup> Complete blood counts often reveal neutrophilia, lymphopenia, and eosinopenia. Urinalysis may reveal a low specific gravity and occasionally glucosuria. A serum chemistry panel may reveal any combination of the following: hyperglycemia, hypercholesterolemia, and lipemia.<sup>94</sup> The definitive diagnosis and treatment of pituitary pars intermedia dysfunction in horses is discussed elsewhere in this text.

**FIGURE 13-33** Horse with pituitary pars intermedia dysfunction. The long hair coat did not shed in the spring.

### HYPOTHYROIDISM

Hypothyroidism in the horse is rare, and much of the information on this endocrinopathy is anecdotal.<sup>98-100</sup> Horses with naturally occurring hypothyroidism reportedly have a wide range of clinical signs, including loss of mane and tail hairs, muscle weakness, hyperpigmentation, seborrhea, lethargy, poor performance, infertility, agalactia, myxedema, and dry, dull, brittle hair. The diagnosis and treatment of equine hypothyroidism is discussed in this text in the chapter on Disorders of the Endocrine System.

## MISCELLANEOUS DISORDERS AFFECTING THE HAIR COAT

### ANAGEN DEFLUXION AND TELOGEN DEFLUXION

Anagen defluxion refers to a condition in which a disease or drug interferes with anagen hair growth resulting in abnormal hairs or hair shaft abnormalities or both. Hair loss occurs within days of the insult or drug. The condition occurs most commonly in horses with high fevers, systemic illnesses, or malnutrition<sup>21</sup> (Figure 13-34). Typically the mane and tail are not affected.

Telogen defluxion refers to a condition in which a stressful situation causes the sudden cessation of anagen hair growth and the sudden synchrony of many hair follicles in the telogen hair cycle stage.<sup>21</sup> Two to three months later a sudden shedding and a wave of new hair growth occur.

These conditions cannot be distinguished clinically. The diagnosis is based on examining the hair shaft of easily epilated hairs. Anagen defluxion is characterized by dysplastic hairs, the hair shaft may be weak or narrow, and the root end contains a root sheath. Telogen defluxion is characterized by uniform hairs with no shaft abnormalities and a non-pigmented root end lacking a root sheath. Both conditions resolve spontaneously when the animal recovers from the predisposing condition.

### TRICHORRHEXIS NODOSA

Trichorrhexis nodosa is an acquired hair shaft disorder of horses caused by physical or chemical trauma.<sup>86</sup> Overzealous grooming, shampoos, pesticides, alcohol, or solvents are the

**FIGURE 13-34** Foal with telogen effluvium after illness.

most common causes. The lesions are visible without magnification and appear as small white to gray nodules on the hair shaft. The hair shaft fractures and breaks easily at these sites. Microscopically, affected hairs have the appearance of two brooms shoved together. Therapy consists of identifying and eliminating the trauma.

### PIEDRA

Piedra is a rare superficial fungal disease of horses that causes nodules on the hair shaft. Black or white filamentous nodules consisting of tightly packed hyphae are most commonly visible on the mane and tail. Affected hairs break at the site of infection. A definitive diagnosis is made by fungal culture and microscopic identification of the agent *Piedraia* sp. or *Trichosporon beigeli*. Treatment of affected horses includes clipping the hair and applying topical fungicides.

### ABNORMAL SHEDDING: PHOTOPERIOD AND TEMPERATURE RELATED SHEDDING

Most horses have a spring and fall shed. Abnormal shedding in horses may result in large areas of alopecia.<sup>86</sup> Large areas of hair loss may develop on the face, shoulders, or even over the entire body. The pathogenesis is unknown. Skin biopsy is recommended to eliminate infectious or parasitic causes of hair loss. Skin biopsy is normal and shows normal hair follicles in various stages of development. Horses spontaneously recover in up to 3 months.<sup>87</sup>

### ALOPECIA AREATA

Alopecia areata is a rare idiopathic skin disease of horses characterized by focal areas of alopecia.<sup>85</sup> Lesions may be single or multiple, and the underlying skin is otherwise normal. If and when hair regrows, it may be a different color. The diagnosis

is made by biopsy. Classically, in early lesions, skin biopsy shows an accumulation of lymphoid cells around the proximal end of the anagen hair follicles.<sup>86</sup> This change is diagnostic but may require numerous biopsies before being observed. Prognosis is uncertain. In human beings, alopecia areata may resolve spontaneously in 3 to 5 years. Whether spontaneous resolution occurs in horses is unknown.

## ☞ MUCOCUTANEOUS VESICULAR DISEASES

A vesicle is an elevated, fluctuant, fluid-filled lesion of less than 1 cm in size. A vesicular eruption suggests a viral, autoimmune, or irritant cause. In horses, vesicles are transient because the epidermis is thin, and these lesions rupture easily. Erosions or ulcerations are often the first clue that a vesicle-producing disease is present. Additionally, vesicular diseases may masquerade as pustular eruptions. Vesicles in horses rapidly fill with inflammatory cells, making them indistinguishable from frank pustules. In rare instances, horses may develop bullae (>1 cm in diameter) or large vesicles. Occasionally, bullae fill with blood and are red-purple.

### VIRAL CAUSES OF VESICULAR ERUPTIONS

#### EQUINE HERPES COITAL EXANTHEMA

Coital exanthema is a rare contagious venereal disease of horses caused by equine herpesvirus type 3, which occurs worldwide. The disease is transmitted via coitus, insects, fomites, and inhalation. Early lesions begin as papules that rapidly progress to vesicles or bullae or pustules on the vulva or perineum of mares and the penis and prepuce of stallions.<sup>4</sup> Vesicles and bullae also may be present in the mouth or nostril or on the lips. Affected areas commonly become eroded and ulcerative. Lesions are more often pruritic rather than painful. Depigmentation often occurs in areas where lesions have developed and healed. Stress may precipitate recurrences.

The diagnosis is based on the appearance of lesions on the vulva, perineum, penis, or prepuce; skin biopsy; and virus isolation. Histologic findings include hyperplastic superficial and deep perivascular dermatitis with ballooning degeneration and eosinophilic intranuclear inclusion bodies.

Treatment is symptomatic, but corticosteroids are contraindicated. Owners should isolate affected horses and remove broodmares and stallions from the breeding program for a minimum of 4 weeks. The disease has no known effect on fertility.

#### VESICULAR STOMATITIS (SORE NOSE AND SORE MOUTH)

Vesicular stomatitis is caused by a rhabdovirus with two major serotypes: New Jersey and Indiana.<sup>21</sup> The disease affects horses, cattle, and swine and is enzootic in North, Central, and South America. In North America the disease is reportable.

The disease has a seasonal occurrence in summer and fall and is believed to be transmitted to horses by insect bites. Within a group of horses, however, the disease may be transmitted via direct contact. The incubation period is short (24 to 72 hours), and lesions may last for only 3 to 4 days. Infected horses rapidly develop vesicles up to 2 cm in diameter in the mouth and on the lips. These lesions rupture, leaving large painful erosions and ulcers. Affected animals salivate profusely,

and fever and anorexia are common. Rarely, lesions develop on the hooves, prepuce, and teats.

Confirmation of the diagnosis is obtained by serologic examination. Histologic findings are nonspecific and include a hyperplastic epidermis, intercellular and intracellular edema of the epidermis, reticular degeneration, spongiotic microvesicles, and focal necrosis. Superficial and deep perivascular dermatitis is present.

Owners should feed affected horses a soft gruel until oral lesions heal, usually within a few days. Permanent depigmentation may occur in areas of former ulceration. Infection results in immunity for up to 6 months.

#### HORSEPOX

Horsepox is uncommon and has been reported only in Europe. Horsepox is a benign disease, caused by an unclassified poxvirus.

The virus gains access to the body by the respiratory tract or the skin.<sup>101</sup> Systemic spread occurs by the lymphatics. Poxvirus inoculated into the skin may multiply locally, directly enter the blood, and create a primary viremia. The virus causes degenerative changes in the epithelium as a result of virus replication and results in development of vesicular lesions. Poxviruses also cause epithelial hyperplasia by stimulating host-cell DNA synthesis before the onset of cytoplasmic virus-related DNA replication. Ischemia and necrosis occur in the dermis and subcutaneous areas as a result of vascular damage.

Clinical lesions of equine poxvirus infections develop as follows. An erythematous maculopapular eruption develops, followed by the development of vesicles. This stage is transient and may not be observed. Vesicles develop into umbilicated pustules with a depressed center and a raised erythematous border. When the pustule ruptures a crust develops and the lesion heals, often with scarring.

Horsepox may affect horses of any age. The disease is transmitted by direct contact with an infected host or with contaminated grooming tools or tack. Lesions of horsepox are typically vesicles and umbilicated pustules with crusts. Three clinical presentations (oral, leg, and vulvar) have been described.<sup>64</sup> Oral horsepox (buccal horsepox, contagious pustular stomatitis) is characterized by the development of lesions on the inner lips and buccal mucosa. In severe forms, pox lesions may develop in the pharynx, larynx, nostrils, or all of these sites. Leg pox usually develops on the pasterns and fetlocks and often is confused with "scratches" or "greasy heel." Pain and lameness are common. Vulvar pox (genital horsepox) is uncommon, occurring predominantly in severely affected animals. One may observe pyrexia and anorexia early in the course of the three forms of horsepox.

The diagnosis is based on history and clinical signs and confirmed by histologic examination. Intracytoplasmic inclusion bodies demonstrated by routine histopathologic examination of tissue or electron microscopy are diagnostic. Other findings include ballooning degeneration of the epidermis (stratum spinosum), reticular degeneration, acantholysis (loss of cohesion of cell in the granular area), intraepidermal microvesicles, a superficial and deep perivascular dermatitis, and intraepidermal microabscesses and pustules.

Treatment is symptomatic. Most horses recover in 2 to 4 weeks. Occasionally the disease is fatal in severely affected young horses. Recovery produces lifelong immunity. This disease affects human beings and cattle.

## AUTOIMMUNE DISEASES CAUSING VESICULAR LESIONS

Bullous pemphigoid is a rare autoimmune skin disease of horses characterized by the development of vesicles and ulceration of the oral mucosa and occasionally the skin. Bullous pemphigoid is caused by production of an autoantibody (pemphigoid antibody) against a component in the basement membrane of the skin and mucous membranes.<sup>56</sup> The pemphigoid antibody binds to the basement membrane zone and complement fixation occurs, resulting in production of inflammatory mediators chemotactic for neutrophils and eosinophils. These cells release proteolytic enzymes that disrupt the dermal-epidermal cohesion; separation occurs, and a vesicle forms.

In horses, vesicles and bullae develop at the mucocutaneous junction in the inguinal region or in the oral cavity.<sup>85</sup> Skin lesions occur in the axilla and groin. Vesicles and bullae rupture easily and are often crusted and secondarily infected with bacteria. Pain, pruritus, anorexia, fever, and salivation are common.

A definitive diagnosis is made by eliminating other causes of vesicular lesions from the differential list and by skin biopsy. Biopsy of a vesicle or intact bullae is essential; biopsy of crusted or ulcerative lesions will be nondiagnostic. Bullous pemphigoid is characterized by subepidermal vacuolar alterations and subepidermal clefts and vesicles.<sup>1</sup> Neutrophilic and eosinophilic infiltration of the superficial epidermis is common. If direct immunofluorescence testing is performed and the results are positive, one observes a linear deposition of immunoglobulin at the basement membrane zone. Direct immunofluorescence testing is not recommended.

There are few reports of the treatment of bullous pemphigoid in horses.<sup>1,57,85</sup> Treatments have included an initial large dose of prednisolone (1 mg/kg orally every 12 hours) or dexamethasone (0.2 mg/kg orally every 24 hours) to induce remission. After the arrest of new lesion development and healing, one institutes maintenance therapy with alternate-day administration of glucocorticoids at the smallest effective dose. Therapy must be individualized and will most likely be lifelong. The use of adjuvant therapy (e.g., gold salts or azathioprine) has not been reported in horses with bullous pemphigoid but may be useful.

## IRRITANT AND TOXIC CAUSES OF MUCOCUTANEOUS VESICLES

Irritant reactions, toxic chemicals, or allergic reaction to drugs may result in oral mucocutaneous vesicles. One should suspect these causes when lesions develop acutely in the absence of signs of systemic illness, in single animals within a herd, or in horses receiving medications or counterirritants. Mercurial compounds (commonly used in counterirritants) can also cause generalized hair loss, lameness, and emaciation in chronically intoxicated animals. Creosol and cantharidin beetles are common causes of oral ulcers. Foreign bodies such as grass awns may cause mucocutaneous ulceration and vesicles.

## VASCULITIS

Oral ulcers may develop in horses with vasculitis (see the section on Vasculitis and Purpura Hemorrhagica).

## ☪ NECROTIZING SKIN DISORDERS

Necrotizing skin diseases develop from a wide range of causes. The unifying characteristic is that each of these diseases may cause local or widespread full-thickness death of the skin, sloughing of tissue, ulceration, and exudation. A definitive diagnosis of the underlying cause may be difficult in some cases.

## DECUBITAL ULCERS (PRESSURE SORES, SETFASTS, SADDLE GALLS, AND SADDLE SORES)

Decubital ulcers or sores are caused by prolonged application of pressure to an area. Thin and emaciated animals are at greatest risk for development of decubital ulcers.

Pressure sores may develop from poorly fitting tack on the back, neck, or girth of the horse; from recumbency during surgery, even while on suitable bedding; and from casts, leg wraps, or elastic bandages that have become wet or are unevenly wrapped, too tight, or ill fitting. The amount of pressure required to create a decubital ulcer is not great. Tack and saddles may cause lesions over bony prominences or other areas subjected to extended pressure. Capillary circulation is stopped or severely limited, resulting in tissue anoxia and retention of metabolic wastes with tissue damage and death. Most lesions begin as small areas of tissue necrosis and progress to areas of ulceration. Secondary infections are common.<sup>1</sup>

Clinically, early lesions begin with hair loss, swelling, and erythema. A red-purple area of tissue discoloration may be visible. Within a few days, oozing, necrosis, and ulceration become visible. In severe cases the skin loses its elasticity, subcutaneous tissues slough, and the skin may harden. Strands of living tissue may be attached to necrotic tissue. Lesions are often malodorous. Healed lesions tend to scar, and leukotrichia or leukoderma are common sequela.<sup>82</sup>

The diagnosis is based on history and clinical examination. Areas of skin that have lost sensation or have a parchmentlike feel should be suspect.

Treatment of these lesions is difficult. Because of significant capillary and venous congestion, systemic antibiotics are often not effective.<sup>1,82</sup> Wounds are managed best topically. One should clean the wounds daily with copious amounts of water to remove tissue debris and stimulate circulation and should use topical antibiotic creams or ointments (i.e., iodine and chlorhexidine) to prevent secondary infection and to prevent the wound from becoming desiccated. Re-epithelialization and wound healing greatly improve with the use of surgical dressings, but bandaging some lesions may be difficult. Surgical débridement and skin grafting may be indicated in some cases.

## GANGRENE

Gangrene is a clinical term used to describe wet or dry tissue necrosis. Gangrene may result from external pressure, severe edema, burns, frostbite, snake bites, vasculitis, ergotism, fescue toxicosis, or bacterial or viral infections.<sup>1</sup> The characteristic lesion results from occlusion of the venous or arterial blood supply.

Dry gangrene occurs when the arterial blood supply to an area is occluded but the venous or lymphatic drainage is intact.

Wet or moist gangrene is caused by occlusion or impairment of lymphatic and venous drainage plus putrefaction caused by a bacterial infection. Lesions of dry gangrene are dry, leathery, discolored, sunken, and cold to the touch. The skin may take a long time to slough. Lesions of wet gangrene are swollen, discolored, and malodorous.

The diagnosis is most often made by clinical examination and confirmed by biopsy. One must identify and treat the primary cause of gangrene.

## THERMAL INJURIES

### BURNS

Excessive heat (burns) can occur from barn fires, brush fires, accidental spillage of hot solutions, lightning, electrocution, rope burns, counterirritants, or radiation. Barn fires cause most burns in horses.

Large thermal injuries in horses are difficult to manage.<sup>21,102-104</sup> The large surface area of the burn dramatically increases the potential for fluid, electrolyte, and caloric losses. Burns on 50% or more of the body are usually fatal, but this depends on the depth of the burn.<sup>93,95</sup> Massive wound contamination is almost impossible to prevent because of the impossibility of maintaining a sterile environment.<sup>21,101</sup> Horses require long-term restraint to prevent continued trauma; wounds are often pruritic, and self-mutilation is common.<sup>103</sup> Burned horses are frequently disfigured, preventing them from returning to full function.

Burns are classified by the depth of the injury.<sup>21,102-104</sup> First-degree burns involve only the most superficial layers of the epidermis. These burns are characterized by erythema, edema, desquamation of superficial layers of the skin, and pain. The germinal layer of the epidermis is spared, and these burns heal without complication.<sup>21</sup> Second-degree burns involve the entire epidermis and may be superficial or deep. Superficial second-degree burns involve the stratum corneum, stratum granulosum, and a few cells of the basal layer. Deep second-degree burns involve all layers of the epidermis. Clinically, these burns are characterized by erythema, edema at the epidermal-dermal junction, necrosis of the epidermis, accumulation of white blood cells at the basal layer of the burn, eschar (slough produced by a thermal burn) formation, and minimal pain. The only germinal cells spared are those within the ducts of sweat glands and hair follicles. Second-degree burns heal well with good wound care.<sup>21</sup> Third-degree burns are characterized by loss of epidermal and dermal components. Fluid loss occurs, along with significant cellular response at the margins and deeper tissue, eschar formation, lack of pain, shock, wound infection, and possible bacteremia and septicemia. Healing is by contraction and epithelization and occurs only from the wound margins. Infection and problems with wound healing frequently complicate these burns.<sup>21</sup> Fourth-degree burns involve all the skin and underlying muscle, bone, and ligaments.

Burns cause local and systemic effects.<sup>21,27,103,104</sup> Local tissue damage results from massive protein coagulation and cellular death. In the immediate area of the burn, arteries and venules constrict and capillary beds dilate. Capillary wall permeability increases in response to vasoactive amines released as a result of tissue damage and inflammation.<sup>104</sup> These vascular responses result in fluid, protein, and inflammatory cells accumulating in the wound. Vascular sludging, thrombosis, and dermal ischemia occur, resulting in further

tissue damage. The tissue ischemia continues for 24 to 48 hours after the injury and is believed to be caused by the local release of thromboxane  $A_2$ .<sup>21,104</sup> Lipid layers in the skin are destroyed, and a fourfold increase in the loss of fluid occurs. Fluid losses result in increased heat loss from evaporation and an increased metabolic rate. The full extent and depth of the burn may not be evident for several days. Neutrophil function and chemotaxis greatly decrease, predisposing the wound to local infection, bacteremia, and septicemia. The following microorganisms frequently colonize burns: *Pseudomonas aeruginosa*, *Staphylococcus*, *Escherichia coli*, *Klebsiella* spp., nonhemolytic *Streptococcus* spp., *Proteus* spp., *Clostridium* spp., and *Candida* spp.<sup>21,101-103</sup> Systemic effects are life-threatening and include hypovolemia, fluid and electrolyte losses, protein loss, pulmonary edema, anemia, increased basal metabolic rate, increased caloric needs, and depressed cell-mediated and humoral immune responses. Hypovolemia exacerbates a decrease in cardiac output after a circulating myocardial-depressant factor.<sup>27</sup>

The practitioner should treat first-degree burns and superficial second-degree burns immediately with ice or cold water to prevent further tissue necrosis.<sup>21,101</sup> One should apply aloe vera cream or a water-soluble antibacterial cream to the wound to prevent infection. In addition, nonsteroidal analgesics should be administered to alleviate pain and to help reduce dermal ischemia. Aspirin at 10 to 20 mg/kg orally once or twice daily decreases thromboxane production, may halt further dermal ischemia, and may be the initial drug of choice.<sup>21</sup>

Deep second-degree burns are initially treated as described previously; however, these burns tend to form blisters that should be left intact as long as possible because the vesicular fluid is a good medium for reepithelialization.<sup>21,102,103</sup> One should trim ruptured blisters, clean the area with copious amounts of water, and cover the wound with an antibacterial dressing or xenograft or allow an eschar to form.<sup>21,102-104</sup> The bandage should allow drainage and should be changed at least daily.

Full-thickness burns (third and fourth degree) are treated by occlusive dressing (closed technique), eschar production (exposure technique), continuous wet dressings (semiopen technique), or excision and grafting techniques.<sup>104</sup> The most practical therapy for large burns in horses is the semiopen method, leaving the eschar intact with continuous application of moist bandages and antibacterial agents. The moist dressings help prevent heat and moisture loss from the eschar, provide protection of the eschar, and help prevent bacterial invasion in the wound.

Routine use of systemic antibiotics is not recommended in burn patients. Short-term systemic antibiotics may be useful in the initial 3 to 5 days after the burn to minimize bacterial colonization of burns and systemic sepsis.<sup>104</sup> In the absence of sepsis, systemic antibiotics are contraindicated. Extensive use of antibiotics may cause altered microbial flora in the gut and in mucous membranes, which may predispose the patient to infections from antibiotic-resistant gram-negative bacteria or from fungi.<sup>105</sup> Topical medications should be water-based, should be applied and removed easily, should not interfere with wound healing, and should be excreted or metabolized readily. Silver sulfadiazine and aloe vera are effective. Silver sulfadiazine is effective against gram-negative bacteria, causes no discomfort to the horse, penetrates eschar, and has a 24-hour duration of action. Aloe vera is reported to relieve pain,

decrease inflammation, stimulate cell growth, and kill bacteria and fungi. Aloe vera is most useful in the early treatment of wounds. Several excellent references for further information on long-term medical and surgical management of horses with large thermal burns are available.<sup>21,102-104</sup>

### FROSTBITE

Frostbite occurs when tissue is exposed to extreme cold. Sick, debilitated, and neonatal animals are at increased risk. Cold temperatures inhibit cell metabolism and cause tissue dehydration, cell disruption by ice crystals, ischemia, and vascular damage. The most commonly affected areas are the glans penis, ear tips, coronary bands, and heels.<sup>1</sup> The initial lesion of frostbite is paleness of the skin. Erythema, scaling, and hair loss follow. Pigment loss may occur. In severe cases, necrosis and dry gangrene occur.

Mild cases of frostbite do not require treatment. More severe cases require rapid thawing in warm water (41° to 44° C).<sup>1</sup> After rewarming, one should apply antibiotic ointments without steroids to the area. In severe cases with necrosis and sloughing, topical wet soaks and symptomatic therapy with antibiotics may be needed to prevent sepsis. One should not attempt surgical débridement until an obvious demarcation is present between viable and nonviable tissue. Previously frostbitten areas may be more susceptible to cold injury.

### CHEMICAL TOXICOSIS

In addition to causing disorders of the hair coat, selenosis may result in necrosis and sloughing of the hoof (see the section Chemical and Plant Causes of Coat Abnormalities).

### STACHYBOTRYOTOXICOSIS

Stachybotryotoxicosis is a mycotoxicosis caused by the toxins of the fungus *Stachybotrys atra*.<sup>1</sup> This fungus grows on hay and straw and produces toxins referred to as macrocyclic trichothecenes. These toxins cause bone marrow suppression, profound neutropenia, thrombocytopenia, and necrotic-ulcerative lesions of the skin and mucous membranes.

Commonly, lesions begin at the mucocutaneous junction as focal areas of necrosis and ulceration. Petechiae, ulcers, large areas of necrosis, catarrhal rhinitis, suppurative rhinopharyngitis, and laryngitis follow. Skin lesions occur as early as 24 hours after ingestion of the toxin. Systemic signs include lethargy, anorexia, weight loss, hyperactivity, proprioceptive deficits, colic, muscular stiffness, and second-degree atrioventricular block. Affected animal develops hemorrhagic diathesis, hemorrhagic enteritis, and septicemia and die.

The diagnosis is based on history, clinical signs, and finding the toxin in the feed. If one recognizes toxicosis early in the course of the disease, withdrawal of affected feed has resulted in resolution of signs. Animals with extensive lesions and chronic exposure have a poor prognosis.

### BITES AND STINGS OF VENOMOUS INSECTS, SPIDERS, AND REPTILES

Many species of snakes, spiders, and insects have venomous bites and stings. Except for snake bites, these animals lack sufficient quantity of venom to cause more than transient pain or local inflammation. Venoms contain a variety of substances, including enzymes, peptides, polypeptides, amines,

and glycosides, which act locally by causing tissue necrosis and vascular thrombosis and hemorrhage or systemically by causing widespread hemolysis and neurotoxicity.

### SNAKE BITE

Of the poisonous snakes in the United States, bites from rattlesnakes, water moccasins, and copperheads occur most commonly in horses.<sup>106</sup> The venom from snakes is hemotoxic and proteolytic and produces extreme local swelling with significant tissue and red blood cell destruction.

Most bites occur in the spring and summer. Horses are most commonly bitten on the nose, head, neck, and legs. Snake bites may or may not involve envenomation and may be dry or wet. Bites in which no venom is injected swell minimally and are only slightly painful (dry bite). When envenomation occurs (wet bite), rapid swelling, pain, and local hemorrhage develop, usually within 60 minutes of the bite. Fang marks are often difficult to find because of tissue swelling. Edema, erythema, and tissue necrosis develop over days, and the skin may slough (Figure 13-35). Bites occurring on the face or head are serious because of the risk of respiratory and nasal edema. If respiratory distress is severe, the horse may need a tracheotomy.

Snake bites should be treated symptomatically. One should clean the wound and provide hydrotherapy with cold water to minimize swelling. If swelling is already present, warm hydrotherapy may stimulate circulation and removal of tissue edema. Whether hydrotherapy increases the absorption of venom in the early stages of the bite is unknown, however. Broad-spectrum antibiotics are indicated to prevent secondary infection. The use of glucocorticoids is controversial but may be beneficial in decreasing inflammation and pain. Nonsteroidal anti-inflammatory agents also may be beneficial. Surgical débridement and wound closure may be necessary if severe necrosis and sloughing occur. Although specific antivenoms are available, they are of limited use. Maximal benefit is attained only when they are administered within hours of the bite. Additionally, the volume of anti-venom necessary to treat snake bites in horses may be cost prohibitive.

**FIGURE 13-35** Face of a horse after being bitten by an Eastern diamondback rattlesnake.

### FIRE ANT BITES

Fire ants, *Solenopsis* spp., are common in the southern United States. Single or small numbers of stings are acutely painful and rapidly develop into a pustule or crust. Horses are bitten most commonly on the legs, nose, and ventrum, but massive exposure can occur if the horse rolls on an anthill and is bitten by hundreds or thousands of ants. Complications of massive exposure include infection, anaphylactic shock, bronchospasms, and sloughing of the epidermis. Single or multiple small numbers of solitary stings usually require little or no treatment. Applying an antibiotic ointment to minimize the chance of myiasis is prudent; otherwise, wounds heal without complication. If massive exposure has occurred, one may need to use systemic antibiotics and nonsteroidal anti-inflammatory drugs to decrease pain and swelling.

### SPIDER BITES

Black, brown, and red widow spiders (*Latrodectus* spp.) and the brown recluse (*Loxosceles reclusa*) spider are common in America. In Australia the black house spider (*Ixauticus*) causes painful bites.<sup>106</sup> Spider bites are characterized by hot, edematous, painful swellings in the area of the bite. The brown recluse spider has a dermal necrotoxin that may cause severe dermal necrosis, but this has not been reported in horses.

Treatment is symptomatic. Cold ice packs applied to the area, and systemic glucocorticoids or antihistamines, or both, may be helpful. Spraying the environment of the horse with a parasiticide is important. Owners should remove discarded furniture, newspapers, old cloths, and trash from the premises because these are favorite living areas for venomous spiders.

### VASCULITIS AND PURPURA HEMORRHAGICA

Vasculitis is an inflammatory reaction occurring in the wall of the blood vessel (Figure 13-36). Vasculitides are classified by inflammatory cell type. Neutrophilic vasculitides are subdivided further into leukocytoclastic (neutrophil nuclei undergo karyorrhexis) or nonleukocytoclastic.

The immunologic mechanisms involved are typically type I and type II hypersensitivity reactions.<sup>21</sup> Equine viral arteritis, equine influenza, *C. pseudotuberculosis*, and *Streptococcus* spp. (especially *S. zooepidemicus* subsp. *equi*) infections may result in vasculitis.<sup>35</sup> Vasculitis also may occur after *Rhodococcus equi* pneumonia, cholangiohepatitis, and some antibiotic treatments. The underlying cause is often not identified.

Idiopathic vasculitis has no known breed, sex, or age predilection. The most common locations for lesions are the distal limbs, ears, lips, and periocular areas.<sup>1</sup> Oral ulcers and bullae may be present. Skin lesions consist of purpura, edema, and erythema. Systemic signs may include pyrexia, depression, anorexia, weight loss, and lameness.

Purpura hemorrhagica is an acute noncontagious disease of horses characterized by extensive edema and hemorrhage of the subcutaneous tissue. Hemorrhage in the mucosae and viscera are common. Most cases occur after strangles or equine influenza.<sup>1</sup> Clinical signs usually develop within 2 to 4 weeks of the respiratory infection. Urticaria followed by pitting edema of the distal limbs, head, and ventral abdomen is common. Severe edema of the head may compromise breathing.<sup>17</sup> Tissue exudation and sloughing may occur. Pain and pruritus are rare. Affected horses usually are depressed, reluctant to move, and often anorectic.

The diagnosis of vasculitis is made by skin biopsy. Obtaining skin biopsy specimens from lesions 8 to 24 hours of age is important because these lesions tend to have the most diagnostic changes. Lesions more than 24 hours old may be nondiagnostic because of intense secondary cellular infiltrates or necrosis. Skin biopsy reveals neutrophilic, eosinophilic, lymphocytic, or mixed cellular infiltrates in the vessel wall. Fibrinoid degeneration and hemorrhage are common.<sup>64</sup> Direct immunofluorescence testing is occasionally useful as an adjunctive diagnostic aid.

Prognosis for horses with vasculitis is unpredictable.<sup>27</sup> Therapy of vasculitis is discussed elsewhere in this text.

### PANNICULITIS AND FAT NECROSIS

Panniculitis refers to inflammation of the subcutaneous fat. This condition is rare in horses and results from widespread death of lipocytes. Fat cells are vulnerable to trauma, ischemia, and neighboring inflammation. When lipocytes are damaged, lipid is released and undergoes hydrolysis into glycerol and fatty acids. Fatty acids are potent inflammatory agents that elicit further inflammatory reactions.<sup>21</sup>

Panniculitis may be precipitated by a wide range of causes, including trauma, infections, autoimmune disease, pancreatic disease, glucocorticoid therapy, vasculitis, vitamin E deficiency, and idiopathic causes. In the horse, few cases have been reported, and the causes of those were obscure. Vitamin E deficiency was suspected in a few horses.<sup>76</sup>

Clinically, horses with panniculitis show deep-seated nodules and plaques.<sup>21</sup> Lesions may be single or multiple and vary in size. Nodules may be hard and well-defined or soft and ill-defined. Initially, lesions are not fixed to the overlying

FIGURE 13-36 Horse with vasculitis resulting from strangles.

skin, but as the disease progresses, nodules become cystic and rupture onto the skin surface. The ulcerating nodules drain a yellow to brown to bloody oily material. Pain varies. Healed lesions may leave depressed scars. Affected animals may be febrile, depressed, lethargic, and anorectic.

A definitive diagnosis is made by skin biopsy. Samples should be obtained for histopathologic evaluation by deep excisional biopsy using a scalpel blade because skin biopsy punches do not obtain sufficiently deep samples to be diagnostic. One should request special stains (i.e., periodic acid–Schiff, Gomori's methenamine silver, Brown and Brenn) for causative agent. Skin biopsy reveals lobular to diffuse pyogranulomatous inflammation in the panniculitis.

The practitioner should identify and treat underlying causes appropriately. Idiopathic panniculitis may respond well to prednisolone at 1 to 2 mg/kg orally once daily for 7 to 14 days or to a single treatment of dexamethasone at 20 to 30 mg intramuscularly.<sup>21,76</sup> Clinical improvement usually occurs within 7 to 14 days. Relapses occur, and the horse may require lifelong therapy.

## ☉ DERMATOSIS OF THE LOWER LIMB

Skin diseases of the lower limbs of horses are common dermatologic problems. These diseases may be extensions of generalized dermatoses or unique clinical syndromes.

### INFECTIOUS DISEASES OF THE LOWER LIMB

#### BACTERIAL PASTER FOLLICULITIS

Bacterial folliculitis of the pastern is caused by *Staphylococcus aureus*, *Staphylococcus hyicus*, or  $\beta$ -hemolytic streptococci.<sup>82,106</sup> This disease is considered a primary pyoderma, but the mechanism by which organisms initiate the disease is unknown.

Lesions are limited to the posterior aspect of the pastern and fetlock region and may affect single or multiple limbs. The initial lesion consists of papules and pustules that eventually coalesce and produce large areas of ulceration and suppuration. The disease is not associated with systemic signs.

The diagnosis is based on clinical signs, skin scrapings, cytologic examination of the exudate, Gram stain, and bacterial culture and sensitivity. Cytologic examination of pustule contents usually reveals large numbers of neutrophils engulfing bacteria.

Sedation may be necessary for initial treatment because lesions are painful.<sup>106</sup> One should clip hair from affected areas and wash the area daily in an antimicrobial scrub or shampoo (e.g., chlorhexidine shampoo or scrub) and should apply an appropriate antibiotic ointment without corticosteroids twice daily. Systemic antibiotic therapy is not usually necessary.

#### ULCERATIVE LYMPHANGITIS

Ulcerative lymphangitis is a bacterial infection of the cutaneous lymphatics of horses. Lesions are most common on the hindlegs, especially distal to the hock, and consist of hard to fluctuant nodules that abscess, ulcerate, and drain pus. Individual nodules may heal, but new lesions develop. Cording of the regional lymphatics, edema, and fibrosis are common. Regional lymph nodes usually are not involved.

A definitive diagnosis is based on direct smear, Gram stain, and culture of a nodule. Skin biopsy reveals superficial and deep perivascular dermatitis that may be suppurative or

pyogranulomatous. Special stains (Brown and Brenn, and Gram) may reveal the organism.

If one treats the disease early, therapy may be effective and may prevent permanent disfigurement and debilitation. The drug of choice pending culture and sensitivity is procaine penicillin 20,000 to 80,000 IU/kg intramuscularly every 12 hours for 30 days or longer. Adjunct hydrotherapy may be beneficial. After fibrosis develops, prognosis is poor.<sup>106</sup> One should clean the affected area daily with copious amounts of water and wash it with an antimicrobial scrub (e.g., chlorhexidine).

#### VIRAL PAPILOMATOSIS

Equine viral papillomatosis (warts) is caused by a DNA papovavirus.<sup>101</sup> Viral papillomatosis is common in horses and occurs most frequently in horses less than 3 years of age. No sex or breed predilection exists. Transmission appears to be by direct contact. Groups of young horses are often affected more frequently than horses of the same age housed individually. Lesions are most common on the muzzle, genitalia, and distal legs and are usually multiple and resemble papillomatosis of other species.

A definitive diagnosis is made by skin biopsy. Epithelial proliferation without connective tissue proliferation is typical.

Benign neglect is the best treatment for these lesions; spontaneous remission almost always occurs. One should consider surgical removal only when the lesion interferes with function. Anecdotal reports that surgical removal or damage to part of the lesion induces remission of the lesion are unproven.<sup>83</sup> In fact, controlled studies suggest that such intervention might increase the duration of the lesions.<sup>83,106</sup> Efficacy of autogenous vaccines is unproven.

#### SPOROTRICHOSIS

The dimorphic fungus *S. schenckii* causes sporotrichosis, which was discussed in detail under Infectious Causes of Nodules.

A cutaneous lymphatic form of sporotrichosis may localize to the distal extremities of horses. The lymphatics become corded, and large nodules ulcerate and drain a thick brown-red discharge. Regional lymph nodes are not involved. Edema is rare. Diagnosis and treatment have been discussed previously.

### PARASITIC DISEASES OF THE LOWER LIMB

The common parasitic diseases of horses have been discussed previously (see Parasitic Skin Diseases). Infestations of lice, *Chorioptes* spp., and chiggers are the most common parasitic dermatoses that cause lower limb pruritus.

### NEOPLASTIC AND NONNEOPLASTIC PROLIFERATION DISEASES OF THE LOWER LIMBS

#### KELOIDS

A keloid is a nonneoplastic fibroblastic response that occurs on the pastern of horses. Clinically the keloid resembles a cluster of grapes. A definitive diagnosis is determined by biopsy. These lesions do not respond to surgical excision, and in fact surgery may exacerbate them.<sup>21,106</sup> The best treatment for keloids is by intralesional injection of triamcinolone acetonide (not to exceed 20 mg per horse). Unfortunately, most lesions are so massive that response to therapy is poor.

## HEMANGIOMATA

Hemangiomas are benign tumors of the endothelial cells of blood vessels. Lesions occur most commonly in horses less than 1 year of age, and some horses are born with them.<sup>83</sup> Hemangiomas tend to be solitary tumors occurring on the distal limbs. The clinical appearance varies and may be circumscribed, nodular, firm to fluctuant, blue to black in color, dermal or subcutaneous, hyperkeratotic, or verrucous. Ulceration and bleeding are common.

Confirmation of the diagnosis is made by skin biopsy, which reveals proliferation of blood-filled vascular spaces lined by single layers of well-differentiated endothelial cells.<sup>37,83</sup> Equine hemangiomas are characterized by a multinodular capillary hemangioma with hyperplasia and hyperkeratosis of the overlying epidermis.

Surgical excision is the treatment of choice. Equine verrucous hemangioma is difficult to excise, and cryosurgery may be beneficial. Recurrence is common.

## AUTOIMMUNE DISEASES OF THE LOWER LIMBS

### PEMPHIGUS FOLIACEUS

Pemphigus foliaceus was discussed under Immunologic Causes of Exfoliation. In some horses the condition affects only the coronary band.<sup>1</sup> The coronary band of all four limbs is crumbly, degenerating, and exudative. Pain, lameness, and edema of the lower limb may occur.

### SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus is a multisystemic autoimmune disease that is rare in horses. Profound lymphedema of the lower limbs may be the only clinical sign. The disease is treated with immunosuppressive doses of prednisolone (2 mg/kg orally every 12 hours). The prognosis is grave.

### VASCULITIS

Vasculitis was discussed earlier under Vasculitis and Purpura Hemorrhagica. In some horses, cutaneous vasculitis is restricted to the white skin of the pasterns and face of horses in the summer.<sup>1</sup> Characteric lesions are erythema, swelling, pain, and exudation, and lesions may resemble photodermatitis, which suggests a photoinduced cause. Edema of the pastern and face is significant.

### LEUKOCYTOCLASTIC VASCULITIS

Leukocytoclastic vasculitis or photoaggravated vasculitis is a relatively common but poorly understood disease.<sup>80</sup> Immune deposits (immunoglobulin G or complement component 3 or both) around the vessel walls have been detected in early skin lesions using direct immunofluorescence. The fact that unpigmented skin appears to be affected suggests a role of ultraviolet light in the development of this dermatologic problem. Drug reactions may play a role and a recent report suggested that *Staphylococcus* spp. bacterial infection as an underlying cause. This dermatologic condition generally affects mature horses. The skin lesions are confined to the lower limb (Figure 13-37). A lack of pigment in the affected area is the most common finding, but pigmented skin has also been reportedly diagnosed with this condition. Lesions are usually multiple and well marked. Initially, erythema and exudation occur,

FIGURE 13-37 Horse with leukocytoclastic vasculitis.

which progresses to crusting and open sores or ulcerated areas. The affected area may ooze, and swelling is present. Chronic cases may develop a rough or “warty” surface. This condition is more painful than pruritic. The diagnosis for this condition is made by skin biopsy. On histopathologic examination, leukocytoclastic skin lesions will have inflammation around the blood vessels with blood vessel degeneration and clots involving the small vessels in the superficial dermis. Treatment consists of systemic corticosteroids at relatively high doses for 1 week and reduced doses for another 4 to 6 weeks. A reduction in ultraviolet light exposure by bandaging the affected leg or stabling the horse indoors during daylight hours or both is thought to be beneficial. Application of sun block (minimal sun protection factor of 20) is thought to be beneficial.

### PASTERM DERMATITIS (GREASY HEEL AND SCRATCHES)

Skin disease of the lower limbs is a common and frustrating problem in horses. Pastern dermatitis, scratches, greasy heel, and mud fever are colloquial terms for a moist exudative dermatitis of the caudal heel and pastern area. The reader should remember that these terms are nonspecific and describe a variety of inflammatory skin conditions of the lower limbs of horses.

The pathogenesis of this syndrome is not understood completely. The initial lesion may be a primary infection or may follow a predisposing factor such as PF or mites. Horses with long fetlock hair or horses housed in muddy paddocks, unsanitary conditions, or rough stubbly pasture are at risk for

**FIGURE 13-38** Pastern dermatitis.

pastern dermatitis. The problem is common in horses worked on tracks consisting of grit particles, which can cause micro-trauma to the skin.

Clinical signs depend greatly on whether the condition is acute or chronic and whether the owner has treated the lesions. Many horse owners do not recognize the acute development of skin diseases, minimizing the opportunity to identify the underlying cause. To complicate matters further, many owners treat these lesions before seeking veterinary care. Many common over-the-counter medications can induce irritant or allergic reactions, making distinguishing between these reactions and the original skin disease almost impossible.

Regardless of the cause, clinical signs are similar (Figure 13-38).<sup>106</sup> Acute lesions usually begin at the heel. Pain, swelling, moist exudation, and hair loss are common. As the disease process continues, lesions spread proximally and anteriorly. Matting of the hair occurs, and the horse may be noticeably lame. Crusting is common. If the underlying disease process involves a vasculitis, ulceration may be present. If the disease is left untreated, a foul odor develops. Because of the constant flexion in the area, fissures often develop. In Draft horses, vegetative granulomatous growths commonly result. Lesions may

occur on one or multiple limbs or just on extremities with white markings.

A definitive diagnosis requires a complete medical history. Liver function tests are essential in any horse in which the lesions are limited to the unpigmented areas of the skin. One should perform *Dermatophilus* preparations, fungal cultures, and skin scrapings in all cases. In horses with long hairs on the fetlocks, the hair should be combed thoroughly with a fine-toothed metal comb, which is often the only successful method for finding lice. In difficult cases, tissue samples should be submitted for bacterial or fungal culture.

Correct therapy requires identifying the underlying cause. The reader can find specific therapy for most of the diseases elsewhere in this chapter or in the references. In all cases, one should clip the long hairs of the fetlock area and thoroughly wash the affected area with an antimicrobial scrub (e.g., 2% chlorhexidine). Iodine preparations should be avoided because they can be irritating. One should remove all crusts and exudation, daily if necessary, and should avoid exposing the horse to moistures and irritants. Horses with idiopathic greasy heel often respond well to cleaning of the area, improved hygiene of the stall, and systemic corticosteroid therapy (assuming bacteria are not the cause). Large doses of prednisolone (e.g., 1 mg/kg orally once daily) may be necessary to induce remission of clinical signs. One should not decrease the dose of glucocorticoids too rapidly or relapse may occur. If oral prednisolone does not induce remission, dexamethasone at 0.02 to 0.04 mg/kg orally once daily for 3 to 5 days may be effective.

## ☞ SYSTEMIC DISEASES WITH CUTANEOUS MANIFESTATIONS

Reviewing all the skin diseases that may have systemic clinical signs is beyond the scope of this chapter. The author has made an effort to include the most common systemic findings in this chapter. Table 13-2 provides a brief summary.

TABLE 13-2

<b>Skin Diseases with Systemic Manifestations</b>		
<b>Disease</b>	<b>Cutaneous Signs</b>	<b>Systemic Signs</b>
<b>ENVIRONMENTAL</b>		
Gangrene	Wet: moist swelling, discoloration, malodorous, tissue decomposition Dry: dry, discolored, leathery skin	Depends on underlying cause; fever
Burns	Superficial: erythema, edema, pain, vesicles Deep: necrosis, ulceration, anesthesia, scarring	Shock, respiratory compromise
Selenosis	Painful coronary band, sloughing and necrosis of hoof, rough hair coat, progressive loss of long hairs of mane and tail	Lameness, weight loss
Arsenic poisoning	Severe seborrhea, ulcer, nonhealing wounds, hypertrichosis	Gastroenteritis, emaciation, variable appetite
Mercury poisoning	Progressive alopecia	Gastroenteritis, lameness, emaciation
Iodism	Severe dry seborrhea with or without hair loss	Cough, variable appetite, joint pain, seromucoid nasal discharge, lacrimation
Hepatogenous photosensitization	Erythema, edema, pruritus, pain, in white or light-skinned area; vesicles and bullae may progress to oozing, necrosis, and sloughing	Acute: hepatic encephalopathy, icterus, depression, decreased appetite Chronic: weight loss, depression neurologic signs
Ergotism	Swelling of coronary band, necrosis of feet, sloughing of ears, tail, feet	Lameness of hind legs, fever, weight loss, poor appetite
Leucenosis	Hoof dystrophies, shedding of hair	Laminitis, lameness
Hairy vetch toxicosis	Cutaneous plaques and papules that ooze yellow pus; pruritus; hair loss	Conjunctivitis, anorexia, pyrexia, weight loss
<b>BACTERIAL DISEASES</b>		
Strangles	Limb edema; edema of lips, eyelids; petechial hemorrhages of mucous membranes and sclera	History of acute contagious upper respiratory infection; pyrexia, mucopurulent nasal discharge; abscesses in the mandibular or retropharyngeal lymph nodes
<i>Corynebacterium pseudotuberculosis</i> abscesses	Single or multiple deep abscesses that develop slowly or rapidly; 50% occurring in the pectoral or ventral abdominal area; ventral midline edema	Pitting edema, depression, fever, lameness, internal abscess, prolonged fever, abortion
Dermatophilosis	Exudative crusted lesions on dorsal trunk, face, pastern, or coronets	Depression, fever, lethargy, poor appetite, weight loss, lymphadenopathy; lesions on legs may cause edema, pain, and lameness.
Actinobacillosis	Thick-walled abscess of soft tissue	In newborn foals, disease is a highly fatal septicemic disease, and skin lesions are rare.
Clostridial infections	Malignant edema: swelling at site of infection, pitting edema, local erythema; skin may become hot to touch, painful, or slough; crepitus Blackleg: hot, painful, swelling that progresses to a cold painful swelling with edema and subcutaneous emphysema	High fever, anorexia, muscle tremors, acute death possible within 24-48 hours
Glanders (farcy) <i>Burkholderia mallei</i> (not in United States)	Subcutaneous nodules begin most commonly on medial aspect of hock; lesions rapidly ulcerate and drain a honey-colored material; lymphadenopathy and cording of lymphatics is common	Respiratory infection that rapidly leads to death
<b>FUNGAL DISEASE</b>		
<i>Histoplasma farciminosum</i> (epizootic lymphangitis)	Unilateral nodules on face, head, neck and occasionally trunk; nodules initially are firm but rupture and exude light-green, blood-tinged exudate; large ulcer may form and lesions may spread bilaterally	Lacrimation, conjunctivitis, and respiratory signs may occur

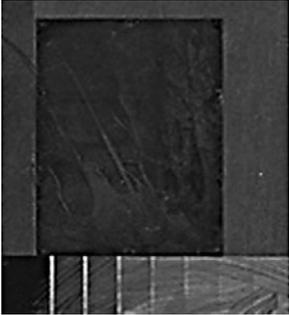

TABLE 13-2

<b>Skin Diseases with Systemic Manifestations—cont'd</b>		
<b>Disease</b>	<b>Cutaneous Signs</b>	<b>Systemic Signs</b>
<b>PARASITES</b>		
Lice	Pruritus, scaling, alopecia	Anemia in severe infestations with sucking lice
Black flies	Painful papules, and wheals that may become vesicular, hemorrhagic, and necrotic; lesion may be localized to ears or intermandibular areas	Toxin in bite can cause increased capillary permeability; depression, weakness, staggers, tachypnea, tachycardia, weak pulse, shock, and possible death
<b>IMMUNE-MEDIATED DISEASES</b>		
Atopy	Chronic pruritic urticaria, excoriations, alopecia, lichenification	Respiratory difficulty, especially on expiration
Pemphigus foliaceus	Crusts, scales, oozing, annular eruption, matting of the coat; lesions may be limited to coronary band	Depression, weight loss, poor appetite, pyrexia
Bullous pemphigoid	Vesicles and bullae in mouth, groin, and axilla; crusts, ulcers	Anorexia, depression, fever
Systemic lupus erythematosus	Lymphedema, panniculitis, alopecia, leukoderma; scaling of face, neck, and trunk	Polyarthritis, thrombocytopenia, proteinuria, fever, depression, weight loss
Transfusion reactions and graft-versus-host disease (may occur in horse after unmatched blood transfusion)	Exfoliative to ulcerative dermatitis, ulcerative stomatitis	Diarrhea, increased heart and respiratory rates, lacrimation, muscle fasciculation
Erythema multiforme	Symmetric maculopapular lesions, urticaria that results in annular arciform or polycyclic shapes; wheals that do not disappear	Occurs after pregnancy, drugs, neoplasia, connective tissue disease, and infections or may be idiopathic
Vasculitis	Purpura, edema, erythema, necrosis, crusts; purpura hemorrhagica causes edema and hemorrhagic swelling in tissue, mucosa, and viscera	May occur after strangles or influenza; depression, fever, reluctance to move, colic, diarrhea
Equine exfoliative eosinophilic dermatitis and stomatitis	Scaling and crusting that progress to generalized exfoliation, alopecia, ulceration, and exudation; variable pruritus	Severe, progressive weight loss; no diarrhea, ravenous appetite
Equine cutaneous amyloidosis	Papules, nodules, and plaques over the head and neck that develop rapidly	Diffuse nodules in upper respiratory tract may cause severe dyspnea
<b>ENDOCRINE DISEASES</b>		
Hypothyroidism	Dull rough hair coat, delayed shedding of coat, edema of face and limb	Anecdotal reports of laminitis, infertility, anhidrosis, anemia, myopathy; weight gain and decreased food intake; skeletal limb disorders have been reported in foals
Pituitary paors intermedia dysfunction	Long shaggy hair that fails to shed; mane and tail are unaffected	Polydipsia, polyuria, muscle wasting, weight loss, lethargy, swayback appearance, pendulous abdomen, blindness, chronic infections, neurologic disorders or signs
<b>SWEAT GLAND DISORDERS</b>		
Anhidrosis	Acute episode: none Chronic: dry hair coat, excessive scaling, partial alopecia, pruritus	Acute: labored breathing, fever, flared nostrils, lack of sweating, collapse, death Chronic: polydipsia, polyuria, poor appetite, loss of body condition
<b>MISCELLANEOUS DISEASES</b>		
Panniculitis	Firm to fluctuant nodules most commonly found on trunk in subcutaneous tissue that ruptures and drains an oily yellow-brown to bloody discharge	Anorexia, depression, lethargy, pyrexia
<b>NEOPLASTIC DISEASES</b>		
Hemangioma and hemangiosarcoma	Two types: (1) well-circumscribed nodules that are blue-black in appearance; (2) dark hyperkeratotic and verrucous lesions that bleed easily	Anemia
Lymphosarcoma	Single or multiple dermal-to-subcutaneous nodules, especially on trunk	Internal organ involvement; usually fatal

# DISORDERS OF THE HEMATOPOIETIC SYSTEM

## CHAPTER 14

*Debra C. Sellon, L. Nicki Wise*

The hematopoietic system includes the blood and blood-forming tissues of the body. Peripheral blood cells are essential for tissue oxygenation, immune surveillance and clearance of foreign antigens, coagulation, and inflammatory reactions. Because of the interactions of blood with other body tissues and organs, alterations in blood parameters often reflect dysfunctions elsewhere in the body, and evaluation of the blood and its constituents has become an essential component of many diagnostic efforts.

This chapter discusses the basics of hematopoiesis and hematopoietic metabolism as they relate to specific disease conditions in the horse. Included is a discussion of the erythron, leukon, platelets, and hemostatic mechanisms of the horse.

### ERYTHRON

Erythropoietic tissue of the bone marrow and the circulating erythrocytes may be referred to as the *erythron*, to emphasize their organlike function. Erythrocytes are essential for delivery of oxygen to all tissues of the body. The complex maturation and development of erythrocytes and their pivotal role in survival of all body tissues make them uniquely reflective of many pathologic conditions. An understanding of the erythron and its responses to perturbations in homeostatic mechanisms throughout the body can provide the astute clinician with invaluable clues in unraveling difficult diagnostic dilemmas.

### PHYSIOLOGY

*Erythropoiesis* refers to the process of development and maturation of erythrocytes. Knowledge of the metabolic processes of these cells is critical to understanding pathologic processes that interfere with their primary function of tissue oxygenation.

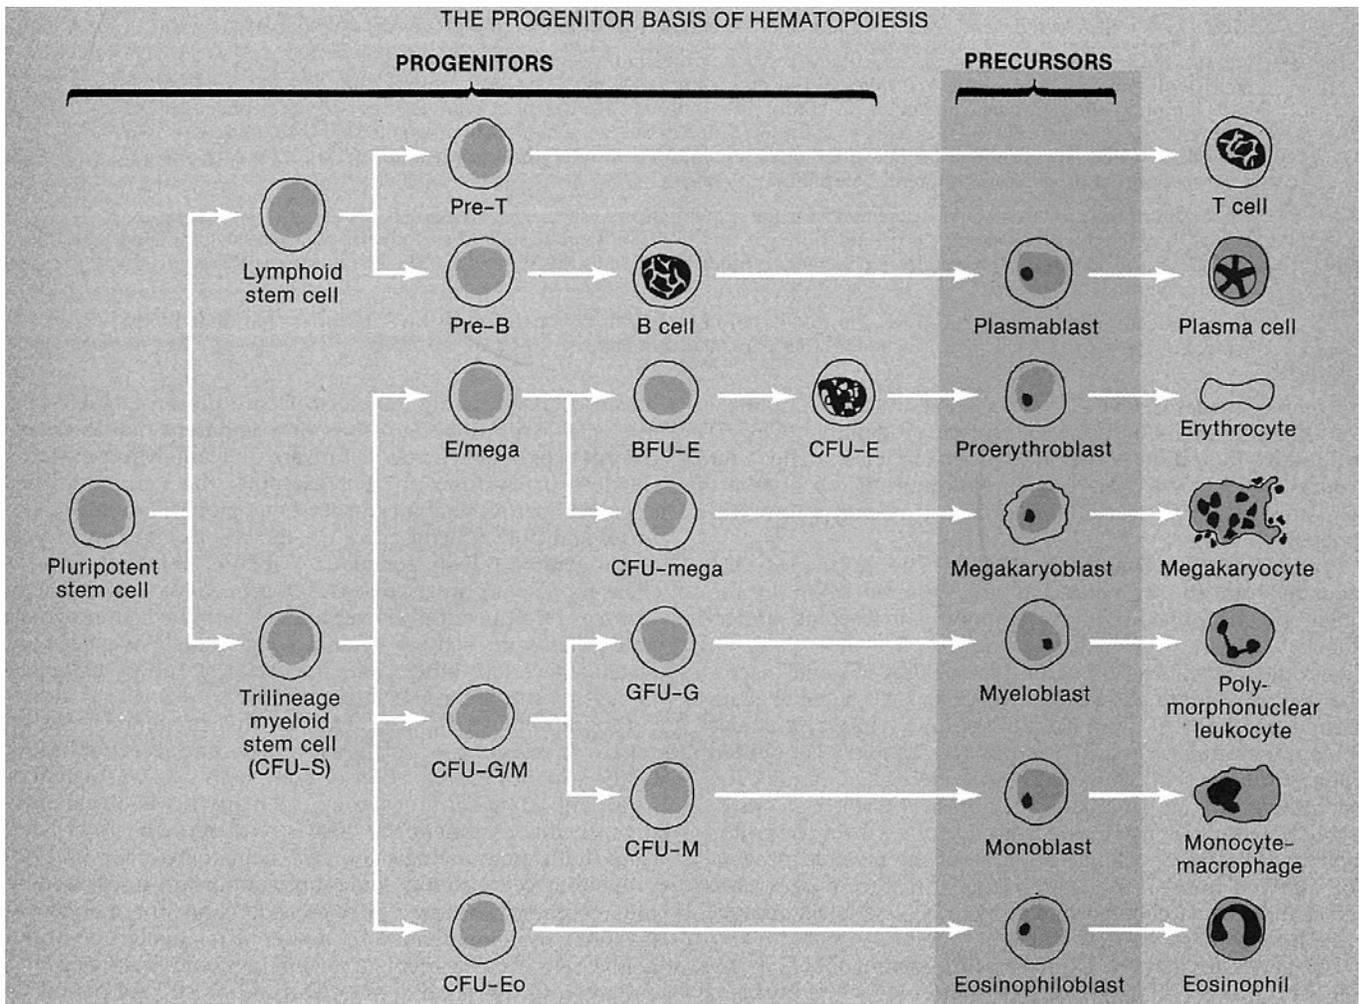

In the fetus, the cellular elements of blood are produced almost exclusively in the liver and spleen. As the body matures and differentiates in utero, hematopoiesis gradually shifts to the marrow cavities so that at birth the bone marrow is the main organ of hematopoiesis. As an animal ages, bone marrow hematopoiesis decreases and fat infiltrates much of the previously active marrow. In the older adult animal, active hematopoiesis is limited to the marrow of the vertebrae, ribs, sternum, skull, and pelvis, as well as to the epiphyseal marrow of the humerus and femur.

Erythrocyte production begins from a pluripotent colony-forming unit stem cell capable of differentiating into erythroid-, myeloid-, megakaryocytoid-, or lymphoid-producing cell lines. The stem cell is capable of self-renewal to provide a continuing supply of pluripotent stem cells. The direction of differentiation is determined in part by the types and quantities of cytokine mediators to which the stem cell is exposed at the time it begins to divide. The exact combinations of mediators necessary to direct differentiation into each line are not understood entirely. In erythrocyte development the stem cell undergoes sequential mitotic divisions to produce the committed erythrocyte progenitor burst-forming unit, followed by erythroid colony-forming units. These two stages are capable of limited replicative self-renewal but are committed ultimately to differentiate into erythrocytes (Figure 14-1). Burst-promoting activity depends on the presence of various cytokines, including interleukin 3 (IL-3), IL-4, and granulocyte-macrophage colony-stimulating factor. The erythroid colony-forming unit cell is the immediate precursor stage of the first morphologically recognizable erythrocyte precursor, the proerythroblast.

Initial stages of erythrocyte development depend greatly on the presence of the glycoprotein hormone erythropoietin, which the kidney produces in response to renal hypoxia and is an absolute requirement for erythrocyte progenitor cell maturation and differentiation. The absence of erythropoietin, as in patients with chronic renal disease, is associated with potentially severe nonregenerative anemia. Erythrocytosis, an increase in the circulating red blood cell (RBC) mass, is associated with excess secretion of erythropoietin in certain disease conditions.

Bone marrow proerythrocytes undergo four successive divisions followed by a period of maturation to produce 16 erythrocytes. Sequential divisions produce basophilic erythroblasts, polychromatophilic erythroblasts I and II, and orthochromic erythroblasts. The orthochromic erythroblast becomes a reticulocyte by ejecting its nucleus. Reticulocyte production requires approximately 72 hours; 24 to 48 hours later the reticulocyte will have matured into an erythrocyte.

Iron is an essential component for hemoglobin synthesis and thus for erythropoiesis. The diet of the horse normally contains an abundance of readily available iron. Absorption is most efficient in the duodenum but may occur at almost any part of the gastrointestinal tract. The amount of iron

**FIGURE 14-1** Schematic representation of the progenitor basis of hematopoiesis. Maturation is depicted from left to right with circulating blood cells as the final product on the far right of the drawing. Progressive amplification of progenitors and precursors as they mature and differentiate is not shown. *CFU-S*, Colony-forming unit, spleen; *CFU-G/M*, CFU-granulocyte/macrophage; *CFU-Eo*, CFU-eosinophil; *BFU-E*, burst-forming unit, erythroid; *CFU-mega*, CFU-megakaryocyte; *CFU-G*, CFU-granulocyte; *CFU-M*, CFU-monocyte; *CFU-E*, CFU-erythrocyte. (From Wyngaarden JB, Smith LH, editors: *Cecil textbook of medicine*, ed 18, Philadelphia, 1988, WB Saunders.)

absorbed from the gastrointestinal tract varies with the systemic iron status of the animal. Absorption increases in iron-depleted animals and decreases in animals with ample iron stores. Unabsorbed iron passes through the remainder of the tract and is lost in feces. Horses, especially young foals, supplemented with excessive dietary iron can develop hemochromatosis, hepatic cirrhosis, and liver failure.<sup>1-4</sup>

After absorption the blood transports iron complexed with the protein transferrin. In the liver, spleen, and bone marrow, iron is transferred to molecules of the storage protein ferritin. Approximately 30% of body iron is present in the storage proteins ferritin and hemosiderin (a complex aggregation of ferritin molecules). Only minute amounts of iron are complexed to the transport protein transferrin at any given time. Minor quantities of iron are also present in myoglobin and various electron transport molecules and enzymes. The hemoglobin of senescent erythrocytes removed from the peripheral circulation is degraded in cells of the mononuclear phagocyte system in the spleen, liver, and bone marrow. Iron ultimately is recycled to the bone marrow or liver to be used in synthesis

of hemoglobin for new erythrocytes. Almost 70% of total body iron is present in hemoglobin.

Hemoglobin is synthesized in the mitochondria of the developing erythroblast and consists of four polypeptide chains (two  $\alpha$  and two  $\beta$  in the adult) and a heme moiety. Heme is the functional portion of the hemoglobin molecule and contains an iron atom held in place by the four pyrrole rings of a porphyrin molecule. The iron in hemoglobin must be in the ferrous form ( $\text{Fe}^{2+}$ ) to bind oxygen reversibly. Heme iron oxidized to the ferric form ( $\text{Fe}^{3+}$ ) forms methemoglobin, and the molecule is no longer capable of transporting oxygen.

The normal life span of equine erythrocytes in circulation is approximately 150 days.<sup>5,6</sup> Mononuclear phagocytes of the spleen, liver, and bone marrow remove senescent RBCs from circulation. Transferrin transports released iron to RBC precursors in the marrow. Heme in phagocytic cells undergoes enzymatic degradation to biliverdin and then bilirubin. Phagocytic cells release unconjugated bilirubin into the circulation, where it binds to plasma albumin. Hepatocytes take up unconjugated bilirubin, which is conjugated and excreted via the bile into

the gastrointestinal tract, where it is converted to urobilinogen and then stercobilin. Intravascular or extravascular hemolysis often results in increased serum unconjugated bilirubin concentrations.

During intravascular hemolysis, ruptured erythrocytes release hemoglobin, which combines with haptoglobin, an acute phase protein normally present in plasma, to be carried back to the liver, where hemoglobin is converted to bilirubin and excreted. If the level of hemoglobin exceeds the carrier capacity of hemoglobin, then the result is free hemoglobin in the plasma. Free plasma hemoglobin is filtered readily across the renal glomerulus and reabsorbed by renal tubular epithelial cells. Hemoglobin and other related pigment molecules, including myoglobin, are potentially nephrotoxic, and excessive intravascular hemolysis may result in acute renal failure.

The mature erythrocyte is an anucleate cell incapable of de novo protein synthesis to replace enzymes or other proteins that have been used during normal metabolism. Binding, transport, and delivery of oxygen to tissues does not require energy expenditure by the erythrocyte, but maintaining iron and various cellular proteins in a reduced state essential for proper function does require energy. Maintenance of appropriate electrolyte gradients across the RBC membrane also requires energy. Glucose is the main in vivo energy source for erythrocytes. RBCs differ from other cell types in the absence of the Krebs (tricarboxylic acid) cycle. Glucose must be metabolized via the anaerobic glycolytic (Embden-Meyerhof) pathway or via the hexose monophosphate shunt. The enzymes involved in these metabolic pathways are critical to RBC survival and rare hereditary deficiencies have been described in the horse. The deficiencies of either glucose-6-phosphate dehydrogenase (G6PD) or flavin adenine dinucleotide (FAD) resulted in hemolytic anemia and persistent methemoglobinemia, respectively.<sup>7,8</sup>

The body must maintain iron, hemoglobin, some critical RBC enzymes, and several membrane proteins in a reduced form for appropriate activity. High intracellular concentrations of glutathione (GSH), a sulfhydryl-containing tripeptide, are important for reduction of sulfhydryl groups of hemoglobin and other erythrocyte proteins. Reduction reactions

involve the conversion of GSH to its oxidized form (GSSG), which then is returned to the reduced form (GSH) by the action of GSH reductase. When the functional ferrous form of iron (Fe<sup>2+</sup>) in hemoglobin is oxidized to the ferric form (Fe<sup>3+</sup>), the resulting methemoglobin is incapable of carrying oxygen. Small amounts of methemoglobin (1% to 2% of total hemoglobin) are produced normally in erythrocytes. This methemoglobin is reduced to functional hemoglobin primarily via the action of the enzyme methemoglobin reductase.

## EVALUATION OF THE ERYTHRON

Laboratory evaluation of the blood and bone marrow provides diagnostic clues that may aid the practitioner in diagnosing and treating a variety of disorders. Knowing the tests that are available and developing an understanding of how and why they are performed aids one in interpreting the results.

### PERIPHERAL BLOOD EVALUATION

Most clinical laboratories now use automated cell counters for evaluation of peripheral blood. These counters are capable of determining RBC counts, hemoglobin, packed cell volume (PCV), and various erythrocyte indices. Tables 14-1 and 14-2 list normal values for the horse.<sup>9,10</sup> These values are intended as guidelines only. Each laboratory should establish its own normal values for each species.

Red blood cell count, hemoglobin, and PCV are the most frequently used parameters for assessing the quantity of erythrocytes in circulation. In the normal horse, hemoglobin concentration is approximately one third of the PCV. This value increases in horses with intravascular hemolysis and hemoglobinemia. RBC count, hemoglobin concentration, and PCV decrease rapidly during the first weeks of life in the equine neonate. This decrease has been attributed to decreased erythrocyte production, a shorter RBC life span in the neonate, and hemodilution. During this period, mean RBC volume also decreases to the point that cells would be classified as *microcytic* if compared with normal adult values.<sup>11</sup>

Evaluation of RBC indices can be helpful in characterizing anemia. If these parameters are not included in automated

TABLE 14-1

### Reference Ranges for Equine Hematologic Parameters\*

Parameter	Units	Light Horse <sup>†</sup>	Draft Horse <sup>‡</sup>	Miniature Horse <sup>§</sup>	Donkey <sup>¶</sup>
RBC count	10 <sup>6</sup> /μl	6.0-10.0	5.5-9.5	4.3-10.3	4.7-9.0
Hemoglobin	g/dl	12.0-17.0	8.0-14.0	9.0-16.0	9.5-16.5
PCV	%	32-50	24-44	24-42	28-47
MCV	fl	42-58	—	38-61	46-67
MCH	μg	15-20	—	14-23	16-23
MCHC	g/dl	32-38	—	33-40	32-36

RBC, Red blood cell; PCV, packed cell volume; MCV, mean corpuscular volume; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration.

\*Numbers are for comparison only. Each laboratory should establish its own normal values.

Percheron	7.39 ± 1.08	11.7 ± 1.4	—	—	—	—
Mixed cold-blooded	7.76 ± 1.23	—	33.0 ± 7.0	42.3	—	—

From Moms DD: Review of anemia in horses. I. Clinical signs, laboratory findings and diagnosis, *Vet Clin North Am Equine Pract* 11:27-34, 1989; modified from Jain NC, editor: *Schalm's veterinary hematology*, ed 4, Philadelphia, 1986, Lea & Febiger.

RBC, Red blood cell; Hgb, hemoglobin; PCV, packed cell volume; MCV, mean corpuscular volume; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration.

blood analyses, then they may be calculated from the PCV, RBC count (in millions), and hemoglobin (in g/dl) as presented in Box 14-1. Some automated cell counters also report RBC distribution width.

Peripheral blood evaluation is not complete without a thorough examination of a stained blood smear to assess erythrocyte morphology. The normal equine erythrocyte is a biconcave disc; however, in contrast to other species, most equine RBCs lack distinct central pallor. Equine RBCs normally exhibit a strong tendency toward rouleau formation, a coin-like stacking or grouping of erythrocytes. This tendency causes equine erythrocytes to sediment rapidly after collection, and one should mix all samples thoroughly, immediately before any evaluation. Excellent pictures of normal and abnormal equine erythrocyte morphologic condition are available in a variety of texts, and the reader is referred to those to aid in recognition of the following cell types<sup>12,13</sup>:

**Poikilocyte:** Any abnormally shaped erythrocyte. Poikilocytosis usually is reserved for description of RBCs that exhibit a variety of morphologies. If one particular shape predominates, then one should use a more specific description.

**Anisocytosis:** A variability in the size of erythrocytes, usually associated with an increased RBC distribution width.

**Polychromasia:** A variability in the color of erythrocytes usually caused by a variable hemoglobin and RNA content.

**Spherocyte:** Spherical erythrocyte observed in some horses with immune-mediated hemolysis.

**Echinocyte:** Burr cell with short, regularly spaced spicules projecting from the RBC surface. Echinocytes may be associated with uremia.

**Acanthocyte:** Spur cell with irregularly shaped spicules extending from the RBC surface. Acanthocytes may be associated with liver disease or gastrointestinal malabsorption.

**Elliptocyte:** Ellipsoid or oval erythrocyte found in animals with iron deficiency or myelophthisic anemia.

**Leptocyte:** Thin, flat RBC frequently associated with hepatic disease or iron deficiency.

**Codocyte:** Target cell with a dense central area of hemoglobin surrounded by a pale zone. Codocytes may be associated with hypochromic anemias or hepatic disease.

RBC, Red blood cell; PCV, packed cell volume; MCV, mean corpuscular volume; MCHC, mean corpuscular hemoglobin concentration.

**Howell-Jolly bodies:** Basophilic nuclear remnants seen in the cytoplasm of erythrocytes. Approximately 10 in 10,000 erythrocytes contain Howell-Jolly bodies in the normal horse.<sup>13</sup>

*Heinz bodies*: Oxidized precipitated hemoglobin indicating oxidative damage to the RBC, usually resulting in intravascular or extravascular hemolysis. One may see Heinz bodies best using new methylene blue stain but may observe them in smears using Wright's stain as round structures protruding from the edge of the RBC membrane.

Occasionally, specialized tests of erythrocyte function or stability are indicated. Osmotic fragility tests measure the resistance of erythrocytes to *in vitro* hemolysis when incubated in increasingly hypotonic sodium chloride (NaCl) solutions. Erythrocytes from horses with immune-mediated hemolytic anemia (IMHA) frequently are more fragile than RBCs from normal horses.<sup>14,15</sup> The direct antiglobulin or Coombs' test is also helpful for diagnosing IMHA. Coombs' test detects immunoglobulin (Ig) or complement on the surface of circulating erythrocytes. The Coombs' reagent should contain antisera to immunoglobulin G (IgG), immunoglobulin M (IgM), and the third component of complement (C3). One incubates washed erythrocytes from the patient with Coombs' reagent and observes for agglutination. The cells can be incubated at 10° C to detect cold reactive antibodies or at 30° C to detect warm reactive antibodies.<sup>13</sup> Because agglutination is the end point of the direct Coombs' test, autoagglutination of blood is considered diagnostic of immune mediated hemolysis. One must differentiate autoagglutination from rouleau formation by dilution of an RBC suspension with isotonic saline. Saline disperses rouleau formation but does not affect true autoagglutination. The indirect Coombs' test detects the presence of circulating anti-RBC antibody in the serum by incubating patient serum with normal equine erythrocytes and monitoring for agglutination.

### BONE MARROW EVALUATION

Examination of the bone marrow of a horse is indicated if one identifies or suspects a disorder of the hematopoietic system but cannot diagnose it from information gathered by history, physical examination, and routine laboratory tests.<sup>16</sup> Bone marrow aspirates or core biopsies may be useful in characterizing anemias, evaluating iron stores, or explaining quantitative or qualitative abnormalities of blood cells.

One may collect equine bone marrow aspirates or biopsies from the sternum,<sup>16-18</sup> tuber coxae,<sup>16,19</sup> or proximal ribs.<sup>16,20</sup> The sternal aspirates are obtained from the ventral midline between the front legs. This site is preferable in most horses because hematopoietic activity persists throughout life, bones are not covered by a large muscle mass, and the marrow cavity is covered by only a thin layer of bone.<sup>16</sup> One may attempt an aspirate of the tuber coxae in young horses by directing the needle toward the opposite coxofemoral joint. The costal marrow is collected from the proximal portion of an easily palpable cranial rib, usually beneath the latissimus dorsi and serratus posticus muscles.<sup>20</sup> Any large-gauge (16 gauge or larger) bone marrow needle with stylet can be used to collect marrow aspirates. The needle should be at least 2 inches long. The veterinarian clips the appropriate area and surgically scrubs it, injects a small amount of local anesthetic into the subcutaneous and periosteal tissues, and makes a stab incision through the skin and subcutaneous fascia. Forcing the bone marrow needle through the bone and into the marrow cavity may require considerable pressure and rotational movement.

The veterinarian removes the stylet from the needle; uses a sterile syringe containing a small quantity of anticoagulant to

aspirate red-colored marrow, discontinuing aspiration when blood is visible in the hub of the syringe; withdraws the needle; and smears marrow from the hub of the syringe and the needle on glass microscope slides as for blood smears. Alternatively, one injects the marrow sample into a Petri dish. On visualization, the clinician transfers spicules to a glass slide for staining. One may obtain core marrow biopsies using a 10-gauge Jamshidi needle and fixing the sample for routine histopathologic analysis.<sup>16,21</sup>

Marrow samples should first be examined at low magnification for evidence of cellularity, distribution of fat cells, and heterogeneity of progenitor cell populations. At higher magnification, one may evaluate individual progenitor series and estimate a bone marrow myeloid-to-erythroid ratio (M:E) by counting 500 to 800 cells.<sup>12</sup> Descriptions and pictures of bone marrow progenitor cells are reported elsewhere, and the reader is referred to these for identification of cell types present in bone marrow aspirates or biopsies.<sup>12,13,19</sup> Normal M:E in the horse has been reported to range between 0.5 and 3.76.<sup>17,18,20</sup> Ratios of less than 0.5 are considered indicative of erythrocyte regeneration or myeloid suppression.<sup>22</sup> Special histochemical stains for iron (Prussian blue stain) are available to evaluate peripheral iron stores in the horse.<sup>23</sup> In many horses with hemolytic anemia, bone marrow macrophages may be visible with phagocytosed RBCs.

Myelophthisis is a reduction in the cellular elements in the bone marrow, frequently a result of myelofibrosis, proliferation of fibrous tissue in the marrow. Myelodysplasia implies accumulation of abnormal cells in the bone marrow. These cells are often not dysplastic in the truest sense of the word but rather result from myeloproliferative neoplasia.

### IRON STATUS EVALUATION

Adult horses do not often develop abnormalities in iron status because iron is readily available in most forages and horses have a natural ability to store iron. However, evaluation of systemic iron status may aid in characterizing hematologic abnormalities, especially in the investigation of anemias. Several laboratory parameters can aid in the identification and classification of abnormalities of iron metabolism. The peripheral blood smear may provide initial clues. Microcytic, hypochromic erythrocytes often are seen in animals with disturbances of iron metabolism. One may confirm these observations by calculating the mean corpuscular volume (MCV) and mean corpuscular hemoglobin concentration (MCHC) of peripheral blood erythrocytes. Measurement of serum ferritin provides a reliable index of stored hepatic and splenic iron in the horse. Serum ferritin concentration in 28 normal horses was  $152 \pm 54.6$  ng/ml. A bone marrow aspirate examined after special iron stains is also an excellent means of assessing the pool of storage iron. Serum iron concentration reflects the total quantity of transport iron in the plasma (i.e., the quantity of iron bound to transferrin). Normal equine values of  $120 \pm 5.0$   $\mu\text{g/dl}$ <sup>24</sup> and  $108$   $\mu\text{g/dl}$ <sup>25</sup> have been reported. The total iron-binding capacity (TIBC) reflects the amount of iron that plasma transferrin could bind if fully saturated. Normal TIBC in the horse has been reported as  $388 \pm 8.1$   $\mu\text{g/dl}$ .<sup>24</sup> One calculates the percentage of transferrin saturation from the serum iron concentration and the TIBC. Percentage transferrin saturation is normally approximately 30%. Serum iron concentration increases dramatically for 48 to 72 hours after administration of corticosteroids, but TIBC and serum ferritin concentrations do not.<sup>26</sup>

In healthy foals at birth, serum iron and ferritin concentrations are lower than those of adult horses but very rapidly increase over the first 24 hours of life to levels greater than that of adults because of absorption of colostrum iron. This is accompanied by a very high-percent saturation of transferrin with iron.<sup>11,27</sup> The high transferrin saturation makes foals quite susceptible to iron toxicity in the first 24 to 72 hours of life. A small amount of orally administered iron can be absorbed and exceed the iron-binding capacity of serum with free or unbound iron reaching tissues, especially the liver, resulting in acute hepatic failure.<sup>28</sup> Iron, ferritin, and transferrin saturation values gradually decrease to less than normal adult concentrations, reaching a minimum concentration at 3 weeks and returning to normal adult values by 6 months of age. The PCV of neonatal foals correlates closely with these changes: PCV is relatively high in the first few days of life followed by a decrease in PCV to less than adult values by 2 weeks of age. Iron supplementation does not change these hematologic parameters.

## DISORDERS OF THE ERYTHRON

### ERYTHROCYTOSIS

Erythrocytosis or polycythemia is a real or apparent increase in the circulating RBC mass and may be classified as *relative*, caused by a decrease in plasma volume, or *absolute*, caused by a real increase in RBC numbers. Animals with persistent erythrocytosis have muddy red to blue mucous membranes, prolonged capillary refill time, weakness, lethargy, and exercise intolerance. Despite the large RBC mass in the circulation, oxygen delivery to the peripheral tissues often decreases because of increased blood viscosity and sludging in small vessels. Persistent erythrocytosis may lead to complications including hypertension, tissue hypoxia, thrombosis, and hemorrhage.<sup>29</sup>

**Relative Erythrocytosis** Relative erythrocytosis or polycythemia may occur because of hemoconcentration or splenic contraction. Hemoconcentration occurs when total plasma volume decreases without any change in total RBC numbers in circulation. Clinical dehydration is usually evident, with slow capillary refill time, dry mucous membranes, and prolonged skin tenting. Dehydration may occur with excessive water losses accompanying diuresis, diarrhea, or excessive sweating, as well as with decreased water intake. Endotoxic shock results in dehydration and hemoconcentration by causing a shift of water from plasma to the interstitial space. An increase in total plasma protein usually accompanies relative erythrocytosis caused by hemoconcentration. An exception to this occurs with concurrent loss of protein and body water (e.g., in horses with severe protein-losing diarrhea or glomerulonephritis). In these horses, total plasma protein may be normal or decreased in the presence of a high PCV. The PCV of hemoconcentrated horses usually returns to normal after intravenous fluid therapy, unless water losses continue.

The spleen of the resting horse may harbor up to one third of the total circulating erythrocyte volume. Exercise, endogenous epinephrine release caused by excitement or stress, and exogenous epinephrine administration results in splenic contraction that may increase the PCV by as much as 50%.<sup>30-33</sup> This relative erythrocytosis is not accompanied by a significant increase in total plasma protein. If the horse is allowed to relax in a nonstressful environment, then PCV usually returns to normal within a few hours.

**Absolute Erythrocytosis** Absolute erythrocytosis occurs when increased erythropoiesis causes an increase in PCV, RBC count, and hemoglobin concentration. Plasma volume and plasma protein concentration remain normal.

Primary absolute erythrocytosis (including polycythemia vera) is rare and considered a myeloproliferative disorder of the bone marrow.<sup>29</sup> Serum erythropoietin concentrations are decreased to normal and  $P_{aO_2}$  is normal. This condition may be accompanied by thrombocytosis or leukocytosis. Severe erythrocytosis has been described in two horses with normal serum erythropoietin levels.<sup>29,34</sup>

Secondary absolute erythrocytosis may be appropriate or inappropriate, depending on the presence or absence, respectively, of tissue hypoxia. Appropriate secondary absolute erythrocytosis is associated with increased circulating erythropoietin levels caused by chronic hypoxia from right-to-left shunting of blood in the heart or great vessels, chronic pulmonary disease, or adaptation to high altitude. The most common cardiac anomalies associated with erythrocytosis are complex defects such as tetralogy or pentalogy of Fallot, although a number of other defects, including ventricular septal defect, eventually may result in right-to-left shunting and secondary erythrocytosis.<sup>35</sup> Horses with this condition frequently have cyanotic mucous membranes and an audible heart murmur. One can document chronic hypoxia by measuring the  $P_{aO_2}$ . Oxygen saturation concentrations of less than 92% usually are required for stimulation of erythropoiesis.<sup>29,36</sup> One may confirm the diagnosis with cardiac radiography, ultrasonography, angiocardiology, or cardiac catheterization with blood gas and pressure analyses.

Erythrocytosis is rare in horses with chronic lung disease. Auscultation of animals with chronic lung disease severe enough to result in hypoxia likely would reveal abnormal lung sounds such as wheezes and crackles. Thoracic radiographs aid in assessing the extent and severity of the problem. One should direct treatment of these animals toward correction or alleviation of the primary problem. If this is not possible, then periodic phlebotomy and removal of several liters of blood helps decrease blood viscosity and may improve the quality of life of these horses.

Inappropriate secondary absolute erythrocytosis occurs after increased erythropoietin or other hormone release in the absence of tissue hypoxia. Although reported in horses with metastatic carcinoma and thoracic lymphoma,<sup>37,38</sup> this condition is most common in horses with hepatic neoplasms or renal abnormalities. These animals have a normal or nearly normal  $P_{aO_2}$ . In human beings, hydronephrosis, renal cysts, and embryonal nephromata have been associated most frequently with this paraneoplastic syndrome. In the horse, secondary absolute erythrocytosis has been described in association with hepatocellular carcinoma and hepatoblastoma. All affected horses have been less than 3 years of age, and concurrent elevations in serum erythropoietin concentrations,  $\alpha$ -fetoprotein concentrations, or both have been described.<sup>39-41</sup> These horses had a persistently elevated PCV that did not decrease with intravenous fluid therapy, normal plasma protein concentrations, and mild to moderate elevations in hepatic enzymes. A horse with erythrocytosis that occurred after metastatic carcinoma also has been described.

Most horses with primary or secondary erythrocytosis have a guarded to poor prognosis. If an underlying disease exists, then one should treat it appropriately. Intermittent phlebotomy may provide supportive therapy.<sup>29</sup>

## ANEMIA

Anemia is a decrease in the circulating RBC mass caused by an imbalance in the rate of loss or destruction of erythrocytes and the rate of their production in the bone marrow. Anemia is not considered a primary diagnosis but rather a hematologic abnormality resulting from an underlying disease process. Anemia is defined most frequently as a decrease in PCV or RBC numbers. Hemoglobin also is decreased, except in cases of intravascular hemolysis. A systematic approach to characterization of the anemia can provide valuable clues in the diagnosis of an underlying disease process. All anemias may be classified as *regenerative* or *nonregenerative* based on bone marrow response to the decrease in circulating RBC mass. Regenerative anemia results from loss of intact erythrocytes from circulation (hemorrhage) or accelerated destruction of RBCs (hemolysis) and is characterized by an increase in effective erythropoiesis in the bone marrow. Nonregenerative anemia occurs after systemic abnormalities or because of intrinsic bone marrow disease and results from a lack of appropriate marrow erythropoiesis in response to normal or accelerated RBC senescence or destruction.

Anemia also may be characterized on the basis of erythrocyte size (MCV) and hemoglobin content (MCHC). Normocytic normochromic anemia accompanies many chronic systemic disease processes, including renal and hepatic failure, endocrine abnormalities, neoplastic conditions, and chronic infections. Microcytic hypochromic anemia (low MCV and MCHC) is associated classically with iron deficiency anemia. Small erythrocytes, characterized by a low MCV, are normal in foals. Macrocytic anemia (increased MCV) occasionally occurs in horses after a severe hemolytic or hemorrhagic crisis. Large erythrocytes, characterized by a high MCV, are normal in older horses, especially those over 20 years of age.

Clinical signs of severe anemia relate to decreased tissue oxygenation and the physiologic compensatory mechanisms intended to alleviate this hypoxia. Signs include pallor of the mucous membranes, tachycardia, polypnea, weakness, lethargy, and a systolic heart murmur caused by decreased viscosity and increased turbulence of the blood as it flows through the heart and great vessels. Horses with mild to moderate anemia may have no obvious clinical signs or may have only lethargy and slightly pale mucous membranes. Other clinical signs, including fever, icterus, and hemoglobinuria, may be present in anemic horses and reflect the primary pathophysiologic process involved.

**Regenerative Anemia** When erythrocytes are lost from the circulation at an accelerated rate by hemorrhage or hemolysis, the bone marrow responds by increasing its rate of erythrocyte production and release into the peripheral circulation. Documentation of an active regenerative response is important in diagnosis and prognosis of many cases of anemia. An increase in the number of reticulocytes in the peripheral circulation and an increase in the MCV are considered accurate indicators of a regenerative response in the bone marrow of most species. Unfortunately, in the horse, reticulocytes are not routinely released into the peripheral circulation, even during a strong regenerative bone marrow response. An equine-specific, automated hematology instrument that was used in a horse with severe hemolytic anemia revealed the presence of a low level of reticulocytes in the peripheral circulation. This analysis was based on detection of nucleic acids within the RBCs by flow cytometry.<sup>42,43</sup> Increases in MCV are inconsistent

but tend to be slightly more common after hemolysis than after acute blood loss.<sup>44-46</sup> A slight anisocytosis that is quantitatively assessed through changes in RBC distribution width can be observed in equine peripheral blood after acute hemorrhage or hemolysis.<sup>46-48</sup>

Because of the difficulty in documenting a regenerative bone marrow response with conventional methods, several erythrocyte parameters have been investigated as markers of RBC regeneration in the equid.<sup>49-51</sup> G6PD, creatine,<sup>49</sup> and adenosine-5-triphosphate<sup>52</sup> increase in equine erythrocytes during a regenerative response, but tests for these are not available in most veterinary laboratories. The most practical, reliable method of assessing the erythrocyte regenerative response in an anemic horse, aside from serial PCV analysis, is bone marrow analysis. A bone marrow M:E of less than 0.5 is considered evidence of erythrocyte regeneration.<sup>22</sup> Reticulocyte counts in the bone marrow are also indicative of a regenerative response in the horse. Normal equine bone marrow contains approximately 3% reticulocytes, but this may increase to as high as 66% in response to severe blood loss.<sup>21,22</sup>

**Hemorrhage** Blood loss anemia may develop acutely or chronically. In many cases the source of the hemorrhage is obvious but in others is not. Internal hemorrhage (into body cavities) permits the body to reuse blood components. Approximately two thirds of the erythrocytes lost into the abdomen or thorax are autotransfused back into the circulation within 24 to 72 hours. The other one third are lysed or phagocytized, and the iron and protein are reused. External hemorrhage (including hemorrhage into the gastrointestinal tract) prevents reuse of these components. Accelerated bone marrow erythropoiesis is usually evident by 3 days after acute hemorrhage and is maximal by 7 days.<sup>12</sup> Box 14-2 lists differential diagnoses for blood loss in the horse.

Clinical signs of hemorrhage in the horse vary depending on the duration and severity of blood loss. Horses may lose up to one third (approximately 10 to 12 L) of their blood volume acutely without dying. Acute loss of large quantities of blood results in severe hypovolemic shock with tachycardia, polypnea, pale mucous membranes, poor venous distention, weakness, and oliguria. Initially, RBC parameters in the remaining circulating blood appear normal because all blood components have been lost in equal volumes. Physiologic compensatory mechanisms induce redistribution of interstitial fluid into the vasculature and eventually result in decreased RBC numbers and total protein in the peripheral blood. This redistribution may take up to 24 hours after acute hemorrhage. The difficulty in estimating the severity of blood loss during the first 24 hours after hemorrhage is compounded by the many erythrocytes that can be stored in the equine spleen and released into the circulation as a consequence of endogenous catecholamine release. After vascular equilibration, hematologic parameters should reveal a decrease in PCV, total RBC count, and hemoglobin with no change in associated RBC indices (MCV, MCHC, and MCH). Anemia caused by hemorrhage usually is accompanied by panhypoproteinemia because of significant loss of plasma proteins. A neutrophilic leukocytosis commonly is apparent by 3 hours after hemorrhage; platelets may increase as well if they have not been consumed by excessive coagulation.<sup>12</sup>

One may diagnose blood loss into the thoracic cavity by thoracic radiography, ultrasound, or thoracocentesis and may diagnose blood loss into the abdominal cavity by ultrasound or abdominocentesis. Horses with severe hemorrhage into the

abdominal cavity may exhibit signs of colic or abdominal discomfort. One may differentiate intra-abdominal hemorrhage from inadvertent splenic aspiration or laceration of a subcutaneous blood vessel by the presence of erythrophagocytosis and absence of platelets and may differentiate recent hemorrhage into the abdominal cavity from diapedesis across compromised bowel or old hemorrhage by the presence of platelets in fresh blood. One may observe gastrointestinal blood loss as melena or hematochezia. More commonly, gastrointestinal hemorrhage is not severe enough to result in these overt signs, and feces appear normal.

Brood mares in the periparturient period can suffer from rupture of the middle uterine, utero-ovarian, or external iliac arteries.<sup>53,54</sup> The ruptured vessel can lead to blood loss into the peritoneal cavity, into the broad ligament or serosa of the uterus, or into the lumen of the uterus itself.<sup>55</sup> This condition should be considered possible in any mare up to 48 hours after foaling exhibiting the aforementioned clinical signs of acute blood loss, as well as lethargy, colic, and sweating. Older mares<sup>53,56,57</sup> or multiparous mares<sup>58</sup> are at the greatest risk and a link between age and declining serum copper concentrations, vascular degeneration, and fatal hemorrhage has been proposed.<sup>54</sup> Therapy for hemorrhage discussed in the following sections pertains to this form of hemorrhage as well. Oxytocin can also be used to enhance uterine involution.

Effective treatment of acute blood loss anemia must begin with finding and eliminating the source of hemorrhage. In many animals, this source is readily apparent, and direct pressure or surgical ligation of ruptured vessels is indicated. Internal hemorrhage or postpartum hemorrhage is more difficult to control because immediate surgery to access the site of hemorrhage is usually not an option. In horses with acute severe hemorrhage the administration of isotonic crystalline intravenous fluids may aid tissue oxygenation by increasing peripheral blood volume and perfusion pressures. Administration of hypertonic saline solution (4 to 5 ml/kg of 7.5% NaCl) or hydroxyethyl starch (5 to 10 ml/kg) may be beneficial for rapid volume expansion after achieving adequate hemostasis.<sup>59</sup> However, volume expansion has the potential risk of exacerbating hemorrhage if one cannot achieve hemostasis. Use of hypertonic or colloidal solutions should be followed by administration of appropriate isotonic crystalline fluid therapy.

Polymerized ultrapurified bovine hemoglobin is an alternative oxygen-carrying fluid that has been administered to horses, including postpartum mares, in lieu of whole blood transfusion.<sup>60,61</sup> Although expensive and used with variable success, this product has the advantages of compatibility without crossmatching and long shelf life.

Naloxone, a  $\mu$ -specific opioid antagonist, has been recommended for use in horses with acute hemorrhage. Evidence

suggests that endogenous opioids are involved in the pathophysiology of shock and that administration of naloxone may decrease some of the associated cardiovascular derangements.<sup>62</sup>

Aminocaproic acid is an antifibrinolytic drug that has been used in human patients to reduce hemorrhage during various surgical procedures. In horses, it has been suggested that aminocaproic acid may be useful if a hyperfibrinolytic state exists.<sup>63</sup> This drug has been used to treat mares suffering from periparturient hemorrhage.<sup>55</sup> Pharmacokinetic studies in the horse suggest that a loading dose of 70 mg/kg intravenously (diluted in 1 L of saline and given over 20 minutes) followed by a constant-rate infusion at 15 mg/kg/hr is safe and achieves target blood concentrations. However, clinical efficacy research is lacking.<sup>64</sup>

The Chinese herb Yunnan Baiyao has been used with some evidence of efficacy in human patients with hemorrhage. The mechanism of action for this inexpensive herb is unclear but proposed effects include decreased bleeding and clotting times, platelet effect, and vasoconstriction. The drug decreased template bleeding times and activated clotting times in anesthetized ponies,<sup>65</sup> and it is advocated as an adjunctive treatment protocol for mares with periparturient hemorrhage.<sup>55</sup> A dose of 8 mg/kg orally every 6 hours has been suggested, but clinical trials are needed.

If 20% to 30% of the total blood volume is lost acutely, then blood transfusion from a compatible donor horse is indicated. More detailed discussion of the principles of blood and blood product therapy occur later in this chapter. Hemorrhage into a large body cavity frequently is followed by autotransfusion of erythrocytes back into the peripheral circulation. Therefore one should not remove blood from these spaces unless necessary to stop continued bleeding (because the blood is interfering with vital organ function) or to lavage potentially septic sites.

Horses with subacute hemorrhage (over a few days) usually begin to show clinical signs of severe anemia when the PCV declines to 15% to 20%. The same clinical signs may not be noticeable in horses with chronic blood loss (over weeks to months) until the PCV reaches 12% or less. Blood lactate concentration and central venous pressure may be used as indicators of the need for transfusion or to monitor cardiovascular responses to transfusion in horses with acute blood loss. Increased blood lactate concentrations and decreased central venous pressures are early indicators of blood loss. Post-transfusion, the pressures and blood lactate concentrations should rapidly return to near normal.<sup>66</sup> Because these laboratory parameters are so variable and potentially misleading, one should base treatment decisions on the clinical signs in the individual patient and not necessarily on defined target clinical laboratory parameters.

A horse with subacute to chronic blood loss anemia severe enough to result in peripheral tissue hypoxia as a result of inadequate RBC mass to supply needed oxygen exhibits tachycardia, polypnea, pale mucous membranes, weakness and lethargy, and possibly a mild to moderate systolic heart murmur caused by reduced viscosity and increased turbulence of the blood. If these signs are severe, then blood transfusion is indicated. As with acute hemorrhage, one must identify the source of the blood loss.

Other treatment is supportive and should be designed to eliminate the primary problem. If external blood loss has occurred over weeks to months, then body iron stores may

be depleted, a particularly common problem with chronic gastrointestinal bleeding. Depletion of iron slows or stops effective bone marrow erythropoiesis so that these animals have laboratory parameters typical of iron deficiency anemia. One may identify low serum iron, low marrow iron stores, and increased TIBC, accompanying a hypochromic, microcytic anemia. Dietary iron may be supplemented orally with ferrous sulfate at a dose of 2 mg/kg body mass. One should not administer iron dextran parentally to horses because it has been associated with sudden death in this species. If iron must be administered intravenously, then iron cacodylate solutions are available.

Administration of human recombinant erythropoietin to horses results in increased RBC mass and tissue oxygenation.<sup>67</sup> After experimentally induced anemia, horses receiving concurrent recombinant erythropoietin and iron supplementation had RBC counts and reticulocyte parameters that indicated enhanced regeneration.<sup>43</sup> However, repeated administration of human recombinant erythropoietin may result in production of antibodies against the drug that cross-react with, and inhibit the activity of, naturally produced equine erythropoietin. The end result is a potentially fatal nonregenerative aplastic anemia that persists until antibody levels are depleted.

Because of the lack of peripheral signs of a bone marrow regenerative response in the horse, accurately assessing the regenerative efforts of bone marrow after hemorrhage may be difficult. One may evaluate serial bone marrow aspirates if this information is critical, but in most cases, monitoring increases in PCV over time is adequate. After experimental phlebotomy to mimic blood loss anemia in the horse, PCV increased approximately 0.672% per day, more slowly than in other species.<sup>52</sup> Experimentally, the bone marrow erythroid response peaked at 9 days after phlebotomy, coinciding with the lowest marrow M:E ratio. Regeneration of the erythroid compartment was incomplete 31 days after hemorrhage.<sup>68</sup>

**Hemolysis** Intravascular or extravascular destruction of erythrocytes can occur in a variety of disorders. During intravascular hemolysis, hemoglobin released from destroyed erythrocytes combines with plasma haptoglobin, and tissue mononuclear phagocytes remove the haptoglobin-hemoglobin complex. Plasma haptoglobin levels decrease as intravascular hemolysis increases.<sup>69,70</sup> When plasma haptoglobin binding is exceeded, free hemoglobin accumulates in the plasma and is eliminated via the kidneys. Thus the hallmarks of intravascular hemolysis are hemoglobinemia and hemoglobinuria. Horses recovering from a severe hemolytic episode are more likely to have a demonstrable increase in MCV than are horses recovering from acute blood loss.<sup>44,45,71</sup>

The most common causes of hemolysis in horses are immune-mediated disease, oxidant-induced damage to erythrocytes, and infectious diseases. However, acute hemolytic anemia of adult horses has been associated with a wide variety of pathologic conditions (Box 14-3). Dimethyl sulfoxide administered intravenously at concentrations of 50% or greater results in severe intravascular hemolysis.<sup>72</sup> Hemolytic-uremic syndrome is characterized by acute renal failure, microangiopathic hemolytic anemia, and intravascular coagulation. Erythrocytes become damaged as they pass between fibrin strands deposited in the lumen of small renal vessels. Thrombocytopenia may occur concurrently.<sup>73,74</sup> Hemolysis has been reported in horses ingesting leaves of the northern red oak (*Quercus rubra* L. var. *borealis*). Other associated clinical signs included abdominal pain, constipation, and increased coagulation times.<sup>75</sup> Administration of significantly hypotonic or

hypertonic solutions to horses also may result in intravascular hemolysis. All these conditions are uncommon in the horse.

**Immune-Mediated Hemolytic Anemia** Immune-mediated hemolytic anemia develops when an animal produces antibodies that attach to the surface of RBCs. Primary IMHA is an autoimmune process in which antibodies are directed against surface antigens and occurs when a normally suppressed B-lymphocyte clone proliferates and produces an antibody directed against normal RBCs.<sup>76</sup> Secondary IMHA is more common than true autoimmune disease. Antibodies attach to the surface of erythrocytes for several possible reasons: (1) alterations in the RBC membrane produced by a primary viral, bacterial, or neoplastic disease process; (2) antigen-antibody complex deposition on the surface of RBCs; or (3) drugs that cause immunoproteins to react indirectly with RBCs.

Drug-induced immune-mediated hemolysis may occur via three mechanisms<sup>77</sup>:

1. The drug may combine with RBC membranes and may be recognized as foreign by the body. An antibody to this new

antigen develops and destroys the drug-coated erythrocytes. These animals have a positive direct Coombs' test.

2. The drug may complex with a carrier molecule in the blood and induce an immune response, and the drug-carrier-antibody complex attaches to RBC membranes in a complement-mediated process that leads to hemolysis.
3. Occasionally, a drug may induce true autoantibody production that leads to RBC destruction.

Antibody-coated RBCs are unable to pass through the microcirculation of the spleen, become sequestered there, and are destroyed or phagocytized. If RBC membrane is lost in excess of intracellular contents, then spherocytes with an increased osmotic fragility form. Most immune-mediated hemolysis is extravascular; however, if the antibody fixes and activates complement, then intravascular complement-mediated hemolysis may result.<sup>13</sup>

IMHA may be classified as *warm* or *cold hemagglutinin disease* based on the optimal temperature at which the autoantibody agglutinates the host RBCs. Many clinical pathologists believe that these designations can be arbitrary and reflect an in vitro phenomenon rather than in vivo pathogenesis. Classically, in cold hemagglutinin disease, the antibody involved is IgM, complement is activated, and the liver is the primary site of removal of injured RBCs from the circulation. In warm hemagglutinin disease, IgG more commonly is involved, and the spleen is the primary site of RBC sequestration.<sup>13,78,79</sup> Warm hemagglutinins are frequently incomplete (i.e., they do not cause autoagglutination).<sup>78</sup> Warm<sup>80,81</sup> and cold<sup>78,82</sup> hemagglutinin anemia have been described in the horse.

Primary and secondary IMHA are uncommon in the adult horse.<sup>48</sup> Onset of disease is usually insidious, and many horses have fever, lethargy, and weight loss or have signs referable to a primary disease process. Routine hematologic and biochemical analyses frequently reveal decreased RBC numbers, spherocytosis, increased MCV, anisocytosis, and an increased total and indirect bilirubin. Most cases of immune-mediated hemolysis involve extravascular RBC destruction; however, if intravascular hemolysis is occurring, then hemoglobinuria will occur. One confirms the diagnosis by documenting a regenerative erythropoietic response in the bone marrow, increased erythrocyte fragility in hypotonic saline, autoagglutination, and a positive direct antiglobulin or Coombs' test. The Coombs' reagent used should contain antisera to IgG, IgM, and C3. One must differentiate autoagglutination from rouleau formation by dilution of a cell suspension with isotonic saline. Saline disperses rouleau formation but does not affect true autoagglutination. Flow cytometry has been used to confirm a diagnosis of IMHA in an affected horse by identifying and quantifying the amount of erythrocyte surface-bound antibody.<sup>83</sup>

In human beings, IMHA has been associated with lymphoreticular neoplasms, a variety of viral and bacterial diseases, inflammatory or granulomatous diseases, and generalized autoimmune disorders such as systemic lupus erythematosus. One may have difficulty distinguishing between primary autoimmune hemolytic anemia (AIHA), in which autoantibodies are directed against an abnormal epitope on the erythrocyte membrane, and nonspecific immune complex deposition on the surface of erythrocytes, usually occurring via attachment to Fc or complement receptors. In the horse, immune-mediated hemolysis has been reported in association with *Clostridium perfringens* septicemia and myositis,<sup>42,48,79</sup> an unclassified respiratory infection,<sup>48</sup> purpura hemorrhagica,<sup>82,84</sup> a streptococcal abscess,<sup>82</sup> and lymphosarcoma.<sup>14,82,84</sup> Regardless of the exact

sequence of events leading to antibody deposition on the surface of erythrocytes, affected horses show clinical signs similar to those described for primary AIHA, and clinical pathologic data and diagnosis are similar.

IMHA that occurs after treatment with penicillin has been documented in horses.<sup>85-88</sup> Most affected horses have not been hemoglobinuric, indicating predominantly extravascular hemolysis. IMHA in the horse also has been associated with administration of trimethoprim-sulfamethoxazole.<sup>89</sup> Although not documented as causing immune-mediated hemolysis in the horse, drugs that have caused this problem in other species include tetracycline, rifampin, cephalosporins, chlorpromazine, and various nonsteroidal anti-inflammatory drugs (NSAIDs). In all reported cases of drug-induced IMHA in horses, the problem has resolved with discontinuation of administration of the offending therapeutic agent and appropriate supportive care.

Neonatal isoerythrolysis is an important form of immune-mediated hemolysis in the foal<sup>90</sup> and is discussed in detail elsewhere in this text.

Immune-mediated anemia resulting in intravascular and extravascular hemolysis may be present in horses with equine infectious anemia (EIA) (see the following discussion). Infected horses may have a positive result on the Coombs' test or exhibit autoagglutination, especially during acute disease. Immune-mediated anemia also has been described in a horse with systemic lupus erythematosus.<sup>91</sup>

Therapy of immune-mediated hemolysis is similar regardless of the initiating factor (or factors) involved. One should discontinue any previously administered drug and treat specific underlying primary disease processes. If hemolysis is severe and life threatening, then the veterinarian should administer blood transfusions from a compatible donor (see the discussion on blood transfusion). If the horse has severe intravascular hemolysis with hemoglobinuria, then one should initiate intravenous fluid therapy to protect against pigment-induced nephropathy.

Several cases of immune-mediated hemolysis in the horse have been at least transiently responsive to corticosteroid therapy.<sup>14,48,80</sup> One horse experienced complete disease remission after a 10-week regimen of glucocorticoids.<sup>76</sup> Parenterally administered corticosteroids are recommended initially, and dexamethasone is probably the drug of choice. One should titrate the amount and frequency of administration to the response of the individual animal, but an initial dose of 30 to 40 mg dexamethasone may be tried in an adult horse. Ideally, administration of corticosteroids in the morning minimizes interference with the circadian rhythm of endogenous corticosteroid release from the adrenal gland. However, in an acute hemolytic crisis, twice-daily administration of dexamethasone is recommended until RBC numbers cease to decline. After stabilization, one should decrease corticosteroid doses to once daily, then every other day, and gradually discontinue the therapy. If the horse requires long-term therapy, then one may administer prednisolone orally with a declining every-other-day dosage. Potential complications of corticosteroid therapy in the horse include laminitis and secondary infections. Exacerbation of primary infectious conditions also may occur in cases of secondary autoimmune hemolysis treated with corticosteroids. Caution is recommended, especially when using corticosteroids at a high dose or for a prolonged period. One horse with IMHA refractory to corticosteroid therapy was treated successfully with cyclophosphamide at 1.1 mg/kg intramuscularly once daily and azathioprine at 1.1 mg/kg intramuscularly once daily.<sup>92</sup>

**Oxidative injury to RBCs** is evident from Heinz body formation, hemolytic anemia, and methemoglobinemia. Heinz bodies are aggregations of oxidized precipitated hemoglobin. They are small, round, blue-black, refractile granules near the cellular margin of erythrocytes stained with new methylene blue.<sup>93</sup> Heinz bodies damage the erythrocyte membrane, disturbing intracellular tonicity and resulting in rupture of the cell (intravascular hemolysis). Cells of the mononuclear-phagocyte system of the spleen and liver may recognize damaged RBC membranes as abnormal and remove the RBCs from the peripheral circulation (extravascular hemolysis). One mechanism by which the RBCs protect themselves is through the production of reduced nicotinamide adenine dinucleotide phosphate (NADPH) via the pentose pathway. Several enzymes are essential to this pathway, including the rate-controlling enzyme G6PD.

Oxidation of iron in the hemoglobin molecule from the normal ferrous state ( $Fe^{2+}$ ) to the ferric state ( $Fe^{3+}$ ) forms methemoglobin. Erythrocytes normally produce methemoglobin, which cellular enzymes like FAD rapidly convert back to hemoglobin. In addition, cellular GSH acts to decrease the amount of methemoglobin formed by competing with hemoglobin for oxidizing agents.<sup>94</sup>

Methemoglobin is incapable of carrying oxygen, and excessive accumulation results in a brownish discoloration of blood. Methemoglobin formation alone does not result in hemolysis,<sup>95</sup> but toxins simultaneously may oxidize the sulfhydryl groups of the globin moiety of methemoglobin. This oxidation causes methemoglobin denaturation and precipitation, Heinz body formation, and intravascular hemolysis. Pathologic methemoglobin accumulation in the blood most frequently results from exposure to an oxidative toxin that overwhelms the protective mechanisms of the body but also may result from a decreased rate of reduction of physiologically produced methemoglobin.

The aforementioned enzymes involved in erythrocyte metabolism are essential, and a deficiency of any of these enzymes can cause a decrease in the erythrocyte life span and a form of anemia. Several genetic alterations that lead to these deficiencies have been identified in human beings and dogs; however, only three have been identified in the horse thus far, and all result in clinical signs typical of oxidative RBC injury.

A deficiency of G6PD in human beings is the result of a well-described X-linked genetic mutation that is relatively common. When subjected to oxidative insult, affected individuals develop hemolytic anemia and hyperbilirubinemia.<sup>96</sup> A 6-month-old American Saddlebred colt was diagnosed with this disorder via a series of tests including G6PD assays, electron microscopy, and numerous other erythrocyte assays. The colt had no history of exposure to exogenous oxidants but was suffering from a significant dermatitis. This was assumed to be the source of endogenous oxidants, and the hemolytic anemia improved as the dermatitis resolved. Management of these cases may simply include prevention of inflammation and other forms of oxidative stress. Although most clinicians believe that this disorder is inherited in horses as it is in human beings, this has not been confirmed.<sup>7</sup>

Two adult horses, a Spanish Mustang and a Kentucky Mountain Saddle Horse, were diagnosed with FAD deficiencies through a series of tests including flavin assays. Both horses had persistent methemoglobinemia, eccentrocytosis, and pyknotocytosis on laboratory analysis. Hemoglobin crystals were identified in the Mustang. Neither horse was profoundly anemic nor were exogenous oxidants identified.<sup>8</sup>

Familial methemoglobinemia and hemolytic anemia caused by decreased erythrocyte GSH reductase and intracellular GSH have been described in two Trotter mares.<sup>97</sup> These mares displayed findings similar to those with FAD deficiency.

Acute hemolytic anemia and methemoglobinemia can develop in horses after ingestion of wilted red maple (*Acer rubrum*) leaves.<sup>71,98-101</sup> The toxic principle is uncertain, but gallic acid, a strong oxidant, has been implicated in conjunction with another unidentified agent.<sup>102</sup> Freshly harvested leaves are not dangerous but become toxic when dried and remain so for at least 30 days. Overnight freezing of the leaves does not affect toxicity. Affected horses present most commonly in late summer and fall, often with brownish discoloration of the blood (massive methemoglobinemia) and peracute death within 12 to 18 hours of exposure. A more prolonged hemolytic syndrome characterized by icterus, methemoglobinemia, hemoglobinuria, bilirubinemia, bilirubinuria, fever, and possibly death may occur 5 days or more after ingestion of wilted leaves. Horses may initially present for evaluation of colic.<sup>101</sup> Laboratory evaluation of horses with the hemolytic syndrome of red maple leaf toxicosis frequently reveals Heinz body anemia, depletion of RBC-reduced GSH, and increased RBC osmotic fragility.<sup>99</sup> Normal methemoglobin concentration in equine blood is 1.77% of total hemoglobin.<sup>97</sup> Horses with red maple leaf toxicosis may have methemoglobin concentrations of close to 50% of total hemoglobin.<sup>100</sup>

Treatment of horses with red maple leaf toxicity includes eliminating access to the toxic leaves, whole blood or packed cell transfusions as needed, and general nursing care. The veterinarian should treat all exposed animals with activated charcoal via nasogastric tube to decrease absorption of toxin, even if several days have elapsed since exposure. Massive intravascular hemolysis may result in pigment-induced nephropathy. Fluid diuresis is indicated to prevent or treat this complication. One should use potentially nephrotoxic drugs with caution. Some clinicians have suggested dexamethasone administration to stabilize cellular membranes, but administration of corticosteroids is associated with an increased mortality rate in affected horses.<sup>98,101,103</sup> Methylene blue therapy has been attempted in some horses without success.<sup>71</sup> Because methylene blue may potentiate hemolysis, its use is not advisable. Two horses with severe hemolysis and methemoglobinemia caused by ingestion of red maple leaves were treated with large doses of ascorbic acid (vitamin C), but administration of this drug is not significantly associated with survival.<sup>101,103</sup> Ascorbic acid is thought to convert methemoglobin to reduced hemoglobin and may supplement endogenous protective mechanisms.<sup>104</sup> One may give adult horses a dose of ascorbic acid at 30 mg/kg twice daily in intravenous fluids.<sup>103</sup>

Prognosis for horses with red maple leaf toxicosis is guarded to poor and is not associated with initial physical examination findings or laboratory abnormalities at the time of presentation.<sup>101</sup> Horses are at risk for pigment nephropathy and acute anuric renal failure, colic, diarrhea, and laminitis.<sup>100</sup> Mortality rates have been reported at approximately 60%.

Outbreaks of Heinz body anemia have been reported in horses with access to unharvested onions<sup>105</sup> or overgrazed pasture covered with wild onions (*Allium canadense*).<sup>93</sup> The toxic principle in onions is *n*-propyl disulfide. Treatment should include removal from access to the plants, activated charcoal via nasogastric tube to reduce absorption of the toxin, and blood transfusions and supportive care as indicated.

Heinz body anemia in horses also has been reported after phenothiazine administration. Toxicity appears to depend on individual susceptibility and some as yet unidentified environmental factors. Groups of animals may be affected at a dose that is generally considered safe, and animals in poor condition may be more susceptible to toxicity.<sup>106</sup> Although a 30-g dose for a 1000-lb horse is considered safe, one report described poisoning in six of nine horses treated with 25 g of phenothiazine.<sup>107</sup> Because phenothiazine is no longer widely used as an equine anthelmintic, reports of its toxicity are becoming rare.

Nitrate poisoning is associated with methemoglobin formation in horses but only rarely with intravascular hemolysis. Although it has been speculated that the horse might be more susceptible to nitrate poisoning than other simple-stomach species because the cecum and colon provide an optimal environment for microbial reduction of nitrate to nitrite,<sup>71,108,109</sup> nitrate toxicity appears to be extremely rare in horses.

Heinz body anemia has been reported in one horse with lymphosarcoma.<sup>110</sup> The authors could not confirm access to known oxidative toxins and presumed the anemia to be caused by the neoplastic process by an unidentified mechanism. Several horses that endured severe subcutaneous burns developed intravascular hemolytic anemia because of oxidative damage to RBCs. The mechanism of the damage to the RBC is not fully understood but does seem to correlate with severity of burns.<sup>111</sup>

**Equine infectious anemia virus (EIAV)** is a viral disease of horses known colloquially in the United States as *swamp fever* because of its high prevalence in Gulf Coast states where climatic conditions are favorable for transmission. The causative agent is a member of the lentivirus genus of the family Retroviridae. Infected horses may have one of three clinical syndromes: (1) acute infection, (2) chronic infection, or (3) inapparent carrier.<sup>112,113</sup>

Acutely infected horses show fever, lethargy, and anorexia within 30 days of exposure. The most consistent hematologic abnormality in these horses is thrombocytopenia, although anemia also may be present. Many acutely infected animals show few if any recognizable clinical signs, and definitive diagnosis may be difficult because some of these horses are not yet seropositive. Most horses seroconvert by 40 days after infection.

The horse chronically infected with EIAV has classic signs of recurrent fever, weight loss, ventral edema, and anemia. These animals are seropositive by the agar gel immunodiffusion (AGID or Coggins) test or by competitive enzyme-linked immunosorbent assay (C-ELISA). Each cycle of disease is associated with the emergence of a new antigenic strain of the virus, temporary evasion of the host immune response, and replication of the virus to high titer.

The anemia from which the disease derives its name results from intravascular and extravascular hemolysis of complement-coated RBCs and an impaired bone marrow response.<sup>114-117</sup> Each febrile episode is associated with thrombocytopenia, but platelet counts rebound rapidly as temperature returns to normal. Thrombocytopenia may result from immune<sup>118</sup> or nonimmune<sup>119</sup> platelet destruction or decreased platelet production in the bone marrow.<sup>120</sup>

Most EIAV seropositive horses are clinically normal and never show any recognizable clinical signs. However, they have immune-related blood abnormalities (hyperglobulinemia, decreased percentage of CD5<sup>+</sup> and CD4<sup>+</sup> lymphocytes) consistent

with ongoing viral activity.<sup>121</sup> These animals are inapparent carriers of the virus and remain infected for life. They have circulating infectious virus in their blood and remain a threat to other horses for the rest of their lives. Regardless of disease stage (acute, chronic, or inapparent carrier), virus is found *in vivo* primarily in tissue macrophages and endothelial cells.<sup>122-124</sup>

Transmission of EIAV occurs predominantly by the intermittent feeding of hematophagous insects such as horseflies and deerflies. Flies are strictly mechanical vectors, and virus does not appear to survive more than 30 to 120 minutes on their mouthparts. Chances of transmission are greatest when flies feed on horses undergoing a febrile, viremic episode. However, horseflies can transmit virus from inapparent carrier horses to uninfected animals under field conditions, so all seropositive horses must be considered infectious for life.

EIAV also can be transmitted iatrogenically with blood product transfusions and previously used or improperly sterilized needles, surgical instruments, tattooing instruments, dental equipment, or any other blood-contaminated materials. Virus occasionally is transmitted across the placental barrier from an infected mare to its foal. Mares experiencing a febrile episode during gestation are more likely to give birth to infected foals than are asymptomatic mares. Of foals born to chronic carrier mares, approximately 10% are virus and antibody positive.<sup>125,126</sup> Virus transmission to foals may occur by ingestion of colostrum and milk from infected mares.<sup>126,127</sup> Foals born to antibody-positive mares usually are seropositive for EIAV at 24 hours of age because of absorption of colostrum immunoglobulins. This colostrum immunity is usually undetectable by 6 months of age.<sup>126,127</sup>

The Coggins test and C-ELISA are recognized by the U.S. Department of Agriculture as valid and reliable for the diagnosis of EIAV. Good correlation has been reported between Coggins test results and C-ELISA results.<sup>128</sup> A few horses have been identified, however, with consistently negative or equivocal AGID results that were proved subsequently to be infected.<sup>129,130</sup>

No specific antiviral therapy for EIAV is available. Treatment of an animal requires supportive therapy as indicated during febrile episodes. Minimizing environmental stress may be helpful in decreasing the severity and recurrence of clinical signs. All EIA reactor horses (seropositive) must be permanently identified using the National Uniform Tag code number assigned by the United States Department of Agriculture (USDA) to the state in which the reactor was tested, followed by the letter "A". A hot brand, chemical brand, freeze-marking, or lip tattoo may be used and must be applied by a USDA representative. Brands must be at least 2 inches high and applied to the left shoulder or left side of the neck. Lip tattoos should not be less than 1 inch high and ¾ inches wide and should be applied to the inner surface of the upper lip of the reactor. Reactor horses must be separated from other horses by quarantine at the premises of origin, euthanasia, or movement to a federally approved diagnostic or research facility. The remaining horses on the premises must be serologically tested for EIA with repeat testing at 30 to 60 day intervals until no new cases are found. The premises are released from quarantine when all tests have been negative for a minimum of 60 days after the last reactor equid was removed.<sup>131</sup>

Federal law prohibits interstate travel of horses that have tested positive for EIAV. Interstate movement of infected horses is allowed under three conditions: (1) back to the farm of origin, (2) to slaughter, and (3) to a diagnostic laboratory or approved research facility. Before interstate movement,

reactors must be identified officially using the national uniform tag code number assigned by the U.S. Department of Agriculture to the state in which the reactor was tested, followed by the letter A. A hot iron, chemical brand, or freeze-marking may be used. Markings must be at least 2 inches high and applied to the left shoulder or left side of the neck.

Despite the significant decline in the incidence of EIAV in the United States since these control measures were implemented in the mid-1970s, propagating epizootics still occur.<sup>132</sup> Veterinarians should advise horse owners to do the following:

1. Require a negative EIAV test as part of every prepurchase examination.
2. Require all new arrivals on a farm to have documentation of a recent negative EIAV test, and test all horses on the farm annually.
3. Practice excellent fly control.
4. Encourage all events involving the congregation of horses to require documentation of a recent negative EIAV test.
5. Thoroughly disinfect any surgical items contacting equine blood before use on another horse.
6. Do not share or reuse needles and syringes between horses.

**Equine piroplasmiasis** results from infection with one or both of two species of hemoprotozoan parasite: *Babesia caballi* and *B. equi*. These intraerythrocytic parasites are found in subtropical locales and transmitted predominantly by tick vectors. Although classified in the genus *Babesia*, *B. equi* may be related more closely to the theilerial organisms.<sup>133</sup> *Babesia equi* undergoes some developmental stages in lymphocytes and apparently lacks transovarial tick transmission typical of most *Babesia* organisms. Iatrogenic transmission has occurred through administration of contaminated blood products and use of unsterilized or shared needles or surgical instruments.

Piroplasmiasis is only enzootic in those areas where the tick vector can survive the winter such as South and Central America, the Caribbean, and areas within Africa, Europe, and the Middle East. *Babesia caballi* infection has previously been diagnosed in horses in Florida and is spread by the tropical horse tick *Dermacentor nitens*. In the United States, *D. nitens* has been found in southeastern Florida and occasionally in Texas. Only rarely has *B. equi* infection been confirmed in horses in the United States, and none of the ticks commonly found in this country are known to transmit this organism. The United States is currently considered *Babesia* free. Horses raised in *Babesia*-endemic areas frequently are infected with the organisms without ever showing recognizable clinical signs. Clinically recovered horses remain infected, asymptomatic carriers of the organism as well, and stress may precipitate clinical relapse. Horses with *B. caballi* infection may clear the organism spontaneously after 12 to 42 months, whereas horses infected by *B. equi* do not appear to clear the organism spontaneously.<sup>134</sup> Infected animals develop a strong active immunity that depends on the continuing presence of the organism (premunity). They may be reinfected readily, soon after the organism is eliminated from the body. An infected dam will passively transfer antibodies to offspring but antibody levels are undetectable by 63 to 77 days of age.<sup>135</sup> No evidence of cross-protection exists between the two species of *Babesia*.<sup>136</sup>

Previously unexposed adult horses develop clinical signs of disease within 1 to 4 weeks of exposure. The horse may have fever, depression, dyspnea, pale or icteric mucous membranes, ecchymoses of the nictitating membrane, constipation, colic, and dependent edema. As anemia worsens, affected horses

may develop diarrhea. Massive intravascular destruction of parasitized erythrocytes occasionally occurs, resulting in hemoglobinuria. Cardiac arrhythmias may develop as a result of myocardial damage.<sup>137</sup> Clinical disease with *B. caballi* lasts a few days to a few weeks, and mortality is usually low. Horses infected with *B. equi* generally have a more severe clinical course and may die within 24 to 48 hours of initial signs.

Diagnosis can be made by identification of the *Babesia* organism in blood smears stained with a Giemsa-type stain. The absence of *Babesia* organisms in the peripheral blood does not exclude the diagnosis of piroplasmiasis because parasitemia may be brief and occur before the onset of recognizable clinical signs. Several diagnostic tests are also available. A complement fixation (CF) test was previously recommended as a means of identifying both the actively infected and the carriers. The indirect fluorescent antibody (IFA) test is a more sensitive test than the CF test, especially for latent infections.<sup>138</sup> However, the most sensitive test, and therefore the most appropriate test for screening asymptomatic carriers, is the competitive inhibition enzyme-linked immunosorbent assay (CI-ELISA).<sup>139</sup> Because native horses in the United States are rarely infected with this organism, the United States has instituted strict regulations for import of horses from endemic areas. Before import, all horses must undergo mandatory testing by the Animal and Plant Health Inspection Service using the CI-ELISA. This test is considered the standard for identification of inapparent carriers and is now commercially available to horse owners and veterinarians.<sup>140</sup> The World Organization for Animal Health lists the ELISA and IFA tests as prescribed tests for equine piroplasmiasis with the CF test as an alternative test.

Treatment of piroplasmiasis varies depending on the location of the horse and the desired goal of treatment. In animals that reside in *Babesia*-endemic areas, suppressing clinical signs without eliminating the organism from the body is desirable, because premunition depends on the continued presence of the parasite at low levels. Clinical signs exhibited by carriers usually subside after one intramuscular injection of imidocarb dipropionate (Burroughs Wellcome Co., Research Triangle Park, N.C.) at 2.2 mg/kg. Owners who wish to move their horses to or enter *Babesia*-free areas should isolate them from all tick vectors and should have them treated to eliminate the organism. Administration of imidocarb dipropionate organism for treatment of *B. caballi* has shown variable results. Elimination of the organism was achieved at 2 mg/kg intramuscularly once daily for 2 days.<sup>141</sup> However, recent research has shown that long-term elimination was not achieved with doses as high as 4.7 mg/kg every 72 hours for five doses.<sup>142</sup> *B. equi* is a more difficult organism to eliminate from the horse, and four doses of imidocarb at 4 mg/kg intramuscularly at 72-hour intervals had variable efficacy in eliminating the carrier state.<sup>143-145</sup> In one study by Frerichs, Allen, and Holbrook,<sup>144</sup> the foregoing treatment regimen successfully cleared 13 of 14 horses of the infection, whereas in a more recent study by Kuttler, Zaugg, and Gipson,<sup>143</sup> this treatment regimen cleared none of nine geldings of infection. This wide difference in efficacy may be because of strain differences in drug susceptibility. Potential adverse effects of imidocarb administration include salivation, restlessness, colic, and gastrointestinal tract hypermotility. Donkeys appear to be sensitive to the toxic effects of imidocarb, and eight donkeys treated with the drug died.<sup>144</sup> Although the antitheilerial drug buparvaquone at 4 to 6 mg/kg intravenously or intramuscularly is therapeutically effective in horses acutely infected with *B. equi*, it is not consistent in clearing infection in carrier horses.<sup>146</sup>

**Severe Hepatic Disease** Acute intravascular hemolysis and anemia may develop in the terminal stages of acute or chronic hepatic failure in horses and is characterized by hemoglobinemias, hemoglobinuria, and icterus.<sup>147</sup> Onset and progression are rapid, and the condition is usually fatal; however, signs of hemolysis may subside if the liver disease is treated successfully.<sup>148</sup> Affected erythrocytes have increased osmotic fragility. Hemolysis may result from decreased structural integrity of the erythrocyte membrane caused by alterations in exchangeable RBC membrane lipoproteins and the effect of bile acids on erythrocyte metabolism during liver failure.<sup>13</sup>

**Microangiopathic Hemolysis** This disorder occurs after thrombosis or fibrinoid change within the lumen of small blood vessels,<sup>149</sup> is typical of chronic disseminated intravascular coagulation (DIC), and has been reported in horses.<sup>73</sup> The resulting hemolysis is usually mild.

**Nonregenerative Anemia** A variety of intrinsic or extrinsic factors may suppress normal bone marrow erythropoiesis, resulting in anemia caused by a failure to replace senescent RBCs adequately as they are removed from circulation (Box 14-4). The most common disorders associated with nonregenerative anemia in the horse are iron deficiency; chronic inflammatory, endocrine, or neoplastic diseases; and generalized bone marrow failure. Dietary factors often are incriminated in these abnormalities but only rarely are involved. Severe protein deprivation may result in decreased erythropoiesis as the body becomes deficient in synthesizing hemoglobin and

Chronic hepatic disease  
Chronic renal disease  
Recent hemorrhage or hemolysis

other cellular proteins. Folic acid and cobalamin (vitamin B<sub>12</sub>) deficiencies cause macrocytic hypochromic anemia in human beings, but they are associated rarely with anemia in domestic animals, including the horse. Horses do not have an absolute dietary requirement for vitamin B<sub>12</sub>, which is produced by bacterial action in the gut and absorbed from the lower gastrointestinal tract.<sup>150</sup> Anemia associated with hypothyroidism is thought to be functional, following a lowered metabolic rate. Normocytic normochromic anemia responsive only to thyroid replacement therapy has been reported in one horse.<sup>151</sup>

**Iron Deficiency** Iron deficiency in the horse is associated only rarely with low dietary iron intake or absorption. More commonly, iron deficiency results from chronic external blood loss. In initial stages of iron deficiency, the only detectable abnormalities reflect decreased iron storage pools: a low serum ferritin concentration and decreased stainable iron in the bone marrow. Progression of the condition affects erythropoiesis adversely. These animals have a decrease in the percentage saturation of plasma transferrin, an increased TIBC, and increased numbers of hypochromic erythrocytes (decreased MCHC). Fulminant iron deficiency anemia leads to abnormal development of erythrocytes in the bone marrow late in the maturation process. Cells continue to divide in the late rubricyte stage, without sufficient iron to continue heme synthesis. The result is the release of small cells with decreased hemoglobin concentration into the peripheral circulation (decreased MCHC and MCV).

Treatment of iron deficiency anemia should concentrate initially on the identification and elimination of the source of chronic iron loss. In the horse, occult blood loss occurs most frequently from the gastrointestinal tract and may be verified with a fecal occult blood test. Chronic gastrointestinal ulceration after phenylbutazone administration is a well-recognized phenomenon and is more frequent and severe in ponies than in horses. Gastrointestinal parasites, especially *Strongylus vulgaris* and small strongyles, occasionally may result in chronic blood loss and subsequent iron deficiency. Many iron-containing hematinics are available commercially, and oral supplementation with a product containing ferrous sulfate is probably best. Parenteral iron dextran solutions have been associated with fatal anaphylactoid reactions in horses. If parenteral administration is essential, then 1 g of iron cacodylate administered intravenously for an adult horse generally is considered safe.

Neonatal foals in the first few days of life have high serum iron concentrations and a high percentage saturation of transferrin.<sup>11,27</sup> As a result they are quite susceptible to iron toxicity if they receive oral or intravenous supplements. Administration of oral digestive inoculants containing ferrous fumarate to neonatal foals was associated with a fatal toxic hepatopathy characterized by icterus, hepatic atrophy, bile duct hyperplasia, lobular necrosis, and intrahepatic cholestasis.<sup>2,28</sup> Researchers have concluded that little beneficial effect occurs on hematologic variables when giving healthy foals oral iron supplementation.<sup>152</sup>

In contrast, older foals may be more susceptible than adults to the development of iron deficiency anemia because of their naturally lower levels of iron during growth (after the first week of life). In a survey of iron status in hospitalized horses, only six animals with iron deficiency were identified on the basis of low serum ferritin and serum iron concentrations. All six were foals younger than 5 weeks of age.<sup>153</sup> Foals, although technically iron deficient, rarely develop anemia as

a result. A severe anemia attributed to a significant iron deficiency was identified in a foal that concurrently suffered from septicemia.<sup>154</sup> The source of the deficiency was not identified and considered multifactorial, including lack of access to dirt and pasture and low dietary iron intake.

**Chronic Disease** Chronic inflammatory conditions and neoplasms frequently are associated with a mild to moderate normocytic, normochromic, nonregenerative anemia. This anemia has been attributed to several abnormalities. A block of iron released from reticuloendothelial storage (ferritin and hemosiderin) results in an unavailability of iron for heme synthesis. Horses with anemia of chronic disease typically have a decreased serum iron concentration, normal to decreased TIBC, decreased transferrin saturation with iron, normal to increased serum ferritin concentration, and normal to increased bone marrow storage iron. In addition to altered iron mobilization, a defective response of the bone marrow to circulating erythropoietin and a decrease in RBC life span during many chronic diseases are apparent. The anemia of chronic disease rarely is associated with clinical signs of decreased tissue oxygenation. Therapy is directed at the primary disease process. Oral iron supplementation is not indicated because systemic iron stores are usually normal to increased.

**Bone Marrow Suppression** Anemia caused by selective bone marrow suppression of erythropoiesis is unusual in the horse. Selective erythroid hypoplasia has been reported as a sequela to administration of recombinant human erythropoietin to horses.<sup>155,156</sup> Anemia is thought to result from production of antibodies that cross-react with erythropoietin, inhibiting erythropoiesis. Treatment is with blood transfusions and corticosteroids. Prognosis for recovery is fair to guarded.

Pancytopenia (decreased circulating erythrocytes, leukocytes, and platelets) has been described in horses with aplastic bone marrow disorders<sup>157-159</sup> and with myelophthitic diseases. Myelophthisis is a reduction in the cellular elements of the bone marrow, frequently a result of metastatic neoplasia or myelofibrosis, a proliferation of fibrous tissue in the marrow. Myelodysplasia implies accumulation of abnormal cells in the bone marrow. These cells are not usually dysplastic in the truest sense of the word, but rather they result from myeloproliferative neoplasia. Hematopoietic neoplasia is rare in the horse and is discussed in more detail later in this chapter. These conditions usually result in concurrent anemia, leukopenia, and thrombocytopenia. Diagnosis is by identification of abnormal cells in bone marrow aspirates.

Bone marrow from horses with aplastic anemia is generally devoid of hematopoietic precursor cells because of a congenital or acquired failure of stem cell function. Acquired aplasia may be associated with bacterial and viral infections, chronic renal or hepatic disease, neoplasia, irradiation, or drug therapy. In most cases a predisposing factor is not identified.<sup>157-162</sup> Because of the shorter life spans of the cells, leukopenia and thrombocytopenia usually precede anemia.<sup>12</sup> Diagnosis depends on bone marrow biopsy. If one cannot obtain adequate marrow by serial aspirates, then one must obtain a core biopsy sample. Hypoplastic marrow is yellow because of fatty infiltration with a mixture of cell types, but the number of erythroid, myeloid, and megakaryocytoid cells is decreased.<sup>12</sup> Aplastic anemia is thought to be an autoimmune disorder in some cases, and some horses have apparently benefited from therapy with corticosteroids and anabolic steroids.<sup>157</sup> These drugs stimulate erythropoietin production and increase sensitivity of the stem cell receptors to erythropoietin.

Temporary or permanent bone marrow aplasia has been associated with the administration of a variety of drugs in other species. Transient hypoplastic anemia after phenylbutazone administration has been reported in one horse.<sup>82</sup> Aplastic anemia has been induced experimentally by feeding of trichloroethylene-extracted soybean oil meal to horses or by irradiation.<sup>163</sup> Chloramphenicol produces transient and irreversible forms of bone marrow dysfunction in human beings, and similar reactions are possible in other species. One always should handle chloramphenicol with caution because human toxic reactions appear to be idiosyncratic and may be associated with absorption of low amounts of the drug. Any ongoing drug therapy should be discontinued in horses with aplastic anemia, and supportive therapy should be administered. Some cases of drug-induced bone marrow failure are temporary, and hematopoietic function returns to normal with time if secondary complications are not severe. One may administer compatible whole blood transfusions to horses with severe anemia or thrombocytopenia, and systemic antibiotics and strict isolation from other animals may be considered for horses with severe leukopenia.

Bone marrow erythropoiesis frequently is suppressed in horses with chronic renal disease. Suppression generally is attributed to a decrease in erythropoietin production by the kidneys. Recombinant erythropoietin has been used successfully in cats and human beings with severe anemia associated with renal disease.

## ☞ LEUKON

The leukon consists of circulating leukocytes, their precursor cells, and the tissues that produce them. This includes the granulocytes (neutrophils, eosinophils, and basophils), monocytes and macrophages, and lymphocytes. The leukon provides the primary effector cells for immune surveillance and clearance. This discussion provides a brief description of the production of these cells and their quantitative abnormalities in peripheral blood. Excellent pictures of the various developmental stages of equine leukocytes in the bone marrow and peripheral blood are available in other texts, and the reader is referred to these for identification of cell types.<sup>12,13</sup>

## NEUTROPHILS

### PHYSIOLOGY

Granulocytes and mononuclear phagocytes originate from a common committed progenitor cell in the bone marrow. Under the influence of cytokines—including granulocyte-macrophage colony-stimulating factor, monocyte colony-stimulating factor, granulocyte colony-stimulating factor (G-CSF), and various interleukins—this stem cell proceeds along a path to granulocyte or monocyte production. Cytokine signals for constitutive leukocyte production differ from those during periods of increased demand for specific cell types. The progenitor cell undergoes successive mitotic divisions from myeloblast (the first recognizable precursor of neutrophils) to promyelocyte and myelocyte. Mitosis does not occur as the cell matures from metamyelocyte to band cell to mature neutrophil. Mature neutrophils are stored in the bone marrow until needed. The peripheral neutrophil pool is equally divided between circulating cells and cells adhered to the endothelium of small vessels (the marginated pool).<sup>164</sup> Circulating neutrophils have a half-life of 10 1/2 hours in the

horse<sup>165</sup> and eventually migrate into peripheral tissues, where they live several more days.

Neutrophils alter their distribution between storage, circulating, and marginating pools in response to various endogenous and exogenous stimuli. The marginating neutrophils are mobilized into the circulating pool in response to exercise, epinephrine, or stress. Glucocorticoids increase the rate of neutrophil egress from the bone marrow storage pool and decrease egress from the circulation.<sup>166,167</sup>

Neutrophils are attracted to sites of infection and inflammation by soluble chemotactic factors released during proinflammatory reactions. Neutrophils ingest and kill invading microorganisms and release additional factors that further propagate inflammation at the site of tissue injury.

The morphology of neutrophils on a stained smear of blood or body fluids (e.g., peritoneal or pleural fluid) aids in interpretation of the significance and severity of many disorders. Toxic changes in circulating neutrophils occur in response to inflammation and include cytoplasmic basophilia, cytoplasmic granulation and vacuolation, and appearance of Döhle's bodies (slate gray inclusions caused by retention and aggregation of rough endoplasmic reticulum).<sup>13</sup> Degenerative changes result from altered cell membrane permeability and include hydropic degeneration of the nucleus and a spreading out of the nuclear chromatin so that it more completely fills up the cytoplasm of the cell. Aged neutrophils may exhibit hypersegmented, pyknotic nuclei with round, tightly clumped chromatin. Aged neutrophils most commonly are visible in tissue fluids. Idiopathic hypersegmentation of blood neutrophils of one Quarter Horse, unrelated to any clinical disease, has been described.<sup>168</sup>

### DISORDERS OF NEUTROPHILS

**Neutropenia** Neutropenia is a decrease in the number of circulating neutrophils and may be acute (occurring transiently over 24 to 48 hours) or chronic (lasting several days to months). Acute neutropenia most commonly results from a shift of neutrophils from circulating to marginating pools. Endotoxin is a potent stimulus for margination of circulating neutrophils with sequestration in pulmonary capillaries.<sup>164</sup> Experimentally, administration of endotoxin to horses results in neutropenia within 90 minutes and return to baseline numbers within 6 to 18 hours.<sup>169</sup> Endotoxemia is probably the common denominator in the neutropenia associated with various equine gastrointestinal disturbances including strangulating obstruction, peritonitis, enteritis, and salmonellosis. Neutropenia is a common finding in acute septicemia in the adult and is considered an aid for diagnosis of sepsis in the neonate.<sup>170</sup> A variety of bacterial, rickettsial, and viral disorders also may be associated with neutropenia in the horse.

Chronic neutropenia may result from increased peripheral use of neutrophils or decreased bone marrow production. Neutropenia may accompany severe infectious or inflammatory diseases such as pleuritis, pneumonia, peritonitis, internal abscessation, enteritis, burns, vasculitis, or immune-mediated diseases. Neutropenia caused by increased use often is accompanied by appearance of immature cells in circulation. As tissue demand increases, the bone marrow releases progressively more immature band cells into circulation.<sup>12</sup> This regenerative left shift is an appropriate response to high tissue demand for neutrophils. In animals with a degenerative left shift, the number of immature band cells or metamyelocytes in circulation exceeds the number of mature neutrophils because tissue

use exceeds the capacity of the bone marrow to increase production.<sup>13</sup> A degenerative left shift is considered a poor prognostic indicator.

Neutropenia caused by bone marrow suppression may occur in horses with pancytopenia from a variety of causes (discussed previously). Myeloproliferative disorders including granulocytic leukemia also may result in chronic neutropenia.<sup>171</sup> Alloimmune neonatal neutropenia (ANN), an immune-mediated neutropenia in newborn foals, has been described in several breeds.<sup>172-174</sup> This disease is confirmed by flow cytometric identification of increased neutrophil surface-bound antibody. Affected foals require treatment with prophylactic antibiotics during the recovery period. They may also benefit from administration of G-CSF as described below. The neutrophil count generally returns to normal within 1 month. A syndrome of neutropenia and thrombocytopenia is described in related Standardbreds. A heritable cyclic neutropenia was suspected. Most affected horses died from complications of infectious diseases, thrombocytopenia, or both.<sup>175</sup>

Administration of canine or bovine recombinant G-CSF to normal newborn foals results in a profound increase in blood neutrophil count after a single subcutaneous injection of 6 µg/kg.<sup>174,176,177</sup> The factor may also benefit foals recovering from septicemia. Recombinant G-CSF is reported to improve recovery of adult horses when administered after experimental bowel resection.<sup>178</sup>

**Neutrophilia** Many of the same disorders associated with neutropenia may be associated alternatively with neutrophilia. Endogenous or exogenous glucocorticoids or epinephrine, excitement, exercise, or stress may result in neutrophilia.<sup>13,179</sup> Any infections or inflammatory process in any part of the body may result in neutrophilia. Many neoplastic conditions also are accompanied by peripheral neutrophilia. A rebound neutrophilia is common in later stages of endotoxemia.

The balance between bone marrow production and tissue use determines the magnitude of a neutrophilic response. A regenerative left shift is not uncommon in animals with neutrophilia because of excessive tissue demand. A severe neutrophilia with significant left shift including metamyelocytes and myelocytes indicates serious inflammatory disease and is termed a *leukemoid response* because of its similarity to granulocytic leukemia.<sup>12</sup>

## EOSINOPHILS

Eosinophils arise from the same bone marrow precursor as neutrophils and mononuclear phagocytes. They may be distinguished first from neutrophils at the early myelocyte stage and eventually develop characteristic bright red-staining cytoplasmic granules. IL-5 is critical in the differentiation and maturation of eosinophils. The prominent cytoplasmic granules of eosinophils contain a variety of substances, including major basic protein, peroxidase, and various hydrolytic enzymes. Eosinophils are important in parasite immunity and are involved in some hypersensitivity reactions. Eosinopenia may result from acute infections, corticosteroid or epinephrine administration or release, or stress. Peripheral eosinophilia most commonly results from parasitic infections, including habronemiasis, strongylosis, and pediculosis. Occasionally, allergic reactions also may result in peripheral eosinophilia. Eosinophilic myeloproliferative disease has been described in the horse.<sup>180</sup> A marked eosinophilia also has been seen in horses with lymphosarcoma and transitional cell carcinoma.<sup>181</sup>

## BASOPHILS

Basophils also originate from the common granulocyte-macrophage precursor cell and mature into cells with basophilic cytoplasmic granules. They are the least common of the circulating granulocytes, and basopenia is not clinically significant. Basophils live in the blood approximately 6 hours and then migrate into tissues, where they exist another 10 to 12 days.<sup>13</sup> Basophils are involved in mediating some hypersensitivity reactions. Increased numbers of circulating basophils may occur with allergic, inflammatory, or neoplastic diseases or in association with lipemia.

## MONONUCLEAR PHAGOCYTES

Monoblasts are the first recognizable bone marrow precursors of peripheral blood monocytes, originating from a pluripotent marrow precursor. After progressing through the promonocyte stage, monocytes are released into the peripheral blood where they circulate for a few days before migrating into tissues to mature into tissue macrophages. The role of mononuclear phagocytes in orchestrating immune and inflammatory reactions has long been underplayed. These cells are critical in regulating inflammation through release of proinflammatory cytokines such as tumor necrosis factor (TNF), IL-1, and platelet-activating factor. Mononuclear phagocytes phagocytose microbial organisms, particulate debris, and possibly neoplastic cells. They process these foreign antigens and present them to T lymphocytes in a form that initiates specific immune responses. They produce cytokines, including granulocyte-macrophage colony-stimulating factor, that are critical for regulation of hematopoiesis. They are responsible for removal of senescent cells and activated coagulation factors from circulation. Quantitative abnormalities of monocytes rarely are encountered in equine medicine, but monocytosis may be observed in some cases of chronic inflammation.

## LYMPHOCYTES

Lymphocytes are the primary mediators of humoral and cell-mediated immune responses. They originate from an uncommitted bone marrow progenitor cell that is capable of differentiating into a committed lymphopoietic precursor or a granulocyte-macrophage precursor cell. Committed lymphopoietic progenitor cells differentiate into T lymphocytes that mature during migration through the thymus or B cells that appear to differentiate in the marrow and then migrate to lymph nodes. Circulating lymphocytes are predominantly T cells and represent only a small fraction of the total lymphocyte pool. Most lymphocytes reside in the spleen, lymph nodes, and other lymphoid tissue of the body.

The spleen contains the greatest number of lymphocytes in the adult horse. The spleen plays a major role in immune defense. The large number of phagocytic cells in the spleen facilitates filtering of senescent blood cells, particulate debris, and microorganisms from the blood. Hemoglobin is degraded, and iron is stored in splenic phagocytes pending reuse for erythropoiesis. The spleen is also important as a reservoir of RBCs and platelets, as discussed previously.

Lymphopenia is associated with glucocorticoid administration, stress, many viral infections, and combined immunodeficiency of Arabian foals. Lymphocytosis is associated with epinephrine administration, excitement, exercise, lymphocytic

leukemia, and chronic immune stimulation. As horses age, the number of lymphocytes in their peripheral blood gradually decreases.<sup>182,183</sup>

## HEMATOPOIETIC NEOPLASIA

### MYELOID NEOPLASIA

Neoplasia that results in unregulated proliferation of leukocytes can be categorized as myeloid neoplasia and lymphoid neoplasia. Lymphoid forms, including lymphosarcoma, are more common. Myeloid neoplasia is characterized by uncontrolled proliferation of one or more marrow-derived blood cell lines. When neoplastic cells are observed in peripheral circulation, the disease process is termed *leukemia*. Forms of myeloid neoplasia that have been described in the horse include acute and chronic granulocytic leukemia,<sup>171,184,185</sup> myeloblastic leukemia,<sup>186</sup> myelomonocytic leukemia,<sup>187-190</sup> monocytic leukemia,<sup>191</sup> eosinophilic myeloproliferative disorder,<sup>180</sup> and malignant histiocytosis.<sup>192</sup> Regardless of the involved cell line, the eventual outcome is significant myelophthisis with loss of normal marrow elements.

No age predilection is apparent for equine myeloid neoplasia.<sup>171,180</sup> Common clinical signs include depression, weight loss, edema, anemia, and mucosal petechial hemorrhages. Fever,<sup>180,187,189,190</sup> peripheral lymphadenopathy,<sup>187,190</sup> nonhealing wounds,<sup>185</sup> hemorrhagic diathesis,<sup>180</sup> and oral ulcers<sup>187,188</sup> were identified in some of the horses.

Most affected horses are anemic and thrombocytopenic; total white blood cell counts may be decreased, normal, or increased. Common clinical signs and hematologic parameters can be explained by severe destruction of normal bone marrow resulting in inadequate production of erythrocytes, platelets, and normal leukocytes. This predisposes affected horses to hemorrhagic diathesis, infection, and inadequate oxygenation of tissues.

Definitive diagnosis can often be made by observation of abnormal cells on a peripheral blood smear. Abnormal leukocytes typically predominate in bone marrow aspirates and may be identified in peripheral lymph node aspirates. Acute leukemia is defined as more than 20% blast cells in the peripheral circulation, whereas chronic leukemias lack a significant number of blast forms in the blood.<sup>185</sup> Exact identification of cell type can be difficult because of abnormal cellular architecture in neoplastic cells. As a result, additional staining and cytochemical analysis is often needed for a specific diagnosis.

The cause of myeloid neoplasia remains uncertain. Treatment with cytotoxic<sup>190</sup> drugs and with steroids<sup>186,184</sup> has been attempted in affected horses with no success. Appropriate long-term combination chemotherapy protocols have not been attempted. Compared with lymphoid neoplasia, presentation of clinical signs as a result of myeloid neoplasia is often acute and patients rarely survive for more than a few weeks after diagnosis. Horses that suffer from forms that are better differentiated tend to have a longer duration of clinical signs before presentation, but unfortunately the prognosis remains the same.<sup>193</sup> Postmortem examinations have revealed the presence of abnormal leukocytes within various organs, most commonly the liver and spleen.

### LYMPHOID NEOPLASIA

The most common type of neoplasia to involve the equine hemolymphatic system is lymphosarcoma.<sup>194</sup> Four anatomic forms have been described (generalized, intestinal,

mediastinal, and cutaneous) based on the major site of tumor involvement<sup>194,195</sup>; however, the forms overlap substantially, both clinically and pathologically. Rarely, horses can develop lymphocytic leukemia either as a primary neoplastic condition or, much more commonly, as a sequela to lymphosarcoma that has metastasized to the marrow.<sup>193</sup>

The typical age of onset of lymphoid neoplasia in horses is between 5 and 10 years,<sup>196</sup> although lymphosarcoma has been documented in horses ranging in age from birth through 25 years.<sup>197-199</sup> No breed or gender predilection exists. The incidence of disease is unknown; however, reported prevalence of affected horses at autopsy is between 2% and 5%, and less than 3% of all tumors are classified as *lymphoma*.<sup>200</sup> Lymphocytic or lymphoblastic leukemia is quite rare in horses, so conclusions regarding age, breed, and gender predilections are difficult to interpret.<sup>193,201-203</sup>

**Cause and Pathogenesis** A viral cause of equine lymphosarcoma has not been documented<sup>204,205</sup>; however, one report describes viruslike particles in the lymph node of a foal with lymphosarcoma that died shortly after birth.<sup>199</sup> A congenital or genetic predisposition is possible, because tumors were observed in an aborted fetus and in two horses less than 1 year of age.<sup>206</sup> Clinical signs and laboratory changes of lymphosarcoma generally are caused by loss of normal organ and tissue function after infiltration by lymphocytes or physical obstruction by tumor masses or the excessive generation of tumor cell cytokines.<sup>206</sup> Data on immunophenotyping of equine lymphosarcoma are conflicting. Histologic examination of tumor cells typically reveals a heterogeneous cell population. Previous research indicates that the majority of equine lymphoma is B-cell lymphoma, with many of these described as T-cell rich B-cell lymphomas. A more recent report suggested the opposite: T-cell lymphoma is more prevalent than B-cell lymphoma.<sup>206</sup> Anatomically, T-cell lymphoma is commonly associated with mediastinal tumors and B-cell tumors tend to be more multicentric. Too few cases of lymphocytic leukemia have been described to draw accurate conclusions regarding cytologic classification, but T-cell lymphoma tends to predominate.

Decreased serum concentrations of IgM and other indications of immunosuppression have been observed in horses with lymphosarcoma.<sup>207-210</sup> A decreased serum IgM concentration is defined as  $\leq 23$  mg/dl. A recent study found that IgM concentrations should not be used as a screening test for equine lymphoma because of extremely poor sensitivity.<sup>211</sup> Other neoplastic lymphocytes may arise from autoreactive B-cell clones that produce antibodies responsible for gammopathies and immune-mediated cytopenias. Neoplastic proliferation of large granular lymphocytes with natural killer cell activity was described in one horse.<sup>212</sup>

**Clinical Signs and Laboratory Findings** Lymphosarcoma most commonly presents as a chronic, progressive disease with a sudden onset of more significant clinical signs. The most common clinical signs of lymphosarcoma are chronic weight loss, ventral subcutaneous edema, and regional lymphadenopathy.<sup>213,214</sup> Peripheral lymphadenopathy is not observed frequently. Other clinical manifestations are highly variable depending on the organs involved and the duration of the disease process. Sudden death was attributed to thoracic lymphoma in one racing Standardbred.<sup>215</sup>

Lymphosarcoma involving the thoracic cavity may cause tachypnea, dyspnea, cough, and pleural effusion.<sup>197,216,217</sup> Lymphoma should also be considered in horses with recurrent pleural effusion.<sup>218</sup> Ultrasound and thoracic radiography

can be useful for the diagnosis if tumors are located in an area that is amenable to imaging with these modalities. If pleural effusion is present, then one frequently identifies neoplastic lymphocytes by routine cytologic evaluation of fluid obtained by thoracocentesis.<sup>183</sup>

If cytologic findings are nondiagnostic but indicative of thoracic lymphoma, then immunophenotyping of the fluid may be performed to identify markers of lymphosarcoma.<sup>218</sup>

Alimentary lymphoma, the most common intestinal neoplasia of horses,<sup>195</sup> causes clinical signs consistent with an infiltrative, inflammatory disorder of the gastrointestinal tract including weight loss, recurrent colic, and diarrhea.<sup>219-221</sup> Weight loss can often be attributed to malabsorptive disease, as well as to the negative energy balance caused by chronic, systemic inflammation.

The regional or generalized occurrence of multiple subcutaneous nodules with histopathologic characteristics of lymphosarcoma, unassociated with other lesions of lymphosarcoma, has been reported in horses.<sup>194,222</sup> Nodules may appear suddenly, grow slowly, remain static or regress, and recur at a later time. Hormonal factors including estrous cycle, pregnancy, lactation, and foaling may influence this cutaneous form of lymphosarcoma. In one horse, cutaneous lymphosarcoma cells were positive for progesterone receptors, and lesions regressed completely after surgical removal of an ovarian tumor.<sup>223</sup>

Tumor masses in localized areas may result in clinical signs referable to dysfunction of involved and adjacent tissues and organs.<sup>204,213,216,224-229</sup> Pharyngeal and laryngeal masses may result in dysphagia and unresponsive nasal discharge. Ocular lymphosarcoma may manifest as uveitis or as infiltrates in palpebral conjunctiva, eyelids, third eyelid, at the corneoscleral junction, or in the retrobulbar area.<sup>230</sup> Lymphosarcoma of the central nervous system may result in ataxia and cranial nerve deficits.<sup>204,229,231</sup> Other manifestations of lymphoma include parotid gland, uterine, bladder, epididymal, and periarticular tumors.<sup>232-236</sup> Angiotrophic T-cell lymphoma, which is characterized by proliferation of neoplastic lymphocytes within the lumen of small vessels, was identified in a Thoroughbred mare with a history of anemia but no abnormalities in the circulating leukocyte examination.<sup>237</sup>

The laboratory findings in horses with lymphosarcoma are highly variable. Hematologic indications of chronic inflammatory disease are common, including neutrophilic leukocytosis, nonresponsive anemia, hyperfibrinogenemia, thrombocytopenia, and hypergammaglobulinemia.<sup>206,214,216</sup> Anemia may result from immune-mediated destruction, decreased production because of some degree of myelophthisis, or a combination of both.<sup>206</sup> Horses with lymphocytic leukemia have lymphocytosis and circulating, neoplastic lymphocytes.<sup>221,238-241</sup>

The total plasma protein concentration may be low, normal, or elevated, but the albumin-to-globulin ratio often is reduced, particularly with gastrointestinal involvement.<sup>221,242</sup> The ventral edema observed does not always result from hypoalbuminemia and is more likely caused by lymphatic stasis or obstruction.<sup>206</sup> Protein electrophoresis produces variable results, with the possibility of either polyclonal or monoclonal gammopathy. Polyclonal gammopathies are nonspecific and may be due in part to the production of acute phase proteins, Ig, tumor cytokines, or secondary infection. A mild increase in liver-derived serum enzymes may occur with hepatic involvement. Hyperbilirubinemia usually is caused by anorexia or hemolysis.

A variety of paraneoplastic syndromes have been identified in association with equine lymphosarcoma. Hypercalcemia occasionally is reported.<sup>226,243-245</sup> Pseudohyperparathyroidism, resulting in hypercalcemic nephropathy and polyuria or polydipsia, has been reported in a horse with splenic lymphosarcoma.<sup>246</sup> In some patients, Coombs'-positive IMHA, immune-mediated thrombocytopenia (IMTP), or both may occur.<sup>14,84,247</sup> Hypereosinophilia has been reported in one pony with intestinal lymphosarcoma.<sup>181</sup> Concurrent intestinal lymphosarcoma and eosinophilic epitheliotropic disease have been reported in a Paso Fino mare.<sup>248</sup> These two cases suggest the possibility that clonal proliferation of lymphocytes occasionally may result in hypersecretion of IL-5 with subsequent eosinophil activation. A case of thoracic lymphoma resulted in paraneoplastic polycythemia because of erythropoietin gene expression from the tumor cells.<sup>38</sup> Paraneoplastic pruritus and alopecia also has been described in a horse with lymphosarcoma.<sup>243</sup>

**Diagnosis** The diagnosis of lymphosarcoma is confirmed by demonstration of neoplastic lymphocytes in affected tissue. Histologic examination of a biopsy from a tumor mass or affected lymph node is the most reliable method, and excisional biopsies are much preferred over needle biopsies or aspirates. Without lymph nodes or other masses accessible for biopsy, antemortem diagnosis is often difficult.<sup>14,197,228,249</sup> Diagnosis is only rarely possible on a peripheral blood smear<sup>238,240</sup> and generally requires careful cytologic evaluation of bone marrow, pleural effusion, or peritoneal fluid.<sup>216,250,251</sup> Between 38% and 50% of horses with the alimentary form of lymphoma have evidence of neoplastic cells on abdominocentesis.<sup>252,253</sup> The clinician rarely is able to locate neoplastic lymphocytes by transcutaneous liver biopsy<sup>254</sup>; however, laparoscopy may be used to visualize a mass for biopsy more clearly.<sup>197</sup> Although the lymphocyte count more commonly is normal or reduced in horses with lymphoma, the presence of atypical or obviously neoplastic lymphocytes on a peripheral blood smear occurs in 30% to 50% of cases.\*

One may palpate splenic enlargement, internal lymphadenopathy, or abdominal masses on rectal examination. The character of these masses can then be defined further through ultrasonography.<sup>256</sup> Abdominocentesis may reveal inflammatory changes in the fluid (increased nucleated cell count and protein concentration), but identifying neoplastic cells in abdominal fluid of horses with alimentary or abdominal lymphosarcoma is not common.

Radiography and ultrasonography may be useful in locating and perhaps enabling biopsies of masses in the thorax or abdomen. Often, diagnosis of lymphosarcoma is possible only by exploratory laparotomy or postmortem examination.<sup>14,219,228,249</sup>

The morphologic condition of neoplastic lymphocytes in horses is highly variable.<sup>198</sup> On cytologic preparations they often appear as large lymphoid cells with a variable nucleus-to-cytoplasm ratio, multiple nucleoli, nuclear chromatic clumping, cytoplasmic basophilia, and vacuolation. Mitotic figures and binucleate cells may be visible. The cytologic diagnosis of lymphosarcoma is best left to those experienced in evaluation of equine fluid specimens, because normal reactive lymphocytes and mesothelial cells may be difficult to distinguish from well-differentiated neoplastic cells. Histologically, the

\*References: 14, 207, 214, 238, 254, and 255.

neoplastic cellular morphology also varies, but destruction of normal tissue architecture by a population of lymphoid cells aids the diagnosis. More advanced diagnostic techniques may be used to specifically analyze the neoplastic cell line and its immunologic characteristics. These tests include cytochemical staining, immunophenotyping using both flow cytometry and immunohistochemistry, and immunologic function testing.<sup>193</sup>

**Treatment** Clinical experience in treating horses with lymphosarcoma is limited, because horses tend to be greatly debilitated by the time of diagnosis. Resection of localized tumors may be curative or at least significantly prolong survival.<sup>257</sup> Several solitary tumors located in areas such as the perineum and the nasal cavity have been treated successfully with high-dose radiation.<sup>258</sup> Remission of generalized disease can be transiently achieved through the use of cytotoxic drugs, immunomodulators, and immunosuppressants.

Chemotherapeutic regimens and dosages have been adapted from human and small animal oncology and are now being used with some success in the equine lymphoma patient. Controlled clinical research supporting the use of these drugs is lacking, but case reports and anecdotal evidence support their use where appropriate. The drugs are dosed on a square meter calculation of body surface area, and the protocols generally use a combination of cytotoxic and immunosuppressive drugs administered over several weeks to months depending on the severity. Most commonly used protocols include cytosine arabinoside, cyclophosphamide, vincristine, chlorambucil, doxorubicin, L-asparaginase, and prednisolone.<sup>218,259</sup> One report suggests a remission rate of as high as 50% for several months to a year in horses diagnosed with multicentric lymphoma using a protocol of prednisolone, vincristine, and cytosine arabinoside.<sup>259</sup> Immunosuppressive doses of dexamethasone have also been effective in reducing the size of some tumors and severity of clinical signs for up to 18 months.<sup>247</sup> The cutaneous form of lymphosarcoma is often responsive to corticosteroid and progestin therapy or a combination of low-dose cyclophosphamide and immunotherapy with an autologous tumor cell vaccine.<sup>260</sup> However, abrupt discontinuation or insufficient duration of therapy may result in recurrence of cutaneous lesions in a more aggressive and rapidly progressive form.<sup>261</sup> Treatment of lymphocytic leukemia with the aforementioned therapies has been less rewarding. These drugs are typically very expensive, and remission has not been established in the horse with any of various reported protocols.

The prognosis for equine generalized lymphosarcoma is grave for long-term survival. Most horses die or are euthanized within 6 months of diagnosis; however, with increased use of chemotherapy in the horse, these survival times may begin to increase. Horses with lymphocytic leukemia typically do not survive for more than several weeks after a diagnosis regardless of treatment strategy.<sup>193</sup>

## PLASMA CELL MYELOMA

Plasma cell myeloma (multiple myeloma), characterized by proliferation of neoplastic plasma cells in the bone marrow, spleen, liver, and lymph nodes, is rare in horses. Clinical signs include weight loss, weakness, recurrent fever, ventral edema, hemorrhage, lameness, and posterior paralysis.<sup>262-266</sup> Recurrent infections secondary to the lack of normal immunoglobulins are not uncommon. Renal failure has also been described in affected horses. In human beings and dogs, skeletal pain and

pathologic fractures result from neoplastic invasion of bone that causes osteolytic “punched-out” lesions<sup>267,268</sup>; osteolysis, however, does not occur consistently in horses.

Laboratory findings include anemia, hypercalcemia, azotemia, and hyperproteinemia with monoclonal gammopathy. A diagnosis of plasma cell myeloma should be considered in horses that demonstrate hypercalcemia with normal parathyroid hormone (PTH), elevated parathyroid hormone-related protein (PTH-rP), and hyperglobulinemia.<sup>269</sup> Light-chain proteinuria is variable. If any degree of lameness is noted, then radiographs of the affected limb are warranted. Criteria for diagnosis of plasma cell myeloma include plasmacytosis in the bone marrow or a soft tissue lesion, evidence of invasiveness, and the presence of monoclonal gammopathy or light-chain proteinuria.<sup>267</sup> The degree of plasmacytosis observed in the bone marrow is variable, because marrow involvement may be focal rather than diffuse. Examination of multiple samples from different areas of marrow are recommended whenever possible. If protein electrophoresis yields nonspecific results, then it is recommended to perform radioimmunoassay to quantify specific Ig classes.<sup>269</sup> AL amyloidosis, which is commonly associated with multiple myeloma in human beings, was diagnosed in one horse with concurrent multiple myeloma.<sup>270</sup>

Histologic and clinicopathologic findings in some horses with multiple myeloma can be quite similar to those of lymphosarcoma; therefore achieving a definitive diagnosis may be difficult.<sup>271,272</sup> Of the 15 horses with plasma cell myeloma described to date in the literature, none have been successfully treated. Horses typically survive for no more than 2 years after initial diagnosis. Management of horses with multiple myeloma generally includes careful monitoring and treatment of recurrent infections as needed.<sup>273</sup>

## PLATELETS

Platelets are circulating anucleate fragments of bone marrow megakaryocytes that are essential for the formation of primary hemostatic plugs. Platelets adhere to injured vascular endothelium, release substances that initiate and propagate hemostatic events, and provide a phospholipid surface for activation of several coagulation factors.<sup>274</sup> Platelets also are important proinflammatory elements that interact with endothelium, mononuclear phagocytes, neutrophils, and fibroblasts in initiation and propagation of inflammation.

## PHYSIOLOGY

Platelets ultimately originate from the same pluripotent stem cell as erythrocytes and leukocytes. This stem cell undergoes successive divisions, becoming progressively more differentiated. The colony-forming unit megakaryocytoid cell is committed fully to platelet production. Polyploid megakaryoblasts double their DNA content by a process of endomitosis, becoming megakaryocytes, the largest of the hematopoietic cells of the bone marrow, within 5 days. The highly compartmentalized cytoplasm of the megakaryocyte ultimately disintegrates to release up to 8000 platelets into the peripheral circulation. Various cytokines, including IL-3, thrombopoietin, and IL-6, are essential for this process of differentiation, maturation, and release.

The mature platelet is a complex anucleate cell fragment that accumulates many substances in a variety of secretory

granules. These include dense bodies containing adenosine diphosphate (ADP), adenosine triphosphate (ATP), calcium, and serotonin;  $\alpha$ -granules that accumulate various procoagulant factors, albumin, platelet-derived growth factor, thrombospondin, and platelet factor 4; and lysosomal granules with acid hydrolases.<sup>274</sup> Glycoprotein receptor molecules are embedded in the external lipid bilayer membrane and interact with extracellular proteins that mediate platelet adhesion and aggregation. The external lipid membrane of the platelet invaginates into the interior to form a complex canalicular system important for secretory function. A second internal membrane system, the dense tubular system, supplies enzymes for arachidonic acid metabolism and is involved in sequestration and release of calcium.<sup>275</sup>

When a circulating platelet contacts exposed vascular subendothelial collagen, platelet surface receptors recognize and attach to the damaged endothelium in a process known as *adhesion*. Normal adhesion requires von Willebrand's factor (vWF), a glycoprotein found in vascular endothelium and platelets and present in plasma as a multimolecular complex with coagulation factor VIII. (The role of vWF in platelet adhesion is separate from the role of factor VIII in secondary hemostasis, which is discussed later. The two activities are referred to as *VIII:vWF* for the platelet adhesion mediated by vWF and as *VIII:C* for the coagulative protein.) The glycoprotein P-selectin is another essential platelet surface receptor that is involved in primary hemostasis by enhancing interactions between platelets, endothelial cells, and leukocytes. Expression of P-selectin offers a possible platelet surface marker for platelet activation.<sup>276</sup>

Adhesion of platelets attracts additional platelets in a process known as *aggregation*. Primary aggregation is reversible and not associated with platelet degranulation. Irreversible secondary aggregation begins with release of ADP from platelet granules and production of thromboxane  $A_2$  (TXA<sub>2</sub>) via metabolism of arachidonic acid in the platelet membrane. Substances that promote aggregation usually do so by decreasing the concentration of intracellular cyclic adenosine monophosphate by inhibiting adenylate cyclase or by stimulating phosphodiesterase.<sup>274</sup> Equine platelets exhibit reversible aggregation when exposed to serotonin and arachidonic acid and exhibit irreversible aggregation when exposed to ADP.<sup>277</sup> Platelet-platelet bridging requires fibrinogen attachment to a newly exposed binding site on activated platelets.<sup>275</sup> Thrombospondin, a glycoprotein released from platelet  $\alpha$ -granules, is also integral in the platelet aggregation response. Platelet aggregation is responsible for formation of the initial hemostatic plug (primary hemostasis) at any site of vascular injury.

Arachidonic acid release from the membranes of the platelet-dense tubular network and its subsequent metabolism are critical to platelet aggregation. Arachidonic acid is a polyunsaturated fatty acid normally attached to the second glycerol carbon atom of many membrane glycerophospholipids. Arachidonic acid may be released by the direct action of phospholipase  $A_2$  or by the sequential actions of phospholipase C and diglyceride lipase. Free arachidonic acid is metabolized via a cyclooxygenase pathway to form prostaglandins and TXA<sub>2</sub> or via a lipoxygenase pathway to form various eicosanoids. TXA<sub>2</sub> is a potent platelet activator, stimulating platelet aggregation and vasoconstriction. Although platelets preferentially produce TXA<sub>2</sub> via the cyclooxygenase pathway, vascular endothelial cells produce prostacyclin (prostaglandin  $I_2$ ), a potent inhibitor of platelet aggregation and a strong vasodilator. The

balance between TXA<sub>2</sub> production by platelets and prostacyclin production by vascular endothelium appears to regulate platelet aggregation in vivo.<sup>274,275</sup>

As with erythrocytes, platelets can be sequestered in the spleen and splenic contraction can increase the number of circulating platelets by 30% to 50%. In horses, splenectomy results in substantial and persistent increases in platelet counts.<sup>13</sup> Normal equine platelets have a life span of 4 to 5 days.<sup>278</sup> As platelets age, tissue macrophages of the spleen, liver, and bone marrow remove them from circulation.<sup>279</sup>

## DISORDERS OF PLATELETS

### THROMBOCYTOPENIA

Thrombocytopenia is a decrease in the number of circulating platelets. Normal platelet counts in the horse are slightly less than in other species, with higher counts in horses younger than 3 years of age and in male horses.<sup>280</sup> Most laboratories define thrombocytopenia in the horse as a peripheral platelet count of less than 100,000 per microliter. Clinical signs of thrombocytopenia in the horse reflect abnormal primary hemostasis and include petechial and ecchymotic hemorrhages of mucosal membranes, epistaxis, increased bleeding after venipuncture, melena, or hyphema.<sup>281-286</sup> Clinical bleeding usually is associated with platelet counts of less than 30,000 per microliter. Decreased numbers of circulating platelets can result from decreased production of platelets in the bone marrow, increased destruction of platelets, sequestration of platelets, or increased use of platelets during processes of coagulation (Box 14-5).

Proper sample collection and platelet counting is essential before one can make a diagnosis of true thrombocytopenia in a horse.<sup>279</sup> One can obtain an accurate platelet count in most horses from a blood sample obtained with ethylenediamine tetraacetic acid (EDTA) as the anticoagulant. However, the platelets of some horses consistently clump in EDTA, resulting in an inaccurate count or pseudothrombocytopenia.<sup>287</sup> An experienced technician always should examine a stained blood smear visually to assess the presence of platelet clumps. Platelet clumping may occur as a result of in vivo or in vitro platelet activation.<sup>279</sup> When in doubt, reassessing the platelet count in a blood sample anticoagulated with sodium citrate instead of EDTA is advisable. Platelet clumping and pseudothrombocytopenia also have been described in equine blood samples collected using low-molecular-weight heparin as an anticoagulant.<sup>288</sup>

**Decreased Platelet Production** Thrombocytopenia only infrequently results from decreased platelet production.<sup>289</sup> Primary bone marrow disease is diagnosed by bone marrow analysis, and caution must be used when interpreting megakaryocyte numbers from equine bone marrow aspirates. Megakaryocytes may be absent or present in low numbers in aspirates, even though adequate numbers are present in the intact marrow, possibly because of trapping of these large cells within the subendothelial layer of marrow sinuses. Bone marrow core biopsies are preferred for adequate evaluation of megakaryocyte numbers in the horse. Flow cytometric enumeration of thiazole orange-positive platelets in peripheral blood may be useful as a noninvasive test to assess platelet production.<sup>290</sup>

Because of the short life span of platelets in the peripheral circulation, thrombocytopenia is a common abnormality in animals with generalized bone marrow suppression of any

## BOX 14-5

**DIFFERENTIAL DIAGNOSES FOR THROMBOCYTOPENIA IN THE HORSE****Decreased Platelet Production**

Hereditary defects  
 Myelophthisis  
 Myeloproliferative disease  
 Idiopathic pancytopenia  
 Myelosuppressive drugs  
   Phenylbutazone  
   Chloramphenicol  
   Estrogens  
   Trichlorethylene-extracted soybean meal  
 Irradiation

**Increased Platelet Use**

Intravascular coagulation  
   Disseminated intravascular coagulation (DIC)  
   Localized  
     Hemolytic uremic syndrome  
     Hemangioma  
 Hemorrhage  
 Thrombosis

**Platelet Sequestration**

Splenomegaly

**Increased Platelet Destruction**

Infectious diseases  
   Equine infectious anemia (EIA)  
   *Anaplasma phagocytophilum*  
 Immune-mediated diseases  
   Autoimmune disease  
   Systemic lupus erythematosus  
   Idiopathic disease  
   Secondary disease  
   Neoplasia (lymphosarcoma)  
   Bacterial infection  
   Viral infection  
   Drugs  
   Neonatal alloimmune disease  
 Drugs or toxins  
 Snakebites

**Laboratory Error**

cause. Thrombocytopenia with dramatically decreased bone marrow megakaryocyte numbers has been reported in horses with a variety of myeloproliferative disorders.<sup>171,180,187,264</sup> Thrombocytopenia also is recognized in horses with idiopathic pancytopenia<sup>156,160</sup> and drug- or toxin-induced myelosuppression.

A syndrome of neutropenia and thrombocytopenia has been described in related Standardbreds. A heritable cyclic neutropenia was suspected. Most affected horses died from complications of infectious diseases, thrombocytopenia, or both.<sup>175</sup>

**Increased Platelet Destruction** A variety of pathophysiologic events may increase the rate at which platelets are removed from circulation. Most of these disorders are

accompanied by a compensatory bone marrow megakaryocytosis best identified with core marrow biopsies. Immunoglobulin deposition on the surface of platelets is the most common cause of accelerated platelet destruction. Cells of the mononuclear phagocyte system, especially splenic macrophages and hepatic Kupffer's cells, remove antibody-coated platelets from circulation. Nonimmune mechanisms of accelerated platelet destruction include drug- or toxin-induced platelet damage and snake bites. Thrombocytopenia of controversial cause has been described in human beings and horses receiving heparin therapy.<sup>291,292</sup>

**Immune-Mediated Thrombocytopenia.** Most cases of idiopathic thrombocytopenia in the horse likely are the result of an immune-mediated increase in platelet destruction. The initiating factors of this condition often are not identified, but immune-mediated destruction of platelets may be associated with viral or bacterial infections, neoplastic conditions such as lymphosarcoma, and with other immunemediated disorders, including IMHA, glomerulonephritis, and systemic vasculitis.<sup>281</sup> Circulating platelets from human beings with IMTP have increased quantities of surface-bound IgG, IgM, or complement.<sup>293-295</sup> The mechanics of antibody attachment to platelets are similar to those described for IMHA. True autoantibodies may be produced against normal platelet surface antigens or against novel platelet antigens that have developed in response to a primary disease process. Circulating immune complexes may attach to platelets nonspecifically via Fc or complement receptors. Antibodies also may be directed against foreign molecules, such as drugs, that have attached themselves to platelet membranes. Regardless of the source of the antibody, mononuclear phagocytes remove Ig-coated platelets from the circulation, principally in the spleen and liver.<sup>296</sup>

Horses with IMTP may have petechial and ecchymotic hemorrhages of mucosal membranes, epistaxis, increased bleeding after venipuncture, melena, or hyphema.<sup>281-286</sup> Clinical bleeding usually is associated with platelet counts of less than 30,000 per microliter. Patient history and a careful physical examination are critical for identifying underlying disease. An AGID or Coggins test for EIA is indicated. One should evaluate other coagulation parameters, including prothrombin time (PT) and partial thromboplastin time (PTT), to identify complex coagulative defects such as those seen with DIC (discussed in a subsequent section). A bone marrow analysis usually reveals normal to increased numbers of megakaryocytes. However, if antibodies against platelet membranes cross-react with megakaryocyte membrane antigens, megakaryocytes may be decreased or absent in the bone marrow.<sup>297</sup>

Confirmation of IMTP in horses can be difficult, requiring demonstration of increased quantities of platelet-bound antibody. This can be accomplished by measuring platelet factor 3 or by performing flow cytometry. Platelet factor 3 is a platelet membrane phospholipid released when platelets are injured. Addition of patient plasma containing released platelet factor 3 to platelet-rich plasma from a normal horse results in accelerated clotting of the sample. Unfortunately, this test is difficult to perform consistently, results vary, and most veterinary laboratories do not offer the assay. Direct fluorescent antibody testing and flow cytometric assay for platelet surface IgG and IgM have been described in horses with IMTP.<sup>117,298</sup> Direct and indirect immunoradiometric assays and an indirect enzyme-linked immunosorbent assay (ELISA) for detection of platelet-bound antibody also have been described.<sup>299,300</sup> These tests are not widely available, however, and require careful

control and interpretation. In the absence of an easy, accurate, and reliable method for definitive diagnosis of IMTP in the horse, one may make a presumptive diagnosis in horses with a low platelet count, normal coagulation parameters (PT and PTT), and no evidence of excessive consumption of platelets (i.e., DIC).

Any current medication being administered to horses suspected of having IMTP should be discontinued immediately. If life-threatening hemorrhage is occurring, then transfusions of fresh whole blood or platelet-rich plasma are indicated. Most horses respond to therapy with parenterally administered corticosteroids.<sup>281,285</sup> Corticosteroids appear to act by suppressing the phagocytic activity of mononuclear phagocytes, inhibiting antibody synthesis, increasing effective platelet production, and reducing capillary fragility. One should tailor the corticosteroid dose and route of administration to the individual patient to achieve the best results with the lowest possible dose. Horses with IMTP have been reported to respond to dexamethasone at 0.1 mg/kg intravenously or intramuscularly twice daily.<sup>282,285</sup> One always should taper corticosteroid administration gradually to once-daily morning administration to decrease interference with endogenous corticosteroid release. If long-term maintenance therapy is necessary, every-other-day or every-third-day administration of the lowest effective dose is indicated. Maintenance therapy may be oral or parenteral. Potential complications associated with corticosteroid administration in the horse include laminitis, secondary infections, and iatrogenic hyperadrenocorticism.

Occasionally, horses with IMTP fail to respond to parenteral corticosteroid therapy. Two such horses responded favorably to azathioprine at 3.0 mg/kg orally once daily.<sup>286</sup> However, a recent study on the pharmacokinetic properties of azathioprine indicates that the drug has poor bioavailability in the horse when administered orally at the previously recommended dose and that clinical trials for efficacy are needed.<sup>301</sup> Azathioprine has been used in human beings and dogs with IMTP and acts as an immunosuppressive agent interfering with humoral and cell-mediated immune function. Vincristine is a vinca alkaloid used to treat refractory IMTP in human beings. Vincristine therapy was successful in treating one horse with idiopathic IMTP<sup>302</sup> and unsuccessful in treating another.<sup>286</sup> Alternative treatments for IMTP that have been effective in other species include danazol (a synthetic analog of androgenic steroids and progesterone), gamma globulin infusions, and splenectomy.<sup>303</sup>

Neonatal alloimmune thrombocytopenia has been described in horse and mule foals.<sup>299,300,304</sup> A syndrome of presumptive neonatal alloimmune thrombocytopenia, mucosal erosions, and skin lesions has been described in foals of several breeds. These foals respond to supportive care with judicious administration of corticosteroids and transfusions of platelet-rich plasma. Long-term prognosis is good, but platelet counts can take 30 days or longer to stabilize at more than 10,000 per microliter.

**Equine Infectious Anemia Virus.** Acute febrile episodes of EIAV are accompanied by a sharp decline in platelet count followed by a rapid rebound as fever and viremia resolve. This thrombocytopenia is probably multifactorial in origin. Circulating platelets have increased quantities of IgG and IgM on the surface<sup>117</sup> and show evidence of in vivo activation, possibly indicating enhanced nonimmune-mediated destruction of platelets.<sup>118</sup> Bone marrow megakaryocytes are not infected during acute disease<sup>117</sup>; however, evidence exists of decreased

bone marrow production of platelets in horses with EIA, possibly because of altered cytokine production in the bone marrow.<sup>119,305,306</sup> The thrombocytopenia of EIAV may contribute to petechia and ecchymoses but rarely is associated with a severe bleeding diathesis. EIAV is discussed in detail in previous sections.

**Equine Granulocytic Ehrlichiosis.** Infection with the obligate, intracellular, rickettsia *Anaplasma phagocytophilum* (formerly *Ehrlichia equi*) can result in a syndrome of fever, anorexia, depression, petechia and ecchymoses, icterus, ventral edema, and ataxia lasting 3 to 16 days. Involuntary recumbency with seizurelike activity was observed in a horse diagnosed with anaplasmosis.<sup>307</sup> Consistent hematologic abnormalities regardless of clinical presentation include thrombocytopenia, leukopenia, and mild anemia.<sup>308,309</sup> Clinical signs are more severe in adult horses than in those younger than 4 years of age. Foals younger than 1 year of age often experience only fever.<sup>309,310</sup> Most infected horses originate from the foothills of northern California, but infections also have been diagnosed in horses from other parts of the country.<sup>310,311</sup> Most cases of ehrlichiosis occur in late fall, winter, and spring, and the disease is known to be transmitted by several species of the *Ixodes* spp. tick. Tick control is recommended for prevention of disease in endemic areas.

Granular inclusion bodies may be visible in the cytoplasm of neutrophils and eosinophils during routine cytologic examination using any Wright's or Giemsa type of stain. One may see inclusion bodies best under oil immersion, and they appear as pleomorphic, blue-gray to dark-blue spoke-wheel shapes.<sup>309</sup> Inclusion bodies represent a cluster of coccobacillary organisms, varying in size between 0.2 to 5  $\mu\text{m}$  in diameter, within cytoplasmic membrane-bound vacuoles. The appearance of cytoplasmic inclusion bodies correlates closely with the onset of fever, and they remain visible for approximately 10 days.<sup>308</sup>

Serologic diagnosis using the IFA test has historically been the standard method for diagnosis of equine anaplasmosis.<sup>312</sup> However, as many as 50% of normal horses in endemic areas of California have antibodies against the organism.<sup>313</sup> A polymerase chain reaction (PCR) test to detect the organism's DNA offers a means to confirm a diagnosis early in the course of the disease with comparatively high sensitivity and specificity. Animals that are experimentally infected become PCR positive on approximately the fifth day after infection but do not show clinical signs until day 7. Seroconversion occurs quickly after clinical signs become apparent at approximately days 12 to 16. Extrapolating the results of this study to clinical situations suggests that PCR is likely to be positive before onset of clinical signs and that IFA should be performed early with suspicion of disease so that seroconversion can be accurately assessed.<sup>312</sup>

Mortality is rare in horses with ehrlichiosis; most untreated animals recover over 2 weeks and acquire a sound immunity against reinfection for at least 2 years.<sup>308,309</sup> Death, when it occurs, is usually associated with secondary infections that are the result of immunosuppression or trauma because of ataxia.<sup>314</sup> One experimentally infected horse died with signs consistent with systemic inflammatory response syndrome, shock, and DIC.<sup>315</sup> Treatment with oxytetracycline at 7 mg/kg intravenously once or twice daily for up to 7 days may hasten recovery. One should provide supportive therapy, including intravenous fluids, leg wraps, and stall confinement for the severely ataxic horse, as indicated.<sup>308,309,311</sup> In animals that

die or are killed, necropsy lesions include petechial and ecchymotic hemorrhages, edema, and icterus. Histologically, small arteries and veins are inflamed, and mild inflammatory vascular or interstitial lesions may be present in kidneys, heart, brain, and lungs.<sup>308</sup>

**Increased Platelet Use** Rapid use of circulating platelets occasionally occurs and may be appropriate, as in the case of massive trauma or external hemorrhage, or inappropriate, as in some cases of systemic or localized activation of hemostatic mechanisms. Thrombocytopenia accompanying hemorrhage or trauma is usually mild to moderate and rapidly reversible. DIC is a complex disorder of hemostasis resulting from widespread systemic activation of coagulation mechanisms. This microvascular coagulation rapidly uses circulating platelets, and thrombocytopenia is a common result. Affected animals have a variety of other abnormalities detectable by routine coagulation testing. Horses with DIC and normal platelet counts may have abnormal platelet function, inhibiting the use of those platelets. In one study of horses presented to a veterinary referral hospital, DIC after gastrointestinal or inflammatory diseases was the most common cause of thrombocytopenia.<sup>289</sup> In horses evaluated for colitis, approximately half of the horses had platelet counts less than 100,000,<sup>316</sup> and in horses that underwent surgery for correction of a large colon torsion, a decreased platelet count was significantly associated with increased mortality.<sup>317,318</sup> The section on DIC provides more information on the pathophysiology, diagnosis, and treatment of this disorder.

Localized activation of coagulation may occur in some disease conditions, including neoplasia and renal disease. Thrombocytopenia has been reported accompanying hemangiosarcoma in the horse<sup>319-321</sup> and is associated with vascular tumors in human beings and dogs.<sup>322,323</sup> Hemolytic uremic syndrome is an unusual condition in the horse characterized by acute renal failure with microangiopathic intravascular hemolysis and disseminated or renal intravascular coagulation. Thrombocytopenia is a common finding in affected horses.<sup>73,74</sup>

## THROMBOCYTOSIS

Thrombocytosis is an increase in the number of circulating platelets. Increased bone marrow production of megakaryocytes may occur as a primary myeloproliferative disorder or in association with other neoplastic conditions, including polycythemia vera. Thrombocytosis more commonly is associated with acute or chronic inflammatory disorders or follows acute hemorrhage.<sup>324</sup> Mild thrombocytosis also may occur during and immediately after exercise or excitement caused by splenic contraction and release of sequestered platelets into the peripheral circulation. Thrombocytosis is usually asymptomatic, and specific therapy is not indicated. Thrombocytosis rarely may be associated with venous thrombotic tendencies, and one may consider anticoagulation therapy in these cases.

## FUNCTIONAL DEFECTS OF PLATELETS

Functional defects of platelets can result in clinical signs similar to those of thrombocytopenic patients, despite a normal to increased platelet count. The most widely used laboratory tests to assess platelet function are bleeding time and platelet aggregation studies. Bleeding time depends on the number and function of platelets, the level of vWF, and vascular integrity. One performs the test by inverting the lower lip and making

a vertical incision 1 mm deep by 5 mm long, with a template bleeding time device (Surgicutt, International Technidyne Corp., Edison, N.J.). After 30 seconds the blood is removed with Whatman filter paper. Then the previous step is repeated every 15 seconds until one no longer detects blood on the filter paper, and the total time is recorded.<sup>325</sup> Alternatively, one may make an incision on the caudolateral aspect of the foreleg with proximal venostasis using a sphygmomanometer cuff above the carpus.<sup>326,327</sup> The site should be shaved before testing. Normal bleeding time varies, depending on the technique and site of incision, and one must establish the time for each technique. The veterinarian should evaluate a normal control horse concurrently with the patient. A platelet aggregometer can be used to measure the aggregation of platelets in response to ADP, serotonin, epinephrine, arachidonic acid, thrombin, ristocetin, collagen, and collagen-related peptide.<sup>328-330</sup> One should collect whole blood samples with sodium citrate as an anticoagulant and prepare platelet-rich plasma by centrifugation.

Congenital defects in platelet function are rare but have been identified in horses. Glanzmann thrombasthenia is a rare, heritable platelet disorder that has been thoroughly described in human beings and dogs. Four horses including a Standardbred,<sup>331</sup> an Oldenburg,<sup>332</sup> a Quarter Horse, and a Thoroughbred cross<sup>333</sup> have been diagnosed with the condition. The platelet dysfunction was due to an amino acid change in the gene for the platelet fibrinogen receptor, integrin  $\alpha$ IIb  $\beta$ <sub>3</sub>.<sup>334</sup> Horses present for clinical bleeding, most commonly in the form of epistaxis. Platelet count and coagulation times are normal, whereas mucosal bleeding time is significantly prolonged and clot retraction is markedly reduced. Results of aggregometry testing are consistent with an inability of the platelets to bind to fibrinogen; flow cytometry reveals decreased surface integrin  $\alpha$ IIb  $\beta$ <sub>3</sub>.<sup>332,333</sup> Treatment was attempted in these horses with tapering doses of dexamethasone with no apparent change in the occasional bleeding and laboratory abnormalities.

Another heritable thrombasthenia caused by a platelet fibrinogen-binding defect has been identified in a population of Thoroughbreds.<sup>330,335,336</sup> The clinical condition was identified in a mare and its offspring, prompting a survey of a population of Thoroughbreds in that area. The syndrome observed in the Thoroughbred mare and its filly resembled Glanzmann thrombasthenia in clinical presentation and basic laboratory analysis. However, aggregometry and flow cytometry results differ in that platelets of the affected horses bind in reduced amounts to fibrinogen in the presence of thrombin.<sup>336</sup> Aggregometry often demonstrates the inability of the platelets to bind in the presence of collagen.<sup>330</sup> Although the genetic basis of this disorder remains unclear, a secretion defect is believed to be related to either abnormal platelet granule contents or intracellular signaling. The population study reported an incidence of 0.7% (3/444 horses) of this disorder, yet none of the horses in the screening program exhibited clinical signs. When appropriate, flow cytometry should be used to screen for this heritable disease.<sup>335</sup>

Researchers have described von Willebrand's disease in the horse.<sup>337</sup> Because the disease is not an inherent platelet defect, it is discussed later in this chapter (with hereditary defects of coagulation).

Acquired platelet functional defects may be associated with uremia, acute myelodysplastic diseases, and dysproteinemias, as well as after the administration of various drugs. Abnormal responses to platelet aggregating agents and increased bleeding time have been described in normal human and equine

neonates,<sup>325,329</sup> and neonatal foals may have an increased susceptibility to platelet-associated hemorrhagic diathesis.

Many human beings and animals with uremia exhibit abnormal hemostasis, most of which is attributable to abnormal platelet function and likely is caused by abnormalities in the biochemical processes necessary for platelet aggregation and granule release. Human beings with myeloproliferative and lymphoproliferative disorders may have abnormal platelet shapes and decreased aggregation and secretion.<sup>338</sup> Dysproteinemia in these patients may result in platelet dysfunction when abnormal proteins coat platelets or endothelium and interfere with normal adhesion and aggregation. A hemorrhagic diathesis caused by platelet dysfunction has been described in one horse with monoclonal gammopathy and lymphoproliferative disease.<sup>271</sup>

Drugs used in equine medicine and associated with abnormalities of platelet function in human beings include penicillins, cephalosporins, quinidine, chlorpromazine, halothane, and NSAIDs.<sup>338</sup> NSAIDs act by inhibiting cyclooxygenase, an enzyme critical for the formation of prostaglandins, prostacyclins, and thromboxane from arachidonic acid. As previously discussed, TXA<sub>2</sub> is a strong stimulus for platelet aggregation and release reactions and is a potent vasoconstrictor. Aspirin covalently acetylates cyclooxygenase, and because platelets are anucleate cells, they are incapable of producing new enzyme. The result is an irreversible inhibition of platelet cyclooxygenase that can be corrected only when the body clears aspirin from the circulation and the bone marrow releases new platelets. In contrast, other NSAIDs produce only a temporary inhibition of cyclooxygenase by reversibly binding to the enzyme. Template bleeding time is prolonged in horses that have received aspirin, phenylbutazone, or flunixin meglumine.<sup>327,328,339,340</sup> The effect is most pronounced after aspirin therapy, and a dosage of 17 mg/kg once daily for 3 days increases bleeding time for at least 3 days after discontinuation of therapy.<sup>327</sup> The minimal effective dose of aspirin to decrease thromboxane generation is 5 mg/kg; the duration of decrease is dose dependent.<sup>341</sup>

## ☞ HEMOSTASIS

The vascular system provides a closed conduit for the circulation of fluid and cellular components of blood. Exchange of substances across the vessel surfaces is controlled carefully. The body must repair any disruption in the closed network of blood vessels rapidly and efficiently to prevent excessive loss of critical blood elements into the extravascular environment. This repair process requires interaction between the injured vessel wall, platelets, and soluble proteins and accessory molecules in the blood. The end result is a stable fibrin mesh that prevents loss of blood while the vascular endothelium regenerates. When endothelium has been repaired, fibrinolytic reactions occur to remove fibrin and re-establish vessel patency. A careful balance of coagulative and fibrinolytic processes must occur to maintain optimal circulatory capacity without loss of blood. The body also must control procoagulative forces carefully to prevent inappropriate activation that might result in thrombosis of normal vessels with subsequent tissue and organ ischemia.

## PHYSIOLOGY

Primary hemostasis is the process of platelet interaction with the vessel wall to achieve a temporary plug of the vascular defect. Secondary hemostasis involves the interaction of

soluble coagulation factors to produce a stable fibrin mesh that reinforces the platelet plug. The body carefully regulates hemostatic mechanisms via an intricate network of positive and negative feedback with inhibitors and potentiators of coagulation and fibrinolysis.

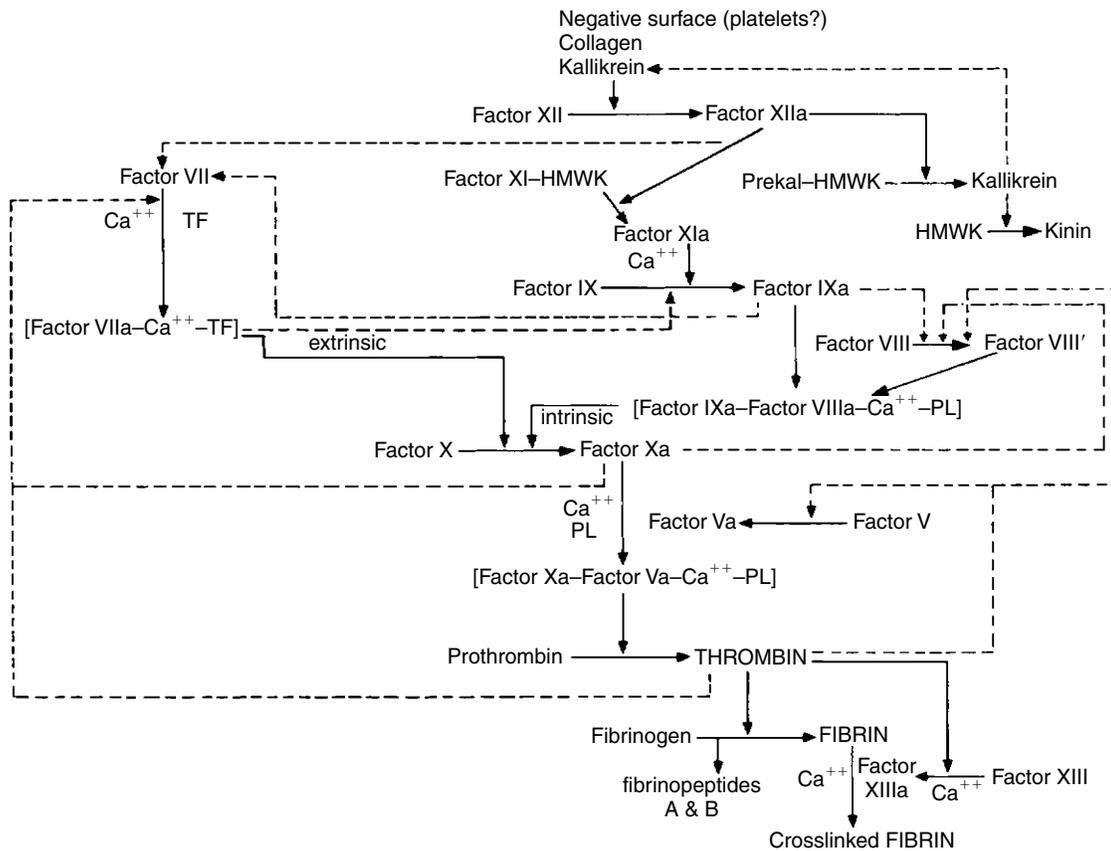

The initial vascular response to injury is intense vasoconstriction to divert blood from the site. Anticoagulative processes associated with vascular endothelium, including synthesis of prostacyclin and plasminogen activators and uptake and degradation of proaggregating molecules,<sup>13</sup> prevent the interaction of normal intact vascular endothelium with circulating platelets. Exposure of subendothelial collagen at the site of vascular injury triggers platelet adherence with interaction between endothelial vWF and platelet receptors. The function of platelets in primary hemostasis has been discussed in detail already. Platelet adhesion stimulates a release reaction involving platelet secretory granules. Contents of these granules (including ADP, ATP, serotonin, platelet factors 3 and 4, TXA<sub>2</sub>, and acid hydrolases) attract other platelets in a process of irreversible platelet aggregation at the site of vascular injury. Platelet aggregation provides a favorable environment for accumulation and activation of the intrinsic and extrinsic coagulation systems.

The classic coagulation pathway has traditionally offered a concept of hemostasis based on and under the control of protein coagulation factors. The system involves sequential activation of inactive precursor factors (Table 14-3) by limited proteolysis (Figure 14-2). Activated factors are indicated by the letter *a* after their numeric designation. Most coagulation factors are classified as *serine proteases* because of a critical serine residue at the active site of the enzyme. This serine is exposed after cleavage of a short peptide during activation of factor precursors.

Although commonly discussed as separate pathways, intrinsic and extrinsic coagulation cascades interact at many levels and are considered more accurately as part of one highly complex system. For the sake of simplicity, however, they are

TABLE 14-3

Coagulation Factors	
Factor	Synonym
I	Fibrinogen
II	Prothrombin
III	Tissue factor, tissue thromboplastin
IV	Calcium
V	Proaccelerin, labile factor
VI	Not assigned
VII	Proconvertin, stable factor
VIII	Antihemophilic factor
IX	Christmas factor
X	Stuart-Prower factor
XI	Plasma thromboplastin antecedent
XII	Hageman factor
XIII	Fibrin-stabilizing factor
Prekallikrein	Fletcher factor
High-molecular-weight kininogen	Fitzgerald factor

**FIGURE 14-2** Schematic representation of blood coagulation showing the numerous interactions between coagulation factors in the classic extrinsic and intrinsic pathways. *Arrow*, Primary action; *dashed arrow*, actions of secondary importance; *a*, activated form; *HMWK*, high-molecular-weight kininogen; *TF*, tissue factor; *PL*, phospholipids; *Prekal*, prekallikrein. (From Morris DD: Recognition and management of disseminated intravascular coagulation in horses, *Vet Clin North Am Equine Pract* 4:115-143, 1988.)

discussed separately. The liver produces most soluble coagulation factors. Mononuclear phagocytes are responsible for clearing activated clotting factors from the circulation.

Contact of soluble coagulation factors with negatively charged subendothelial collagen and with the various products of the platelet release reaction initiates the intrinsic coagulation system. This initial contact phase (see [Table 14-3](#)) requires interaction of coagulation factor XII, high-molecular-weight kininogen (HMWK), and prekallikrein to accelerate production of the activated form of factor XII (designated *XIIa*). Factor XIIa in turn catalyzes the limited proteolysis of factor XI to XIa. Elements of the contact phase reaction are also capable of inducing parallel pro-inflammatory reactions by initiating kinin and complement cascades. The importance of this contact phase reaction to *in vivo* coagulation is questionable. Human beings and animals with hereditary deficiencies of the proteins involved in this reaction (factor XII, HMWK, or prekallikrein) rarely show any clinical bleeding tendencies. In contrast, deficiency of almost any other coagulation factor, including factor XI, results in profound hemorrhagic tendencies.

Factor XIa, in the presence of calcium, activates factor IX. Factor IXa forms a molecular complex with factor VIIIa and calcium on a phospholipid membrane surface to catalyze the conversion of factor X to Xa. Platelet membranes are thought to provide the phospholipid surface for this reaction. Activation of factor X is the point of interaction between the extrinsic and intrinsic systems.

The extrinsic coagulation system begins with formation of a molecular complex between tissue factor (TF; thromboplastin), factor VIIa, and calcium ions on a platelet phospholipid surface to catalyze the conversion of factor X to Xa. Factor Xa is capable of activating factor VII to VIIa in a feedback loop that increases the production of both. In a slower reaction that appears to be important *in vivo*, the TF VIIa-calcium complex is also capable of activating factor IX.<sup>342</sup> TF is present in virtually every tissue of the body, and a variety of insults can initiate the extrinsic coagulation system, including vascular endothelial damage, endotoxin, antigen-antibody complexes, RBC hemolysis, and local areas of tissue necrosis.

Formation of factor Xa marks the beginning of what classically is termed the *common pathway of coagulation*. Factor Xa complexes with factor Va and calcium on a phospholipid membrane to convert prothrombin to thrombin enzymatically. Thrombin in turn is the catalyst for formation of fibrin from fibrinogen. Thrombin is also important in the activation of factors V, VIII:C, and XIII, forming positive feedback loops that potentiate the coagulative process and promote platelet aggregation. Fibrin monomers aggregate, and factor XIIIa catalyzes the formation of covalent cross-linkages between the monomers to stabilize the clot.

The cascade concept of the physiology of hemostasis has recently been revisited because several disease processes cannot be adequately explained. Many experts now believe that coagulation should be viewed as three overlapping steps

termed *initiation*, *amplification*, and *propagation*.<sup>343</sup> This series of events is dependent on two cells: the TF-bearing cell located extravascularly and the platelet. In a normal physiologic state, coagulation is prevented until necessary by limiting contact of these two cell types. Once an injury to a vessel has occurred, the two come into contact and the process of coagulation begins.

Initiation begins as a vessel is damaged, plasma is exuded, and it comes in contact with the TF-bearing extravascular cells. Factor VIIa binds to TF and after activation by several proteases forms a factor VIIa-TF complex. This complex in turn activates factors X and IX. Factor Xa goes on to activate factor Va, and together this prothrombinase complex, located on the surface of TF-bearing cells, forms small amounts of thrombin. If factor Xa leaves the cell surface, then it is quickly inhibited. In contrast, factor IXa can move from cell to cell without rapid inhibition.

The amplification phase also involves the aforementioned damage to the vessel that is significant enough to allow exudation of platelets and factor VIII-vWF into the extravascular space. Platelets adhere to the extravascular matrix and interact with the small amount of thrombin that was produced on the surface of the TF-bearing cells. This thrombin enhances platelet adhesion, activates other platelets, and activates factors Va and VIIIa on the platelet surface. This activation allows vWF to be released, further enhancing platelet adhesion and aggregation. These activated platelets with factors Va and VIIIa bound to their surfaces are the basis for the propagation phase.

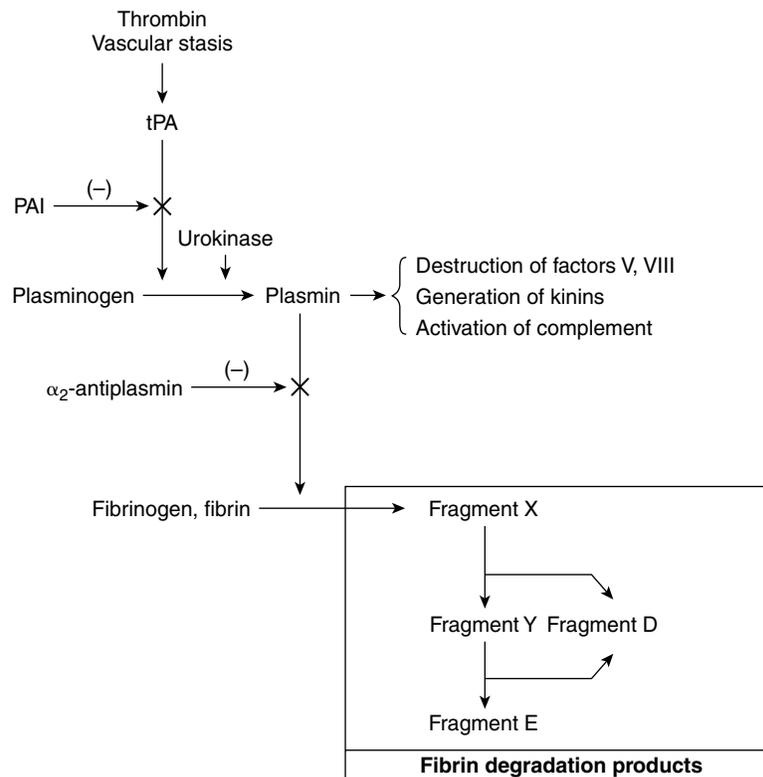

Propagation involves the formation of two additional complexes. Factor IXa that was activated by the factor VII-TF complex during the initiation phase, binds to activated platelets. Factor IXa then forms a complex (tenase complex) with factor

VIIIa already on the platelet cell surface. This complex activates factor Xa that is present on the platelet surface. Factor Xa then forms a complex with already platelet bound factor Va (prothrombinase complex) that causes a marked increase in thrombin formation (enough to bind fibrinogen and form a clot).<sup>343</sup>

Inhibitors of procoagulative elements in part maintain a balance between clot formation at sites of vascular injury and pathologic thrombosis. Several physiologically important systems for in vivo procoagulant inhibition have been described. The most important of these is plasma antithrombin III (AT III), responsible for 50% to 75% of plasma antithrombin activity. AT III inhibits all serine proteases generated during the coagulation process, including thrombin; factors Xa, IXa, XIa, and XIIa; plasmin; kallikrein; and the anticoagulants protein C and protein S. Heparin interacts with AT III, causing a conformational change that increases the activity of AT III 1000-fold.<sup>344</sup>

Tissue factor pathway inhibitor (TFPI) is a protein that reversibly inhibits factor Xa and then as a complex with Xa, can inhibit the factor VII-TF complex at the level of the endothelial cell. Another of the main anticoagulative systems involves protein C, protein S, and thrombomodulin. As the primary clot is formed, small pieces of thrombin are lost within the vasculature. When this thrombin comes in contact with an intact endothelial cell, it binds to thrombomodulin, which in turn activates proteins C and S. These vitamin K-dependent serine proteases act to inactivate factors Va and VIIIa and prevent inappropriate clotting. This system acts mainly on endothelial cells rather than platelets.<sup>345</sup>

The fibrinolytic system is responsible for eventual remodeling and removal of a stable fibrin clot to restore blood flow (Figure 14-3). Because small amounts of fibrin production

**FIGURE 14-3** Major fibrinolytic reactions (see text for details). A negative sign (–) indicates inhibition of a specific reaction. *tPA*, Tissue plasminogen activator; *PAI*, plasminogen activator inhibitor. (From Kolbuck CN, Ames TR, Geor RJ: *The horse: diseases and clinical management*, Philadelphia, 1995, WB Saunders.)

and subsequent fibrinolysis occur continuously in vivo, the body must maintain a delicate balance between procoagulant and fibrinolytic processes to prevent widespread thrombosis or hemorrhage. The principal enzyme of the fibrinolytic system is plasmin, normally present in plasma as an inactive precursor, plasminogen. Plasminogen is converted to plasmin proteolytically by endothelial tissue plasminogen activator, an enzyme present in most normal and neoplastic tissue. Endothelial cells adjacent to clot formations release tissue plasminogen activator in response to vascular stasis and a high local concentration of thrombin. Released tissue plasminogen activator has a high affinity for fibrin, localizing it to the adjacent clot for plasminogen activation. Circulating antiplasmins, the most important of which is  $\alpha_2$ -antiplasmin, rapidly inactivate circulating plasmin. Plasmin bound to fibrin is much less accessible for inactivation because plasmin interactions with fibrin obscure binding sites for inhibitors.<sup>346</sup>

Plasminogen also may be activated during the contact phase of the intrinsic coagulation system. Factor XIIa and HMWK interact with prekallikrein to produce kallikrein. Kallikrein activates urokinase, which in turn converts plasminogen to plasmin.<sup>347</sup> Because plasmin can activate factor XII, a potential feedback loop amplification exists. The importance of contact phase activation in vivo is questionable, however.

Plasmin is a serine protease with a high affinity for fibrinogen and fibrin, degrading them into fibrin degradation products (FDPs). Plasmin also may aid in degradation of factors V, VIII, IX, and XI. Fibrin and fibrinogen are split into the clinically significant FDPs including D-dimers, as well as fragments X,Y,O, and E. Increases in the circulating concentrations of these fragments can be attributed to ongoing fibrinolysis. The mononuclear phagocytes of the liver clear FDPs from the circulation.

## EVALUATION OF HEMOSTASIS

Disorders of hemostasis usually may be classified based on clinical signs as abnormalities of primary or secondary hemostasis. Abnormalities of primary hemostasis include vascular diseases and changes in the number or function of platelets. Affected horses usually have signs of mucosal bleeding, petechia and ecchymoses, epistaxis, hyphema, or melena. Platelet function tests were discussed previously. Diagnosis of the vasculitides is discussed in another section.

Disorders of secondary hemostasis usually involve abnormalities in quantity or function of the soluble coagulation factors and present as spontaneous or excessive hemorrhage in response to surgery or trauma. These horses may have hemorrhage into body cavities, hematoma formation, hemarthroses, prolonged bleeding after venipuncture, or external hemorrhage. Most coagulation tests measure the time necessary for clot formation under various circumstances. Coagulation times tend to be longer in horses than in human beings or other domestic animals.<sup>348</sup> Table 14-4 lists some laboratory tests used to assess equine hemostatic function with normal reference values.

Activated clotting time measures the time to clot formation on activation of whole blood by contact with diatomaceous earth. This process bypasses the contact phase of coagulation and is useful in evaluating deficiencies of factors VIII and IX, prothrombin, and fibrinogen. Abnormalities of factor VII and platelets do not appear to alter the activated clotting time.<sup>348</sup> One collects blood directly into a tube containing diatomaceous earth, mixes, incubates the contents at 37° or 38° C, and measures the time until clot formation.

PTT and activated partial thromboplastin time (APTT) measure the activity of factors XII, XI, X, IX, VIII, and V, prothrombin, and fibrinogen. The PTT test is performed by adding platelet-poor plasma to a glass tube containing phospholipid emulsion and calcium and determining the time to

TABLE 14-4

### Reference Ranges for Equine Hemostatic Values\*

Parameter	Units	Value	Reference
Platelet count	per $\mu$ l	75,000-300,000	NCSU <sup>†</sup>
Fibrinogen	g/dl	<400	NCSU
PT	seconds	8.5-9.9	NCSU
APTT	seconds	30-44	NCSU
FDPs	mg/dl	<20	NCSU
AT III	% PNEP	63-131	Johnstone et al. <sup>‡</sup>
AT III	% PNHP	218 $\pm$ 18	Bernard et al. <sup>§</sup>
Plasminogen	% PNEP	64.6-155.9	Welles et al. <sup>  </sup>
Protein C	% PNEP	104.5 $\pm$ 13.8	Welles et al. <sup>¶</sup>

PT, Prothrombin time; APTT, activated partial thromboplastin time; FDPs, fibrin degradation products; AT III, antithrombin III; PNEP, pooled normal equine plasma; PNHP, pooled normal human plasma.

\*These numbers are for reference only. Each laboratory should establish its own normal equine values.

<sup>†</sup>Data from NCSU, North Carolina State University College of Veterinary Medicine Clinical Pathology Laboratory normal equine reference values;

clot formation. One performs the APTT test similarly, except an activating agent is added. PT, also known as *one-stage PT*, measures the function of the extrinsic and common coagulation pathways, including factors V, VII, and X, prothrombin, and fibrinogen. In this test, platelet-poor plasma is mixed with thromboplastin and calcium and the time to clot formation is determined. One may use citrated whole blood or plasma for accurate measurement of PT up to 3 days after collection. A control sample from a clinically normal horse should accompany the patient's sample.<sup>349</sup> Commercially available tests for measurement of PT have been evaluated in horses and found to be accurate when the manufacturer's guidelines were followed and the appropriate reagent was used.<sup>350</sup> In horses with colic, APTT is more reliably elevated and more markedly changed than any of the other routine coagulation tests.<sup>351,352</sup> A prolonged APTT at admission is associated with a negative prognosis.<sup>353</sup> Thrombin time (TT) measures the time to clot formation after addition of thrombin to citrated plasma. TT is only prolonged with abnormalities in fibrinogen quantity or function or in the presence of thrombin inhibitors.

Most commonly, FDPs are measured in the serum using antibody-coated latex beads and monitoring macroscopic agglutination. This test reflects only the presence of D and E fragments. One must collect blood into a special tube containing thrombin and a protease inhibitor (ThromboWellcotest; Burroughs Wellcome Co., Research Triangle Park, N.C.). Commercially available latex agglutination kits for FDPs are not suitable for use in the horse.<sup>353</sup> However, D-dimers, a fibrinogen degradation product, can be measured reliably in horses using latex agglutination kits. An increase in D-dimers occurs in horses with colic,<sup>317,352</sup> laminitis,<sup>354</sup> jugular vein thrombosis, and DIC<sup>355</sup> and may indicate a risk factor for development of a coagulopathy.

Fibrinogen concentration may be easily estimated by refractometer as the difference between plasma protein concentration at room temperature and the concentration after heating plasma to 56° to 58° C for 3 minutes and centrifugation to remove precipitated fibrinogen. Alternatively, fibrinogen may be estimated from the thrombin clot time, which is inversely proportional to the fibrinogen concentration, or by immunologic assays.

Tests for plasma AT III measure the presence or the activity of the protein. Because inactive AT III antigen may be present, functional tests are preferable. Assays of AT III activity are clotting or chromogenic tests that measure residual thrombin activity after one adds the patient sample to a known quantity of thrombin. Normal AT III activity in the horse has been reported as 218% of normal human pooled plasma<sup>356</sup> and 63% to 131% of normal equine pooled plasma.<sup>357,358</sup> Widespread *in vivo* activation of coagulation is the most common cause of decreased plasma AT III activity. This is reliably observed in horses with gastrointestinal disease<sup>317</sup> and is a negative prognostic indicator for some populations of horses.<sup>359,360</sup> Decreased activity has been associated with protein-losing enteropathies or nephropathies and liver disease. Decreased AT III activity has been attributed to consumption of AT III, but the decrease may actually be the result of the loss of albumin or decreased production as seen with liver disease.<sup>361</sup> AT III's role as an acute phase protein in the horse is controversial.<sup>351,352</sup> Increased AT III activity has rarely been reported in horses with hepatic disease.<sup>358</sup>

Specialized assays for various components of the equine procoagulative and fibrinolytic systems have been described and are available only at specialized laboratories. These include assays for thrombin-antithrombin complexes (TAT),<sup>317</sup> protein C,<sup>362</sup> plasminogen,<sup>363</sup>  $\alpha_2$ -antitrypsin,<sup>364</sup> vWF,<sup>337</sup> and factor VIII:C.<sup>365</sup> Mean platelet component (MPC) is a measure of platelet density that reliably decreases when platelets become activated and degranulate. This test was found to be an indicator of platelet activation in both adult horses and ill neonates.<sup>366</sup>

## HEREDITARY DISORDERS OF HEMOSTASIS

Inherited disorders of hemostasis are most common in purebred animals that have been highly inbred. Many of these disorders are inherited in an autosomal recessive fashion; both parents must be carriers of the disorder to produce clinically affected offspring. For practitioners to be able to differentiate between inherited and acquired disorders of hemostasis is essential to advise owners appropriately. Inherited disorders are potentially treatable, but they are incurable. Owners should not use affected animals and their carrier parents as breeding stock. Practitioners see most animals with inherited bleeding problems when they are still young. Owners frequently complain of inappropriate bleeding in response to trauma or surgery or apparently spontaneous external hemorrhage or hematoma formation. As with any inherited defect, one should obtain a careful history and examine the patient and any close relatives, including siblings and parents, if possible. Most inherited defects result from a single-factor abnormality. Routine coagulation studies may narrow the differential diagnoses for these bleeding disorders, but confirmation of diagnosis usually requires specialized tests. In contrast, most acquired defects of hemostasis are characterized by multiple-factor abnormalities, frequently with a severe underlying systemic disorder.

### VON WILLEBRAND'S DISEASE

von Willebrand's factor is a glycoprotein of plasma, platelets, and endothelium required for platelet adhesion to exposed subendothelium and subsequent normal platelet plug formation. In plasma, vWF is bound in a multimolecular complex to coagulation factor VIII. Quantitative or qualitative abnormalities of vWF result in spontaneous bleeding from mucosal surfaces and excessive bleeding after surgery or trauma. Researchers have reported von Willebrand's disease in a Quarter Horse filly<sup>337</sup> that presented for episodes of oral bleeding, conjunctival hemorrhage, and prolonged bleeding at injection sites, as well as in a Thoroughbred mare and foal that presented for episodes of epistaxis. Routine complete blood count (CBC), including platelet count and coagulation times were within normal limits. Another 8-day-old Quarter Horse foal had a fever and numerous focal swellings at various sites around its body. This foal was persistently anemic and hypoproteinemic despite repeated transfusions and at necropsy was found to have significant hemarthrosis and secondary infection.<sup>367</sup> The ELISA for vWF is a sensitive and rapid means for diagnosis of this deficiency. Ristocetin, a co-factor involved in platelet aggregation, is deficient in human beings suffering from type II vWD. This specific deficiency was also identified in the aforementioned related Thoroughbreds.<sup>368</sup> This condition is heritable in human beings and dogs, and reports indicate the same is true in horses. Owners should not use affected animals for breeding.

## FACTOR VIII DEFICIENCY

Classic hemophilia (factor VIII deficiency, hemophilia A) is the most commonly reported inherited defect of hemostasis in the horse. Hemophilia has been diagnosed in Thoroughbred, Standardbred, Quarter Horse, and Arabian colts<sup>365,369-376</sup> with severe spontaneous hemorrhage or excessive hemorrhage related to surgery or mild trauma. Coagulation testing reveals abnormal function of the intrinsic coagulation system, with a prolonged APTT and a normal PT. Diagnosis is confirmed by measuring factor VIII:C activity in plasma. In human beings the severity of clinical signs varies inversely with this value, and the same appears to be true for affected horses. In severely affected horses, factor VIII activity is less than 10% of normal equine plasma.<sup>365,371,373</sup> A less severely affected colt that survived castration and was undiagnosed until 3 years of age had a factor VIII activity of 20% to 30%.<sup>375</sup> As in human, canine, and feline hemophilia, equine factor VIII deficiency is transmitted as an X-linked recessive trait.<sup>370</sup> Carrier mares transmit the defect to 50% of male offspring on average. Carrier female horses usually have a factor VIII:C activity of approximately 50% of normal, although this value may vary widely and even overlap normal values. No cure exists for hemophilia, and the disease is progressively debilitating and potentially lethal. Affected human beings are treated with repeated transfusions of fresh plasma and factor concentrates. Factor IX and XI deficiencies have been reported in one Arabian foal with concurrent factor VIII deficiency.<sup>372</sup>

## COAGULATION FACTOR ABNORMALITIES

In the classic pathway, initiation of the intrinsic coagulation system involves interaction of factor XII, prekallikrein, and HMWK ultimately to activate factor XI. This process usually begins with contact between factor XII and negatively charged molecules such as subendothelium or collagen. Prekallikrein deficiency has been diagnosed in families of Belgian horses<sup>377</sup> and American Miniature Horses.<sup>378</sup> Plasma prekallikrein deficiency is characterized by prolonged APTT with a normal PT. Affected horses may or may not show clinical signs of a bleeding tendency.<sup>377,378</sup> Confirmation of diagnosis is by demonstrating low prekallikrein activity with normal activity of other intrinsic coagulation factors. One also can correct the prolonged APTT by extended incubation with a contact activator.<sup>377,378</sup> In human beings, prekallikrein deficiency is inherited as an autosomal recessive or autosomal dominant trait.<sup>379</sup> The mode of inheritance in horses has not been confirmed, but appearance of the defect in multiple members of some equine families strongly suggests that it is an inherited disorder in this species as well. A similar defect in the contact phase of coagulation, not thought to result from prekallikrein deficiency, was diagnosed in one Quarter Horse gelding with prolonged APTT and normal PT.<sup>380</sup> Researchers did not observe a clinical bleeding problem in association with this defect.

## ACQUIRED DISORDERS OF HEMOSTASIS

### VASCULITIS

Vasculitis, inflammation of blood vessels, may occur as a primary disease process but more commonly is encountered as a secondary complication of infectious, immunologic, toxic, or neoplastic disorders.<sup>381</sup> Hypersensitivity vasculitides are characterized by predominant involvement of small blood vessels in the skin. In most cases the postcapillary venules are

involved. The most common inflammatory pattern is leukocytoclasia, defined by the presence of neutrophilic nuclear debris in and around the involved vessels. Vessel wall necrosis and fibrinoid changes occur.

Clinical signs depend on the type of vessel affected and the severity of the inflammatory response. Vascular occlusion may result in tissue ischemia and necrosis. Increased vascular permeability results in hemorrhage and edema as fluid and cellular constituents of the blood escape into the extravascular space. In horses, vasculitis is characterized by well-demarcated areas of cutaneous edema that may involve any portion of the body.<sup>382</sup> The distal extremities and ventral body wall are affected most commonly, and the edematous area is often hot and painful. Affected horses generally are depressed and reluctant to move. Hyperemia, petechial and ecchymotic hemorrhages, and ulcerations are commonly present on mucous membranes of the mouth, nose, and vulva. Other clinical signs may reflect edema, hemorrhage, and infarction in other body systems. Lameness, colic, diarrhea, dyspnea, or ataxia can result from involvement of vessels in joints, muscles, gastrointestinal tract, respiratory tract, and central nervous system. Subclinical renal disease may occur. Secondary complications such as laminitis, thrombophlebitis, and localized infections are common. Affected skin often weeps serum and eventually sloughs.

The underlying disease, length of illness, other organ involvement, and secondary complications usually determine hematologic and serum biochemical findings in vasculitis; none are characteristic. Neutrophilia, mild anemia, hyperglobulinemia, and hyperfibrinogenemia usually accompany chronic inflammation. The platelet count is often normal to increased but can be low because of a concomitant consumptive coagulopathy or IMTP. With renal involvement, serum creatinine may be elevated or urinalysis may reveal hematuria or proteinuria or both.

### INFECTIOUS DISEASES

Infectious diseases associated with vasculitis and subsequent petechiation, ecchymoses, and dependent edema include EIAV, equine granulocytic ehrlichiosis, and equine viral arteritis (EVA). All three diseases may result in thrombocytopenia, although this is somewhat less common with EVA. The first two are discussed in detail elsewhere in this chapter; a discussion of EVA follows.

An arterivirus of the family Arteriviridae causes EVA. The disease can be characterized by fever, chemosis, lacrimation, rhinitis, focal dermatitis, ventral edema, and occasionally abortion.<sup>383,384</sup> However, many infected horses do not show recognizable clinical signs.

Horses become infected by aerosol or venereal contact with an infected animal. The virus replicates in the intima and media of most arteries, resulting in an inflammatory reaction and cellular influx.<sup>385</sup> Although mares and geldings generally clear the disease, stallions may become asymptomatic carriers of the disease, harboring virus in the accessory sex glands<sup>383,386</sup> and transmitting infection to previously unexposed mares. Infected mares usually make an uneventful recovery from EVA and eliminate the virus from the body. Abortion may occur during or shortly after acute illness or asymptomatic infection as a result of myometrial necrosis and edema leading to placental separation and fetal death.<sup>387</sup> Not all infected mares abort, however, and the incidence of abortion may be strain dependent.<sup>388</sup>

One confirms diagnosis of EVA in mares by serum neutralization assay, demonstrating a fourfold or greater rise in titer between acute and convalescent serum samples. EVA titer may remain elevated for a long time after natural infection, and recovered mares are considered immune to further infection.

Diagnosis of persistently infected, asymptomatic, nonvaccinated stallions depends on a positive serum neutralization test of greater than 1:4, with either isolation of the virus from semen samples or demonstration of seroconversion of an otherwise unexposed mare within 2 weeks of breeding to the suspect stallion.<sup>389</sup> Diagnosis of abortion caused by EVA requires virus isolation from the fetus or the placenta. Recent seroconversion in the mare is highly supportive of a diagnosis of EVA abortion.

A modified live virus vaccine is available but should be reserved for use only in breeding animals.<sup>388</sup> It should be administered annually to mares while open and to stallions or teasers 3 to 4 weeks before the breeding season.<sup>390</sup> Vaccinates should be isolated for 21 days after vaccination because of virus shedding during this time frame. Infections caused by the vaccine strain cannot be distinguished from natural infection. Most breeding facilities require a negative serologic result before acceptance of semen, stallions, or broodmares. Any breeding animal that may be potentially exported must have a negative serologic test followed by an appropriate vaccination record before export.<sup>391</sup> Vaccine records should be carefully managed as to provide protection and allow accurate diagnostic testing.<sup>392,393</sup> One may offer supportive care to acutely infected animals and should isolate them from uninfected animals, especially pregnant mares.

## IMMUNOLOGIC DISEASES

Most noninfectious cases of vasculitis in the horse are thought to be immune mediated. Small cutaneous vessels most commonly are affected, resulting in edema that may progress to skin infarctions, necrosis, and exudation.<sup>381</sup> The best characterized of these disorders is purpura hemorrhagica after *Streptococcus equi* subsp. *equi* infection. However, vasculitides of undetermined cause also have been described in the horse.<sup>284,394</sup> Most of these cases appear to have an immune-mediated cause. The antigenic stimulus of hypersensitivity vasculitis is usually a microbe, drug, toxin, or foreign or endogenous protein. The deposition of circulating immune complexes with subsequent vessel wall damage is probably the major event in the pathogenesis of these vasculitic syndromes. Soluble immune complexes, formed in moderate antigen excess, become deposited in blood vessel walls in areas of increased permeability. Deposited immune complexes activate complement with resulting formation of C5a, a potent chemotactic factor for neutrophils. Infiltrating neutrophils release lysosomal and other cytoplasmic enzymes such as elastase and collagenase that directly damage vessel walls. The net effect is vessel wall leakage and luminal compromise, resulting in edema, hemorrhage, thrombosis, and ischemic changes in supplied tissues.

Aside from vessel wall necrosis, vasculitis results in vascular dysfunction characterized by a net increase in vasoconstriction and platelet aggregation, which contribute to tissue ischemia.<sup>395</sup> The diseased endothelium releases endothelin, a polypeptide that causes contraction of underlying smooth muscle<sup>396</sup> and produces fewer dilator substances such as endothelial-derived relaxing factor.<sup>397</sup> Injury to the vessel wall also results in diminished prostacyclin production, which usually serves to maintain vasodilation and platelet nonreactivity.<sup>267</sup>

Thus endothelial dysfunction contributes ultimately to vessel failure after vasculitis.

The factors that determine which individuals develop hypersensitivity vasculitis remain undefined. Genetic predisposition, altered immunoregulatory mechanisms, and the amount, relative size, and type of complement components in circulating immune complexes are important in determining the potential risk of developing vasculitis (because these factors determine how quickly the mononuclear phagocyte system clears immune complexes).<sup>398</sup> Perhaps even more significant in this potential risk are genetic and acquired differences in the number and activity of receptors for complement and IgG on erythrocytes and macrophages. The difference can affect immune complex handling and distribution greatly.<sup>399,400</sup> Receptors for complement and the Fc of IgG mediate immune complex transport to and removal by the macrophages of the mononuclear phagocyte system. Physical factors such as turbulence of blood flow, hydrostatic pressure within vessels, and previous endothelial damage likely determine the size, type, and location of blood vessels involved in vasculitis. Researchers believe that the propensity for lesion formation in the skin of dependent body portions likely is caused by the hydrostatic pressure in affected postcapillary venules in these areas.<sup>267</sup>

## DIAGNOSIS

The diagnosis of vasculitis depends on demonstration of typical histologic changes (e.g., leukocytoclasia, fibrinoid necrosis) in involved vessels. One should obtain full-thickness punch biopsies (6 mm in diameter) of skin in an affected area and preserve it in 10% formalin for histopathologic study. The skin in the designated area may be clipped but not scrubbed before sampling. One can process the samples saved in Michel's transport medium subsequently for immunofluorescence analysis to detect immune complexes.<sup>401</sup> Multiple biopsies from various sites are optimal in reaching a diagnosis, because distribution of histologic lesions and immune complexes is patchy. However, affected skin is often on the distal limbs where risk increases for cellulitis or exuberant granulation tissue. The irregular distribution of histologic lesions, coupled with difficulty in obtaining biopsies, makes the definitive diagnosis of vasculitis difficult. Often a diagnosis of vasculitis is based on history, clinical signs, and response to therapy.

Purpura hemorrhagica is a syndrome of cutaneous vasculitis that can develop several weeks after infection with *Streptococcus equi* subsp. *equi*, *S. equi* subsp. *zooepidemicus*, influenza virus, *Corynebacterium pseudotuberculosis*, or equine herpesvirus. Purpura hemorrhagica also has been described as an adverse side effect of antistreptococcal vaccination in the horse. Purpura hemorrhagica after infection with *S. equi* subsp. *equi* has been attributed to deposition of circulating immune complexes consisting of IgA and *S. equi* subsp. *equi* M protein in small subcutaneous vessels.<sup>402</sup> In approximately 30% of affected horses, no viral, bacterial, or vaccine cause is identified.<sup>381,403</sup> Horses are often febrile with ventral edema, especially of the distal limbs. Affected animals frequently have great pain and are reluctant to move. Petechia and ecchymoses may be present on oral, nasal, and conjunctival mucous membranes. Extensive skin necrosis and sloughing often follow severe swelling. A more severe infarctive form of purpura has also been described.<sup>404</sup> Affected horses develop areas of infarcted skin, as well as areas of ischemic damage in the intestines, kidneys, and skeletal muscles. Reports show increased mortality with this form and indicate that older horses

repeatedly vaccinated or exposed to *S. equi* subsp. *equi* may be at an increased risk of developing the syndrome.

Horses with purpura hemorrhagica are not usually thrombocytopenic but frequently have laboratory evidence of chronic inflammatory disease, including increased fibrinogen and total plasma protein, as well as neutrophilia.<sup>381</sup> Careful monitoring of physical examination parameters and lab values is important to rapidly identify changes in the disease including kidney and skeletal muscle involvement.<sup>404</sup> If *S. equi* subsp. *equi* is the possible inciting cause, then M protein titers can be measured. Titers in horses suffering from *S. equi* subsp. *equi*-induced purpura are often very high, but lower titers can be hard to interpret in horses that have been exposed to or vaccinated against the organism.<sup>405</sup> Cutaneous biopsy of affected areas may confirm the diagnosis. Histopathologically, a leukocytoclastic vasculitis characterized by neutrophilic accumulation in and around small dermal and subcutaneous vessels occurs.

### TREATMENT

The aims in the therapy of equine vasculitic syndromes are (1) to remove the antigenic stimulus if possible, (2) to reduce vessel wall inflammation, (3) to normalize the immune response, and (4) to provide supportive care. Regardless of the cause, vasculitis in horses generally warrants aggressive nursing care, which one should institute immediately. Hydrotherapy can minimize edema, and pressure wraps are useful on the limbs. Animals that become severely depressed and fail to drink or those with dysphagia caused by pharyngeal edema require fluids, intravenously or via nasogastric tube. A tracheostomy may be necessary in horses with stridor and dyspnea that occurs after edema of the upper respiratory tract. Phenylbutazone, flunixin meglumine, or other NSAIDs are indicated to reduce vascular inflammation and provide analgesia. The disease also may warrant corticosteroid administration. Long-term antimicrobial therapy is indicated to reduce the incidence or severity of cellulitis or other septic sequelae.<sup>403</sup>

Because no treatment effectively eliminates EIA or EVA from the body, neither disease warrants specific therapy. Although equine anaplasmosis spontaneously resolves, elimination of the organism by oxytetracycline therapy considerably shortens the clinical course of disease.

When the cause is unknown, vasculitis can be difficult to treat because the antigenic stimulus remains undefined and may not be eliminated easily. One should discontinue administration of any drug being used at the time that signs occur. A thorough search for an underlying infection or neoplasia is warranted. Horses with a recent history of strangles or that have been exposed to the disease should receive procaine penicillin G at 22,000 U/kg intramuscularly twice daily or potassium penicillin G intravenously four times daily for at least 2 weeks. One should drain accessible abscesses and examine and culture the guttural pouches via endoscopy. Even though the sensitizing infection usually has resolved by the time signs of purpura hemorrhagica occur, ongoing sepsis and antigen production prolong the allergic vasculitis. Although the use of corticosteroids for treating hypersensitivity vasculitis was once controversial,<sup>267</sup> research and clinical experience suggest that horses with purpura hemorrhagica or idiopathic vasculitic syndromes respond favorably to corticosteroid therapy. Of the 53 cases documented, all were treated with corticosteroids, resulting in a 93% recovery rate.<sup>381,403</sup>

Mild cases of vasculitis may resolve without immunosuppressive therapy, but life-threatening edema involving the upper respiratory tract or causing organ system dysfunction necessitates early aggressive corticosteroid treatment. One should administer dexamethasone (0.05 to 0.2 mg/kg intravenously, intramuscularly, or orally once or twice daily) at the dose and rate necessary to reduce edema. Prednisolone may be substituted at 0.5 to 1.0 mg/kg orally twice daily for dexamethasone, but prednisone should not be used because it has poor oral absorption in the horse. After edema and hemorrhages start to resolve, one may reduce the corticosteroid dose gradually (by 10% to 15% every 1 to 2 days) while carefully monitoring the horse for relapse. It is not uncommon for horses with purpura hemorrhagica to require corticosteroid and antibiotic therapy for a period of 4 to 6 weeks before edema permanently resolves.

Occasionally, horses suffer disease flare-ups that require the corticosteroid dose to be increased over the previously efficacious level. In these instances, flunixin meglumine may enhance steroid efficacy. Antimicrobials are indicated throughout the period of systemic corticosteroid administration to reduce the incidence and severity of secondary sepsis.

### PROGNOSIS

The prognosis for vasculitis depends on the initiating disease process. With early aggressive therapy and supportive care, most horses recover from purpura hemorrhagica within 4 weeks, although numerous sequelae may prolong the convalescence. A 93% recovery rate was reported in one study<sup>403</sup>; however, horses that suffer from the severe infarctive form carry a much poorer prognosis for recovery.<sup>404</sup> Dermal infarction in the distal limbs often leads to skin sloughing followed by exuberant granulation tissue and may require excision followed by skin grafting. Laminitis and various infections such as cellulitis, pneumonia, colitis, and thrombophlebitis are common and may be related to long-term corticosteroid therapy.

EVA and equine anaplasmosis carry a good prognosis, and disease confers some immunity to reinfection. Horses with EIA are infected persistently and may suffer recurrent clinical relapses. Horses with idiopathic vasculitic syndromes have an unpredictable response to therapy, and some have a poor prognosis. Inadequate resolution of hypersensitivity vasculitis in human beings usually is caused by failure to identify the antigenic stimulus or completely eliminate it from the body.<sup>267</sup> Although in most horses remission is spontaneous, some have debilitating cutaneous disease or develop systemic necrotizing vasculitis with a poor prognosis.

### THROMBOCYTOPENIA

When circulating platelet counts decrease to less than 30,000 per microliter, a bleeding diathesis frequently occurs. Affected horses have petechial and ecchymotic hemorrhages of mucosal membranes, epistaxis, increased bleeding after venipuncture, melena, or hyphema.<sup>281-286</sup> Similar signs may occur in horses with platelet function defects. Disorders involving alterations in platelet number or function are described in previous sections.

### VITAMIN K DEFICIENCY

Vitamin K is a fat-soluble vitamin essential for a final step,  $\gamma$ -carboxylation, in the hepatic synthesis of many coagulation factors. The serine proteases, including factors II, VII, IX, and

X, require  $\gamma$ -carboxylation of glutamate before they are biologically functional. Vitamin K deficiency results in a gradual decrease in functional coagulation factors in circulation that ultimately can end in a clinical syndrome of inappropriate bleeding. The rapidity with which coagulation factor concentrations in circulation decline depends largely on the half-life of those factors in circulation. Factor VII has a plasma half-life in the dog of 4 to 6 hours (compared with 41, 14, and 16 hours for factors II, IX, and X, respectively) and reaches a critical concentration in the circulation more rapidly than other vitamin K–dependent factors.<sup>406</sup> As a result, coagulation studies early in the course of vitamin K deficiency may reveal abnormalities in the extrinsic coagulation system (prolonged PT) with a normal intrinsic system (normal APTT). As the condition progresses, however, extrinsic and intrinsic coagulation parameters are abnormal.

All green leafy feeds, including hay and fresh pasture, contain high concentrations of vitamin K. For this reason, foals before weaning have decreased vitamin K levels as compared with adult horses.<sup>407</sup> Researchers also believe that vitamin K is synthesized by the intestinal microflora of many species. As a result, vitamin K deficiency only rarely results from an absolute deficiency of the nutrient in the diet. More commonly, deficiency results from an inability of the horse to absorb or use dietary vitamin K. Chronic intestinal malabsorption of lipids can result in clinical bleeding problems. One may assess dietary fat absorption by feeding 150,000 IU of vitamin A (another fat-soluble vitamin) in corn oil with grain and measuring increases in serum vitamin A concentration.<sup>408</sup> Concentrations should double over 12 to 24 hours. Fat absorption depends on bile acid secretion from the liver, and chronic cholestatic disorders also can result in decreased vitamin K absorption.

Antagonism of vitamin K by warfarin or other dicumarol derivatives is a more common clinical problem than is absolute vitamin-K deficiency. The dicumarol derivative warfarin has been advocated as an oral anticoagulant for use in horses with navicular disease<sup>409</sup> or jugular thrombophlebitis.<sup>410</sup> Warfarin also is the active ingredient in many rodenticides, and accidental exposure to toxic doses of the compound is possible. Warfarin is an effective antagonist of vitamin K and inhibits the production of functional coagulation factors II, VII, IX, and X. Warfarin therapy may begin with a daily dose of 0.018 mg/kg orally and increase in increments of 20% to achieve the desired therapeutic effect,<sup>409</sup> which usually results in a final dose of 0.012 to 0.75 mg/kg daily.

Concurrent administration of other drugs, especially phenylbutazone, may increase the risk of warfarin-induced hemorrhage. Phenylbutazone acts by competing with warfarin for binding sites on plasma albumin, increasing the concentration of free warfarin in circulation. Similarly, hypoalbuminemia can increase the risk of warfarin toxicosis. Thyroxin and corticosteroids lower the necessary therapeutic dose of warfarin by enhancing receptor affinity and increasing clotting factor catabolism. Rapid withdrawal of drugs that induce hepatic microsomal enzyme metabolism, such as rifampin, chloramphenicol, and barbiturates, also can potentiate toxicosis because these drugs enhance warfarin metabolism.

Because factor VII has the shortest half-life of the vitamin K–dependent factors, warfarin affects the extrinsic coagulation system more rapidly than the intrinsic system, and determination

of PT is the most commonly used method for monitoring the effectiveness of warfarin anticoagulative therapy. An increase in PT of 1.5 to 2.5 times baseline is recommended as a therapeutic goal of warfarin anticoagulation.<sup>410,411</sup>

Toxic doses of warfarin result in spontaneous hemorrhage that may be life threatening. One makes a diagnosis of warfarin toxicity based on a history of exposure, clinical evidence of hemorrhage (bleeding from body orifices or into body cavities, hematoma formation, or clinical pathologic indications of blood loss anemia), prolonged PT or PTT with normal platelet count and fibrinogen and FDP concentrations, and response to exogenous vitamin K administration.<sup>412</sup>

Because warfarin interferes with the final stages of clotting factor synthesis, administration of vitamin K<sub>1</sub> at up to 1.0 mg/kg subcutaneously rapidly reverses toxicity.<sup>410</sup> One may repeat this dose every 4 to 6 hours until PT returns to normal, followed by daily monitoring for 3 to 4 days.<sup>413</sup> PT returns to normal approximately 5 days after the last dose of warfarin without administration of supportive therapy; administration of vitamin K<sub>1</sub> results in a return of PT to baseline within 24 hours.<sup>413,414</sup> In horses with severe bleeding, one should administer whole blood transfusions concurrently to replace plasma clotting factors. The horse should improve within 1 to 2 hours. One may administer smaller doses of vitamin K<sub>1</sub> orally, concurrent with warfarin, to titrate the anticoagulant effects of the latter.<sup>415</sup>

Second-generation anticoagulant rodenticides such as brodifacoum have a prolonged half-life (1.2 days) and lower median lethal dose compared with warfarin.<sup>415</sup> As a result, their potential for adverse effects are greater. History of exposure is important because therapy requires prolonged antidotal therapy.<sup>416</sup> Aggressive symptomatic and supportive therapy is often unsuccessful.<sup>417</sup>

Toxicosis caused by ingestion of moldy sweet clover (*Melilotus* spp.) hay is reported in all herbivores.<sup>418</sup> White sweet clover (*Melilotus alba*) and yellow sweet clover (*M. officinalis*) contain coumarin. When sweet clover hay is cured improperly, numerous fungi (e.g., *Penicillium*, *Mucor*) propagate; these fungi convert coumarin to 4-hydroxycoumarin, which condenses to dicumarol.<sup>419</sup> Animals that ingest sufficient quantities of moldy hay develop severe coagulation dysfunction within 2 to 7 days with internal and external hemorrhaging.<sup>42</sup> Continued ingestion of moldy hay can result in a lethal hemorrhagic crisis. One should consider toxicity as a diagnosis in horses with history of access to moldy sweet clover hay and can confirm the diagnosis with coagulation tests described previously for warfarin toxicosis. Suspect hay should be destroyed because toxic concentrations of dicumarol may remain for up to 4 years.<sup>419</sup>

One may treat clinical bleeding episodes resulting from inadequate vitamin K and subsequent deficiency in the levels of vitamin K–dependent coagulation factors in circulation with parenteral vitamin K<sub>1</sub> (phylloquinone) injections at a dosage of 0.3 to 0.5 mg/kg. Subcutaneous injection is recommended because intravenous administration has resulted in a high incidence of adverse reactions in other species. One ultimately must address underlying gastrointestinal or hepatic disorders as well. Parenterally administered vitamin K<sub>3</sub> (menadione sodium bisulfite) is nephrotoxic in horses at the manufacturer's recommended dose and should not be administered.<sup>421</sup> Horses that receive vitamin K<sub>3</sub> may show signs of colic, hematuria, azotemia, and electrolyte abnormalities consistent with acute renal failure.

## HEPATIC DISEASES

Severe hepatic disease often is associated with hemorrhagic tendencies caused by decreased production of coagulation factors II, V, VII, IX, and X and fibrinogen. Impairment of bile acid secretion may impair absorption of the fat-soluble vitamins, resulting in decreased production of the vitamin K–dependent clotting factors. Hepatic Kupffer's cells are responsible for removal of many activated coagulation factors and FDPs from the circulation. Increased circulating FDPs inhibit normal platelet function and generation of fibrin. These abnormalities may combine to initiate DIC. A severe bleeding diathesis is a poor prognostic indicator in horses with hepatic disease.

## DRUG-INDUCED ALTERATIONS IN HEMOSTASIS

A variety of pharmaceutical agents can alter hemostatic mechanisms. Incorrect or poorly monitored administration of these agents may result in hemorrhagic tendencies in the horse.

### ASPIRIN

Aspirin causes an irreversible inhibition of platelet function. The mechanisms and implications of this effect are discussed in previous sections.

### HEPARIN

Heparin is a mucopolysaccharide complex of variable molecular weight that potentiates the activity of AT III in neutralizing coagulation factor X and increasing the rate of inactivation of other serine proteases (factors II, IX, XI, and XII).<sup>422,423</sup> Potentiation of AT III activity is attributed primarily to lower-molecular-weight forms of the molecule that inhibit factors X and XII, with minimal inhibitory effects on thrombin and factors IX and XI.<sup>423</sup> Heparin has been advocated for maintenance of the patency of indwelling catheters, prophylaxis for venous thrombosis and laminitis, anticoagulation of whole blood transfusions, prevention of postoperative peritoneal adhesions, and treatment and prevention of DIC.<sup>422,424-427</sup> Efficacy remains controversial with reports supporting and denying the effects of heparin.<sup>428,429</sup>

Bleeding complications associated with unfractionated heparin therapy are uncommon, but administration of protamine sulfate at up to 1 mg for every 90 to 100 U of heparin has been recommended in horses with heparin-associated hemorrhage.<sup>422</sup> Protamine sulfate forms a stable salt with heparin and with soluble fibrinogen monomers. If the FDP concentration increases in a patient, then precipitation of these salts may result in intravascular infarction, and use of protamine sulfate is contraindicated.

The most pronounced adverse effect associated with unfractionated heparin administration in the horse is a significant reduction in the circulating RBC mass.<sup>291,430</sup> Doses of 160 to 320 U/kg subcutaneously twice daily for nine doses resulted in a significant decrease in RBC numbers, PCV, and total hemoglobin, and an increase in MCV, with a rapid return of values to baseline after discontinuation of therapy.<sup>291</sup> Because heparin is known to increase the activity of mononuclear phagocytes, decreased RBC numbers originally were hypothesized to result from an enhanced phagocytosis of erythrocytes.<sup>430</sup> However, decreased RBC numbers now are thought to result primarily from *in vivo* erythrocyte agglutination.<sup>431,432</sup> One can reverse this agglutination *in vitro* by adding a trypsin

solution to the RBC suspension. Decreases in RBC numbers and increases in MCV associated with heparin administration are most likely artifactual, resulting from the measurement of multiple agglutinated cells as single units.<sup>432</sup> Unfractionated heparin administration in horses (160 U/kg subcutaneously twice daily) also has been associated with development of large plaques of painful edema.<sup>433</sup>

Low-molecular-weight heparin (LMWH) is derived from unfractionated heparin by solvent extraction or gel filtration. The resulting drug is made up of smaller molecules and has more reliable anticoagulant properties, better bioavailability, and a longer half-life in human beings.<sup>434</sup> The pharmacokinetic properties of LMWH have been studied in the horse, and appropriate dosages have been identified.<sup>435</sup> An injection of 50 IU/kg of LMWH once daily was compared with unfractionated heparin at tapering dosages between 150 to 100 IU/kg twice daily in horses with colic.<sup>436</sup> Significantly more jugular vein problems were observed in horses receiving unfractionated heparin and adverse effects, including decreased PCV and prolonged APTT and TT, were markedly increased in the unfractionated group as compared with the LMWH group. Efficacy trials for the use of LMWH in prevention and treatment of hypercoagulability are lacking, but LMWH may offer fewer adverse effects as compared with horses treated with the unfractionated form. The use of this drug is often confounded by its expense in the horse.

## DISSEMINATED INTRAVASCULAR COAGULATION

DIC is a condition of pathologic activation of coagulative and fibrinolytic systems, ultimately leading to microvascular ischemia and secondary organ dysfunction. Human research indicates that the inflammatory cytokine cascade that results from massive trauma or sepsis is intimately associated with the development of a hypercoagulable state that can ultimately lead to DIC.<sup>437</sup> DIC may be acute or chronic, systemic or localized, and frequently is characterized by severe hemorrhage caused by consumption of coagulation factors, but it also may manifest as a pronounced thrombotic tendency due to a hypercoagulable state. The type and severity of clinical signs depend on the initial stimulus for pathologic systemic coagulation activation, the duration and extent of activation, the availability of coagulation factors, and the relative strengths of activation of procoagulant and fibrinolytic forces. The final result in horses with severe DIC is often widespread ischemic organ failure, severe hemorrhage, and death.

DIC is not considered a primary diagnosis and occurs after a variety of disorders triggered by many different mechanisms. In the horse, DIC most commonly is associated with gastrointestinal disease or sepsis.<sup>438-448</sup> The common initiating factor in most cases is endotoxin, the external lipopolysaccharide cell wall of gram-negative bacteria. Endotoxin can activate factor XII directly to initiate the intrinsic coagulation pathway and may cause widespread damage to vascular endothelium, exposing subendothelial collagen and releasing tissue thromboplastin to trigger the coagulation pathways. Endotoxin damages platelets, inducing aggregation and activation, and exposing platelet factor 3. Other conditions associated with DIC include intravascular hemolysis, bacteremia (gram positive or gram negative), viremia, neoplasia, circulating immune complexes, immune thrombocytopenia, fetal death in utero, burns, hepatic disease, renal disease, and vasculitides. Virtually any primary disease process may initiate DIC by injury

to blood cells, increasing the availability of phospholipid surfaces, injury to vascular endothelium, or tissue injury and subsequent release of thromboplastin.<sup>449</sup>

As widespread activation of proinflammatory pathways occurs, kinins are generated and the complement cascade is stimulated.<sup>449</sup> Cytokines involved in the activation of this cascade include TNF- $\alpha$ , IL-1, IL-6, and IL-8.<sup>450</sup> Factor XIIIa is responsible for initiating kinin formation by activating kallikrein, which in turn proteolytically converts HMWK to kinins. Bradykinin, the most physiologically important of the kinins, enhances vascular permeability, dilates some blood vessels, and stimulates migration of leukocytes into the extravascular space.<sup>451</sup> Plasmin activates the complement cascade and induces neutrophil chemotaxis, increases vascular permeability, and destroys RBCs and platelets, releasing membrane phospholipoprotein and ADP to act as procoagulants. Complement products can activate factor XII.

In response to endotoxin, mononuclear phagocytes release procoagulant substances including TF, platelet activating factor, TNF, and IL-1.<sup>452</sup> These phagocytic cells are responsible for removal of activated clotting factors and FDPs from the circulation. Massive concentrations of activated clotting factors or FDPs, or impairment of phagocytic function, can lead to abnormally high levels of either element in the blood. Activated clotting factors then remain available for continued coagulative events. Elevated FDP levels in the peripheral circulation can inhibit fibrin monomer polymerization and thrombin formation and also coat platelet membranes, interfering with aggregation.

The clinical signs associated with DIC in the horse vary widely and reflect the primary disease process, the duration and severity of coagulation activation, and the balance between procoagulant and fibrinolytic forces. Horses seldom show severe bleeding diathesis after DIC, and less severe forms of DIC in which the horse may be in a subclinical hypercoagulable state may go unnoticed. Careful clinical examination may reveal petechia and ecchymoses of mucous membranes and prolonged bleeding from venipuncture sites. Many horses exhibit an increased tendency to venous thrombosis after venipuncture.<sup>442</sup> Other clinical signs may reflect organ dysfunction after microvascular thrombosis and tissue ischemia. In the kidney, organ dysfunction may occur as tubulointerstitial disease and acute renal failure. In the foot, DIC may contribute to digital ischemia and laminitis<sup>424,425,438,442</sup>; however, experimentally induced laminitis was not associated with significant changes in hemostatic parameters.<sup>364</sup> Many horses with DIC have clinical signs reflecting poor peripheral perfusion and shock, including prolonged capillary refill time, cool extremities, and tachycardia, which may result from the primary disease process or occur after DIC-induced microvascular occlusion and inflammation.

Diagnosis of DIC depends on the results of a variety of tests assessing the quantity and function of coagulative substances. The most commonly evaluated parameters in horses are platelet count and function, PT, PTT, activated clotting time, and FDPs. Platelet counts usually are decreased in horses with DIC.<sup>439-442,444,447</sup> In horses with normal platelet counts, platelet function frequently is impaired.<sup>438</sup> Although coagulation times may be shorter early in the disease, rarely does one examine horses at this time. Most horses have reached a stage of hemorrhagic tendency, largely because of consumption of coagulative elements, by the time DIC is recognizable. These patients have increased PT, PTT, and activated clotting time. Because DIC accelerates fibrinolytic processes, elevations in

circulating FDPs and D-dimers occur commonly.<sup>438,442,444,447</sup> In contrast to other species, horses with DIC commonly have normal to increased fibrinogen concentrations.<sup>352,438,442,447</sup> Fibrinogen acts as an acute phase reactant protein in the horse, and inflammation, which accompanies most cases of DIC in the horse, stimulates accelerated hepatic production.

Several other laboratory tests may aid in diagnosis of DIC in the horse. Decreased plasma AT III concentrations are considered a sensitive indicator of DIC in human beings.<sup>453</sup> Because AT III is bound irreversibly to serine proteases in the plasma, AT III is consumed rapidly during pathologic intravascular coagulation. AT III activity has been shown to decline in horses with experimentally induced large colon torsion.<sup>445</sup> This decline was reversible in horses that survived and persisted in horses that died. In horses with naturally occurring colic or acute colitis, plasma AT III activity is decreased significantly.<sup>357,439,440</sup> One does not always find decreases in AT III activity, however, and normal activity has been reported in ponies with coagulopathy after equine ehrlichial colitis.<sup>443</sup> Because AT III is a small protein, it may be lost from circulation in most disease conditions associated with hypoalbuminemia, including protein-losing enteropathies and nephropathies.<sup>454</sup> Increased plasma AT III activity has been associated with hepatic disease in the horse.<sup>357</sup>

Assays for equine  $\alpha_2$ -antiplasmin, plasminogen, and protein C have been described, and normal values have been reported.<sup>362-364</sup> Plasma  $\alpha_2$ -antiplasmin concentrations were decreased in ponies with coagulopathy after equine ehrlichial colitis. Plasminogen concentrations were increased in these ponies, possibly indicating a role of plasminogen as an acute phase reactant.<sup>443</sup> Plasma protein C concentrations may be decreased in human beings with DIC.<sup>455</sup> One may determine individual coagulation factor levels, but such determination rarely provides more information than PT or PTT.

Diagnostic criteria for DIC in the horse have not been defined rigidly. One must assess each patient in the light of the severity and duration of underlying disease processes, clinical appearance, and laboratory hemostatic values. Subclinical DIC may be documented with laboratory evaluation of animals that have no overt clinical signs of pathologic coagulopathy. Multiple hemostatic abnormalities in an animal with thrombotic or hemorrhagic tendencies strongly suggest DIC. Regardless of the definition of DIC, if a high index of suspicion exists, attempted therapy is warranted.

The therapeutic plan for horses with DIC must focus on treatment of the primary underlying disease process. Only by removing the pathologic stimulus for coagulation can procoagulant and fibrinolytic mechanisms be rebalanced effectively. One should administer supportive therapy for shock, decreased tissue perfusion, and acid-base and electrolyte abnormalities. If endotoxemia contributes to the disease process, then one should administer NSAIDs. Low-dose flunixin meglumine therapy (0.25 mg/kg intravenously three times daily) is effective in inhibiting endotoxin-induced cyclooxygenase activity.<sup>456</sup> One should treat animals with sepsis with appropriate antimicrobial agents. Fresh platelet-rich plasma can be introduced intravenously to horses with life-threatening hemorrhage after DIC. Fresh plasma resupplies soluble coagulation factors, and normal platelets may restore primary hemostatic mechanisms. The recommended dose of plasma for use in DIC in other species is typically 10 to 20 ml/kg or 5 to 10 L in the average horse, which is expensive. Because knowledge regarding the efficacy of this treatment is limited, few patients undergo such

aggressive therapy. Administration of whole blood or blood products remains controversial in the treatment of patients with DIC because of the potential for worsening the coagulopathy on administration of fresh coagulation factors. One must consider this possibility, but in the face of life-threatening hemorrhage, benefits may outweigh risks.

Heparin therapy has been advocated for treatment of DIC in other species. Because heparin acts as an anticoagulant by complexing with AT III to inhibit serine proteases, AT III levels must be normal to achieve any benefits from heparin therapy. Heparin administration is controversial in the horse.<sup>422,424-429</sup> As discussed previously in this chapter, the use of LMWH has been advocated over unfractionated heparin because of a tendency for unfractionated heparin to cause erythrocyte agglutination and anemia *in vivo*.<sup>291,432</sup> The recommended dosage of LMWH is 50 to 100 IU/kg for dalteparin and 40 to 80 IU/kg for enoxaparin subcutaneously once daily.<sup>435</sup>

Aspirin, as mentioned previously, acts as an irreversible inhibitor of platelet cyclooxygenase, which leads to a decreased platelet aggregation. It has been used in horses in a hypercoagulable state. Aspirin can be given at 20 mg/kg either orally once daily or every other day; it can be given rectally once daily when oral administration is contraindicated. Adverse effects can include bleeding because of platelet dysfunction or gastrointestinal ulceration.<sup>457</sup>

Pentoxifylline and other methylxanthine derivatives are effective in decreasing the production of inflammatory cytokines, including TNF- $\alpha$ , IL-1, and IL-6, as well as increasing RBC flexibility.<sup>458</sup> This drug acts as a nonspecific phosphodiesterase inhibitor and may be helpful in decreasing clinical platelet activation in the horse.<sup>459</sup> Administration at 10 mg/kg orally twice daily yields appropriate plasma levels; however, long-term administration might require increasing dosages as the clinical response decreases with ongoing treatment.<sup>458</sup>

Other drugs, including etamsylate and recombinant hirudin, have been used successfully in other species for their anti-thrombogenic effects.<sup>460,461</sup> Initial investigation of these drugs in horses have yielded promising results, but further research is required.

Early recognition of DIC and aggressive therapy of underlying disease conditions remain the most effective treatments for the horse with pathologic coagulopathy. Understanding the pathogenesis and diagnosis of DIC will aid the practitioner in this process.

## THROMBOSIS AND THROMBOPHLEBITIS

A thrombus is an intravascular accumulation of fibrin, platelets, and leukocytes that usually occurs at a site of endothelial damage. Three factors may predispose a horse to vascular thrombosis: (1) vascular endothelial injury, (2) vascular stasis or slowing of blood flow, and (3) abnormalities of coagulation processes. After vascular damage, thrombus formation is the normal end result of procoagulative forces. However, pathologic or abnormal thrombus formation may occur in patients with an imbalance of procoagulative and fibrinolytic forces, as in DIC.

The horse appears to be particularly prone to superficial vein thrombosis during periods of systemic activation of coagulation. Jugular vein thrombosis may occur in these animals after a single, apparently atraumatic, venipuncture. Jugular catheter associated thrombophlebitis has been linked to several risk factors including catheter material and experience of

the person placing the catheter,<sup>462,463</sup> but most risk factors are related to the patient. Studies suggest that endotoxemic horses and septicemic horses have an increased susceptibility to thrombosis at the site of indwelling venous catheters.<sup>464</sup> Bilateral jugular vein thrombosis leads to increased intravascular pressures proximal to the thrombus formation and severe edema of the head. This edema may impair respiratory function, necessitating tracheostomy. If one suspects that sepsis is contributing to thrombus formation, then appropriate antibiotic therapy should be initiated. If hypercoagulation may be a predisposing factor for thrombosis, then aspirin administration at 20 mg/kg every other day may be beneficial to inhibit platelet aggregation and release reactions.<sup>338,341</sup> Hot compresses and hydrotherapy may improve collateral blood flow and decrease inflammation at the site of thrombosis. The thrombus eventually should recanalize, and venous flow should return. One may assess recanalization and the size of the thrombus with ultrasound examination of blood flow through the affected vessel.<sup>465</sup> If an underlying disease process is present, then primary care should be directed at correcting this disorder. In horses with unilateral jugular vein thrombosis, one should protect patency of the opposite jugular vein by minimizing prothrombotic trauma to that vessel, including venipuncture or catheter placement.

## BLOOD AND BLOOD COMPONENT THERAPY

Treatment of a variety of equine disorders involves administration of whole blood, plasma, or other blood constituents. One must base therapeutic decisions on clinical signs, laboratory parameters, availability of suitable donor services, and economic considerations.

### WHOLE BLOOD TRANSFUSION

One most commonly administers blood transfusions to horses with anemia severe enough to impair tissue oxygenation. Tachycardia, tachypnea, lethargy, weakness, cool extremities, and pale mucous membranes indicate significant tissue hypoxia and may occur at a PCV as high as 18 or as low as 10, depending on the rapidity of erythrocyte loss. Chronic anemias allow for physiologic adaptation to the low circulating RBC numbers, and severe clinical signs may not be apparent until the PCV is extremely low. Fresh whole blood transfusions also may be indicated in horses with severe hemorrhage associated with DIC to renew supplies of soluble coagulation factors and platelets.

Donor animals should lack detectable circulating alloantibodies against erythrocyte antigens that might be present in the recipient.<sup>466,467</sup> One can use crossmatching to detect existing antibody before transfusion. EDTA-anticoagulated blood and serum should be collected from the recipient and from several potential donor horses. The major crossmatch checks for compatibility between donor RBCs and any alloantibody that might be present in patient serum. The minor crossmatch assesses compatibility between alloantibody that might be present in donor serum and patient RBCs.<sup>13</sup> Both tests are important before transfusion of whole blood; the minor crossmatch is most critical when one contemplates plasma transfusion.

Transfusion of RBCs may sensitize the recipient to produce alloantibody against any incompatible erythrocyte antigens present in donor blood. For this reason, one should consider

routine use of donors that are negative for factors Aa and Qa to prevent the inadvertent sensitization of brood mares against the two most common alloantigens involved in neonatal isoerythrolysis, Aa and Qa.

If crossmatching is not possible, unmatched transfusion for critical patients can be considered. One must weigh the potential adverse effects of a transfusion reaction against the potential benefits to the patient. Most horses without previous transfusions may safely receive a single transfusion or multiple transfusions over 3 to 4 days from an unmatched donor. Chances of an adverse reaction increase when either donors or recipients are mares that have been bred previously. For this reason, male horses or female horses that have never been pregnant are preferred as donor animals for unmatched transfusions.

One safely may remove 5 to 10 L of blood from most adult donor horses. All equipment used for blood or blood product collection and administration should be sterile, and all procedures should be performed with strict attention to aseptic technique. Stock solutions of acid citrate dextrose anticoagulant are available commercially. Alternatively, one may use sodium citrate as an anticoagulant, mixing one part of a 3.2% sodium citrate solution to nine parts whole blood. Plastic blood collection bags with premeasured anticoagulant are convenient and effective for use with horses. Equine RBCs are stable for 35 days after collection when collected and stored in commercially available bags using citrate phosphate dextrose (CPD) as the anticoagulant.<sup>468</sup>

The volume of blood administered to a patient depends on the severity of RBC depletion and the total blood volume. A recommended formula for calculating this is as follows<sup>329</sup>:

$$\text{Body mass (kg)} \times \text{blood volume (ml/kg)} \\ \times [(\text{PCV desired} - \text{PCV observed}) / \text{PCV of donor blood}]$$

Normal blood volume in adult horses is approximately 72 ml/kg.<sup>469</sup> In neonates, blood volume is 151 ml/kg, decreasing to 93 ml/kg at 4 weeks, 82 ml/kg at 12 weeks, and adult values by 4 to 6 months of age.<sup>470</sup> Transfused RBCs survive less than 1 week in the horse, sometimes less than 2 days, and multiple transfusions may be necessary to maintain a patient until bone marrow production can exceed the rate of peripheral RBC destruction or loss.<sup>471</sup>

Blood products should be administered through an intravenous system with an in-line filter. Even with crossmatching of donor and recipient, one should administer the initial 25 to 50 ml of transfused blood slowly over 15 to 30 minutes with close monitoring of patient heart rate, respiratory rate, and behavior. If these parameters remain stable, then the remainder of the transfusion can be administered at a rate of 15 to 25 ml/kg/hr. One should give transfusions to horses with suspected or confirmed endotoxemia or septicemia more cautiously.

Several adverse reactions, immediate or delayed, may be associated with administration of blood or blood components. Mild reactions such as development of urticaria and tachycardia often occur.<sup>472</sup> More severe reactions are characterized by increases in heart and respiratory rates, dyspnea, fever, trembling, weakness, hypotension, diarrhea, abdominal pain, anaphylaxis, shock, or pulmonary edema. Acute hemolytic reactions with hemoglobinemia and hemoglobinuria result from transfusions from a donor with an incompatible blood type. DIC may accompany severe acute hemolysis. One should discontinue the transfusion immediately and

administer supportive therapy. Intravenous crystalline fluids improve peripheral circulation and maintain renal perfusion. NSAIDs may decrease inflammatory reactions.

Febrile reactions are not uncommon during or immediately after transfusions and may result from incompatible leukocyte or platelet antigens or presence of pyrogens in the transfused blood. One should discontinue transfusions if clinical signs are severe. NSAIDs may help in decreasing the febrile response.

Occasionally, blood products become contaminated with bacteria or bacterial products, and their administration can result in severe septicemia and endotoxemia. Affected animals develop uncontrollable shaking, hypotension, weakness, tachycardia, tachypnea, and collapse. If this occurs, the transfusion should be discontinued immediately, supportive care should be provided, and the blood being administered should be cultured. A Gram stain may reveal bacteria if contamination is severe. In this case, one should institute appropriate antibiotic therapy. NSAIDs may help in alleviating the adverse effects of endotoxin.

More delayed reactions to transfusion include transmission of infectious diseases and allosensitization of the recipient. One should test all donor horses regularly for EIAV. Other infectious agents potentially transmittable via blood transfusions include *Anaplasma phagocytophilum* and the equine herpesviruses (EHV). Mares that receive blood transfusions are at risk for producing foals that develop neonatal isoerythrolysis later in life.

## PLASMA TRANSFUSION

Plasma transfusion is indicated in horses with hypoproteinemia sufficient to result in significant fluid loss from the blood to the extravascular space and also is indicated for foals with failure of passive transfer (discussed previously in the text), replacement of some coagulation factors (II, V, VII, X, XIII), reversal of warfarin toxicity, endotoxemia-septicemia, and in some cases of DIC. Selection of donor animals, administration of plasma, and potential adverse reactions are similar to those described for whole blood transfusions. One may estimate the volume (in milliliters) to be administered to a hypoproteinemic horse from the following:

$$\text{Body mass (kg)} \times \text{blood volume (ml/kg)} \\ \times \frac{(\text{albumin desired} - \text{albumin observed})}{\text{albumin concentration of donor}}$$

Plasma volume in adult horses is estimated as 48 ml/kg.<sup>469</sup> In neonates, plasma volume is approximately 95 ml/kg, decreasing to 62 ml/kg at 4 weeks, 53 ml/kg at 12 weeks, and adult values by 4 to 6 months of age.<sup>470</sup> The observed increase in plasma protein after plasma transfusions is often not as great as would be predicted from this formula and most likely is caused by equilibration of administered blood proteins between intravascular and extravascular spaces.

Plasma transfusions should be administered cautiously in the same manner as whole blood transfusions. Severe anaphylaxis is possible, but most reactions are mild and include only urticaria and edema of the face and limbs. Patients should be monitored for these signs, as well as for increased heart rate, increased respiratory rate, sweating, colic, and agitation. Another less common reaction to plasma that has been described is fatal serum hepatitis. The four horses described had received plasma transfusions at 41 to 60 days before

demonstration of clinical signs consistent with severe liver disease. This study estimated the prevalence of this complication to be 0.4% of horses older than 1 year of age receiving plasma transfusions.<sup>473</sup>

Plasma from suitable donors is commercially available. Large equine practices may consider the purchase of plasmapheresis equipment, capable of economically preparing large quantities of pure plasma. One also may prepare plasma by allowing erythrocytes in whole blood to settle by gravity or, preferably, by centrifugation. The plasma is then removed in an aseptic manner and administered through an intravenous system with an in-line filter. Compared with gravity flow, automated plasmapheresis is the preferred method of plasma collection; the effect on hematologic and coagulation factors is mild and of no consequence to the recipient.<sup>474,475</sup>

## BLOOD COMPONENT THERAPY

Continuous-flow centrifugation hemapheresis has been used extensively in human medicine to produce relatively pure blood components for administration to patients needing replacement of one specific blood constituent. This technique is being used increasingly in veterinary medicine and is the preferred method for equine plasma collection. Blood removed from one jugular vein of a donor horse circulates in a closed loop through the blood separation device, with collection of desired blood components and return of unwanted components to the donor via the opposite jugular vein.<sup>476,477</sup> By altering the centrifugal force of the collection device, one may collect plasma, RBCs, leukocytes, or platelets preferentially.<sup>478</sup>

Collection of leukocyte and platelet-rich fractions from horses has been described.<sup>476,478</sup> Platelet transfusions may be indicated in selected horses with thrombocytopenia. Leukocyte transfusions have been beneficial in septic human neonates, and the feasibility and efficacy of granulocyte transfusions in the equine neonate have been investigated.<sup>478,479</sup>

# DISORDERS OF THE GASTROINTESTINAL SYSTEM\*

## CHAPTER 15

### EXAMINATION FOR DISORDERS OF THE GASTROINTESTINAL TRACT

L. Chris Sanchez

#### ☞ PHYSICAL EXAMINATION

Examination of patients with disease of the gastrointestinal tract must include evaluation of the metabolic and cardiovascular status of the patient, because acute conditions of the proximal or distal intestinal tract can lead to endotoxemia and sepsis. Examination of the cardiovascular system (heart, peripheral pulse, and mucous membranes), lungs, and abdomen is essential to detect clinical signs of systemic inflammation from endotoxemia, coagulation disorders, dehydration, ileus, shock, and other abnormalities resulting from injury to the small or large intestine. Clinical signs of systemic inflammation from endotoxemia and sepsis are described elsewhere in this chapter.

One performs the physical examination of the abdomen primarily by auscultation, transabdominal ballottement, and transrectal palpation. Abdominal distention often indicates distention of the large intestine; however, small intestinal distention also can cause visible abdominal distention if a large proportion of the small intestine is involved. Abdominal palpation can be performed in neonatal foals; after several weeks of age, however, the abdominal wall is too rigid to allow effective palpation of intra-abdominal structures.

Abdominal auscultation is particularly useful for assessing the motility of the large intestine. Progressive motility of the small intestine, conversely, is difficult to distinguish by auscultation from nonprogressive motility. The distinct character

of the borborygmi produced during propulsive contractions of the cecum and ascending colon allows evaluation of the frequency and strength of retropulsion and propulsion. Propulsive contractions of the cecum and ventral colon occur every 3 to 4 minutes and give rise to prolonged rushing sounds heard over long segments of intestine. Retropulsive sounds presumably are similar to propulsive sounds, but they occur less frequently. Distinguishing between propulsion and retropulsion is not important clinically because both types of contractions signify normal motility. Interhaustral and intra-haustral mixing contractions produce nonspecific sounds of fluid and ingesta movement that are difficult to distinguish from other borborygmi, such as small intestinal contractions or spasmodic contractions.<sup>1</sup>

Auscultation over the right flank and proceeding along the caudal edge of the costal margin toward the xiphoid allows evaluation of the cecal borborygmi. Auscultation over a similar area on the left side allows evaluation of the pelvic flexure and ascending colon. Typical progressive borborygmi heard every 3 to 4 minutes on both sides of the abdomen indicate normal motility of the cecum and ascending colon. Less frequent progressive sounds may indicate a pathologic condition of the large intestine or may result from anorexia, nervousness (sympathetic tone), or pharmacologic inhibition of motility (i.e.,  $\alpha_2$ -adrenergic agonists such as xylazine).<sup>2-5</sup> Absolute absence of any auscultable borborygmi suggests abnormal motility and indicates ileus resulting from a serious pathologic condition but is not specific to any segment of the intestine.<sup>3,6</sup> If borborygmi are audible but progressive sounds are not detectable, determining whether a significant abnormality exists is difficult.<sup>6</sup> Borborygmi heard more frequently than normal may result from increased motility following feeding; from excessive stimulation from irritation, distention, or inflammation; or after administration of parasympathomimetic drugs such as neostigmine. Large intestinal motility increases in the early stages of intestinal distention regardless of the site.<sup>7</sup> Mild inflammation or irritation of the large intestinal mucosa also can stimulate motility.<sup>3</sup> Parasympathomimetic drugs stimulate contractions and auscultable borborygmi in the large intestine; however, an increase in parasympathetic tone may result in segmental contractions, which actually inhibit progressive motility.<sup>2</sup>

One can detect sand or gravel in the large intestinal ingesta by auscultation behind the xiphoid process. It is possible to hear sand or gravel particles grinding together during

\*The authors wish to acknowledge the work of former contributors to the following sections: Examination for Disorders of the Gastrointestinal Tract, Jennifer L. Davis and Samuel L. Jones; Obstructive Disorders of the Gastrointestinal Tract, Samuel L. Jones; Peritonitis, Charles Dickinson.

progressive contractions of the ascending colon. In one study characteristic sounds were heard on auscultation (5 minutes' duration) after daily administration of sand to healthy horses, none of which developed clinical signs of colic or diarrhea.<sup>8</sup> If the frequency of progressive contractions is low or absent, detecting sand by auscultation is difficult.

Percussion of the abdomen during auscultation can reveal gas in the large intestine. The characteristic *ping* produced by simultaneous digital percussion and auscultation over a gas-filled viscus often is associated with abnormal accumulation of gas under pressure. This technique is particularly useful in foals, ponies, and miniature horses because of the limitations of rectal palpation.

Transabdominal ballottement can be used to detect large, firm masses or an abnormal volume of peritoneal fluid (PF). The usefulness of this technique is usually limited to animals too small to palpate rectally. One can detect soft tissue masses or fetuses by bumping the structures with a hand or fist. If excessive PF is present, a fluid wave can be generated by ballottement; however, this technique is not as useful in horses older than 4 weeks because the abdominal wall is rigid.

Transrectal palpation is the most specific physical examination technique for investigation of intestinal disease and is particularly valuable when evaluating obstructive diseases.<sup>9,10</sup> The primary objectives of transrectal palpation are to assess the size, consistency, and position of the segments of the large intestine; to determine the presence of any distention of the small intestine; and to detect intra-abdominal masses. Evaluation of the wall thickness and texture and the mesenteric structures (blood and lymphatic vessels and lymph nodes) also may aid in diagnosis of large intestinal disease. The interpretation of transrectal palpation findings in light of clinical signs and laboratory results is an important diagnostic aid for developing appropriate treatment strategies for intestinal diseases manifested by abdominal pain. Enlargement of one or more segments of large intestine detected by transrectal palpation provides evidence of obstruction at or distal to the enlarged segment. By systematically evaluating each segment, one can determine the site of obstruction. Obstruction of the pelvic flexure, for instance, results in enlargement of the pelvic flexure and ventral colon, but the dorsal and descending colons are of normal size. Enlargement of a segment of the large intestine usually is accompanied by abnormal consistency of the contents. It is possible to distinguish among gas, fluid, and ingesta and to detect foreign bodies in palpable segments. Accumulation of gas and fluid suggests complete and acute obstruction, whereas accumulation of ingesta suggests chronic and incomplete obstruction. Accumulation of fluid usually indicates ileus. The practitioner must evaluate the consistency of the contents in light of the size of the segment; ingesta in the ventral colon of a dehydrated patient may be firm, but the size of the ventral colon will be normal. Conversely, if the ingesta is firm because of a distal obstruction, the ventral colon will be enlarged.

Displacement of a segment of the large intestine may create an obstruction detectable by enlargement of the segment and accumulation of gas and fluid, even if the site of obstruction is not palpable. Torsion of the ascending colon at the sternal and diaphragmatic flexures results in acute accumulation of gas and fluid proximal to the torsion, causing distention of the left dorsal and ventral colons. Depending on the degree of torsion, the position of the ventral and dorsal colons may not be significantly abnormal. Displacement of

a segment of large intestine often results in incomplete obstruction, and the diagnosis relies solely on detection of the displaced segment in an abnormal position. The position of the displaced segment may not be palpable, and the diagnosis then relies on the inability to find the segment in a normal position. One must take care to ensure that the segment that appears to be displaced is not in a normal position but has become too small to palpate because of a decrease in the volume of ingesta. The cecum, right dorsal and ventral colons, pelvic flexure, and descending colon are palpable in most horses. One should palpate the nephrosplenic space to detect the presence of intestine, usually pelvic flexure, entrapped within the ligament.

Small intestine is not normally palpable in the horse. Distention indicates ileus with gas or fluid retention, usually following a strangulating or nonstrangulating obstruction. Strangulating obstructions result from conditions such as volvulus or torsion, lipoma, and entrapments. Such conditions often are accompanied by severe pain, dehydration, PF changes, and a varying degree of gastric fluid accumulation. The small intestine in these cases is turgid and firm on palpation. One should assess the mesentery and wall thickness in the same manner as for large intestinal disorders. Careful palpation of the inguinal rings in stallions with small intestinal distention is crucial for determining inguinal herniation.

Evaluation of the wall thickness and mesenteric vessels can reveal venous congestion (mural edema and enlarged blood and lymphatic vessels) or inflammation (mural edema with normal vessels). Disruption of arterial blood flow does not cause venous congestion, but the arterial pulse is not detectable. Mesenteric tears may not be palpable, but the entrapped ischemic intestinal segment may be thickened with edema. It is possible to detect acute or chronic inflammation with cellular infiltration of the intestinal wall as thickening of the wall without edema; enlargement of mesenteric lymph nodes also may be noted. One should interpret abnormalities in the wall or vessels in light of the size, consistency, and position of the segment of intestine and the clinical signs. Several conditions involving small intestinal strangulating lesions do not necessarily cause abnormal rectal examination findings until the disease has been present for an extended time. These conditions include diaphragmatic herniae and epiploic foramen entrapments. PF analysis can be normal in these cases as well because the fluid is trapped in the thorax or cranial abdomen.

Nonstrangulating causes of small intestinal distention can be divided further into intraluminal and extraluminal obstructions. Ileal impactions are probably the most common cause of intraluminal obstruction, and on rare occasions the impaction can be palpated in the upper right quadrant, near the ileocecal opening. Intraluminal masses caused by lymphoma, eosinophilic enteritis, foreign bodies, or ascarid impactions often lead to small intestinal distention and are usually indistinguishable from one another on the basis of palpation alone. Small intestine in these cases can be moderately to severely distended, depending on the degree of obstruction. Extraluminal obstructions include abdominal masses, abscesses or tumors, and large colon displacement. One should always palpate the rest of the abdomen carefully to help rule out these causes. Some cases of small intestinal distention result from a physiologic rather than a mechanical obstruction. Ileus may result postoperatively or after inflammatory diseases of the bowel (proximal enteritis) or peritoneal cavity (peritonitis).

The bowel is usually mildly to moderately distended and almost always is accompanied by significant amounts of accumulated gastric fluid.

The small colon is easily distinguishable by the presence of normal fecal balls and an antimesenteric band. In cases of impaction of the small colon, a long, hard, tubelike structure is present in the caudal abdomen, and the band is palpable along the length. Fluid stool is often present in the rectum in these cases, as is tenesmus, and the rectal mucosa is often edematous and occasionally roughened. One can detect and carefully evaluate rectal tears by palpation. Also detectable are mural masses in palpable segments of intestine or mesentery; however, if a mass causes obstruction, it is possible to detect the result of the obstruction in proximal segments of intestine even if the mass is unreachable. Palpation of the mesenteric vessels may reveal thickening and thrombosis, which can lead to ischemia or infarction.

One can perform visual inspection of the mucosa of the rectum and descending colon with a speculum or flexible endoscope and also can evaluate rectal tears or perforations, mural masses, strictures, or mucosal inflammation. One can also perform guided biopsy of the mucosa or masses. The obvious limitations are the amount of fecal material, which can interfere with the examination, and the distance of the lesion of interest from the anus. These techniques offer little advantage over palpation in many cases, unless the patient is too small to palpate.

Examination of the oral cavity in cases of dysphagia or weight loss is a necessary part of the physical examination. One should adequately sedate the horse and use a full-mouth speculum to allow palpation and visualization of all parts of the oral cavity. One should examine the area for abnormal dentition, foreign bodies, fractures, abscesses, and ulceration.

The presence of fluid accumulation in the stomach indicates a decrease or absence in propulsive motions of the small intestine or obstruction of gastric outflow. Decreased small intestinal motility may result from a functional or mechanical blockage. Masses, feed impactions, or strictures in the pylorus or in the proximal duodenum may obstruct gastric outflow. One routinely assesses fluid accumulation in the stomach by siphoning off the gastric contents with a nasogastric tube and examining the fluid for amount, color, and any particular odor. Normal fluid is green and may contain foamy saliva. The volume obtained by gastric lavage is usually less than 4 L. Large volumes of fluid ( $\geq 8$  to 10 L) accumulate in the stomach of horses with proximal enteritis, and the fluid is foul smelling and often has an orange to yellow discoloration. If proximal enteritis is suspected, the fluid can be submitted for culture and Gram staining. *Salmonella* sp. and *Clostridium* sp. have been cultured in some cases. Patients with postoperative ileus also frequently accumulate large amounts of gastric fluid. Horses with strangulating obstructions or luminal obstructions often accumulate moderate amounts of gastric fluid, but the amount is generally less than in horses with proximal enteritis or postoperative ileus. Hemorrhage in the gastric fluid usually indicates devitalized small intestine, stomach wall, or severe gastric ulceration. Fluid with large amounts of food material can indicate a gastric impaction, and one should lavage the stomach until no more ingesta can be obtained. Horses and foals with chronic gastric ulceration in the glandular mucosa of the stomach or in the duodenum may develop strictures and have accumulated fluid in the

stomach. Endoscopy or contrast radiography aids in diagnosing gastric outflow obstruction.

## ☞ DIAGNOSTIC EVALUATION

### CLINICAL PATHOLOGY

Evaluation of the hemogram is essential when assessing conditions of the gastrointestinal tract. However, hematologic alterations associated with diseases of the gastrointestinal tract are often nonspecific, reflecting systemic response to inflammation, endotoxemia, or sepsis. Neutrophilic leukocytosis and normochromic, normocytic anemia with or without hyperfibrinogenemia commonly are associated with chronic inflammatory conditions of the intestine. Anemia from chronic blood loss occurs infrequently in adult horses because of the large iron stores and high concentrations of iron in their diet; anemia usually follows chronic inflammation, as do alterations in the leukon and plasma fibrinogen concentrations. Plasma protein concentrations vary depending on gastrointestinal losses of albumin and globulin and elevation of globulin concentration from antigenic stimulation. Protein-losing enteropathies may manifest predominantly as a hypoalbuminemia or as a panhypoproteinemia. Immunoglobulin quantification can be useful in selected cases; immunosuppression with low immunoglobulin M concentration has been shown to occur in some cases of lymphosarcoma.<sup>11</sup> Parasitic infections, especially strongylosis, may be characterized by elevated serum immunoglobulin G(T) concentration.<sup>12</sup>

Significant alterations of the hemogram do not accompany acute disease of the intestine unless severe inflammation, dehydration, endotoxemia, or sepsis is present. During the early stages of endotoxemia, elevations in circulating concentrations of inflammatory mediators, epinephrine, and cortisol produce characteristic changes in the hemogram. Leukopenia, with neutropenia and a left shift, toxic changes in the neutrophil cytoplasm, and lymphopenia commonly occur.<sup>13</sup> Hemoconcentration and hyperfibrinogenemia are also common. Thrombocytopenia and other coagulopathies are also features of endotoxemia. Indeed, thrombocytopenia may be the earliest indicator of sepsis.<sup>14</sup> Endotoxemia and circulating mediators of inflammation activate the coagulation cascade, causing a hypercoagulable state that can lead to consumption of coagulation factors and coagulation defects manifested as elevated prothrombin time, partial thromboplastin time, fibrin degradation products, and bleeding time and reduced activity of antithrombin III.<sup>15-17</sup> Neutrophilic leukocytosis occurs during the later stages of endotoxemia.<sup>15</sup>

The most common serum biochemical abnormalities with diseases of the large or small intestine are electrolyte imbalances. Serum calcium concentrations are often low with strangulating obstructions and acute inflammatory diseases.<sup>18</sup> Inflammation of the mucosa can severely disrupt electrolyte fluxes. Diarrhea or gastric reflux greatly exacerbates the loss of sodium, potassium, calcium, magnesium, and bicarbonate. Hypoxia and cellular damage caused by ischemia of the intestine may be reflected by an elevated serum phosphate concentration resulting from phosphate leakage from damaged cells.<sup>19</sup> Ischemia and cellular hypoxia in any segment of the intestine also causes a shift in energy metabolism to anaerobic glycolysis, resulting in increased production of lactate and elevated serum lactate concentration. Reduced perfusion of peripheral

tissues from hypotensive shock and intestinal ischemia can cause elevations in serum lactate. However, obstruction of the intestine during ischemia may result in absorption of lactate from the lumen.<sup>20,21</sup> Anion gap is an indirect measurement of organic acid production during states of tissue hypoxia and is a reasonable estimate of serum lactate concentration.<sup>21</sup> Metabolic acidosis may accompany lactic acidemia, but an inconsistent association exists between the two, especially when mixed acid-base imbalances are present.<sup>21,22</sup> Elevations of hepatic enzymes, specifically  $\gamma$ -glutamyltransferase, may occur with large colon displacements, duodenal strictures, or anterior enteritis. An elevated  $\gamma$ -glutamyltransferase is more suggestive of a right dorsal displacement than a left dorsal displacement.<sup>23</sup>

Relative polycythemia from hemoconcentration or splenic contraction and changes in red blood cell deformability from hypoxia or hypocalcemia may increase blood viscosity. Blood viscosity increases in patients with acute obstructive disease. Hyperviscosity reduces perfusion of capillary beds, thereby exacerbating ischemia and tissue hypoxia.<sup>24</sup> Hyperviscosity is one manifestation (along with lactic acidemia, coagulopathies, and clinical signs of shock) of the pathophysiologic events that take place during acute inflammatory or vascular injury to the large intestine. Laboratory tests designed to reflect the systemic effects of endotoxemia, ischemia, sepsis, and shock are important to design therapeutic strategies and monitor response to therapy.

### PERITONEAL FLUID

Abdominocentesis and analysis of PF are diagnostic techniques performed on many patients with disease of the gastrointestinal tract. The veterinarian can quantitate cytologic examination of PF; white blood cell and red blood cell counts; protein, fibrinogen, lactate, phosphate, and glucose concentrations; lactate dehydrogenase, creatine kinase, and alkaline phosphatase activity; and pH. The results of PF analysis may help establish a specific diagnosis and, more important, may reflect inflammatory, vascular, or ischemic injury to the intestine requiring surgical intervention.

PF reflects a sequence of events that takes place during acute vascular injury to the intestine. The PF protein concentration first increases, followed by an increase in the red blood cell count and fibrinogen concentration. A transudative process resulting from vascular congestion and increased endothelial permeability allows small macromolecules (albumin) to escape into the PF, followed by larger macromolecules (globulin and fibrinogen), and finally diapedesis of cells (red blood cells, and then white blood cells).<sup>25,26</sup> If ischemic inflammation of the intestine and visceral peritonitis occurs, an exudative process ensues. Severe inflammation of the intestine and visceral peritoneum causes large quantities of protein and white blood cells, primarily neutrophils, to escape into the PF.<sup>24,26</sup> As damage to the bowel progresses, the protein concentration and red blood cell and white blood cell counts continue to rise. As the degree of irreversible damage to the intestine increases, the PF characteristics become more exudative.<sup>25,26</sup> Eventually, bacteria begin to translocate across the intestinal wall and appear in the PF as the mucosal barrier breaks down. Neutrophils predominate, their cytoplasm becomes granulated, and Döhle's bodies often are visible. If perforation occurs, bacteria and particles of ingesta appear in the PF, and the neutrophils become degenerate (i.e., pyknotic), with karyorrhexis, karyolysis, and smudge cells.

Elevated PF protein concentration is a sensitive indicator of early inflammation, whereas elevated red blood cell counts in the presence of normal white blood cell counts suggest vascular damage without significant tissue ischemia.<sup>26</sup> Of note, the anticoagulant potassium EDTA, but not lithium heparin, can cause an increase in total protein as measured by refractometer, relative to the value obtained from the same sample without anticoagulant.<sup>27</sup> Elevation of the white blood cell count usually indicates severe tissue inflammation or intestinal injury.<sup>20</sup> The gross color of the PF can be helpful in detecting injury and necrosis of the intestine. A serosanguinous appearance indicates vascular injury, whereas orange or brown-red indicates necrosis with the release of pigments such as hemosiderin. Serial samples of PF are most useful in determining the nature and extent of damage to the intestine, but in many cases of ischemia, irreversible tissue damage has occurred by the time PF abnormalities appear.

Tissue hypoxia and ischemia cause a rapid elevation of PF lactate dehydrogenase, creatine kinase, and alkaline phosphatase activity and lactate concentration.<sup>20,21,28,29</sup> Phosphate concentration increases when cellular disruption occurs.<sup>19</sup> PF enzyme activities, phosphate, and lactate concentration increase faster and higher than serum activities.<sup>19-21,28,29</sup> PF pH and glucose concentration tend to decrease during intestinal ischemia but are not as low as in septic peritonitis.<sup>30</sup> Although biochemical alterations may be early indicators of intestinal ischemia and necrosis, they are nonspecific and offer no advantage over conventional methods of PF analysis in many cases. PF alkaline phosphatase has been shown to arise predominantly from degenerating white blood cells, and elevations of other enzyme activities may occur with many inflammatory diseases.<sup>28</sup> Thus the specificity of many tests performed on PF is questionable. However, in selected cases in which conventional PF analysis and physical examination do not provide sufficient information to develop a treatment plan, biochemical analysis of the PF may be useful.

Cytologically examined cells of the PF may reflect chronic inflammatory conditions of the large intestine, especially eosinophilic or lymphocytic processes.<sup>31</sup> Infectious and inflammatory conditions often cause increases in the neutrophil count and may be indistinguishable unless bacteria are visible. One also may detect neoplastic diseases by PF examination. Chronic infection and inflammation may be associated with elevated PF protein and fibrinogen concentrations. Culture of PF usually is required to distinguish bacterial infections from noninfectious inflammation unless bacteria are visible on cytologic examination. However, culture of PF is often unrewarding because factors that are found in inflammatory PF inhibit bacterial growth, and leukocytes phagocytose many bacteria in the PF.<sup>32</sup> Decreases in PF glucose concentrations (<30 mg/dl), and pH (<7.3) are early indicators of a septic process. The glucose concentration and pH in the PF should approximately equal the blood glucose concentration and pH. A PF fibrinogen concentration greater than 200 mg/dl also indicates bacterial infection.<sup>33</sup>

### FECAL EXAMINATION

Gross examination of the feces can provide information about digestion and transit time in the large intestine. Large fiber particles in the feces represent poor mastication or poor digestion in the large intestine. Small, mucus-covered, hard fecal balls indicate prolonged transit through the descending colon, whereas increased fluidity implies decreased transit time. Feces

containing sand or gravel are not necessarily abnormal. However, a significant amount of sand implies that large quantities are present in the colon. Frank blood indicates substantial bleeding into the distal colon (right dorsal colon, small colon, or both) resulting from mucosal damage.

Laboratory analysis of the feces is performed frequently in cases of diarrhea. Fecal cytologic examination and tests for occult blood detect mucosal inflammation, erosion, or ulceration. Severe inflammatory diseases in human beings, invasive bacterial infections in particular, have been shown to increase the shedding of leukocytes in the feces. A higher percentage of horses with salmonellosis and diarrhea have fecal leukocyte counts greater than 10 cells per high power field than horses with negative fecal cultures for *Salmonella*. These results suggest that high fecal leukocyte counts indicate salmonellosis in horses with diarrhea. However, the specificity of this test is probably low. Low fecal leukocyte counts do not rule out salmonellosis.<sup>34</sup>

Fecal occult blood tests detect blood in the feces, presumably from erosion or ulceration of the mucosa, but do not distinguish the source of the blood. Large volumes of blood (1 to 2 L) given by nasogastric tube were required to produce a positive test for occult blood in the feces, but the amount of blood originating from the large intestine required to produce a positive test is unknown. A positive test implies significant hemorrhage into the gastrointestinal tract. Newer, more sensitive tests detect not only occult blood but also degraded blood and may be useful to determine the site and quantity of blood loss.<sup>35</sup> However, large-scale evaluation of these tests is as yet unavailable.

Bacteriologic examination of the fecal flora has been used to quantitate specific bacterial species in the feces of horses with diarrhea. Quantitation of clostridial species may be beneficial in diagnosing clostridial infection of the large intestine.<sup>36</sup> Tests to detect clostridial toxins in intestinal contents or feces are important to determine whether clostridia cultured from the feces are causing disease. The most common bacterial pathogens isolated from the feces of horses are *Salmonella* sp. and *Clostridium* sp. The number of *Salmonella* organisms isolated from the feces of horses with clinical salmonellosis is usually higher than from horses with asymptomatic infections. However, the volume of feces in many cases of acute diarrhea is high, and the concentration of *Salmonella* organisms may be lower than would be expected, accounting for many false-negative fecal cultures. The sensitivity of fecal cultures for detecting *Salmonella* infection may be as low as 20%. Culture of five consecutive daily fecal samples is recommended to increase the sensitivity of the test. Because salmonellae are intracellular organisms, culture of rectal scrapings or a rectal biopsy sample, along with fecal material, may increase the sensitivity of culture for detecting *Salmonella* infection to 50%.<sup>37</sup> One can perform a polymerase chain reaction assay on fecal samples to detect DNA from *Salmonella* sp. The polymerase chain reaction test is more sensitive than culture and is frequently positive in clinically normal horses that continuously shed small amounts of bacteria. Polymerase chain reaction or immunologic tests also may detect *Clostridium perfringens* and *Clostridium difficile* exotoxins in the feces.

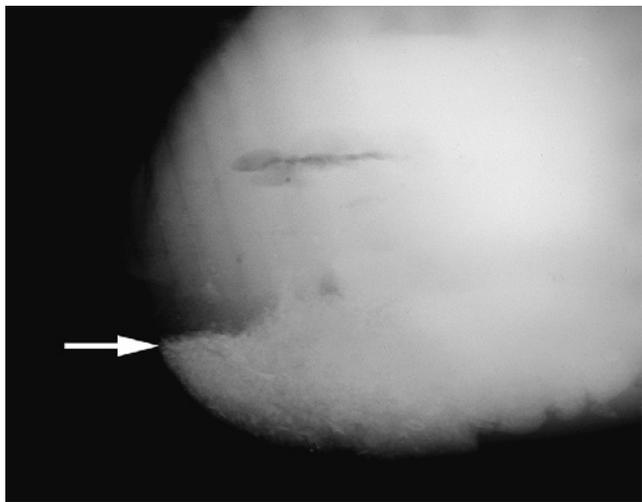

Qualitative fecal examination is a technique to detect nematode and cestode ova, protozoan oocysts, parasitic larvae, and protozoan trophozoites. A direct smear of fecal material is a rapid method to screen feces for ova and oocysts, to detect parasite larvae and trophozoites, and to observe motility of

ciliates and parasite larvae. Fecal flotation is a more sensitive technique for isolating and detecting ova and oocysts because the eggs are concentrated from the sample. Zinc sulfate and sucrose solutions often are used to concentrate less dense ova and oocysts. Zinc sulfate produces less distortion of trophozoites and larvae than sucrose solutions. Fecal sedimentation is particularly appropriate for ciliates, *Giardia* organisms, and trichomonads. Quantitative techniques such as the Cornell-McMaster method allow estimation of the number of eggs per gram of feces and are most appropriate in monitoring parasite control programs.<sup>38</sup>

## RADIOGRAPHY

Survey radiography of the normal esophagus is usually unrewarding but may be useful in horses with esophageal obstructions to determine the extent and location of the obstruction. It is possible to detect foreign bodies or soft tissue masses and, in cases of esophageal rupture, free air and ingesta in the tissues surrounding the esophagus. Pneumomediastinum also may be observed.<sup>39</sup> Thoracic radiographs may be necessary to detect intrathoracic esophageal obstructions, megaesophagus, or cranial mediastinal masses causing extraluminal obstruction. One may use barium swallows or double-contrast esophagrams after resolution of the obstruction to determine whether a stricture, diverticulum, or other underlying disorder is present.<sup>40</sup> Barium sulfate is the usual contrast medium and can be administered orally by way of a dose syringe or nasogastric tube (50 to 100 ml of a 40% barium sulfate suspension or barium paste). Oral administration is preferred for evaluation of swallowing and lesions in the proximal esophagus. Administration of contrast using a nasogastric tube (preferably cuffed) allows for delivery of larger volumes of barium (up to 500 ml) but should be performed without sedation if possible. Administration of contrast material can be followed with air insufflation to create a double-contrast effect. If rupture of the esophagus is suspected or if the contrast material is likely to be aspirated, iodinated organic compounds in an aqueous solution should be used as contrast material.<sup>39</sup> Contrast radiography may be the most definitive method for the diagnosis of primary megaesophagus or other functional disorders such as autonomic dysautonomia (grass sickness) affecting the esophagus.<sup>40</sup> When interpreting esophageal radiographs, the veterinarian should take particular care if the horse is sedated. Acepromazine or detomidine administration causes esophageal dilation in normal horses, especially after passage of a nasogastric tube.<sup>41</sup>

Radiography of the adult equine abdomen is an effective technique in detecting radiodense material in the large intestine, such as enteroliths, sand, and metallic objects.<sup>42,43</sup> One survey demonstrated that radiography has 76.9% sensitivity and 94.4% specificity for diagnosing enterolithiasis.<sup>42</sup> Radiography also can be a useful tool for detecting sand accumulation in the colon that causes diarrhea or impactions (Figure 15-1) and for monitoring resolution in medically treated horses.<sup>44</sup> Recently, an objective scoring system demonstrated greater efficacy and less interobserver variability than a subjective assessment of radiographic sand accumulation in horses with or without a clinical diagnosis of sand colic.<sup>45</sup> The large size and density of the adult abdomen precludes evaluation of soft tissue structures because the detail and contrast of the radiographs are usually poor. One is more likely to obtain diagnostically useful abdominal radiographs from small ponies

**FIGURE 15-1** Radiograph of the cranioventral abdominal region of a weanling colt with diarrhea. The radiopaque accumulation of sand (arrow) in the sternal flexure of the ventral colon is notable.

and miniature horses than from full-size adult horses. Accumulation of gas is visible on radiographs of adult horses, but distinguishing normal intestinal gas from obstruction is often difficult. Horses should be fasted for 24 to 48 hours to reduce the amount of ingesta in the large intestine before radiography, if clinically warranted.

Abdominal radiography is more useful in foals than in adult horses. Radiographs are more detailed, and contrast can be good. Radiographic evidence of gas distention in the large intestine may indicate large intestinal obstruction, and radiographic signs of displacement are often diagnostic. Radiography allows the diagnosis of impactions, intussusceptions, foreign bodies, and other disorders. Functional ileus may be difficult to distinguish from mechanical obstruction.<sup>46,47</sup> Administration of contrast (barium sulfate 30% at 5 ml/kg) through a nasogastric tube increases the diagnostic capabilities of radiography and is especially useful for diagnosis of gastric outflow obstruction in the older foal.<sup>48</sup> Gastric ulceration also is recognizable with contrast radiography in the foal, although this is not as accurate a method as endoscopy.<sup>49</sup> Contrast administered retrograde through a 24-F Foley catheter inserted into the rectum at a dose of up to 20 ml/kg has excellent potential for diagnosing disorders of the small colon, transverse colon, and large colon in foals.<sup>50</sup>

## ULTRASONOGRAPHY

Ultrasonographic evaluation of the abdomen can add valuable information in cases of acute or chronic gastrointestinal disease. Examination of the adult horse requires a 2.5- to 5.0-MHz transducer at minimum. Sector, linear, or curved linear transducers may be used. Clipping of the hair over the area to be examined, along with the application of isopropyl alcohol and ultrasound coupling gel, enhances evaluation. However, a functional exam is often performed with alcohol alone and no clipping of the hair.

To evaluate the abdomen adequately, one must know the anatomic location and normal appearance of the individual organs. In the left cranial abdomen, it is possible to assess the

greater curvature of the stomach between the eleventh and thirteenth intercostal space, and the spleen and the large splenic vein can be used as landmarks. Cases of gastric dilation from gas or impaction appear as an enlargement of the viewing area to cover more than five rib spaces.<sup>51</sup> The veterinarian also can evaluate the stomach for intramural or extramural masses such as abscesses or for squamous cell carcinoma.<sup>52</sup> The lesser curvature is not routinely visible. Assessment of the small intestine should include evaluation for changes in thickness, motility, location, and visibility. Small intestinal loops are easily found in the left lower quadrant of the abdomen, but these normally are visible in other locations. One can visualize the duodenum consistently on the right side of the abdomen deep to the liver in the tenth to twelfth intercostal space or deep to the right kidney at the fifteenth to sixteenth intercostal space. Mural thickening (>4 mm) may occur with edema, infiltrative or proliferative diseases, enteritis, and paralytic or mechanical ileus. Thickening of the small intestinal wall in neonatal foals, with or without the presence of intramural gas shadows, should raise suspicions of clostridial enteritis. One can assess motility by monitoring a specific area for contractions over time.

Ultrasonography can be an accurate method of distinguishing strangulating disorders of the small intestine from nonstrangulating disorders. Strangulated small intestine has thicker walls and a larger diameter than typically observed in nonstrangulating disorders. Strangulating lesions have decreased motility in the incarcerated segments, with normal motility elsewhere.<sup>53</sup> Cases of paralytic ileus or nonstrangulating obstruction have a diffusely decreased peristalsis but not to the degree observed with strangulating lesions.<sup>51,53</sup>

Ultrasonography may be used to diagnose some specific lesions of the small intestinal tract. Ascarids may be visible in foals in cases of ascarid impaction,<sup>51</sup> and epiploic foramen entrapments are identified as edematous loops of small intestine found in the right cranial abdomen.<sup>54</sup> The veterinarian may note small intestinal intussusceptions as targetlike lesions when viewed in cross sections.<sup>55</sup> The presence of bowel loops, stomach, or liver in the thoracic cavity indicates the presence of herniation through the diaphragm and should be confirmed using radiography or surgical exploration.

Evaluation of the large intestine may be difficult because of the large amounts of gas within the lumen. It is also extremely difficult to reliably differentiate between specific segments of the colon ultrasonographically.<sup>56</sup> However, certain disorders are readily identifiable through ultrasonography. The nephrosplenic ligament area can be assessed for bowel entrapment in the left paralumbar fossa. In cases of entrapment the spleen will be pulled away from the body wall, and fluid or gas shadows will be observable dorsal to the spleen, obscuring the kidney, which is normally adjacent and abaxial to the spleen.<sup>57</sup> Small colon, small intestine, or pneumoperitoneum also may produce a gas shadow and obscure the kidney from view.<sup>51</sup>

Sand impactions may appear as hyperechoic bands on the ventral abdominal wall,<sup>51</sup> but ultrasound does not describe the extent of sand accumulation as well as radiographic assessment.<sup>58</sup> Ileocecal and cecocolic intussusceptions may be visible in the upper right paralumbar fossa.<sup>59</sup> In cases of colitis large, fluid-filled colons may be visible with or without intramural edema. The right dorsal colon is consistently located abaxial

to the liver, within the right thirteenth to fifteenth intercostal space, and may be thickened (>5 mm) in cases of right dorsal colitis. Ultrasound also can be a useful tool for evaluating changes in motility over time in a given location.<sup>60</sup>

Evaluation of the abdomen always should include assessment of the peritoneal space for any evidence of an increased amount of PF or increased cellularity of the fluid, as indicated by an increase in echogenicity. Ultrasonography also can be useful in determining the ideal location for abdominocentesis. One also should evaluate the liver, kidneys, and spleen to detect any choleliths, nephroliths, masses, abscesses, or enlargement. Identifying abscesses or tumors not associated with visceral organs may be difficult and depends on their location and surrounding structures.

## NUCLEAR SCINTIGRAPHY

Although more commonly used to diagnose lameness and musculoskeletal problems, nuclear scintigraphy has several uses in the evaluation of the gastrointestinal tract. Proper isolation protocols and waste disposal techniques must be strictly observed.

The procedure requires special gamma cameras and the injection of radioactive materials into the bloodstream. One of two methods may be used: injection of technetium-99m methylene diphosphonate (99mTc-MDP) directly into the blood or injection of 99mTc-labeled leukocytes.<sup>61</sup> The principle of nuclear scintigraphy then lies in increased uptake of the dye or the white blood cells into areas of inflammation. One of the most common uses of nuclear scintigraphy in evaluating the gastrointestinal tract is diagnosis of dental disease. Scintigraphy using 99mTc-MDP proved to be more sensitive in cases of dental disease than was radiography. Scintigraphy was slightly less specific, however, and therefore should be used with radiography or computed tomography for ultimate accuracy.<sup>62</sup> Scintigraphy using radiolabeled white blood cells can support a diagnosis of right dorsal colitis in the horse.<sup>63</sup> Images taken of the abdomen 20 hours after injection showed an increased linear uptake of leukocytes in the region of the right dorsal colon in horses with right dorsal colitis compared with normal horses. Other uses of nuclear scintigraphy include evaluation of metastasis of abdominal tumors to bony areas, assessment of biliary kinetics, and determination of liquid- and solid-phase gastric emptying.<sup>62-64</sup>

## ADVANCED IMAGING

Computed tomography (CT) is becoming increasingly available, and as such, various references are currently available describing the normal anatomy of the equine head as imaged with this modality.<sup>65,66</sup> CT is extremely useful to evaluate dental disease as well as tumors and masses of the head, larynx, pharynx, and proximal esophagus.<sup>67,68</sup> CT also has promise for evaluating abdominal disorders in foals. Most equipment can accommodate animals up to 400 lb. Restrictions of CT as a diagnostic aid include expense, availability, and weight and size limitation.

## ENDOSCOPY

Endoscopic examination of the gastrointestinal tract begins with evaluation of the pharyngeal area for any signs of collapse or dysfunction. One should evaluate the ability of the

horse to swallow. The floor of the pharynx should be clean and free of feed material and foreign bodies. The oral cavity should be examined with the horse under heavy sedation or anesthesia and with the help of a full-mouth speculum. One can examine the teeth for any irregularities, obvious cavities, sharp points, or hooks and the hard and soft palates for completeness and any evidence of ulceration, masses, or foreign bodies.

A 3-m flexible endoscope should be used to examine the esophagus, which is accomplished best by passing the endoscope into the stomach and viewing the esophagus as one withdraws the endoscope while dilating the lumen with air. The esophageal mucosa normally should be a glistening, light pink color. Ulceration can occur with cases of choke or reflux esophagitis or in horses that have had an indwelling nasogastric tube. Erosions may be punctate, linear, or circumferential. One should evaluate carefully for any ulcers to ensure that no areas of perforation through the entire thickness of the esophageal wall exist. Distinguishing normal peristaltic contractions from areas of stricture requires observation of the area and its motility over time. Diverticula also may be noted as outpouchings of the mucosa, sometimes associated with a stricture distally. Megaesophagus, although rare, appears as a generalized dilation of the esophagus. Endoscopy may reveal food or foreign body impactions. The veterinarian always should re-evaluate the esophagus after removing any obstruction to detect the presence of complications (ulceration, rupture) or initiating causes (strictures, diverticula, and masses).

A 3-m flexible endoscope also allows examination of the stomach. The horse should be fasted for at least 12 hours before endoscopy. One can examine the cardia and fundus easily, as well as the margo plicatus. With complete emptying of the stomach (aided with gastric lavage, if necessary), one can also evaluate the pylorus and proximal duodenum. The squamous mucosa should resemble the esophageal mucosa. The glandular mucosa should be glistening red and may have a reticulated pattern. The veterinarian should carefully examine it for evidence of ulceration or masses. Transendoscopic biopsy material can be easily obtained from esophageal, pharyngeal, or gastric masses, and because the biopsy size will be small, several samples should be taken for histopathologic examination. A complete description of gastroscopy and evaluation of gastric and gastroduodenal ulceration is available later in this chapter.

## TESTS OF ABSORPTION AND DIGESTION

D-Glucose or D-xylose absorption tests are useful in determining malabsorption of carbohydrates from the small intestine in horses. The protocol for absorption tests using either carbohydrate is similar. The horse should be fasted for 18 to 24 hours before testing. Increased periods of fasting actually have been shown to decrease absorption of D-xylose and interfere with results.<sup>69</sup> A dosage of 0.5 to 1 g/kg of D-glucose or D-xylose is administered through a nasogastric tube. Administration of sedatives may falsely increase the blood glucose levels and interfere with gastrointestinal transit times. Blood samples are collected to measure glucose or xylose concentrations at 0, 30, 60, 90, 120, 150, 180, 210, and 240 minutes after administration. Additional samples can be taken up to 6 hours after dosing if the results are questionable. One should measure glucose in blood samples collected with sodium

fluoride as an anticoagulant and measure xylose in samples collected in heparinized plasma.

A normal D-glucose absorption test, also known as an *oral glucose tolerance test*, should have a peak between 90 and 120 minutes, and this peak should be greater than 85% above the resting glucose value.<sup>70</sup> *Complete malabsorption* is defined as a peak less than 15% above the resting levels, and *partial malabsorption* is defined as a peak between 15% and 85% above the resting level. It is important to remember that gastric emptying, gastrointestinal transit time, length of fasting, cellular uptake and metabolism, age, diet, and endocrine function influence glucose absorption curves.<sup>70,71</sup> Malabsorption demonstrated by the oral glucose tolerance test is sensitive but not specific. Diseases that may cause a lowered or delayed peak include infiltrative lymphosarcoma, inflammatory bowel disease (lymphocytic-plasmacytic or eosinophilic), cyathostomiasis, chronic colitis (*Salmonella* sp.), multisystemic eosinophilic epitheliotropic disease, food allergies, and small intestinal bacterial overgrowth.<sup>72</sup> D-Xylose absorption tests have some advantages over the oral glucose tolerance test because xylose is not metabolized in the small intestinal mucosa and insulin does not influence its absorption. Gastric and intestinal motility, intraluminal bacterial overgrowth, and renal function still influence xylose absorption because the kidneys clear xylose.<sup>72</sup> The other main drawback to D-xylose is that it is generally available only in research settings. However, xylose measurements are available at many major universities. A normal D-xylose absorption curve should peak between 20 and 25 mg/dl at 60 to 120 minutes after dosing.<sup>73</sup> Decreased xylose absorption can occur in horses with inflammatory bowel disease, lymphosarcoma, multisystemic eosinophilic epitheliotropic disease, cyathostomiasis, extensive small intestinal resections, and any cause of villous atrophy.<sup>72</sup>

Maldigestion is a common occurrence in foals with diarrhea. Bacteria (especially *Clostridium* sp.) and viruses (especially rotavirus or coronavirus) may invade and destroy the villous epithelial cells that manufacture lactase and other disaccharidases, resulting in an inability to digest lactose. In this case continued ingestion of the mare's milk may cause an osmotic diarrhea, which may exacerbate the underlying enterocolitis. The veterinarian can perform lactose tolerance testing to assess the degree of maldigestion by administering D-lactose at 1 g/kg as a 20% solution via nasogastric tube and measure glucose concentrations in the blood at 0, 30, 60, 90, 120, 150, 180, 210, and 240 minutes. A normal curve shows doubling of glucose levels compared with baseline by 60 minutes after administration.<sup>74</sup>

## EVALUATION OF GASTRIC EMPTYING

Assessment of gastric emptying may be useful in cases of gastric and esophageal ulceration, pyloric stenosis, proximal enteritis, and potentially postoperative ileus. However, accurate measurement of gastric emptying can be difficult to assess.

Multiple diagnostic imaging techniques have been used to study gastric emptying times. Contrast radiography can be used to assess gastric emptying in foals. In the normal foal barium remains in the stomach for varying amounts of time, but a significant amount should be gone within 2 hours.<sup>48</sup> Gastric emptying of solid, nondigestible, radiopaque markers also has been used in adult horses and ponies, but the results were variable and unpredictable even in the normal horse.<sup>75</sup> Nuclear

scintigraphy is used commonly in human beings to measure gastric emptying and can be used in horses when available. The technique for measurement of liquid gastric emptying requires oral administration of 99mTc pentenate (10 mCi) and serial images taken of the cranial abdomen. The tracer is usually not visible 1 hour after administration in normal horses.<sup>64</sup> An adaptation of this methodology can be used for measurement of solid phase emptying of a 99m Tc-labeled pelleted ration.<sup>76</sup>

Alternatively, if nuclear scintigraphy is not available, acetaminophen absorption testing can be used as an indirect determination of liquid gastric emptying.<sup>77,78</sup> This test is performed by administering 20 mg/kg of acetaminophen orally and measuring subsequent blood values, then calculating the time to reach maximum serum concentrations and the absorption constant. In human beings the proximal small intestine absorbs almost all of the acetaminophen.<sup>79</sup> The median time to reach peak plasma levels using acetaminophen absorption in horses was 47.7 minutes.<sup>77</sup>

The 13C-octane acid breath test offers an easy, noninvasive method of determining gastric emptying of solids.<sup>76,80</sup> This test is performed by feeding a standard 13C-labeled test meal, and then collecting breath samples using a modified mask. The breath is then analyzed for the ratio of the novel isotope, 13:CO<sub>2</sub>, to the normally produced 12:CO<sub>2</sub>.

## ☞ HISTOPATHOLOGIC EXAMINATION

It is often necessary to perform a histopathologic examination of tissues from the intestine to diagnose chronic inflammatory, infiltrative, or neoplastic conditions, and such examination can be useful in evaluating the extent of injury after obstruction or ischemia. Rectal mucosal biopsies are easy to collect, with few complications. However, to collect a full-thickness biopsy of the intestine requires a surgical approach (flank or ventral midline approach). Laparoscopy offers a safer technique to observe the large intestine and other abdominal structures.<sup>81</sup> The practitioner can obtain biopsies of masses, lymph nodes, and mesentery or intestinal serosa using laparoscopy and mucosal biopsies of the upper gastrointestinal tract using endoscopy.

## ☞ LAPAROSCOPY

Other diagnostic tools, specifically laparoscopy and CT, are available but require specialized equipment and personnel with specific training. Flexible or rigid endoscopes used for laparoscopic evaluation of the abdomen allow for visualization of visceral organs and potentially for collection of biopsy material from masses or organs. Full-thickness biopsies of the intestines are not routinely possible through the laparoscope and usually require flank or ventral midline laparotomy. The laparoscopic procedure can be done with the horse standing or recumbent. Advantages of this technique over a flank or ventral midline celiotomy include smaller incisions, shorter healing time, and shorter procedure time. Disadvantages include the large amount of equipment needed, the high degree of skill involved, and the limitation as a diagnostic modality, rather than a treatment.<sup>82</sup> Clinical applications of diagnostic laparoscopy include the correction of rectal tears; percutaneous abscess drainage, assessment of adhesions, displacements, and integrity of the serosa of various bowel segments; and biopsy of abdominal masses.<sup>81</sup>

## PATHOPHYSIOLOGY OF GASTROINTESTINAL INFLAMMATION

Samuel L. Jones

The inflammatory response of the gastrointestinal tract is a mechanism ultimately aimed at eliminating pathogens, initiating tissue repair, and restoring the gastrointestinal barrier. Blood flow is altered, endothelial permeability increases, cells are rapidly recruited into the tissue, plasma protein cascades are activated, and myriad soluble products are released that coordinate the response, trigger innate and adaptive immunity, and mobilize reparative elements. Although the cellular and vascular response and the secreted mediators of inflammation are important for killing pathogens and limiting invasion of injured tissues by commensal organisms, they can be quite damaging to host cells and proteins if not tightly regulated. Thus if the inciting stimulus is not eliminated quickly, then the inflammatory response itself will cause significant tissue injury. The mechanism regulating inflammation has been the focus of much research to identify therapeutic targets to modulate the damage to host tissues that occurs in many gastrointestinal diseases. Recent work has provided some of the molecular and cellular details of this complex physiology and has led to novel therapeutic strategies for treating inflammation.

### INITIATION OF THE INFLAMMATORY RESPONSE

#### EPITHELIUM

The gastrointestinal epithelium interfaces with a luminal environment that is inhabited by potentially hostile microbial organisms. The epithelium presents a physical barrier to invasion by the flora of the gastrointestinal tract, consisting of the apical cellular membrane, intercellular tight junctions (the permeability of which is highly regulated), and a secreted layer of mucus. When invading pathogens breach the mucosal barrier, potent soluble and neural signals are generated that initiate an inflammatory response.<sup>1</sup> The epithelium can be conceptualized as a sensory organ that detects pathogen invasion to trigger an appropriate host defense and reparative response.

Noninfectious mucosal injury or invasion of epithelial cells by pathogenic organisms such as *Salmonella* activates the synthesis of pro-inflammatory chemokines (chemoattractants) by epithelial cells that triggers a robust influx of neutrophils into the tissue within hours of the damage.<sup>1</sup> Of the chemoattractants produced by epithelium, interleukin-8 (IL-8) has a particularly important role in initiating inflammation by recruiting neutrophils from blood<sup>2-4</sup> and regulating neutrophil migration through tissue matrix adjacent to epithelium.<sup>5,6</sup> Complement fragments such as C5a and bacteria-derived formylated chemotactic peptides also act as potent “end target” chemoattractants that are fully capable of stimulating a robust inflammatory response in the intestine if the epithelial barrier permits invasion of bacteria or the diffusion of bacterial peptides across the mucosa.

Epithelial cells activated during infection produce cytokines such as tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ), arachidonic

acid metabolites, and other pro-inflammatory mediators that activate recruited leukocytes.<sup>7</sup> Microbial products, particularly lipopolysaccharide and other bacterial cell wall components and microbial nucleic acids, are potent activators of leukocytes recruited into the tissue.<sup>8</sup> Mast cells are key sentinel leukocytes that sense microbial invasion, releasing TNF- $\alpha$  that appears to be a critical initiator and regulator of the cellular phase of inflammation.<sup>9</sup> Once the inflammatory response has been initiated, TNF- $\alpha$ ; IL-1 $\beta$ ; and other pro-inflammatory products of neutrophils, monocytes, mast cells, and epithelial cells amplify the inflammatory response.

The enteric nervous system has a key role in sensing and regulating inflammatory responses in the intestine. For example, *Clostridium difficile* toxin A activates a neural pathway that triggers mast cell degranulation and neutrophil influx into the tissue.<sup>10,11</sup> Blockade of this neural pathway is sufficient to abolish the profound inflammatory response induced by toxin A as well as many of the effects of toxin A on enterocyte secretion. Other pathogens and immune-mediated hypersensitivity reactions similarly stimulate inflammation by mechanisms that involve the enteric nervous system. Thus the epithelium interacts in a highly complex manner with the intestinal milieu, the enteric nervous system, and inflammatory cells to regulate the tissue response to injury and infection.

#### MACROPHAGES

Resident macrophages located in the lamina propria, submucosa, and intestinal lymphoid organs are among the first cells beyond the epithelium to respond to infection or injury. Macrophages are activated by microbial products by way of pattern recognition receptors and begin to produce pro-inflammatory molecules important for recruiting and activating neutrophils and monocytes. Pattern recognition receptors recognize microbial molecules such as lipopolysaccharide, lipoproteins, flagellin, peptidoglycan, and nucleic acids to signal the invasion by pathogens.<sup>8</sup> Of the pattern recognition receptors, the lipopolysaccharide (LPS) receptor complex is perhaps the best defined. LPS activates macrophages by way of the CD14-Toll-like receptor 4 complex to initiate transcription of the inflammatory cytokines TNF- $\alpha$  and IL-1 $\beta$ , which synergize with LPS to amplify the macrophage response.<sup>8</sup> LPS, particularly in concert with inflammatory cytokines, stimulates macrophages to produce copious amounts of nitric oxide, which is both microbicidal and vasoactive.<sup>12</sup> Nitric oxide and other nitrogen radicals react with reactive oxygen intermediates (ROIs) generated by the activated oxidase complex to produce some of the most toxic molecules of the host defense system: the peroxynitrites.<sup>12</sup> IL-8 is produced as well to recruit neutrophils. As the response progresses, other inflammatory mediators, particularly the arachidonic acid-derived lipids dependent on inflammation-induced cyclooxygenase-2 and 5-lipoxygenase activity, are produced that have potent vasoactive and pro-inflammatory effects through the activation of endothelial cells, neutrophils, and platelets.<sup>13</sup>

### VASCULAR RESPONSE DURING INFLAMMATION

Four important changes occur in the intestinal vasculature during inflammation: (1) alteration of blood flow; (2) increased vascular permeability; (3) increased adhesiveness

of endothelial cells, leukocytes, and platelets; and (4) exposure of the basement membrane and activation of the complement, contact, and coagulation cascades.

A wide range of mediators alter blood flow during inflammation in the intestinal tract, ranging from gases such as nitric oxide (a major vasodilator of the intestinal vasculature) to lipids (prostaglandins, leukotrienes, thromboxanes, and platelet-activating factor [PAF]), cytokines, bradykinin, histamine, and others. The major sources for these mediators include activated leukocytes, endothelial cells, epithelial cells, and fibroblasts. The primary determinant of blood flow early in inflammation is vascular caliber, which initially decreases in arterioles but then quickly changes to vasodilation coincident with opening of new capillary beds, increasing net blood flow. The increase in blood flow is relatively short lived, as the viscosity of the blood increases because of fluid loss and tissue edema resulting from leaky capillaries. Leukocyte margination, platelet adhesion to endothelial cells and exposed matrix, and areas of coagulation protein accumulation further decrease local circulation.

Increased vascular permeability is initially caused by inflammatory mediator actions on the endothelial cells. Histamine, leukotrienes, PAF, prostaglandins, bradykinin, and other mediators stimulate endothelial cell contraction, and interendothelial gaps form.<sup>14,15</sup> This stage of increased vascular permeability is readily reversible. Concurrently, mediators such as the cytokines TNF- $\alpha$  and IL-1 $\beta$  induce a structural reorganization of the interendothelial junctions, resulting in frank discontinuities in the endothelial monolayer.<sup>16</sup> Cytokines also stimulate endothelial cells to express adhesion molecules that support adhesion of leukocytes and platelets,<sup>17</sup> leading to the next and perhaps most devastating event. Leukocytes (primarily neutrophils) and platelets adhere to exposed basement membranes and activated endothelial cells. Adherent neutrophils and platelets are then exposed to the mediators of inflammation present in the surrounding milieu, which activates the cells to release oxidants and proteases (particularly elastase) that injure the endothelium and have the potential to cause irreparable harm to the microvasculature.<sup>18-20</sup> Marginated neutrophils begin to transmigrate between endothelial cells (as described in later sections), which, if in sufficiently large numbers, disrupt the integrity of the interendothelial junctions, worsening the vascular leakage.<sup>19</sup>

These stages of enhanced vascular permeability can be conceptualized as a mechanism to allow plasma proteins to enter the tissues and to potentiate the critical influx of leukocytes into tissues. However, if they are not regulated precisely, alterations in both hydrostatic and oncotic forces and irreversible damage to the vascular bed may have devastating consequences. Moreover, inappropriate activation of plasma protein cascades and leukocytes by activated endothelium and exposed matrix proteins can contribute to systemic inflammation (systemic inflammatory response syndrome, or SIRS; see the section on gastrointestinal ileus for more information) characterized by hypotension, generalized vascular leak syndrome, and multiorgan dysfunction, which may be fatal. Phosphodiesterase inhibitors reduce endothelial permeability in ischemia-reperfusion injury and other models of inflammation-induced vascular leakage<sup>21,22</sup> by increasing endothelial tight junction integrity and thus may be a viable therapeutic strategy to

prevent or reduce the permeability alterations associated with inflammation.

## CELLULAR EFFECTORS OF INFLAMMATION

### ENDOTHELIAL CELLS

Endothelial cells respond to products of activated epithelial cells and macrophages in the intestinal tissue to recruit cells and humoral mediators of inflammation into the tissue. Activated endothelial cells display a range of molecules critical for neutrophil and platelet adhesion. The role of endothelial cells in mediating neutrophil recruitment is discussed in more detail later in this chapter. Intercellular permeability is increased to expose basement membrane proteins that trigger humoral defense systems (complement, coagulation, and contact system cascades) and to provide access for these macromolecules to the tissue. Endothelial cells are an important source of inflammatory mediators that amplify the response and vasoactive substances (particularly nitric oxide) altering blood flow.

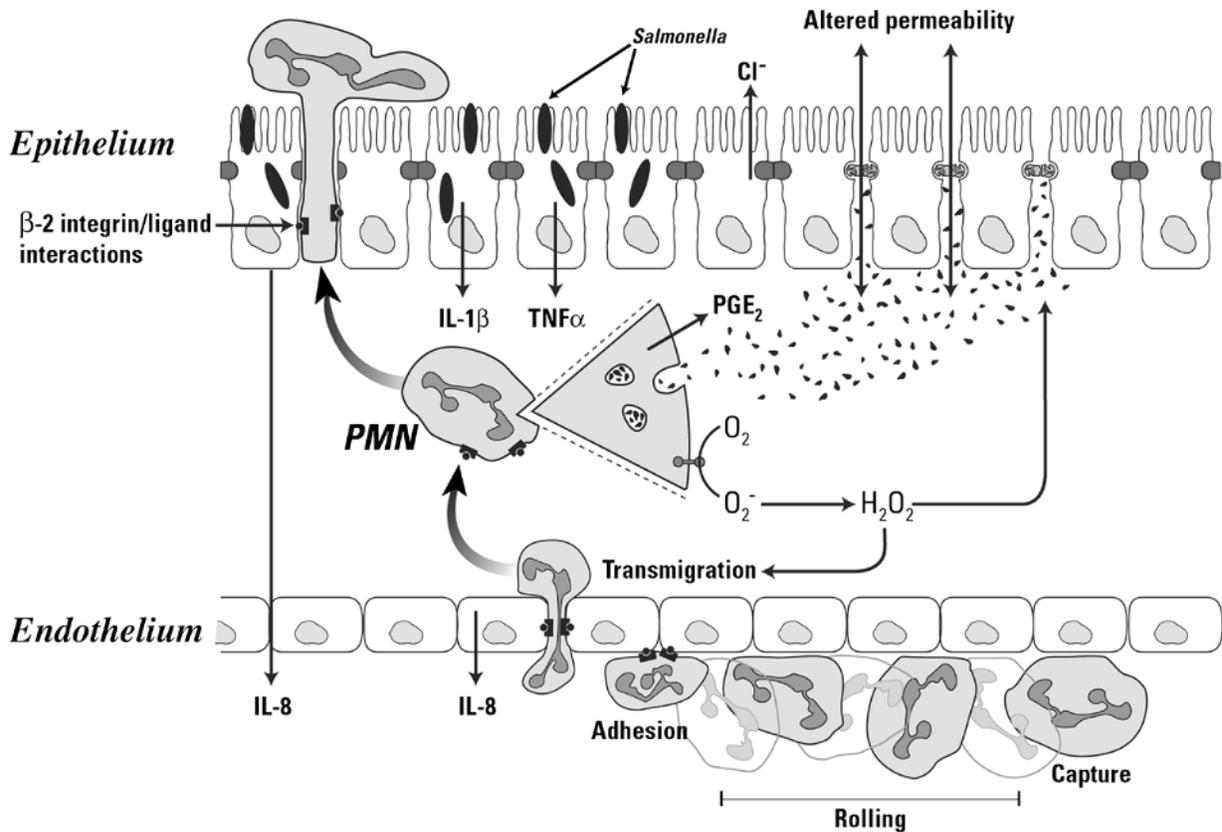

### NEUTROPHILS

#### RECRUITMENT

Infection or injury to the gastrointestinal mucosa causes an influx of leukocytes from the blood that lay the foundation of the inflammatory response. Neutrophils, the first to arrive during inflammation, have a dominant role in the acute response. Within minutes neutrophils are recruited into the tissue, where they are activated to release products that not only are lethal to pathogens and pro-inflammatory but also may damage host cells and tissues.<sup>23</sup> Not surprisingly, much attention has been paid to the role of neutrophils in the pathophysiology of many inflammatory conditions.<sup>24</sup> Neutrophil depletion is protective in many models of gastrointestinal inflammatory disease. Of interest to clinicians, blockade of neutrophil migration into inflamed tissues prevents many of the pathophysiologic events associated with infectious enteritis, ischemia-reperfusion injury, and other gastrointestinal diseases.<sup>18,25-29</sup>

Neutrophil transendothelial migration is a multistep process that is temporally and spatially regulated and has a degree of cell type specificity (Figure 15-2). The predominant sites of neutrophil transendothelial migration are in the postcapillary venules and, in some tissues, capillaries. Endothelial cells in these vessels respond to cytokines and other soluble signals by expressing molecules that promote neutrophil adhesion and transmigration, including selectins and counter receptors for integrins. As neutrophils flow through these vessels, they are first tethered to activated endothelium. Tethering is mediated by selectin molecules expressed on neutrophils (L-selectin) and on activated endothelial cells (P- and E-selectins), which bind to PSGL-1, ESL-1, and other mucin counter-receptors.<sup>30,31</sup> The function of tethering is to increase the exposure of the neutrophil to activating chemokines presented on the surface of the endothelial cells.

Stimulation of neutrophils by IL-8 and other chemokines activate the second step of transendothelial migration. Chemokine binding to their receptors on the neutrophil generates signals that activate the binding of integrin adhesion receptors to their ligands, called *intracellular adhesion molecules* (ICAMs)

**FIGURE 15-2** Depiction of neutrophil responses during intestinal inflammation in response to salmonella infection. Salmonellae infect epithelial cells, stimulating the production of chemokines (interleukin-8 [IL-8]), cytokines (IL-1 $\beta$  and tumor necrosis factor- $\alpha$  [TNF- $\alpha$ ]), and other proinflammatory mediators. Endothelial cells stimulated by inflammatory mediators produce chemoattractants (such as IL-8) and display adhesion molecules that promote neutrophil emigration. The three steps of neutrophil (polymorphonuclear [PMN]) emigration—capture/rolling (mediated by selectins), adhesion (mediated by  $\beta_2$  integrins), and transendothelial migration (mediated by integrins and platelet/endothelial cellular adhesion molecule [PECAM])—occur on activated endothelium. Chemoattractant molecules such as IL-8 trigger neutrophil emigration. In inflamed tissues cytokines (IL-1 $\beta$  and TNF- $\alpha$ ) and a variety of other pro-inflammatory mediators stimulate the neutrophil oxidase complex to produce reactive oxygen intermediates (ROIs;  $O_2^-$  and  $H_2O_2$  and their derivatives). Activated neutrophils degranulate to release proteases and other hydrolases, cationic peptides (defensins), myeloperoxidase, and other products into the tissue. Activated neutrophils synthesize a variety of inflammatory mediators, including prostaglandins ( $PGE_2$ ) that modulate the inflammatory response. The products of activated neutrophils (ROIs, proteases, and mediators) stimulate epithelial secretion and alter tight junction permeability, promoting diarrhea. Neutrophils eventually migrate across the infected epithelium by a mechanism that involves integrins, disrupting tight junction integrity and increasing permeability to bacterial products, thus exacerbating the inflammatory response.

or *vascular cell adhesion molecules* (VCAMs), expressed on endothelial cells in inflamed mucosa. Integrin ligation to ICAMs arrests the tethered neutrophils, resulting in firm adhesion to the endothelium. Of the integrins expressed on neutrophils, the  $\beta_2$  integrins have a particularly important role in transendothelial migration. Calves and people with the disorder leukocyte adhesion deficiency (LAD) illustrate the requirement for  $\beta_2$  integrin-mediated adhesion in neutrophil function. LAD is a result of an autosomal recessive trait resulting in the lack of the  $\beta_2$  integrin expression. The neutrophils from affected individuals cannot migrate into most tissues and do not function normally, resulting in poor tissue healing and profound susceptibility to infection, especially at epithelial barriers.<sup>32,33</sup> Other integrins also have a role in transendothelial migration.  $\beta_1$  Integrins mediate transendothelial migration in some cells

and seem to be particularly important for mediating emigration of monocytes into many tissues.<sup>34</sup>

Following this firm adhesion step, neutrophils migrate through the endothelium along a chemotactic gradient of IL-8 and other chemoattractants, such as C5a and LTB<sub>4</sub>.<sup>3,19,35</sup> Neutrophils migrate across the endothelial monolayer at intercellular junctions by way of a mechanism involving a series of integrin-ligand interactions mediated by both  $\beta_2$  and  $\beta_1$  integrins and other adhesion molecules<sup>31</sup> that is generally capable of maintaining the integrity of the endothelial barrier.<sup>36</sup> However, massive flux of neutrophils through the endothelium alter endothelial tight junctions and injure the basement membrane, resulting in increased endothelial permeability to molecules as large as plasma proteins and even endothelial cell detachment from the basement membrane.<sup>19,20</sup> Nonintegrin

molecules such as platelet-endothelial cell adhesion molecules (PECAMa) also are involved in transendothelial migration of neutrophils.<sup>31</sup> Homotypic binding of PECAMs on adjacent endothelial cells form part of the intercellular junction. Neutrophils express an integrin of the  $\beta 3$  family that can bind PECAM, and through sequential binding of  $\beta 3$  integrins to PECAM, the neutrophil can “unzip” the intercellular junction and migrate through, closing it behind itself.

### ACTIVATION

A key feature of neutrophils and other leukocytes is the requirement for integrin-mediated adhesion to extracellular matrix (ECM) proteins or other cells to achieve an optimal effector phenotype.<sup>37</sup> Critical components of the ECM in inflamed tissues include fibronectin, fibrinogen, and vitronectin, deposited in tissues as a result of plasma leakage and by synthesis of new proteins by stromal cells and resident macrophages in response to inflammatory mediator activation. The changing composition of the matrix proteins deposited in tissues during inflammation serves as a cue as to the nature of the tissue environment for recruited inflammatory cells as they become activated. Individual gene expression studies have demonstrated that adhesion to matrix proteins induces the expression of cytokines and chemokines and their receptors, arachidonic acid–derived lipid mediator synthases, metalloproteinases, growth factors, transcription factors, and other genes that influence the differentiation and activation of inflammatory cells.<sup>38</sup> Reactive oxygen intermediate production, phagocytosis, degranulation, and other effector functions stimulated by inflammatory mediators and bacterial products are optimal only when neutrophils are adherent to the ECM.<sup>37</sup> Adhesion to distinct ECM proteins selectively activates signaling pathways and gene expression of neutrophils, monocytes, and other leukocytes with differing abilities to promote certain functions such that the composition of ECM in many ways controls the development of the ultimate effector phenotype. Thus integrin-mediated adhesion provides a mechanism whereby neutrophils and other leukocytes can sense the complex tissue environment and respond appropriately.

Of the activators of neutrophils at sites of inflammation, complement (C3-opsonized particles), cytokines (TNF- $\alpha$  and IL-1 $\beta$ ), PAF, immune complexes, and bacterial products are among the most potent stimuli. Other mediators produced during inflammation may modify neutrophil activity, particularly formylated bacterial peptides, chemokines, complement fragments (C5a), leukotriene B<sub>4</sub> (LTB<sub>4</sub>), and prostaglandins. Activated neutrophils are highly phagocytic; produce large amounts of ROI; degranulate to release myeloperoxidase, cationic antimicrobial peptides (defensins), serine proteases (mainly elastase), and metalloproteinases; and secrete inflammatory mediators (TNF- $\alpha$ , IL-1 $\beta$ , prostaglandins, leukotrienes, and others) (see Figure 15-2).

### MAST CELLS

Mast cells strategically reside in mucosal tissues, including the submucosa and lamina propria of the gastrointestinal tract, and constitute a crucial first line of defense at epithelial barriers. However, they are also important effector cells of the pathophysiology of inflammatory gastrointestinal diseases.<sup>39</sup> Experimental depletion of mast cells, genetic deficiency in the development of mast cells, or pharmacologic stabilization of mast cells to prevent degranulation all have a protective effect

in a variety of models of gastrointestinal inflammatory disease, including dextran- or trinitrobenzenesulfonic acid–induced colitis<sup>40,41</sup>, ischemia-reperfusion injury,<sup>42,43</sup> and immediate hypersensitivity responses.<sup>44</sup>

Mast cells are activated by a wide variety of microbial products and host-derived mediators.<sup>45</sup> Among the activators of mast cells, the so-called anaphylatoxins (complement fragments C3a, C5a, and C4a) are extremely potent stimuli causing release of mediators of inflammation. In addition, mast cells are the primary effector cells of IgE-mediated anaphylaxis (Type I hypersensitivity reactions) by virtue of their high affinity receptors for IgE. Cross-linking of receptor-bound IgE on mast cell surface by antigens (i.e., food antigens) causes rapid degranulation, resulting in the explosive release of granule contents.<sup>46</sup> Neural pathways in the intestine also regulate mast cells. Mast cells respond to enteric pathogen invasion via neural reflexes that stimulate the release of inflammatory mediators.

Activated mast cells release preformed histamine, 5-HT, proteases, heparin, and cytokines from granules. Activation also stimulates de novo synthesis of a range of inflammatory mediators, including prostaglandins, PAF, and leukotrienes. Transcription of a number of peptide mediators, such as the cytokines TNF- $\alpha$  and IL-1 $\beta$  among many others, also increases upon stimulation of mast cells. Mast cell products have profound effects on the vasculature, increasing endothelial permeability and causing vasodilation.<sup>47</sup> Moreover, mast cell–derived mediators markedly enhance epithelial secretion by a mechanism that involves the activation of neural pathways and direct stimulation of epithelial cells.<sup>46</sup> In particular, the mast cell granule protease tryptase operating via the protease-activated receptor-2 is a key regulator of gastrointestinal physiologic responses during inflammation, including epithelial secretion and intercellular junction integrity, motility, and pain responses.<sup>48,49</sup> Mast cell products significantly alter intestinal motility, generally increasing transit and expulsion of intestinal contents. Mast cell–derived leukotrienes and TNF- $\alpha$  also have a crucial role in host defense against bacterial pathogens, acting to recruit and activate neutrophils,<sup>50,51</sup> and are crucial players in the mechanism regulating dendritic cell function and adaptive immune responses.<sup>52</sup>

Mast cells have a newly identified role in host defense and inflammatory responses to bacterial pathogens.<sup>9</sup> Their role is in part due to the release of pro-inflammatory mediators during bacterial infection, which is critical for recruiting and activating other innate host defense cells such as neutrophils. However, mast cells are also phagocytic, have microbicidal properties, and can act as antigen presenting cells to the adaptive immune system.<sup>9</sup> The role for mast cells in host protective responses appears to be as a sensor of bacterial invasion. Unlike IgE-mediated responses, bacterial products seem to elicit a highly regulated and selective response from mast cells.

## ☞ HUMORAL MEDIATORS OF INFLAMMATION

### COMPLEMENT

The complement cascade is a fundamental part of the inflammatory response. Activation of the complement cascade, either by immune complexes (classical pathway) or by bacteria or bacterial products, polysaccharides, viruses, fungi, or host cells

(alternative pathway), results in the deposition of complement proteins on the activating surface and the release of soluble proteolytic fragments of several complement components.<sup>53</sup> In particular, activation of either pathway results in the deposition of various fragments of the complement protein C3, which are potent activators of neutrophils and monocytes.<sup>53</sup> Opsonization of particles with C3 fragments constitutes a major mechanism of target recognition and phagocyte activation.<sup>54</sup> During the activation of the complement cascade culminating in deposition of C3, soluble fragments of C3 (C3a), C5 (C5a), and C4 (C4a) are liberated. These fragments, termed *anaphylatoxins*, have potent effects on tissues and cells during inflammation. Perhaps most notably, they are chemotactic for neutrophils (particularly C5a), activate neutrophil and mast cell degranulation, and stimulate reactive oxygen metabolite release from neutrophils.<sup>53</sup> The termination of the complement cascade results in the formation of a membrane attack complex in membranes at the site of complement activation. If this occurs on host cells such as endothelium, the cell may be irreversibly injured. Although the primary source of complement is plasma, epithelial cells of the gastrointestinal tract also produce C3, suggesting that local production and activation of the complement cascade during inflammation occurs in intestinal tissues.

It is clear that if the regulatory mechanisms of the complement cascade fail, then the inflammatory response may be inappropriate and tissue injury can occur. The role of complement in gastrointestinal inflammation has been most extensively studied in models of ischemia-reperfusion injury. Activation of the complement cascades has a major role in altered endothelial and epithelial permeability in these models. Several lines of evidence support the importance of complement in intestinal injury. Mice deficient in C3 or C4 are protected against ischemia-reperfusion injury.<sup>55</sup> Moreover, administration of monoclonal antibodies against C5 reduced local and remote injury and inflammation during intestinal reperfusion injury in a rat model.<sup>56</sup> Administration of a soluble form of complement receptor 1, a regulatory protein that halts the complement cascade by dissociating C3 and C5 on host cell membranes, reduced mucosal permeability, neutrophil influx, and leukotriene B4 production during ischemia-reperfusion injury in rats and mice.<sup>55,57</sup> Although neutrophils and mast cells mediate many of the pathophysiologic effects of the complement cascade, the membrane attack complex may have a primary role in altered vascular permeability during ischemia-reperfusion injury.<sup>58</sup>

## CONTACT SYSTEM

The contact system of plasma is initiated by four components: Hageman factor (HF), prekallikrein, Factor XI, and high-molecular-weight kininogen. HF is a large plasma glycoprotein that binds avidly to negatively charged surfaces.<sup>59</sup> Bacterial cell walls, vascular basement membranes, heparin, glucosaminoglycans, and other negatively charged surfaces in the intestine capture HF and the other three important initiators of the contact system in a large multimolecular complex. Of the surfaces that bind HF, the ECM is an extremely potent activator of the contact system. Once bound, HF is converted to HF- $\alpha$ , which cleaves prekallikrein to kallikrein and Factor XI to Factor XIa. The ultimate result is further cleavage of HF by kallikrein and triggering of the contact system cascade, activation of intrinsic coagulation by Factor XIa, activation of the alternative pathway

by HF, and proteolytic cleavage of high-molecular-weight kininogen by kallikrein, releasing biologically active kinins.

The products of the contact system, particularly bradykinin, have several important biologic properties that drive many of the vascular and leukocyte responses during inflammation.<sup>59</sup> Bradykinin induces endothelial cell contracture and intracellular tight junction alterations that increase vascular permeability to fluid and macromolecules. Bradykinin also affects vascular smooth muscle contracture, resulting in either vasoconstriction or vasodilation, depending on the location. Bradykinin also increases intestinal motility, enhances chloride secretion by the intestinal mucosa, and intensifies gastrointestinal pain. In neutrophils kinins stimulate the release of many inflammatory mediators, including cytokines, prostaglandins, leukotrienes, and reactive oxygen intermediates.<sup>60</sup> Kallikrein cleaves C5 to release C5a, a potent chemotactic factor for neutrophils, and thus has a role in recruiting and activating inflammatory leukocytes.

The plasma kallikrein-bradykinin system is activated in a variety of acute and chronic inflammatory diseases of the gastrointestinal tract.<sup>61,62</sup> Recent evidence has demonstrated that blockade of the pathophysiologic effects of bradykinin has clinical applications. Oral or intravenous administration of the bradykinin receptor antagonist icatibant reduces the clinical signs, onset of diarrhea, and many of the histopathologic changes in experimental models of colitis in mice.<sup>63</sup> Inhibition of kallikrein by oral administration of P8720 attenuated the intestinal inflammation, clinical score, and systemic manifestations in a model of chronic granulomatous enterocolitis.<sup>62</sup> Thus the contact system is a viable therapeutic target for inflammatory diseases of the intestine.

## TISSUE INJURY DURING INFLAMMATION

Changes in blood flow to the mucosa and other regions of the intestine that reduce perfusion of the tissues can potentiate the initial damage caused by infection or injury. For example, reperfusion of ischemic tissues is associated with platelet and neutrophil clumping in the small vessels of the mucosa, which can impede blood flow.<sup>64</sup> Platelets are activated and adhere to exposed basement membrane and activated endothelial cells and provide a surface for leukocyte adhesion. The accumulation of platelets and leukocytes can significantly reduce vessel diameter and blood flow while potentiating local coagulation and thrombus formation.

Soluble mediators released by activated leukocytes and endothelial cells also affect blood flow. Histamine and the vasoactive lipids derived from arachidonic acid (leukotrienes, prostaglandins, thromboxane, prostacycline, and PAF) have a prominent role in regulating local perfusion during inflammation and may have systemic effects on blood flow as well. Procoagulant mediators released by inflammatory cells in response to the inflammatory process (i.e., tissue factor produced by macrophages or endothelial cells), exposed basement membrane proteins, and bacterial components can trigger the contact system and the coagulation and complement cascades, the products of which affect blood flow. Nitric oxide, whether produced by endothelial cells or leukocytes (macrophages), is a potent regulator of blood flow and has a significant role in the control of perfusion during inflammation.<sup>65</sup> Many of the mediators that affect perfusion also affect endothelial permeability, altering osmotic and hydrostatic

balance and tissue edema. In extreme cases local and systemic coagulopathies initiated by vascular injury and absorption of microbial products and inflammatory mediators induce a hypercoagulable state, leading to microthrombus formation, which can reduce blood flow or macrothrombus formation, causing tissue infarction.

The cellular mediators of inflammation have the potential to inflict severe injury to intestinal tissues. Neutrophils have an important role in the pathophysiology of many intestinal diseases, including ischemia-reperfusion injury,<sup>18,25</sup> infectious enterocolitis,<sup>26,28,66</sup> nonsteroidal anti-inflammatory drug-induced mucosal ulceration,<sup>29</sup> and others. Depletion of neutrophils, blockade of their emigration into tissues, or inhibition of neutrophil activation reduces the severity of these and other inflammatory diseases.<sup>67</sup> Thus many anti-inflammatory therapies are emerging that specifically target neutrophil adhesion, migration, and activation.

Migration of neutrophils through endothelium during emigration into inflamed tissues is remarkable in that the permeability of the endothelial monolayer is preserved under most circumstances. However, there is a limit above which neutrophil migration alters the permeability characteristics of the endothelium. The effect is in part physical in that the mere movement of large numbers of neutrophils through the endothelium is sufficient to mechanically disrupt the tight junctions and in part due to toxic products of neutrophils that damage endothelial cells and basement membranes.<sup>64,68</sup> Serine proteases (particularly elastase) and metalloproteinases released by degranulating neutrophils liquefy tissue matrix proteins and cleave cell surface proteins that make up endothelial intercellular junctions to ease neutrophil migration to the site of infection.<sup>23</sup> These degradative enzymes are particularly damaging to basement membranes and the cellular barriers of the endothelium, thus contributing to vascular permeability (and local tissue edema) and thrombosis. The permeability may be affected to the extent that not only water but also macromolecules (e.g., albumin, matrix proteins, complement) leak into the interstitium. Blockade of neutrophil adhesion to endothelium with anti- $\beta$ 2 integrin antibodies has a sparing effect on the microvasculature in experimental intestinal ischemia-reperfusion injury, reducing the alterations in vascular permeability and histopathologic evidence of microvascular damage.<sup>64</sup>

Similar to the endothelium of inflamed tissues, massive neutrophil transmigration occurs across the epithelium in response to infection or injury. Neutrophil transepithelial migration increases epithelial permeability by disrupting tight junctions.<sup>68</sup> Like the endothelium, neutrophils disrupt the epithelial barrier mechanically as they migrate through (see Figure 15-2). Proteases, particularly elastase, degrade basement membrane components and tight junction proteins. Protease activated receptor-2 activated by neutrophil granule serine proteases alter epithelial and endothelial tight junction integrity. Pro-inflammatory products of activated neutrophils (TNF- $\alpha$  and IFN- $\gamma$ ) increase tight junction permeability by direct effects on enterocytes. Prostaglandins released by activated neutrophils stimulate epithelial secretion, thus contributing to diarrhea. Subepithelial accumulation of neutrophils can lead to de-adhesion of the epithelial cells from the basement membrane and mild to severe ulceration. The physiologic result of the effects of neutrophils and their products on the epithelial barrier includes protein-losing enteropathy and absorption of bacterial cell wall constituents, which potentiates the local and systemic inflammatory responses.

Neutrophils in inflamed tissues stimulated by potent host-derived activators (such as IL-1 $\beta$  and TNF- $\alpha$ ) and bacterial products (LPS) release copious amounts of reactive oxygen intermediates (see Figure 15-2). Although these oxygen and oxyhalide radicals are important for killing pathogens, they are also potentially toxic to epithelial and endothelial cells and matrix proteins. Reactive nitrogen intermediates (RNIs), produced primarily by macrophages during inflammation, combine with ROI to form peroxynitrites, which are particularly toxic.<sup>12</sup> In addition to injury to mucosal tissues, ROI also have an as yet ill-defined role in recruiting and activating neutrophils, thereby potentiating the inflammatory response.<sup>69</sup> In support of the role of ROI in inflammatory diseases of the gastrointestinal tract, administration of inhibitors of ROI production or pharmacologic ROI scavengers can be protective in many models of reperfusion injury or enterocolitis. Many therapies are aimed at inhibiting neutrophil activation, and effector functions in tissues have been evaluated for use in intestinal diseases. Phosphodiesterase inhibitors, by causing cyclic adenosine monophosphate (cAMP) accumulation in neutrophils, are anti-inflammatory by virtue of their ability to suppress neutrophil activation and ROI production. New phosphodiesterase inhibitors selective for the predominant neutrophil isoform of phosphodiesterase hold promise for use in many inflammatory diseases.

Subepithelial mast cells also have an important role in altering epithelial permeability in inflamed intestine. During the intestinal hypersensitivity response subepithelial mast cell release of mast cell protease tryptase by degranulation increases epithelial permeability via an effect on tight junctions.<sup>44,70,71</sup> This alteration in tight junction permeability results in enhanced transepithelial flux of macromolecules, including proteins and bacterial products. Cytokines released by mast cells and phagocytes also regulate tight junction permeability. IL-4, a product of mast cells and macrophages, has been demonstrated to increase epithelial permeability.<sup>72</sup> Moreover, TNF- $\alpha$  and IFN $\gamma$ , products of many inflammatory cells, synergistically increase tight junction permeability.<sup>73</sup>

## PATHOPHYSIOLOGY OF DIARRHEA

*L. Chris Sanchez*

Acute equine colitis causes rapid, severe debilitation and death in horses (more than 90% of untreated horses die or require euthanasia).<sup>1</sup> Since 1919 several reports have described a number of acute diarrheal conditions in the horse that appear to share a common characteristic clinical presentation.<sup>2</sup> Diarrhea associated with acute equine colitis occurs sporadically and is characterized by intraluminal sequestration of fluid; moderate to severe colic (abdominal pain); and profuse watery diarrhea with resultant endotoxemia, leukopenia, and hypovolemia.<sup>3,4</sup> Causes of acute colitis and therapeutic options are discussed elsewhere in this chapter.

Although the mechanisms responsible for the fluid losses are not known, inflammatory cells may play an integral role because this condition is characterized by large numbers of granulocytes infiltrating the large intestinal mucosa.<sup>5-9</sup> Equine cecal and colonic tissues collected during the acute stages of experimentally induced acute equine colitis

(Potomac horse fever, lincomycin with and without *Clostridium* spp. inoculation, nonsteroidal anti-inflammatory drug administration) reveal the presence of numerous neutrophils and eosinophils in the lamina propria and submucosa.<sup>5,8,10,11</sup> Granulocyte-derived reactive oxygen intermediates are crucial to antimicrobial defenses in the gut and stimulate chloride and water secretion by interactions with enterocytes.<sup>12,13</sup> Normal equine intestinal tissue is unique compared with that in most other mammalian species for a preponderance of eosinophils located in the intestinal mucosa and submucosa.<sup>14,15</sup> Production of ROIs by stimulated phagocytic granulocytes following mucosal barrier disruption may be responsible for the massive fluid secretory response that occurs during the early stages of acute equine colitis.

*Colitis* refers to inflammation and mucosal injury of the colon and cecum (typhlocolitis) that may occur in response to a number of causes.<sup>16</sup> The cause of the colonic injury may be well-defined such as in naturally occurring infectious or experimentally induced colitis. However, many cases of human and animal diarrhea have a speculative or unknown diagnosis or no diagnosis. Irrespective of the underlying or initiating cause of colonic injury, the colon apparently has a limited repertoire of responses to damage because most forms of colitis demonstrate similarities in histopathologic appearance and clinical presentation. Various degrees of mucosal erosion and ulceration, submucosal and mucosal edema, goblet cell depletion, and presence of an inflammatory cellular infiltrate within the mucosa and submucosa are common to many types of human and animal colitis.<sup>15,16</sup> Characteristic clinical manifestations include intraluminal fluid sequestration; abdominal discomfort; hypovolemia; and most often profuse, watery diarrhea.

## ☉ PATHOPHYSIOLOGY OF COLITIS

Large bowel diarrhea results from abnormal fluid and ion transport by cecal and colonic mucosa. Loss of fluid by the large intestine can result from malabsorptive or hypersecretory processes and is often a combination of the two.<sup>17</sup> Colonic secretory processes are a function of the crypt epithelium, whereas absorptive processes are limited to surface epithelial cells.<sup>18,19</sup> Under normal baseline conditions an underlying secretion by crypt epithelium is masked by a greater rate of surface epithelial cell absorption. Abnormal forces influencing the rates of secretion and absorption can result in massive, uncontrolled secretion and malabsorption by large intestinal mucosal epithelial cells, leading to rapid dehydration and death.<sup>17-19</sup>

Two intracellular processes control colonic secretion: the cyclic nucleotide cAMP and cyclic guanosine monophosphate (cGMP) and the calcium system.<sup>20,21</sup> Agents may activate adenylyl cyclase (vasoactive intestinal peptide, prostaglandin E<sub>2</sub> [PGE<sub>2</sub>]) or guanylyl cyclase (bacterial enterotoxins) and induce increases in cAMP or cGMP, respectively. This reaction causes phosphorylation of specific protein kinases that induce the actual apical and basolateral membrane transport events. Increases in intracellular free calcium may arise from cyclic nucleotide-dependent release of stored calcium within the cell or from increased calcium entry across the cell membrane.<sup>17-19</sup> Calcium may act through calmodulin, which then can activate membrane-phosphorylating protein kinases.

At least four central systems control intestinal secretion: (1) the hormonal system, (2) the enteric nervous system, (3) bacterial enterotoxins, and (4) the immune system.<sup>21,22</sup>

Hormonal control of colonic electrolyte transport is exerted primarily through the renin-angiotensin-aldosterone axis.<sup>23</sup> The enteric nervous system controls transport through three separate components: (1) extrinsic nerves of the parasympathetic and sympathetic pathways; (2) intrinsic ganglia and nerves, which secrete a variety of neurotransmitters, including peptides; and (3) neuroendocrine cells (intraepithelial lymphocytes) that reside in the epithelium and release messengers onto the epithelial cells in a paracrine manner.<sup>17,21-23</sup> Many bacterial enterotoxins can induce intestinal secretion by cAMP or cGMP signal transduction.<sup>24</sup> Bacterial enterotoxins can stimulate release of mediators (such as substance P) from primary afferent neurons, which then affect enteric neurons, often propagating neurogenic inflammation.<sup>25</sup>

Preformed inflammatory mediators such as histamine, serotonin, or adenosine and newly synthesized mediators such as prostaglandins, leukotrienes, PAF, various cytokines, the inducible form of nitric oxide, and reactive oxygen metabolites can initiate intestinal secretion by directly stimulating the enterocyte and by acting on enteric nerves indirectly to induce neurotransmitter-mediator intestinal secretion.<sup>22</sup> For instance, when added to the T84 colonic cell line, the known mast cell mediators histamine, adenosine, and PGD<sub>2</sub> induce chloride secretion.<sup>26,27</sup> Prostaglandins of the E and F series can cause an increase in chloride secretion in intact tissue and isolated colonic cells.<sup>28,29</sup> Leukotrienes, PAF, and a number of cytokines have been shown to have no effect on T84 cell secretion but have a significant effect on electrolyte transport in intact tissue, suggesting that intermediate cell types may be involved in these secretory responses.<sup>30-32</sup>

The epithelial cell chloride secretory response occurs via prostaglandin- and adenosine-mediated increases in cellular cAMP, whereas histamine acts by H<sub>1</sub> receptor induction of phosphatidylinositol turnover, production of inositol triphosphate, and mobilization of intracellular calcium stores.<sup>22</sup> Lipoxygenase products (leukotrienes) are capable of activating a colonic secretory response and do not appear to involve the cyclic nucleotides or calcium ions.<sup>30</sup> Phagocyte-derived reactive oxygen mediators (ROMs) can induce colonic electrolyte secretion in vitro, suggesting that oxidants may contribute directly to the diarrhea associated with colitis.<sup>33</sup> Reactive oxygen species initiate the secretory response by increasing cellular cAMP or stimulating mesenchymal release of PGE<sub>2</sub> or prostacyclin, which in turn stimulates the epithelial cell or enteric neuron, respectively.<sup>33-36</sup> Sodium nitroprusside, an exogenous source of nitric oxide, stimulated an increase in chloride secretion in rat colon that was mediated by cyclooxygenase products and enteric neurons.<sup>37</sup> Table 15-1 summarizes inflammatory mediator-induced epithelial cell chloride secretion.

## ☉ ROLE OF INFLAMMATORY CELLS

Acute colitis rarely develops as a result of a simple cause or effect phenomenon but instead is influenced by many extrinsic and intrinsic host and microorganism factors. Inflammatory mediators released from mast cells and monocytic or granulocytic phagocytes cause intestinal chloride and water secretion and inhibit neutral sodium and chloride absorption.<sup>21,22,52</sup> Inflammatory cells, particularly the phagocytic granulocytes, play an important role in mucosal pathophysiology in cases of colitis.<sup>13,53</sup> Large numbers of these cells are observed on histopathologic examination of tissues from human and animal cases of colitis. Products of cell activation stimulate direct and

TABLE 15-1

<b>Inflammatory Mediators that Stimulate Epithelial Cell Chloride Secretion</b>		
<b>Mediator</b>	<b>Action</b>	<b>Reference</b>
Prostaglandin E <sub>2</sub>	Increases Cl secretion Decreases neutral NaCl absorption	38
Vasoactive intestinal peptide	Increases cAMP-mediated NaCl secretion	39
Endotoxin	Activates cholinergic nerves Increases Na absorption Increases cell membrane permeability	40 41
Serotonin	Increases fluid and electrolyte secretion	42
Interferon- $\gamma$	Decreases tight junctions and causes increase in cell membrane permeability	43
Interleukin-1 and interleukin-1 $\beta$	Increase prostaglandins E <sub>2</sub> and F <sub>1</sub> $\alpha$ and thromboxane B <sub>2</sub> .	44
Histamine (H <sub>1</sub> )	Increases Cl secretion via Ca-mediated pathways	26,45
Bradykinin	Increases Cl secretion through prostaglandin-mediated pathways	46,47
Reactive oxygen mediators	Increase Cl secretion	33, 48
Thromboxanes	Increase Cl secretion Decrease neutral NaCl absorption	49
Lipoxygenase products	Increase Cl secretion via prostaglandin-mediated pathways	50
Platelet-activating factor	Increases Isc (Cl secretion)	51
Adenosine	Increases Cl secretion	27

cAMP, Cyclic adenosine monophosphate.

indirect secretory responses in intestinal cells and tissues.<sup>21,22</sup> Products of phagocyte secretion may amplify the inflammatory signal or have effects on other target cells in intestine such as enterocytes and smooth muscle cells.

## ☞ ROLE OF PHAGOCYTE-DERIVED REACTIVE OXYGEN METABOLITES

The nicotinamide adenine dinucleotide phosphate (NADPH)-oxidase system of phagocytes (neutrophils, eosinophils, monocytes/macrophages) is a potent inducer of superoxide radicals used as a host defense mechanism to kill invading microorganisms.<sup>13</sup> During inappropriate stimulation such as

inflammation, trauma, or ischemia followed by reperfusion, increased levels of toxic oxygen species are produced, causing damage to host tissues. Engagement of any of several receptor and nonreceptor types including phagocytosis mediators, chemotactic agents, various cytokines, and microbial products can stimulate phagocytes.<sup>13</sup> Resident phagocytes or those recruited to colonic mucosa early in the disease process are considered to augment mechanisms causing fluid and electrolyte secretory processes, a so-called amplification process.<sup>54,55</sup>

Activation of the respiratory burst results in the production and release of large amounts of superoxide anion (O<sub>2</sub><sup>-</sup>) and H<sub>2</sub>O<sub>2</sub>.<sup>56</sup> In addition to these ROMs, activated phagocytes secrete peroxidase enzyme (myeloperoxidase from neutrophils and eosinophil peroxidase from eosinophils) into the extracellular space. The peroxidases catalyze the oxidation of Cl<sup>-</sup> by H<sub>2</sub>O<sub>2</sub> to yield HOCl, the active ingredient in household bleach products. The peroxidase-H<sub>2</sub>O<sub>2</sub>-halide system is the most cytotoxic system of the phagocytes; HOCl is 100 to 1000 times more toxic than O<sub>2</sub><sup>-</sup> or H<sub>2</sub>O<sub>2</sub>. HOCl is a nonspecific oxidizing and chlorinating agent that reacts rapidly with a variety of biologic compounds, including deoxyribonucleic acid (DNA), sulfhydryls, nucleotides, amino acids, and other nitrogen-containing compounds. HOCl reacts rapidly with primary amines to produce the cytotoxic N-chloramines. The mechanisms by which these substances damage cells and tissue remain speculative, but possibilities include direct sulfhydryl oxidation, hemoprotein inactivation, protein and amino acid degradation, and inactivation of metabolic co-factors of DNA.<sup>57</sup> Luminal perfusion of specific ROMs increased mucosal permeability, and serosal application caused increases in Cl<sup>-</sup> secretion in vitro.<sup>58</sup> Tissue myeloperoxidase activity, an index of tissue granulocyte infiltration, is used clinically and experimentally to assess degree of intestinal inflammation.<sup>59</sup> Myeloperoxidase activity is elevated in acute flare-ups of human inflammatory bowel disease and various animal models of acute colitis.<sup>59-61</sup> The acute inflammatory response in these conditions is characterized predominantly by neutrophils, the predominant source of myeloperoxidase activity. However, this assay measures total hemoprotein peroxidase, which includes monocyte and eosinophil peroxidase in addition to neutrophils.<sup>62</sup> Moreover, levels of peroxidase activity in equine circulating eosinophils are greater than in circulating neutrophils,<sup>63</sup> and this may apply to resident tissue eosinophils as well.

Arachidonic acid metabolites are thought to play a role in intestinal inflammation in diarrheal disease.<sup>22</sup> Elevated levels of these intermediate metabolites have been demonstrated in natural disease and experimental models of colitis and appear to parallel increases in ROMs in inflamed intestine.<sup>64</sup> Addition of H<sub>2</sub>O<sub>2</sub> or HOCl to rat colonic tissue in Ussing chambers induces PGE<sub>2</sub> release and active Cl<sup>-</sup> secretion.<sup>36,65</sup> Prostaglandins can stimulate increases in Cl<sup>-</sup> secretion in intact intestinal tissue<sup>35,65,66</sup> and in isolated colonic T84 cells.<sup>34,36</sup> Interactions between ROMs and mesenchymal release of PGE<sub>2</sub>/PGI<sub>2</sub> may be relevant to the mechanisms producing the diarrheic condition. Fibroblasts co-cultured or juxtaposed to colonic T84 cells greatly increased the Cl<sup>-</sup> secretory response to H<sub>2</sub>O<sub>2</sub> in vitro through the release of PGE<sub>2</sub>.<sup>34</sup> In addition, equine colonic mucosa has an increased sensitivity to endogenously released prostaglandin by exhibiting a significant secretory response under in vitro conditions.<sup>67</sup>

## ☞ ROLE OF ENDOTOXIN, MALNUTRITION, IMMUNODEFICIENCY, AND INTESTINAL MICROFLORA

### ENDOTOXIN

Endotoxin, the LPS component of the outer cell wall of gram negative bacteria, is present in large quantities in the large intestine of healthy horses.<sup>63,67</sup> The intact bowel forms an effective barrier to the transport of significant amounts of these highly antigenic toxins, but the diseased gut absorbs these macromolecules in large amounts, causing the subsequent adverse systemic effects that are often life threatening.<sup>68</sup> A complete review of endotoxemia and systemic inflammatory response syndrome (SIRS) is presented later in this chapter.

Endotoxins trigger mucosal immune cells and subsequent release of inflammatory mediators in cases of colitis. The first report of experimentally induced endotoxemia described clinical signs and hematologic findings that closely paralleled those reported for severe colitis in horses.<sup>69</sup> Studies in which endotoxin was administered intravenously in human beings and laboratory animals caused significant dose-related gastrointestinal changes, ranging from mild diarrhea to bloody, watery diarrhea.<sup>70,71</sup> In vitro studies on the effects of endotoxin on intestinal water and electrolyte transport in adult male rats showed a significant decrease in net colonic sodium absorption and increased colonic permeability.<sup>41</sup> In animal models of protein energy deficiency, endotoxin-induced mortality increased compared with that of well-nourished control animals. Endotoxin depresses lymphocyte responses to specific mitogens.<sup>72</sup> Thus the adverse effects of malnutrition and endotoxin are mutually aggravating. In horses endotoxin negatively affects gastrointestinal motility, including in the cecum and right ventral colon, and perfusion.<sup>73</sup>

### IMMUNODEFICIENCY

The importance of a normal immune system to the defense of the mucosal surface of the gastrointestinal tract is evident in the immunosuppressed state. Primary immunodeficiencies affecting the gastrointestinal tract are well documented. Common agammaglobulinemia is the most frequently reported gastrointestinal disease and causes B cell deficiency-associated giardiasis in other species.<sup>74</sup> In horses severe combined immunodeficiency can result in diarrhea secondary to adenovirus, coronavirus, and *Cryptosporidium* infection.<sup>75,76</sup> Interestingly, selective immunoglobulin A (IgA) deficiency rarely results in intestinal disease because of a speculated increase in mucosal IgM response. However, combined IgA and IgM deficiencies with a higher incidence of intestinal disease occur. A selective deficiency of secretory IgA has been associated with intestinal candidiasis in other species. Certain mucosal pathogens may enhance their pathogenicity by producing IgA proteases.<sup>74</sup> Acquired immunodeficiency or immunosuppression in adults can result from infectious diseases (particularly viral), nutritional deficiencies, aging phenomenon, and drugs (corticosteroids, azathioprine, cyclophosphamide). Chronic salmonellosis was documented secondary to adult-onset B cell deficiency in a Quarter Horse.<sup>77</sup>

## NUTRITIONAL DEFICIENCIES

Nutrition is a critical determinant of immunocompetence and risk of illness.<sup>78</sup> Impaired systemic and mucosal immunity contributes to an increased frequency and severity of intestinal infections observed in cases of undernourishment. Abnormalities occur in cell-mediated immunity, complement system, phagocytic function, mucosal secretory antibody response, and antibody affinity. Morbidity caused by diarrheal disease is increased particularly among individuals with stunted growth rate because of malnourishment.<sup>79</sup> The critical role of several vitamins and minerals in immunocompetence has been substantiated in animals deprived of one dietary element and findings in human patients with single-nutrient deficiency. Nutritional deficiency can cause increased colonization of the intestine with microorganisms, alter the symbiotic characteristics of resident intestinal bacterial populations, and impair defenses of the gastrointestinal tract, allowing increased risk of systemic spread of infection and absorption of macromolecules (in particular, endotoxin).

### INTESTINAL MICROFLORAE

Indigenous microflorae greatly impede colonization of the gastrointestinal mucosa by pathogenic organisms. The ability of a potential pathogen to initiate an infection depends on its ability to breach the mucosal epithelial barrier. Resident microbes protect against pathogens by producing bacteriocidal substances and competing for available mucosal sites and nutrients.<sup>80</sup> In addition, microflorae are important for development of the adaptive immune system.<sup>81</sup> Alterations in the gastrointestinal microflorae, or their interaction with the innate immune response, can lead to disorders such as inflammatory bowel disease and the irritable bowel syndrome in humans.<sup>82</sup> In fact, hyper-responsiveness to commensal bacteria appears vital to the development of inflammatory bowel disease in humans.<sup>83</sup> Whether a similar association is present in horses is currently unknown.

### FACTORS AFFECTING MOTILITY

Disturbances in motility patterns occur during inflammatory diseases of the colon, but the role of motility alterations in the pathogenesis of diarrhea remains unclear. Invasive bacteria cause characteristic motor patterns in the colon consisting of rapid bursts of motor activity that appear to decrease transit time through the large intestine. The result is reduced clearance of bacteria from the large intestine, which may contribute to the virulence of the organism.<sup>84</sup> Absorption of endotoxin and the release of inflammatory mediators such as prostaglandins disrupt the motility patterns of the large intestine, resulting in less-coordinated contractions, and may contribute to the alterations in motility seen with invasive bacteria. Although the effect of endotoxin and prostaglandins on transit time is not profound, the disruption of coordinated activity may play a role in causing diarrhea.<sup>85</sup> Thorough mixing and prolonged retention time of ingesta are important not only in microbial digestion of nutrients but also in absorption of microbial by-products and fluid.<sup>23</sup> The ingesta is viscous and therefore must be mixed to bring luminal ingesta in contact with the mucosa for absorption.<sup>86</sup> In addition, poor mixing increases the thickness of the unstirred layer, decreasing contact of ingesta with the mucosa and decreasing absorption.<sup>23</sup>

Progressive motility must be present, however, if a diarrheal state is to occur.<sup>23</sup> Ileus may be accompanied by increased fluid in the lumen of the large intestine, but without progressive motility the fluid is not passed. Frequently, acute colitis causes a period of ileus characterized by scant stool. Diarrhea is apparent only when motility returns and the ingesta is passed. Increased progressive motility has been suggested to cause diarrhea by decreasing transit time and is thought to play a role in irritant catharsis and in the mechanism of action of some laxatives.<sup>87</sup> Irritation and distention increase motility and may well decrease transit time, but increased secretion also is thought to contribute to diarrhea caused by these substances.<sup>88</sup>

## PATHOPHYSIOLOGY OF MUCOSAL INJURY AND REPAIR

Anthony T. Blikslager

### ☞ MUCOSAL BARRIER FUNCTION

To gain an appreciation of the mechanisms whereby the mucosa is injured and subsequently repaired, it is important to understand how the integrity of the mucosa is physiologically regulated. Regulation of mucosal integrity is referred to as *mucosal barrier function*, which is vital because it prevents bacteria and associated toxins from gaining access to subepithelial tissues and the circulation. However, the mucosa has two conflicting functions: It must serve as a protective barrier while continuing to absorb solutes necessary to maintain well-being of the host. This conflict is most notable at the intercellular (paracellular) space, which allows passage of select solutes and water<sup>1-4</sup> but which does not admit large molecules, including bacterial toxins.<sup>5</sup> The paracellular space is almost exclusively regulated by the tight junction,<sup>6</sup> which is the interepithelial junction at the apical-most aspect of paracellular space. Although these tight junctions were originally viewed as inert cellular adhesion sites, it has become clear in recent years that tight junction permeability is dependent on tissue-specific molecular structure and regulated by a complex array of intracellular proteins and the cytoskeleton. Tight junctions consist of a group of transmembrane proteins that interdigitate from adjacent cells. Although occludin was originally thought to be the predominant tight junction transmembrane protein, a group of proteins termed *claudins* appear to “fine tune” the function of the tight junction. For example, select claudins are responsible for the relative porosity of the barrier to select electrolytes based on their charge within the paracellular space.<sup>7</sup> These transmembrane proteins interact with the cytoskeleton via a series of intracellular proteins, including zonula occludens (ZO)-1, ZO-2, ZO-3, cingulin, and others.<sup>8</sup> In addition, local regulatory proteins such as the small GTPase Rho are critical to tight junction function. In general, the relative contractile state of the actin cytoskeleton determines the degree to which tight junctions are open or closed, but the complexities of regulation of this process are poorly understood.<sup>9,10</sup>

The most sensitive measure of mucosal barrier function is transepithelial electrical resistance, which is measured by mounting mucosa in an *in vitro* system called an Ussing chamber. This measurement is largely a reflection of the permeability of mucosa to ions.<sup>11,12</sup> There are two routes ions

may follow when traversing epithelium: transcellular and paracellular.<sup>5</sup> Since cell membranes have a resistance to passive flow of ions 1.5 to 3 log units greater than that of the epithelium as a whole, measurements of transepithelial resistance largely reflect the resistance of the paracellular space and in particular the tight junctions that regulate paracellular flow of ions.<sup>12</sup> Because tight junctions differ in structure from different portions of the mucosa,<sup>13</sup> measurements of transepithelial resistance reflect the net resistance of epithelium of variable permeability within a given tissue. For example, tight junctions in the intestinal glandular structures called *crypts* are leakier than those in the surface epithelium because of fewer and less-organized tight junction strands.<sup>11,14</sup> Conversely, surface epithelium has a greater number of well-organized tight junction strands that result in epithelium with a relatively high resistance.<sup>11</sup> This correlates well with the absorptive function of epithelium located on the mucosal surface and the secretory function of crypt epithelium. Structure of tight junctions also varies with the segment of intestine. For example, tight junctions have more strands in the ileum than the jejunum, which is reflected by a higher transepithelial resistance in the ileum.<sup>15</sup> In addition, cells are more closely apposed at the level of the tight junction within the colon. This is in keeping with the largely absorptive role of the colon and is advantageous given the hostile microbial environment of the colon.

### GASTRIC MUCOSAL BARRIER FUNCTION

There are four regions of the stomach, based on the type of mucosal lining (in an oral to aboral order): nonglandular stratified squamous epithelium, cardiac epithelium, proper gastric mucosa, and pyloric mucosa.<sup>16</sup> Stratified squamous epithelium has distinct differences in terms of barrier function compared with the remainder of the gastrointestinal tract. This epithelium has baseline transepithelial resistance measurements of approximately 2000 to 3000  $\Omega\text{-cm}^2$ , which is an order of magnitude higher than the adjacent cardiac mucosa.<sup>17,18</sup> Thus the stratified squamous mucosa is exceptionally impermeable. This is the only mechanism this mucosa has to defend itself against injury. The stratified squamous epithelium consists of four layers: the outer *stratum corneum*, *stratum transitionale*, *stratum spinosum*, and the basal *stratum germinativum*. However, not all layers contribute equally to barrier function, which is largely composed of interepithelial tight junctions in the *stratum corneum*, and mucosubstances secreted by the *stratum spinosum*.<sup>17,19</sup> The relative impermeability of stratified squamous mucosa can be demonstrated by the effects of HCl on this type of epithelium *in vitro*, which has very little effect until it reaches a pH of 2.5 or below.<sup>18</sup> Thus, although the majority of the literature on equine ulceration pertains to the effects of HCl and inhibitors of HCl secretion,<sup>20-23</sup> other factors may be critical to the development of gastric ulcer disease.

The site of HCl secretion (proper gastric mucosa) is also protected from so-called back-diffusion of  $\text{H}^+$  ions by a relatively high transepithelial electrical resistance (compared with cardiac mucosa), but there are also a number of other critical mechanisms to prevent acid injury. The gastric mucosa secretes both mucus and bicarbonate, which together form a  $\text{HCO}_3^-$ -containing gel that titrates acid before it reaches the lumen.<sup>11,24</sup> The mucus layer is principally formed by glycoproteins (mucins) secreted by goblet cells but also includes other gastric secretions and sloughed epithelial cells. Mucins consist of core peptides with

a series of densely packed O-linked polysaccharide side-chains that, once secreted, become hydrated and form a viscoelastic gel. However, the mucus layer does not form an absolute barrier to back-diffusion of acid. Thus, for acid that does back diffuse into the gastric mucosa, epithelial  $\text{Na}^+/\text{H}^+$  exchangers are capable of expelling  $\text{H}^+$  once the cell reaches a critical pH.<sup>11</sup>

Recent studies have renewed interest in the protective mechanisms of mucus because of the discovery of a group of compounds secreted by goblet cells called the *trefoil peptides*. The name of these peptides is derived from a highly conserved cloverleaf structural motif, which confers substantial resistance to degradation by proteases, including pepsin. There are three known members of this group, pS2, spasmolytic polypeptide (SP), and intestinal trefoil factor (ITF), the latter of which is solely secreted by goblet cells in the small and large intestine. Both pS2 and SP are secreted by goblet cells within the stomach and are believed to intercalate with mucus glycoproteins, possibly contributing to the barrier properties of mucus.<sup>25</sup> These peptides also play a critical role in repair of injured mucosa.

### ADAPTIVE CYTOPROTECTION

An additional mucosal function that serves to reduce the level of injury is adaptive cytoprotection, wherein application of topical irritants to gastric mucosa results in subsequent protection of mucosa in response to repeated exposure to damaging agents. For example, pretreatment with 10% ethanol protected against mucosal damage in response to subsequent application of absolute ethanol, and this effect was abolished by treatment with the cyclooxygenase (COX) inhibitor indomethacin.<sup>26</sup> The cytoprotective effects of prostaglandins have been demonstrated directly in studies wherein pre-administration of prostaglandins protected gastric mucosa from damage by agents such as concentrated hydrochloric acid and hypertonic saline.<sup>27</sup> Prostaglandins appear to be cytoprotective in the stomach at doses lower than those used to inhibit gastric acid secretion, ruling out a simple antacid mechanism.<sup>28</sup> Although not fully characterized, cytoprotection has been attributed in part to prostaglandin-stimulated mucus production.<sup>29</sup> An associated beneficial effect of prostaglandins is the increased production of bicarbonate, which is trapped within mucus on the surface of the mucosa.<sup>30,31</sup> Interestingly,  $\text{PGE}_2$  appears to lose its cytoprotective activity in the presence of the mucolytic agent *N*-acetylcysteine. Attention has also been directed at enhanced mucosal blood flow as a potential mechanism for prostaglandin-mediated cytoprotection. For example, pretreatment with prostaglandin  $\text{I}_2$  ( $\text{PGI}_2$ ) protected against ethanol-induced mucosal damage as a result of increased mucosal blood flow.<sup>32</sup> In addition,  $\text{PGE}_2$ , which is also cytoprotective despite the fact that it does not increase blood flow, prevents vascular stasis associated with irritant-induced vascular damage by inhibiting neutrophil adherence to damaged endothelium.<sup>33,34</sup>

Sensory nerves distributed throughout gastrointestinal mucosa have also been implicated in cytoprotective mechanisms. As an example of their importance in mucosal cytoprotection, pretreatment of newborn rats with capsaicin (which dose-dependently destroys sensory nerves) renders the mature rats more susceptible to gastric injury.<sup>35</sup> Alternatively, use of a low dose of capsaicin, which stimulates rather than destroys sensory nerves, protects gastric mucosa against injurious agents.<sup>36,37</sup> Sensory nerves contain neuropeptides such as calcitonin-gene related peptide (CGRP) and substance P, which may play a protective role via vascular mechanisms. For

instance, CGRP stimulates increased gastric blood flow, which is theorized to reduce injury in much the same way as prostaglandins. In fact, recent studies suggest that the roles of prostaglandins and CGRP in gastric cytoprotection are intimately intertwined. In particular,  $\text{PGI}_2$  is believed to sensitize sensory nerves following treatment with a mild irritant, with resultant increases in CGRP release and mucosal flow. Similar studies have shown that antagonists of CGRP inhibit the cytoprotective action of  $\text{PGE}_2$ .<sup>38</sup> Another neural mediator, nitric oxide, has also been implicated in adaptive cytoprotection. Interestingly, nitric oxide has a number of actions that are similar to those of prostaglandins, including maintenance of mucosal blood flow.<sup>39</sup>

## ☞ INTESTINAL BARRIER FUNCTION

Regulation of barrier function in the intestine is not as well characterized as that of the stomach, although mechanisms of barrier function, including secretion of mucus and regulation of mucosal blood flow, are presumed to be similar. The proximal duodenum also has to protect itself from acid damage as it receives gastric contents, and this involves secretion of mucus and bicarbonate in much the same way as the stomach. One other mechanism that helps both the stomach and the intestine to maintain mucosal barrier function is the speed with which the mucosa repairs. Thus, for a defect to develop in the mucosal barrier, injurious factors have to outpace mucosal recovery. Such recovery initially involves epithelial migration across denuded regions of basement membrane (restitution).<sup>25</sup> This process is so rapid that epithelial defects may be resurfaced within minutes. For example, in bile salt-injured equine colon, denuded surface mucosa was completely covered by restituting epithelium within 180 minutes.<sup>40</sup> In the small intestine intestinal villi greatly amplify the surface area of the mucosal luminal surface, which in turn takes far longer to resurface with restituting epithelium once it has become denuded.<sup>41</sup> However, intestinal villi are able to dramatically reduce the denuded surface area by contracting.<sup>42</sup>

## ☞ MECHANISMS OF GASTRIC INJURY

### STRATIFIED SQUAMOUS MUCOSAL ULCERATION

Although the stratified squamous epithelium is relatively impermeable to HCl, there are a number of factors that can dramatically enhance the damaging effects of HCl in this epithelium. In particular, bile salts and short chain fatty acids (SCFAs) are capable of breaking down the squamous epithelial barrier at an acid pH, thereby exposing deep layers to HCl, with subsequent development of ulceration.<sup>18,43</sup> Relatively high concentrations of SCFA normally exist within the equine stomach as a result of microbial fermentation.<sup>17</sup> These weak acids penetrate squamous mucosa and appear to damage  $\text{Na}^+$  transport activity principally located in the stratum germinativum. Bile salts also may be present in the proximal stomach as a result of reflux from the duodenum. Although such reflux has a relatively high pH, it appears that bile salts adhere to stratified squamous epithelium, becoming lipid soluble and triggering damage once the pH falls below 4.<sup>44</sup> Diet and management (e.g., periods of fasting) also play crucial roles in the development of conditions conducive to gastric ulceration. Typically, there is a pH gradation in horses from proximal to

distal compartments of the stomach, with the lowest pH values in the distal stomach.<sup>45</sup> However, during periods of fasting, this stratification is disrupted such that low pH values may be recorded in the proximal stomach.<sup>46</sup> Fasting conditions also increase the concentration of duodenal contents within the proximal stomach, particularly bile.<sup>44</sup>

### ULCERATION OF PROPER GASTRIC MUCOSA

Proper gastric mucosa is exposed to injurious agents, including pepsin, bile, and acid. The latter is constantly secreted by parietal cells in the horse as an adaptation to near-continuous intake of roughage,<sup>16</sup> but it is tightly regulated by enterochromaffin-like (ECL) cells within the proper gastric mucosa and G- and D-cells, which are present within the pyloric mucosa. Acid secretion is amplified by ECL-released histamine, which interacts with H<sub>2</sub> receptors on parietal cells, and G-cells, which release the prosecretory hormone gastrin. A combination of histamine and gastrin can have a synergistic effect on parietal cell gastric secretion, because these mediators have distinct receptors and second messengers. On the other hand, D-cells are sensitive to an acidic environment and release somatostatin, which inhibits acid secretion.<sup>47</sup> Nonetheless, gastric mucosa may be exposed to acid for prolonged periods of time, particularly in horses that are extensively meal fed and which do not have the benefit of roughage, which tends to buffer stomach contents.<sup>44,47</sup>

Aside from peptic ulceration, induced by combinations of acid and pepsin, research in the human field has revealed the tremendous importance of *Helicobacter pylori* in inducing ulceration. Infection with this organism has the effect of raising gastric pH because of disruption of gastric glands, but it also induces an inflammatory reaction that causes damage.<sup>48</sup> However, to date there is very little evidence that this organism is involved in gastric ulcers in horses. In the absence of a known role for infectious agents in gastric ulceration in animals, ulceration likely develops from injurious factors similar to those found in the proximal stomach, including gastric acid and bile. However, some factors that are important to induction of squamous epithelial ulceration may not be important in development of proper gastric mucosal ulceration. For example, feed deprivation and intensive training reproducibly induce squamous epithelial ulceration in horses but have little effect on proper gastric mucosa in horses.<sup>49</sup> Gastric acid likely plays a key role, whereas other factors, such as nonsteroidal anti-inflammatory drugs (NSAIDs), serve to reduce gastric defense mechanisms. In particular, inhibition of prostaglandin production would reduce mucus and bicarbonate secretion while also reducing gastric mucosal blood flow.<sup>50</sup> Some of the NSAIDs also have a topical irritant effect, although this appears to be of minor significance, because the route of administration (oral or parenteral) seems to have little influence on development of ulceration.<sup>51</sup>

The source of prostaglandins responsible for gastric protection was originally assumed to be COX-1, because this COX isoform is constitutively expressed in gastric mucosa, whereas COX-2 is not expressed in the stomach unless it is induced by inflammatory mediators. However, mice in which the COX-1 gene has been knocked out fail to develop spontaneous gastric lesions,<sup>52</sup> possibly because of compensatory increases in prostaglandin production by COX-2.<sup>53</sup> This concept supports recent data indicating that inhibition of both COX isoforms is required to induce gastric ulceration.<sup>54</sup> From a clinical perspective this

data indicates that drugs selective for either COX-1 or COX-2 may be less ulcerogenic in the horse because they allow the uninhibited COX isoforms to continue to produce protective prostanooids. Because COX-2 elaborates prostaglandins induced by inflammatory stimuli, preferential or selective inhibitors of COX-2 may be particularly useful because of their ability to serve as anti-inflammatory agents that are less ulcerogenic.<sup>55</sup>

### ☞ INTESTINAL ISCHEMIA AND REPERFUSION INJURY

The most notable cause of intestinal mucosal injury in horses, particularly those suffering from colic, is ischemia. Initially, it seems intuitive that reducing gastrointestinal blood supply would injure the mucosa. However, the anatomy of the gastrointestinal tract and the differing structure of the intestinal mucosa at various anatomic locations have a significant influence on the extent of mucosal injury. Furthermore, ischemic injury may be induced by several mechanisms, including occlusion of arterial supply by a thrombus, strangulation of intestinal vasculature, and generalized reduction in blood flow associated with various shock states. In addition, a number of seemingly distinct mechanisms of intestinal injury, such as intestinal distention, also trigger mucosal injury via an ischemic mechanism. Finally, reperfusion injury may also influence the extent of mucosal injury following an ischemic episode, and it has been proposed as a potential site of therapeutic intervention.<sup>56,57</sup> Thus it is critical that the mechanisms of ischemia-reperfusion injury be understood in order to develop an understanding of the severity of various clinical conditions and begin to formulate a therapeutic approach to diseases characterized by this devastating form of injury.

### REGULATION OF INTESTINAL BLOOD FLOW

The intestinal circulation is capable of closely regulating blood flow during periods of low systemic perfusion pressure.<sup>58,59</sup> Local regulation of resistance vessels within the microvasculature is particularly prominent; metabolic end products of ATP cause continued dilation of resistance vessels despite reductions in systemic arterial pressure. This results in continued perfusion of gastrointestinal tissues during the early stages of shock; other organs, such as skeletal muscle, undergo massive shunting of blood as a result of marked increases in the resistance of resistance vessels. The reasons for these differences in regulation are not entirely clear but may be related to the relatively high level of energy required to fuel the intestinal mucosa and the serious systemic effects of breaches in the mucosal barrier. However, as blood flow falls below a critical level, regulatory systems are no longer effective and oxygen uptake by the gastrointestinal tissue decreases, culminating in tissue damage.<sup>58</sup>

The villus tip is the most susceptible region affected by hypoxia in the equine small intestine, largely because of the countercurrent exchange mechanism of blood flow in the small intestinal villus.<sup>58</sup> This countercurrent exchange mechanism is attributable to the vascular architecture, which consists of a central arteriole that courses up the core villus, arborizes at the tip, and is drained by venules coursing down the periphery of the villus.<sup>60</sup> As oxygenated blood flows into the central arteriole, oxygen tends to diffuse across to the adjacent venules, which are flowing in the opposite direction. This series of events takes place along the length of the villus, resulting in a villus tip that is relatively hypoxic even under

normal conditions. Furthermore, when blood flow is reduced, as occurs in hypovolemic or septic shock, the countercurrent exchange of oxygen is enhanced, and the tip becomes absolutely hypoxic.<sup>58</sup> This mechanism might explain why the small intestinal mucosa is more susceptible to ischemic injury, compared with the colon, which has no villi. For example, the duration required to produce severe morphologic damage to the equine colon is approximately 25% longer than that required to produce similar damage to the small intestine.<sup>61</sup>

### ISCHEMIC EPITHELIAL INJURY

Intestinal mucosal epithelium is very susceptible to hypoxia because of the relatively high level of energy required to fuel the Na<sup>+</sup>/K<sup>+</sup>-ATPase that directly or indirectly regulates ion and nutrient flux. The first biochemical event to occur during hypoxia is a loss of oxidative phosphorylation. The resulting diminished ATP concentration causes failure of the energy-dependent Na<sup>+</sup>/K<sup>+</sup>-ATPase, resulting in accumulation of sodium and subsequently intracellular water. The pH of the cytosol drops as lactic acid and inorganic phosphates accumulate from anaerobic glycolysis. The falling pH damages cell membranes, including lysosomal membranes, resulting in the release and activation of lysosomal enzymes into the cytosol, further damaging cellular membranes. Damage to the cell membrane allows the accumulation of high concentrations of calcium in the cytosol, which activates calcium-dependent degradative enzymes.<sup>62</sup> These events result in cytoplasmic blebbing of the basal membrane, with subsequent detachment of cells from the underlying basement membrane.

Recent studies on epithelial injury during ischemia suggest that the majority of epithelial cells undergo programmed cell death (apoptosis) during ischemia and reperfusion rather than necrosis, allowing retention of reusable components of irreversibly injured cells.<sup>63</sup> In one study 80% of detached epithelium during small intestinal ischemia-reperfusion underwent apoptosis.<sup>64</sup> Although the most obvious result of apoptosis is loss of surface epithelium, a number of cells on the lower portion of the villus (in the small intestine) and cells within the crypts may also undergo apoptosis that only becomes evident up to 24 hours following reperfusion of ischemic tissue.<sup>65</sup>

TABLE 15-2

#### Grading System for Ischemia-Reperfusion Injury in Small Intestinal Mucosa

Grade	Description
1	Separation of epithelium at the tip of the villus, creating a small space between epithelium and basement membrane called <i>Grüenhagen's space</i>
2	Loss of epithelium from the tip of the villus
3	Loss of epithelium from the upper third of the villus
4	Complete loss of villus epithelium
5	Injury or loss of epithelium within the crypt in addition to complete loss of villus epithelium

Adapted from Chiu CJ, McArdle AH, Brown R, et al: Intestinal mucosal lesion in low-flow states. 1. A morphological, hemodynamic, and metabolic reappraisal, *Arch Surg* 101:478–483, 1970.

Morphologic changes observed in ischemic-injured small intestinal mucosa follow a similar sequence regardless of whether injury is induced by ischemia alone or ischemia-reperfusion (Table 15-2).<sup>66</sup> Initially, epithelium separates from the underlying basement membrane, forming a fluid-filled space termed *Grüenhagen's space* (Figure 15-3). The mechanism of fluid accumulation in this space is not entirely understood but may result from continued epithelial absorption of NaCl and water, before it has fully detached from neighboring epithelial cells. This fluid accumulation likely exacerbates epithelial separation from the basement membrane. Subsequently, epithelium progressively sloughs from the tip of the villus toward the crypts, which are the last component of the intestinal mucosa to become injured.<sup>67-69</sup> This likely relates to the vascular architecture, because crypts receive a blood supply that is separate from the vasculature involved in the villous countercurrent exchange mechanism. The early morphologic changes observed in the equine large colon during ischemia are somewhat different from those described in the equine small intestine because of the lack of intestinal villi. However, as might be expected, the more superficially located surface cells are sloughed before those in crypts.<sup>61,70</sup> The orderly progression of tissue injury has been used by one group of investigators to accurately predict survival in horses with large colon volvulus. Biopsies were taken from the pelvic flexure, which accurately reflects mucosal changes along the length of the colon,<sup>71</sup> and histologically examined for the width of the crypts and intercrypt interstitial space. The latter measurements were expressed as an interstitium: crypt width (I:C) ratio. Nonviable colon was defined as that which had greater than 60% loss of crypt and an I:C ratio greater than 3. Using this methodology, survival was correctly predicted in 94% of horses.<sup>72</sup>

## STRANGULATING OBSTRUCTION

Since the dramatic decline in *Strongylus vulgaris*-induced colic, which was frequently associated with infarction of intestinal arterial blood supply,<sup>73</sup> the vast majority of ischemic lesions are associated with strangulating obstruction. Therefore it is important to consider mechanisms of ischemic injury in horses with naturally occurring strangulating lesions. The majority of experimental work has assessed either complete ischemia (complete occlusion of the arterial blood supply)<sup>61</sup> or low-flow ischemia (reduction of arterial blood flow).<sup>74,75</sup> However, during intestinal strangulation a disparity between the degree of occlusion of the veins and arteries occurs whereby veins are occluded before arteries because of differences in compliance of vascular walls. Thus strangulating lesions are typically hemorrhagic (hemorrhagic strangulating obstruction) because the arteries continue to supply blood to tissues that have little or no venous drainage. This results in ischemic injury, as previously outlined, but also in tremendous congestion of the tissues. Such hemorrhagic congestion has two opposing effects: It disrupts tissue architecture, including the mucosa and its epithelium, but it continues to provide oxygenated blood to the tissues during much of the ischemic episode. In contrast, when strangulation results in sudden cessation of arterial blood flow (ischemic strangulating obstruction), tissues appear pale, and the mucosa rapidly degenerates because of a complete lack of oxygenated blood.<sup>69</sup> From a clinical standpoint, this makes it difficult to assess the degree of mucosal injury in horses with strangulating injuries, because intestine that may look nonviable (dark red) may in fact have less mucosal injury than that of ischemic strangulated intestine.<sup>76</sup>

An additional consideration in clinical strangulating obstruction is the degree of ischemia that may be induced by intestinal distention. For example, experimental distention (18 cm of H<sub>2</sub>O for 2 hours) and decompression (2 hours) of jejunum resulted in a significant increase in microvascular permeability and a significant decrease in tissue oxygenation similar to that which would be expected with low-flow ischemia.<sup>77,78</sup> In particular, microscopic evaluation of vasculature revealed capillary endothelial cell damage and local edema

formation.<sup>79</sup> These data suggest that distended intestine proximal to an obstruction may undergo mucosal injury despite its relatively normal appearance. Indeed, in one study intraluminal pressures greater than 15 cm H<sub>2</sub>O in naturally occurring cases of colic correlated with a poor prognosis for survival.<sup>80</sup>

## REPERFUSION INJURY

Although it has recently been taken for granted that reperfusion of ischemic tissues results in exacerbation of mucosal injury, it should be remembered that mechanisms underlying intestinal reperfusion injury have been largely defined in laboratory animals under specific conditions.<sup>81-85</sup> On the other hand, studies on reperfusion injury in horses have had some conflicting results.<sup>67,75,86</sup> This may be attributable to the way in which the studies have been performed. In particular, the type of ischemia used in most laboratory animal studies has been low-flow ischemia (in which the blood flow is typically reduced to 20% of baseline flow), whereas studies in horses have used a number of different ischemic models, including various types of strangulating obstruction. Although strangulating obstruction is of great clinical relevance, this type of ischemic insult is less likely to develop into reperfusion injury.<sup>67,87,88</sup> Conversely, low-flow ischemia appears to prime tissues for subsequent injury once the tissue is reperfused, and there is considerable evidence to support the presence of reperfusion injury in horses following low-flow ischemia.<sup>74,75,79,89</sup> Nonetheless, low-flow ischemia may not be a common clinical entity.

In addition to the type of ischemia, there are other factors involved in priming tissues for reperfusion injury, including species and anatomic-specific variation in oxidant enzyme and neutrophil levels (Table 15-3). For example, the foal appears to have very low levels of small intestinal xanthine oxidase, an enzyme that has been shown to play a critical role in triggering reperfusion injury in laboratory animals,<sup>83,84,95</sup> whereas adult levels are much greater, particularly in the proximal small intestine.<sup>94</sup> In addition, horses appear to have low numbers of resident neutrophils in the intestinal mucosa,<sup>96</sup> and it is this population of neutrophils (rather than those recruited from the circulation) that appear to be most critical for induction

TABLE 15-3

### Comparison of Mean Levels of Xanthine Oxidase/Xanthine Dehydrogenase (XO/XDH) and Myeloperoxidase (as an Indication of Granulocyte Numbers) in the Small Intestine of Various Species

Species	Intestinal Segment	Total XO/ XDH (mU/g Tissue)	Myeloperoxidase (U/g Tissue)	Reference
Cat (adult)	Jejunum	80	12	86, 90
	Ileum	NR	NR	
Rat (adult)	Jejunum	405-523	1.9	91, 92
	Ileum	150	NR	91, 93
Pig (6-8 weeks)	Jejunum	3.4 (0)*	NR	91
	Ileum	0.4 (0.9)*	2.2	91

NR, Not reported.

of reperfusion injury.<sup>85</sup> However, studies demonstrating reperfusion injury in the equine colon following low-flow ischemia have shown significant accumulation of neutrophils within the mucosa.<sup>74</sup> Therefore a complete understanding of mechanisms of neutrophilic infiltration and the mechanisms whereby they damage tissue will require further study.

Reperfusion injury is initiated during ischemia when the enzyme xanthine dehydrogenase is converted to xanthine oxidase, and its substrate, hypoxanthine, accumulates simultaneously as a result of adenosine triphosphate (ATP) utilization (Figure 15-4).<sup>56,97</sup> However, there is little xanthine oxidase activity during ischemia, because oxygen is required as an electron acceptor. During reperfusion xanthine oxidase rapidly degrades hypoxanthine in the presence of oxygen, producing the superoxide radical as a by-product.<sup>56</sup> The superoxide radical contributes to oxidative tissue damage and, most important, activates neutrophil chemoattractants.<sup>83,84</sup> Thus inhibition of xanthine oxidase in feline studies of intestinal ischemia/reperfusion injury prevents infiltration of neutrophils and subsequent mucosal injury.<sup>82,83</sup> However, inhibition of xanthine oxidase has had no effect on ischemia/reperfusion injury in equine small intestine<sup>86</sup> and colon,<sup>98</sup> suggesting that either reperfusion injury is simply a continuation of injury initiated during ischemia, as suggested in some equine studies,<sup>62</sup> or that the classic reperfusion injury pathway is activated by alternate sources of ROMs. The latter has been suggested by studies in feline models of ischemia/reperfusion injury, in which the source of a significant proportion of ROMs is unknown, and independent of xanthine oxidase and neutrophils.<sup>82</sup>

In a veterinary review of the pathogenesis of intestinal reperfusion injury in the horse, the concept of a therapeutic window wherein treatment of reperfusion injury would be beneficial was suggested.<sup>56</sup> The basis of this concept is that there are certain conditions under which ischemic injury is minimal and that tissues are severely damaged during reperfusion.<sup>87</sup> Thus, under conditions of low-flow ischemia, very little injury is demonstrated during 3 hours of ischemia, but remarkable injury occurs during 1 hour of reperfusion.<sup>82-84</sup>

**FIGURE 15-4** Intestinal reperfusion injury cascade. Reperfusion injury is initiated by elaboration of superoxide by metabolism of hypoxanthine by xanthine oxidase and subsequent infiltration of neutrophils.

However, a therapeutic window may not exist under conditions of strangulating obstruction wherein severe injury occurs during ischemia and minimal injury occurs during reperfusion.<sup>91</sup> This in turn greatly reduces the clinician's ability to ameliorate ischemia-reperfusion injury with treatments such as anti-oxidants at the time of reperfusion.

## MECHANISMS OF GASTROINTESTINAL MUCOSAL REPAIR

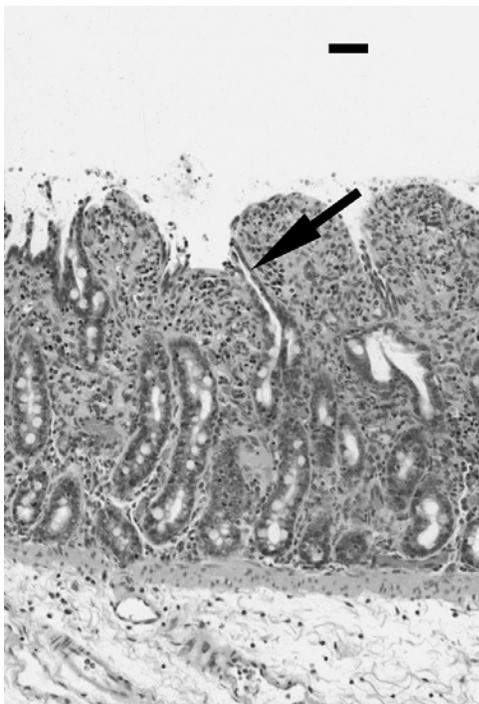

### GASTRIC REPARATIVE MECHANISMS

Mechanisms of gastric repair are highly dependent on the extent of injury. For instance, superficial erosions can be rapidly covered by migration of epithelium adjacent to the wound, a process termed *epithelial restitution*. However, ulceration (full thickness disruption of mucosa and penetration of the muscularis mucosa) requires repair of submucosal vasculature and ECM. This is initiated by formation of granulation tissue, which supplies connective tissue elements and microvasculature necessary for mucosal reconstruction. Connective tissue elements include proliferating fibroblasts that accompany newly produced capillaries that form from proliferating endothelium. Recent studies indicate that nitric oxide is critical to both of these processes,<sup>39,99</sup> which likely explains the reparative properties of nitric oxide in the stomach.<sup>100</sup>

Once an adequate granulation bed has been formed, newly proliferated epithelium at the edge of the wound begins to migrate across the wound. In addition, gastric glands at the base of the ulcer begin to bud and migrate across the granulation bed in a tubular fashion.<sup>101</sup> Epidermal growth factor is expressed by repairing epithelium and appears to facilitate these processes.<sup>102</sup> In addition, these events are facilitated by a mucoid cap, which retains reparative factors and serum adjacent to the wound bed.<sup>50</sup> Once the ulcer crater has been filled with granulation tissue and the wound has been re-epithelialized, the subepithelial tissue remodels by altering the type and amount of collagen. Despite the remodeling process, ulcers tend to recur at sites of previous ulceration, and there is the concern that this remodeling can result in excessive deposition of collagen and fibrosis.<sup>25</sup>

### INTESTINAL REPARATIVE MECHANISMS

Reparative mechanisms are similar in the intestine, except that in the small intestine mucosal villi contribute to mucosal repair. Once intestinal epithelium is disrupted, there are two events that occur almost immediately to reduce the size of the denuded portion of the villus: contraction of the villus and epithelial restitution (Figure 15-5). For example, in porcine ileum subjected to 2 hours of ischemia, villi were 60% of their former height and 50% of the denuded villous surface area was covered in flattened epithelium within 6 hours.<sup>41</sup> Villous contraction appears to be regulated by enteric nerves, because inhibition of enteric nerve conduction prevents villous shortening after injury. The contractile component of the villus is a network of myofibroblasts distributed throughout the lamina propria of the villus and along the central lacteal. Inhibition of villus contraction results in retarded epithelial repair because of the larger denuded surface that remains to be covered by migrating epithelium compared with similarly injured villi that have contracted.<sup>42</sup> Prostaglandin E<sub>2</sub> has also been implicated

**FIGURE 15-5** Histologic appearance of repairing intestinal mucosa 6 hours after a 2-hour ischemic episode. Note blunting of the villus, attributable to villous contraction, and evidence of epithelial restitution (arrows). 1 cm bar = 100  $\mu$ m

in regulating villous contraction, because application of PGE<sub>2</sub> resulted in villus contraction when perfused through normal rat ileum.<sup>103</sup> As villi contract, assuming there is an intact basement membrane, epithelium from the margins of the wound migrates in a centripetal direction to resurface toward the tip of the villus.<sup>42</sup> The process of restitution is similar in denuded colonic mucosa, except that it may proceed more rapidly because of the lack of villi.<sup>41</sup> Epithelial restitution is solely a migratory event that does not depend on provision of new enterocytes by proliferation. Cellular migration is initiated by extension of cellular lamellipodia that receive signals from the basement membrane via integrins. Intracellular signaling converges on the actin cytoskeleton, which is responsible for movement of lamellipodia. Specific components of the basement membrane appear to be critical to the migratory process. For example, application of antibodies to collagen types III and IV, which are important components of intestinal mucosal basement membrane, impeded epithelial restitution.<sup>104,105</sup> Other elements of the basement membrane, including proteoglycans, hyaluronic acid, and noncollagenous proteins such as fibronectin and laminin, may also provide important signals.<sup>106</sup> These subepithelial matrix components that facilitate restitution may form the basis for clinical treatments designed to speed up the repair process, analogous to administration of matrix components to horses with articular cartilage damage.

Although epithelial restitution results in gross closure of previously denuded regions of gastrointestinal mucosa, closure of interepithelial spaces is ultimately required to restore normal epithelial barrier resistance.<sup>107</sup> Because the tight junction is principally responsible for regulating the permeability of the interepithelial space, it is likely that repair and closure of this structure is critical to restore intestinal barrier function.

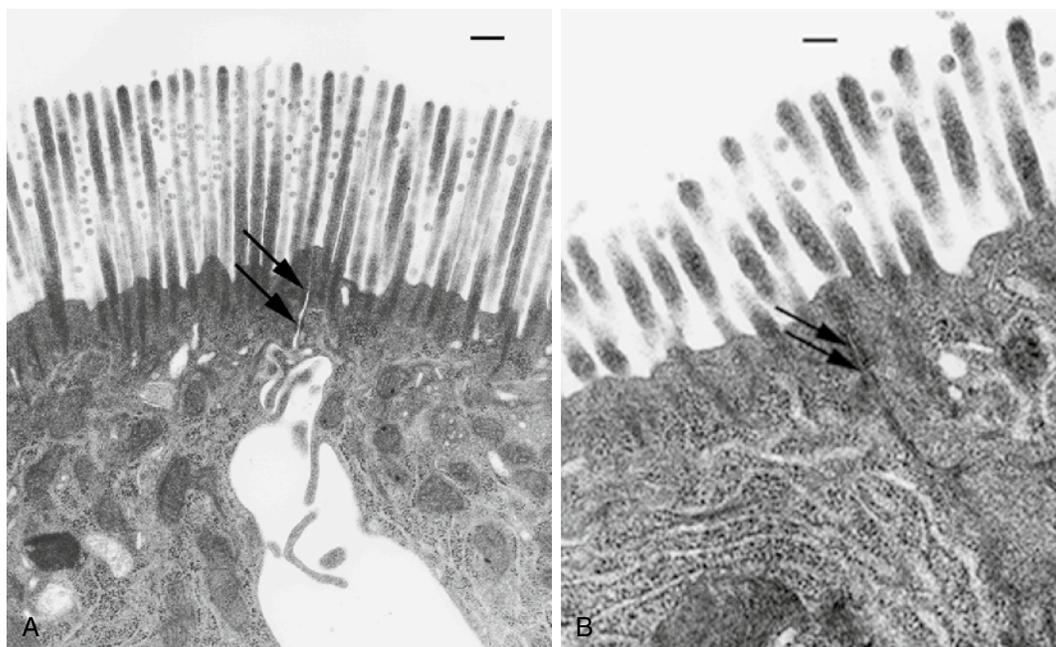

Recent research indicates that prostaglandins play a vital role in recovery of tight junction resistance,<sup>108</sup> indicating that administration of nonselective COX inhibitors to horses with colic, particularly those recovering from strangulating obstruction, may be deleterious. Therefore judicious use of NSAIDs is appropriate until more selective drugs that allow continued production of reparative prostaglandins are available for use in horses in this country. Recent studies have shown that NSAIDs preferential for COX-2 allow for optimal repair of injured intestine as compared to traditional nonselective NSAIDs.<sup>55</sup>

Once the epithelial barrier has been restored, normal mucosal architecture must be re-established to allow normal gut absorptive and digestive function. In porcine ileum subjected to 2 hours of ischemia, the epithelial barrier was restored within 18 hours, but villi were contracted and covered in epithelium with a squamous appearance. Restoration of normal villus architecture required an additional 4 days.<sup>41</sup> The flattened villus epithelium that characterizes restitution is replaced by newly proliferated crypt epithelium. Under normal circumstances, new enterocytes are formed by division of stem cells, of which there are approximately four at the base of each mucosal crypt. Newly divided enterocytes migrate from the crypt onto the villus.<sup>108</sup> During migration enterocytes differentiate and acquire specific absorptive and digestive functions. Fully differentiated enterocytes reside on the upper third of the villus for 2 to 3 days and are then sloughed into the intestinal lumen.<sup>109</sup> This process is accelerated during mucosal repair, which requires increased proliferative rates. Increased proliferation may be stimulated within 12 to 18 hours by a variety of locally available gut-derived factors, including luminal nutrients, polyamines, and growth factors.<sup>41</sup> The return of the normal leaflike shape of the villus occurs subsequent to the appearance of normal columnar epithelium.

## ☞ MEDIATORS OF REPAIR

### PROSTAGLANDINS

Although prostaglandins have been strongly implicated in mucosal cytoprotective function, relatively few studies have assessed their importance in mucosal repair. One study implicated prostaglandins in growth factor-stimulated restitution,<sup>110</sup> but a more prominent role of prostaglandins in mucosal repair is their ability to close interepithelial tight junctions.<sup>107,111,112</sup> For instance, ischemic-injured small intestine rapidly recovers barrier function (as measured in vitro as transepithelial resistance) in the presence of prostaglandins I<sub>2</sub> and E<sub>2</sub>, despite the fact that these prostanoids have relatively little effect on villous contraction and epithelial restitution. However, electron-microscopic examination of tissues reveals dilation of tight junctions in tissues treated with NSAIDs,<sup>112</sup> whereas those additionally treated with prostaglandins have closely apposed tight junctions (Figure 15-6). Prostaglandins stimulate closure of tight junctions via the second messengers cAMP and Ca<sup>2+</sup>,<sup>105</sup> which, interestingly, were among the first mediators found to modulate tight junction permeability.<sup>113,114</sup> Such tight junction closure is of considerable importance to patients with intestinal injury that are treated with NSAIDs because reduced prostaglandin levels may result in increased intestinal permeability. For example, in a study on ischemic-injured porcine ileum, treatment with the NSAID indomethacin resulted in a significant increase in intestinal permeability to inulin and LPS compared with tissues that were additionally treated with PGI<sub>2</sub> and PGE<sub>2</sub>.<sup>107</sup>

**FIGURE 15-6** Ultrastructural appearance of repairing ischemic-injured mucosa. **A**, Restituting epithelium 2 hours after a 1-hour ischemic episode in the presence of the nonselective COX inhibitor indomethacin. Note dilation of the interepithelial space and the apical tight junction (*arrows*), which correlates with a “leaky” intestinal barrier. **B**, Similar restituting epithelium that has been additionally treated with PGE<sub>2</sub> and PGI<sub>2</sub>. Note the close apposition of the tight junction (*arrows*) and the interepithelial space correlated with normalization of intestinal barrier function. 1 cm bar = 6 μm.

## POLYAMINES

The process of restitution is absolutely dependent on a group of compounds called *polyamines*.<sup>115,116</sup> The rate-limiting enzyme in the formation of the polyamines spermine, spermidine, and putrescine is ornithine decarboxylase (ODC). In rats with stress-induced duodenal ulcers, systemic administration of the ODC inhibitor  $\alpha$ -difluoromethyl ornithine significantly reduced polyamine levels and markedly reduced epithelial restitution. Furthermore, intragastric treatment of these same rats with putrescine, spermidine, and spermine prevented the delayed mucosal repair induced by  $\alpha$ -difluoromethyl ornithine.<sup>115</sup> Interestingly, gastric tissue levels of ODC were increased in rats with stress-induced gastric ulcers, suggesting that polyamine production is enhanced during tissue injury and may contribute to the normal rapid rate of epithelial restitution.<sup>117</sup>

The mechanisms whereby polyamines stimulate epithelial restitution are not clear. McCormack et al. hypothesized that polyamines increased transglutaminase activity, an enzyme that catalyzes the cross-linking of cytoskeletal and basement membrane proteins.<sup>118</sup> Further investigation of the role of polyamines in IEC-6 cell migration showed that depletion of polyamines resulted in disruption of the cytoskeleton and reduced the physical extension of lamellipodia.<sup>119</sup> More recent studies have clarified this pathway. In particular, it has been shown that polyamines regulate cytoskeletal cellular migration via activation of the small GTPase Rho-A by elevating intracellular Ca<sup>2+</sup> levels. These elevations in Ca<sup>2+</sup> result from polyamine regulation of expression of voltage-gated K<sup>+</sup> channels and altered membrane electrical potential.<sup>120</sup>

Polyamines also play a role in the normal physiologic regulation of crypt cell proliferation and differentiation.<sup>121,122</sup>

Polyamines are produced by fully differentiated enterocytes at the villous tip and may reach the crypt either within sloughed luminal epithelium or via local villous circulation.<sup>123</sup> After intestinal injury polyamines appear to stimulate enhanced proliferation by increasing the expression of proto-oncogenes, which control the cell cycle.<sup>124</sup> The mechanism whereby polyamines influence gene expression likely relates to the cationic nature of these compounds, which may influence the tertiary structure of negatively charged DNA and ribonucleic acid (RNA).<sup>115</sup>

## GROWTH FACTORS

Locally produced growth factors, including epidermal growth factor (EGF), transforming growth factor (TGF)- $\alpha$ , TGF- $\beta$ , and hepatocyte growth factor (HGF), have the ability to modulate mucosal recovery. The most important of these growth factors in early mucosal repair events is TGF- $\beta$ , which is a potent stimulus of epithelial restitution and modulator of the ECM.<sup>25</sup> Neutralization of TGF- $\beta$  retards epithelial migration in vitro, and it appears that TGF- $\beta$  may serve as a point of convergence for mediators of restitution, because neutralizing TGF- $\beta$  also inhibits the effects of other peptides. However, TGF- $\beta$  paradoxically inhibits epithelial proliferation, thereby reducing the supply of new enterocytes for mucosal repair. Conversely, EGF, produced by the salivary glands and duodenal Brunner's glands, and the related TGF- $\alpha$ , produced by small intestinal enterocytes, are potent stimulants of enterocyte proliferation. These growth factors share approximately 30% of their amino acid structure, bind to the same receptor on the basolateral surface of enterocytes, and are not related to TGF- $\beta$ .<sup>125</sup> The physiologic role of EGF is somewhat difficult to discern

because it is present in the intestinal lumen, with no apparent access to its basally located receptor.<sup>126</sup> However, it has been proposed that EGF acts as a “surveillance agent” that gains access to its receptor during epithelial injury (when the EGF receptor would likely be exposed) to stimulate proliferation.<sup>126</sup> TGF- $\alpha$  presumably has a similar role, but it is present in greater concentrations in the small intestine because it is produced by differentiated villous enterocytes. The mature peptide is cleaved from the extracellular component of the transmembrane TGF- $\alpha$  precursor and released into the lumen.<sup>125</sup>

### TREFOIL PEPTIDES

Another group of proreparative peptides that are locally produced within the gastrointestinal tract are the trefoil peptides. Under physiologic conditions trefoil peptides are secreted by mucus-producing cells at distinct anatomic sites. For example, the trefoil peptide pS2 is produced by gastric epithelium, whereas ITF is produced by small and large intestinal mucosa.<sup>127</sup> However, any of the trefoil peptides may be upregulated within repairing epithelium regardless of anatomic site.<sup>25,128</sup> In addition, trefoil peptides have the ability to induce their own expression, amplifying the level of these reparative factors at sites of mucosal repair.<sup>129</sup> Trefoil peptides are the most potent stimulants of epithelial migration in vitro, and their effects are independent of growth factors, including TGF- $\beta$ .<sup>130</sup> However, recent evidence suggests that EGF receptor activation is required for induction of pS2 and another of the trefoil peptides termed *spasmolytic peptide* in gastric epithelium in vitro. The importance of trefoil peptides to the mucosal repair response in vivo is illustrated by gene knockout studies, in which mice deficient in ITF have dramatically reduced ability to repair intestinal injury.<sup>131</sup> In fact, detergent-induced mucosal injury was lethal because of a lack of restitution as compared with wildtype mice that fully recovered from similar mucosal injury. The fact that restitution was restored by administration of ITF has important therapeutic implications. The mechanism whereby trefoil peptides stimulate epithelial migration is yet to be fully characterized, but it appears to involve translocation of the adherens junction protein E-cadherin, thereby allowing cells to become untethered from neighboring cells.<sup>25</sup>

### INTESTINAL NUTRIENTS

The principal metabolic fuel of enterocytes is glutamine, and for colonocytes it is butyrate. However, recent studies suggest that glutamine and butyrate have more specific proliferative actions aside from their role as nutrients. For example, in the piglet IPEC-J2 enterocyte cell line, glutamine enhanced gene transcription by increasing mitogen-activated protein kinase activity.<sup>132,133</sup> Similarly, butyrate stimulated mucosal growth following colonic infusion in the rat.<sup>134</sup> Because of such growth-promoting actions, glutamine was shown to prevent intestinal mucosal atrophy and dysfunction that accompanies starvation<sup>135,136</sup> and long-term total parental nutrition.<sup>137,138</sup> Additionally, glutamine improves function of transplanted small intestine<sup>139,140</sup> and protects intestinal mucosa from injury if administered before chemotherapy<sup>141</sup> and radiation.<sup>142,143</sup> Intestinal nutrients may also synergize with other proliferative agents. For example, administration of glutamine and TGF- $\alpha$  to porcine ileum that had been subjected to 2 hours of ischemia resulted in a synergistic increase in mitogen-activated protein kinase activity, enterocyte proliferation, and villous

surface area.<sup>41</sup> Although there has been a concern that such early return to normal surface area may result in dysfunctional mucosal digestive and absorptive function because of resurfacing denuded mucosa with immature epithelium, nutrients and growth factors also appear to promote early differentiation. In the case of glutamine and TGF- $\alpha$  restoration of postischemic small intestine, rapid recovery of digestive enzymes was also documented.<sup>144</sup>

## GASTROINTESTINAL ILEUS

L. Chris Sanchez

Effective gastrointestinal motility involves a complex interaction among the enteric nervous system, muscular wall, and luminal contents. Additional factors that influence the net transit of digesta include gravity, the volume and viscosity of the contents, and pressure gradients created by simultaneous contraction and relaxation of adjacent segments of bowel. Casual use of the term *intestinal motility* in veterinary medicine often underestimates the complexity of the processes involved in the transit of intestinal contents. This is particularly true when the term is used to describe the frequency and or intensity of intestinal sounds, or borborygmi. The existence of borborygmi does not always equate with progressive movement of intestinal contents.

Disruption to normal motility occurs commonly in horses for a variety of reasons. Examples of diseases in which altered motility may be present include grass sickness, gastroduodenal ulceration, intraluminal obstruction or impaction, excessive wall distention, strangulating obstruction, peritonitis, and inflammatory disorders such as duodenitis proximal jejunitis and colitis. Ineffective intestinal motility is also a feature of several neonatal diseases, including prematurity, systemic sepsis, and perinatal asphyxia. Certain parasitic infections, electrolyte derangements, and endotoxemia can modify digesta transit in horses of all ages. General anesthesia and specific sedatives, such as xylazine, romifidine, and detomidine, also disturb motility.

## ☞ MANIFESTATIONS OF ILEUS

The inhibition of propulsive bowel activity usually is referred to as *ileus*. Ileus is ascribed most frequently to the condition that occurs after laparotomy and is termed *simple* or *uncomplicated postoperative ileus (POI)*. The term *complicated* or *paralytic ileus* describes intestinal motility disturbed for longer periods after surgery. POI in horses is associated most commonly with surgery of the small intestine, particularly after resection and anastomosis,<sup>1,2</sup> and can have a negative effect on short-term postoperative survival.<sup>3-6</sup> Motility dysfunction likely is present in all horses after laparotomy, but many are affected subclinically and require minimal or no specific intervention. In symptomatic animals clinical signs are apparent shortly after recovery and include colic, tachycardia, dehydration, decreased borborygmi and fecal output, and sequestration of fluid within the stomach. Rectal examination and ultrasound reveal small intestinal distention with rare or absent wall movement. The severity and duration of intestinal stasis varies, lasting from minutes to days.

A specific motility disorder involving the cecum or ileocecolic region occurs sporadically in horses.<sup>7-9</sup> The condition

most commonly occurs after general anesthesia and extra-abdominal surgery, particularly orthopedic and upper airway procedures, and therefore often is categorized as a form of POI. Other cases occur spontaneously, often in animals with painful primary conditions such as uveitis or septic tenosynovitis. In a study of 114 horses diagnosed with cecal impaction, 12 were hospitalized for a condition other than colic at the time of diagnosis and 9 others were being treated with phenylbutazone, most for a musculoskeletal injury.<sup>10</sup> Eight of the 114 horses had undergone general anesthesia in the 8 days preceding diagnosis. The syndrome is frustrating in that clinical signs are often subtle unless cecal perforation has occurred. In horses with a cecal emptying defect after anesthesia, overt signs are usually apparent 3 to 5 days after the procedure. The earliest detectable signs include depression and a reduction in feed intake and fecal output. Ineffective emptying results in overfilling of the cecum with moist contents, which is manifested by signs of mild to moderate colic. If the condition is recognized late or untreated, the cecum may rupture and result in fatal peritonitis.

## PHYSIOLOGY

Current understanding of motility throughout the equine gastrointestinal tract is remarkably limited, and much of our presumptive knowledge comes from work in other species. The enteric nervous system is involved in all aspects of motility, either directly via neurotransmitters or indirectly via interstitial cells of Cajal (ICC), immune, or endocrine regulation. The inherent rhythmicity of electric activity in the intestine is controlled by the ICC, specialized cells that are electrically coupled to myocytes via gap junctions.<sup>11</sup> These cells are responsible for generating and propagating slow wave activity and hence are deemed the pacemaker cells of the intestine. A decrease in ICC density has been observed in horses with obstructive disorders of the large intestine<sup>12</sup> and in the ileum and pelvic flexure of horses diagnosed with equine grass sickness (dysautonomia),<sup>13</sup> although such a decrease was not evident in a horse with dysautonomia that recovered.<sup>14</sup> This alteration in ICC infrastructure appears to result in reduced slow wave activity *in vitro*.<sup>15</sup>

The enteric nervous system primarily controls and coordinates intestinal contraction. A combination of central and autonomic innervation influences events, but contraction does not require external neural input. The parasympathetic supply to the gastrointestinal tract is via the vagus and pelvic nerves, and the sympathetic supply is through postganglionic fibers of the cranial and caudal mesenteric plexuses. A complex network of interneurons within each plexus integrates and amplifies neural input; the intensity and frequency of resultant smooth muscle contractions are proportional to the amount of sympathetic and parasympathetic input. Additional binding sites for a number of other endogenous chemicals, including dopamine, motilin, and serotonin, exist within the enteric nervous system and on smooth muscle cells.<sup>16</sup> Acetylcholine is the dominant excitatory neurotransmitter in the gastrointestinal tract and exerts its action through muscarinic type 2 receptors on smooth muscle cells. Sympathetic fibers innervating the gastrointestinal tract are adrenergic, postganglionic fibers with cell bodies located in the prevertebral ganglia. Activation of  $\alpha_2$ -adrenergic receptors on cholinergic neurons within enteric ganglia inhibits the release of acetylcholine and therefore reduces intestinal contraction.  $\beta_1$ -,  $\beta_2$ -, and  $\beta$ -atypical receptors are

directly inhibitory to the intestinal smooth muscle.<sup>17</sup> Inhibitory nonadrenergic, noncholinergic neurotransmitters include ATP, vasoactive intestinal peptide, and nitric oxide.<sup>18,19</sup> These neurotransmitters are critical for mediating descending inhibition during peristalsis and receptive relaxation. Substance P is a nonadrenergic, noncholinergic neurotransmitter that may be involved in contraction of the large colon.<sup>20,21</sup>

The rate and force of intestinal contractions along the small intestine and large colon of the horse are important determinants of intestinal motility; of even greater importance to the net propulsion of digesta are the cyclical patterns of contractile activity. These patterns are known as the small intestinal and colonic migrating motility (or myoelectric) complexes (MMCs).<sup>22,23</sup> The colonic complex usually originates in the right ventral colon and variably traverses the ascending and descending colons. Many of these complexes are related temporally to a specialized motility event of the ileum, the migrating action potential complex.<sup>24</sup>

## PATHOPHYSIOLOGY

### INFLAMMATION

Local inflammation within the intestinal muscularis and inhibitory neural events are important initiators of intestinal ileus.<sup>25,26</sup> Intestinal inflammation not only is important in primary intestinal diseases in horses, such as duodenitis-proximal jejunitis and colitis, but also is induced after simple intestinal handling during laparotomy. In rodents simple intestinal manipulation causes a cascade of inflammation within the muscularis that results in leukocyte infiltration and subsequent suppression of muscle contractility. The inflammatory response to bowel manipulation is not limited to the affected tissue but can also result in global inflammation and ileus throughout the gastrointestinal tract.<sup>27</sup>

The associated inflammatory events are extremely complex, involving a milieu of pro-inflammatory cytokines, prostaglandins, and leukocytes. Depletion or inactivation of muscularis macrophage function can prevent inflammation associated with intestinal manipulation and associated decreased contractility.<sup>28</sup> Mast cell activation is involved in intestinal manipulation-associated POI in humans.<sup>29</sup> Inflammation associated with colonic manipulation may involve gut-derived bacterial products.<sup>30</sup> Another factor in the development of intestinal stasis after inflammation is the local overproduction of nitric oxide caused by the upregulation of inducible nitric oxide synthase (iNOS) by resident macrophages.<sup>31</sup> iNOS upregulation was important for initiation of the inflammatory response and inhibition of motility. Nitric oxide is a key inhibitory neurotransmitter of the nonadrenergic, noncholinergic system.<sup>19</sup>

In the horse significant neutrophilic inflammation is apparent in jejunum from clinical cases necessitating resection and following a period of recovery in jejunum subjected to 1 or 2 hours of ischemia.<sup>32</sup> The ischemic tissue also had evidence of leukocyte activation, as demonstrated by calprotectin-positive cells in associated tissue histologically.

### DRUGS

The inhibitory effects of  $\alpha_2$ -adrenergic agonists such as xylazine and detomidine on duodenal, cecal, and large colon motility are well described, because these drugs activate presynaptic

receptors within the enteric nervous system.<sup>33-39</sup> Intravenously administered xylazine inhibits cecal and large colon motility for 20 to 30 minutes without seriously disrupting small intestinal myoelectric activity, and detomidine can reduce large intestinal myoelectric activity for up to 3 hours. Detomidine decreases duodenal motility in a dose-dependent fashion.<sup>40</sup> The  $\alpha_2$ -antagonist yohimbine has a weak but positive effect on cecal emptying in normal ponies, suggesting that normal motility is under constant  $\alpha_2$ -adrenergic tone.<sup>34</sup>

Several opioid agonists also have documented inhibitory effects on equine gastrointestinal motility at both a central and peripheral level. Morphine decreased frequency of defecation and fecal moisture content and increased gastrointestinal transit time in normal horses at a dose of 0.5 mg/kg twice daily for 6 days.<sup>41</sup> Single doses of fentanyl or morphine decreased jejunal and colonic MMC activity in ponies, whereas the antagonist naloxone elicited increased propulsive activity in the colon.<sup>42</sup> Fentanyl administered as an intravenous constant-rate infusion did not have an apparent deleterious effect on duodenal motility.<sup>43</sup> Butorphanol, an opioid agonist-antagonist, decreases myoelectrical activity in the jejunum but not pelvic flexure.<sup>44</sup> In another series of experiments, butorphanol alone did not decrease gastric or duodenal motility,<sup>45</sup> but administration in combination with xylazine resulted in a synergistic inhibitory effect that was more pronounced than that obtained by administration of xylazine alone.<sup>39</sup> Administration of butorphanol as a constant-rate infusion appears to have minimal to no effect on global gastrointestinal<sup>46,47</sup> or duodenal motility.<sup>48</sup>

N-butylscopolammonium bromide appears to cause a profound but very short-lived negative effect on duodenal motility, but this effect was not significant between groups.<sup>48</sup> Atropine is a postganglionic blocking agent that binds to muscarinic receptors. When administered at 0.04 mg/kg, atropine inhibits individual small intestinal, cecal, and colonic contractions for about 120 minutes but suppresses small intestinal and colonic migrating complexes for up to 8 hours.<sup>49</sup>

## NEURAL REFLEXES

Neural reflexes also may mediate inhibition of motility associated with peritoneal inflammation and abdominal pain.<sup>50,51</sup> The afferent segment is composed partly of capsaicin-sensitive visceral afferent C fibers that terminate in the dorsal horn of the spinal cord, where they can activate inhibitory sympathetic fibers or synapse directly on the sympathetic ganglia. Consequently, the efferent limb of the reflex expresses increased sympathetic outflow, primarily mediated through stimulation of  $\alpha_2$ -adrenoreceptors, and inhibition of acetylcholine release, which provides the rationale for  $\alpha_2$ -blockade in treating ileus. Intraluminal infusion of capsaicin before abdominal surgery ameliorated the severity of POI in experimental rats. This finding highlights the importance of visceral afferent fibers in the development of POI.<sup>52</sup> Decreasing postoperative inflammation and pain decreases the risk of gastrointestinal ileus in many species in both experimental and clinical studies.

## DISTENTION

Ileus also can occur in association with intestinal obstruction or displacement. Mild to moderate distention of the bowel, such as that occurring in the early stages of an intraluminal obstruction, evokes an increase in local contractile activity.<sup>53,54</sup> Excessive distention results in inhibition of motility

within the distended segment of bowel. Intestinal stasis is not always detrimental and under certain conditions may be protective. Repeated distention for determination of nociceptive threshold has also resulted in an overall decrease in duodenal motility over time, irrespective of other interventions.<sup>43,48</sup>

## ENDOTOXIN

Endotoxemia is a clinical feature of many diseases of the equine gastrointestinal tract, and endotoxins independently can exert a negative effect on intestinal motility and transit.<sup>55</sup> A variety of mediators likely are involved, but activation of  $\alpha_2$ -adrenoreceptors and production of prostanoids appear to be important because pretreatment with yohimbine or NSAIDs (phenylbutazone or flunixin), respectively, ameliorates the inhibitory effects of experimental endotoxin infusion.<sup>56-59</sup> Pretreatment with metocolopromide or cisapride had a similar effect.<sup>60,61</sup> Endotoxin infusion induced an inflammatory response in the intestine of rats that mimicked the response induced by handling during laparotomy.<sup>62</sup> The similarity of the responses was highlighted in a recent study demonstrating that prior exposure of the muscularis to endotoxin protected the intestine from the effects of manipulation.<sup>63</sup> In rats colonic manipulation alone causes transference of intraluminal LPS to the muscularis, which likely contributes to the global gastrointestinal inflammatory response and decrease in contractility associated with tissue manipulation.<sup>30</sup> In response to endotoxin alone, the inflammatory response within the jejunal muscularis is predominantly monocytic, whereas the response to polymicrobial sepsis is predominantly neutrophilic.<sup>64</sup>

## OTHER EFFECTS

The pathophysiology of cecal emptying defect is not known. This syndrome may best mimic POI in human beings, which is generally considered a large intestinal disorder. An important difference in horses is that laparotomy is a rare predisposing factor, and most cases occur in horses undergoing routine extra-abdominal surgical procedures. Thus whether it should truly be classified as a form of POI is subject to debate. General anesthesia itself is a potent inhibitor of gastrointestinal motility in horses, but these effects are short-lived and reversible within hours of anesthetic withdrawal.<sup>23</sup> The return of normal motility in horses after experimental ileus was most delayed in the cecum, suggesting that this may be a common site of ileus in horses.<sup>65</sup> A link between routine postoperative medications, such as phenylbutazone and aminoglycoside antibiotics, has been suspected but not established. An inhibitory effect of NSAIDs on large colon contractility has been demonstrated using *in vitro* techniques.<sup>66</sup> Primary sympathetic overstimulation could be involved because many of the affected animals are young male horses or animals with painful diseases.

The duration of surgery influences the development of small intestinal POI but not cecal emptying dysfunction.<sup>9,67</sup> Technique may have a weak influence on small intestinal POI after jejunojejunostomy. The duration of intestinal ileus was shorter in animals that received a side-to-side stapled anastomosis than those that had a hand sewn end-to-end procedure.<sup>3</sup> The duration of ileus after stapled end-to-end anastomosis was not different from that after either procedure. Jejunocostomy more commonly results in POI than other types of small intestinal resection and anastomosis, whether related to diseases necessitating this procedure or the procedure itself.<sup>68</sup>

Other reported risk factors for the development of POI include age (>10 years), small intestinal resection and anastomosis, breed (Arabians had a greater risk than other breeds), and duration of surgery.<sup>67</sup> A prospective study found small intestinal lesion, high packed cell volume and duration of anesthesia to increase the risk of POI, whereas performance of a pelvic flexure enterotomy and intraoperative administration of lidocaine may have a modest protective effect against POI.<sup>69</sup>

## DIAGNOSIS

The diagnosis of ileus is based on history and physical examination findings. Case inclusion criteria for clinical studies of POI have varied.<sup>67-70</sup> Important tests include determination of heart rate and rhythm, auscultation and percussion of the abdomen, rectal palpation, and passage of a nasogastric tube. A complete blood count with fibrinogen estimation and cytologic analysis of PF may improve the accuracy of diagnosis. Affected animals have varying signs of abdominal discomfort from mild to severe because of accumulation of fluid in the small or large intestine. Decompression of the stomach is important diagnostically and therapeutically in horses with POI after intestinal surgery. Failure to relieve pain with gastric decompression could point toward mechanical obstruction, severe inflammation of the intestine, or peritonitis. Most animals with ileus are depressed and have reduced fecal output and intestinal borborygmi. Intestinal sounds must be interpreted with caution, however, because the presence of borborygmi does not always equate to progressive intestinal motility and may merely reflect local, nonpropagated contractions. Food intake, or the lack thereof, can also significantly alter gastrointestinal sounds.<sup>71</sup>

Rectal palpation findings in cases of persistent POI or duodenitis-proximal jejunitis are usually nonspecific but may include dilated, fluid-filled loops of small intestine. The clinician occasionally can palpate roughened peritoneal surfaces if peritonitis is present. Cecal distention with digesta can be palpated in horses with advanced cecal dysfunction. Distinguishing functional ileus from mechanical obstruction is important and can be difficult, but horses with mechanical obstruction typically have sustained high volumes of gastric reflux that vary little over time and abdominal pain that is typically not relieved by gastric decompression. Abdominal ultrasound in horses with ileus typically reveals mild to moderately fluid-filled hypomotile to amotile small intestine, without alteration in the amount or character of PF or small intestinal wall thickness. Horses with reflux from other causes (peritonitis, mechanical obstruction) will have changes reflective of their disease process. This differentiation is important for appropriate case management because horses with a mechanical obstruction often need either primary or repeat laparotomy, which should not be delayed.

## TREATMENT

The management of intestinal ileus depends on the segment of gastrointestinal tract involved. Therapy for ileus of the proximal gastrointestinal tract involves a combination of gastric decompression, fluid and electrolyte therapy, analgesic therapy, and anti-inflammatory drug therapy. Electrolyte therapy is critical, particularly for maintaining adequate extracellular concentrations of potassium, calcium, and magnesium. Calculation of the volume of fluid to be administered should

include maintenance requirements plus an estimate of losses, especially those lost through gastric decompression. The clinician should consider parenteral provision of calories when feed has been withheld for more than 96 hours, particularly after surgery. Hand walking also may provide some benefit to these animals but is not likely to have a direct effect on intestinal motility.

One should either avoid the previously mentioned drugs, which can have an inhibitory effect on motility, or use them sparingly. Fluid therapy is the key component in managing cecal emptying defect, usually in combination with lubricants or laxatives, such as mineral oil or magnesium sulfate, and with careful use of anti-inflammatory drugs. Horses with primary cecal impaction or impaction caused by an emptying defect may require surgery to prevent fatal rupture. The surgical management of these cases is controversial and may include typhlotomy alone, typhlotomy with a bypass procedure such as ileocolic or jejunocolic anastomosis, or a bypass without typhlotomy.<sup>72</sup> Most horses that undergo simple typhlotomy have an uneventful recovery.<sup>73</sup> In a large retrospective study 44 of 54 horses treated medically survived to discharge, and 37 of 49 horses treated surgically were allowed to recover, 35 of which survived to discharge.<sup>10</sup> Ileocolostomy was performed in only two of the 37 horses treated surgically (one of which survived to discharge), with the remainder receiving typhlotomy without bypass. Survival to 1 year was not statistically different between horses treated medically (18 of 19) and those treated surgically (25 of 28), although six horses had a recurrence of cecal impaction.<sup>10</sup>

Experimental and anecdotal evidence provides a strong rationale for using anti-inflammatory drugs to prevent and treat gastrointestinal ileus, particularly in animals that may have endotoxemia.<sup>74</sup> Flunixin meglumine is used widely in equine practice as an analgesic and anti-inflammatory agent, and it ameliorates many of the adverse systemic effects of endotoxin, particularly those on the cardiovascular system. A potential negative effect of NSAIDs on large intestinal contractility has been suggested. A differential effect on contractility between selective and nonselective COX inhibitors is currently unknown. Broad-spectrum antimicrobials are indicated when sepsis is suspected or for the compromised immune system, as in cases of moderate to severe endotoxemia. Theoretical concerns have been raised regarding the use of aminoglycoside antibiotics in animals with ileus. High concentrations of aminoglycoside antimicrobials inhibited intestinal contractions in exposed sections of intestine *in vitro*, but this inhibitory effect is unlikely to occur at clinically relevant doses.<sup>75</sup>

Motility-enhancing drugs have been advocated to treat gastrointestinal ileus. Unfortunately, information directly pertinent to horses is limited and must be extrapolated cautiously from that of other species because of the differences in intestinal anatomy and physiology. Prokinetic drugs potentially can shorten the length of hospitalization, thereby reducing the cost of treatment and the number of potential complications, such as weight loss, thrombophlebitis, and laminitis. Experimental evidence indicates that prokinetic drugs can minimize the development of postoperative abdominal adhesions.<sup>76</sup> Most prokinetic drugs require a healthy gut wall to enhance intestinal contraction, and downregulation of motilin receptors has been demonstrated in the inflamed equine jejunum.<sup>77</sup> Therefore one should not assume that many of these drugs would be effective in the presence of an inflammatory injury

such as that which can occur after intestinal manipulation at surgery or that associated with duodenitis-proximal jejunitis.

## CHOLINOMIMETICS

Bethanechol is a parasympathomimetic agent that acts at the level of the myenteric plexus and directly on intestinal smooth cells through muscarinic receptors. In the horse this effect is mediated predominantly by the M<sub>3</sub> receptor, but the M<sub>2</sub> receptor may also play a role.<sup>78</sup> Bethanechol is a synthetic ester of acetylcholine and is not degraded by anticholinesterase. Bethanechol has cholinergic side effects, including abdominal discomfort, sweating, and salivation, although these are minimal when the drug is administered subcutaneously or orally at 0.025 mg/kg body mass. Bethanechol has efficacy in diseases that involve abnormal gastric emptying and delayed small intestinal transit and has been shown to increase gastric contractility and hasten the emptying of liquid and solid phase markers from the stomach of normal horses.<sup>79</sup> Bethanechol also increases the strength and duration of wall contractions in the cecum and right ventral colon and consequently speeds up cecal emptying.<sup>34</sup>

Neostigmine increases receptor concentration of acetylcholine by inhibiting cholinesterase. The drug (0.022 to 0.025 mg/kg intravenously) promotes cecal and colonic contractile activity and hastens the emptying of radiolabeled markers from the cecum.<sup>34</sup> Neostigmine has been used to manage small intestinal ileus, but it significantly delayed the emptying of 6-mm beads from the stomach of normal adult horses.<sup>80</sup>

## BENZAMIDES AND DOPAMINE ANTAGONISTS

Metoclopramide acts principally as a 5-hydroxytryptamine 4-receptor (5HT-4) agonist and 5HT-3 receptor antagonist. In contrast to newer generation benzamides, metoclopramide is also an antagonist at dopamine 1 (DA<sub>1</sub>) and 2 (DA<sub>2</sub>) receptors. Antagonism of prejunctional DA<sub>2</sub> receptors facilitates acetylcholine release and smooth muscle contraction. Metoclopramide crosses the blood-brain barrier, where its antagonist properties on central DA<sub>2</sub> receptors can result in extrapyramidal signs, including seizure. Metoclopramide increased contractility of muscle strips *in vitro* in the pyloric antrum, proximal duodenum, and midjejunum.<sup>81</sup> Those *in vitro* data support previous work in which metoclopramide administration restored gastroduodenal coordination of motility in a model of POI.<sup>82</sup> In another study metoclopramide had no effect on jejunal or pelvic flexure myoelectrical activity.<sup>44</sup> Constant intravenous infusion (0.04 mg/kg/hr) of metoclopramide was well tolerated in a population of postoperative horses and significantly decreased the volume and duration of gastric reflux over control and intermittent drug infusion groups.<sup>83</sup>

Cisapride is a second-generation benzamide that acts as a 5HT-4 agonist and 5HT-3 receptor antagonist but is without antidopaminergic action. Stimulation of 5HT-4 receptors within the enteric nervous system enhances release of acetylcholine from the myenteric plexus. Several reports suggest the efficacy of cisapride in managing intestinal disease in horses, including the resolution of persistent large colon impaction, treatment of equine grass sickness, and as a preventative for POI in horses after small intestinal surgery (0.1 mg/kg body mass intramuscularly during the postoperative period).<sup>84-87</sup> The horse erratically absorbs tablets administered rectally, but a method for preparing a parenteral form of the drug from

tablets has been described.<sup>88</sup> Cisapride has the potential to cause adverse cardiac side effects mediated through blockage of the rapid component of the delayed rectifier potassium current that include lengthening of the QT interval and development of torsades de pointes, a potentially fatal arrhythmia.<sup>89</sup> These adverse effects have resulted in withdrawal of the drug in the United States but have not been reported in the horse.

Tegaserod, a 5HT-4 agonist, has been shown to increase pelvic flexure smooth muscle contractility (0.27 mg/kg PO)<sup>90</sup> and hasten gastrointestinal transit time (0.02 mg/kg intravenously) in healthy horses.<sup>91</sup> It has not, to the author's knowledge, yet been objectively evaluated in abnormal horses but may prove useful. In humans this drug was marketed for women with constipation-predominant or mixed symptom irritable bowel syndrome and demonstrated clear benefits in quality of life and gastrointestinal symptoms, but it is currently available only in a restricted fashion because of its association with ischemic colitis and cardiovascular disease.<sup>92</sup>

Domperidone acts as a competitive antagonist at peripheral DA<sub>2</sub> receptors. The drug is a therapeutic agent (1.1 mg/kg/day) for mares grazing endophyte-infected tall fescue, principally because of drug-enhanced prolactin release. The potential prokinetic effects of domperidone have not been studied extensively in horses, but a modest efficacy of domperidone (0.2 mg/kg intravenously) has been demonstrated in experimental ileus in ponies.<sup>84</sup>

## ANTIMICROBIALS

Erythromycin, a macrolide antibiotic, is a direct motilin receptor agonist on smooth muscle cells and also may act within the enteric nervous system to facilitate the release of acetylcholine and motilin. Erythromycin displaces motilin from its receptor in the equine duodenum, jejunum, cecum, and pelvic flexure.<sup>93</sup> Erythromycin enhances gastric emptying in normal horses but has a more pronounced effect on the hindgut.<sup>79,94</sup> Erythromycin lactobionate (1.0 mg/kg IV) hastens cecal emptying in normal animals and induces colonic MMC-like activity across the colon. Administration often is associated with defecation and abdominal discomfort. The prokinetic effect of erythromycin apparent in the ileum, cecum, and pelvic flexure documented in normal horses was reduced in the immediate postoperative period.<sup>95</sup> Similarly, luminal distention and decompression resulted in inflammation and a decreased response to erythromycin.<sup>96</sup> A decrease in motilin receptors in response to luminal distention has been documented in the equine jejunum,<sup>77</sup> and this may explain the difference in response between normal and clinically affected horses. Repeated dosing can cause downregulation of motilin receptors in other species.<sup>97</sup> Because erythromycin can induce diarrhea in adults, it should not be administered over many days.

Potassium penicillin (20 million IU intravenously to adult horses) can stimulate defecation and increase myoelectrical activity in the cecum and pelvic flexure, and these effects are not produced by an equimolar amount of potassium ion given intravenously as potassium chloride.<sup>98</sup>

## OPIOID AND $\alpha$ -ADRENORECEPTOR ANTAGONISTS

Naloxone (0.05 mg/kg intravenously) induces contractile activity in the cecum and left colon.<sup>42</sup> Defecation commonly follows administration of naloxone within 15 to 20 minutes.

N-methylnaltrexone increases jejunal and pelvic flexure contractility *in vitro*<sup>99</sup> and has been shown to prevent the negative effects of morphine on fecal output and intestinal transit time when administered concurrently.<sup>100</sup>

$\alpha_2$ -Adrenoreceptor antagonists such as yohimbine or tolazoline counteract increased sympathetic outflow in response to nociceptive stimulation. Yohimbine infusion (75  $\mu\text{g}/\text{kg}$ ) also may attenuate the negative effects of endotoxin on motility.<sup>56,58</sup>

## LOCAL ANESTHETICS

The use of intravenous lidocaine as a prokinetic has gained tremendous popularity and was reported to be the agent most commonly used by equine surgeons for POI following most gastrointestinal lesions.<sup>101</sup> Lidocaine may exert prokinetic effects by suppressing primary afferent neurons, thereby limiting reflex efferent inhibition of motility.<sup>102</sup> Other proposed mechanisms of action include anti-inflammatory properties, potentially through NF- $\kappa\beta$  signaling<sup>103</sup> or improving mucosal repair.<sup>104</sup> Intravenous lidocaine can also exert analgesic effects, although it was shown to alter somatic but not visceral antinociception in clinically normal horses in one study.<sup>105</sup> Lidocaine increased contractile activity in isolated strips of proximal duodenum *in vitro*.<sup>81</sup> The most commonly cited dosage is a 1.3 mg/kg bolus, typically over 15 minutes, followed by 0.05 mg/kg/min constant-rate infusion. This dosage did not alter MMC duration or spiking activity, nor did it reset the MMC in the jejunum in clinically normal horses<sup>106</sup> or significantly alter a variety of indicators of POI after colic surgery.<sup>107</sup> In another study significantly more horses with POI stopped refluxing within 30 hours following the institution of lidocaine infusion, relative to saline infusion.<sup>108</sup> Lidocaine infusion can be associated with reversible side effects that include muscle fasciculations, ataxia, and seizure. Consequently, the rate of infusion requires close monitoring. Prolonged infusion of lidocaine in the horse appears safe, although accumulation of the GX metabolite has been documented.<sup>109</sup>

## ENDOTOXEMIA

Katharina L. Lohmann, Michelle Henry Barton

*Endotoxemia* is literally defined as the presence of endotoxin in the bloodstream. Most often, however, the term is used to refer to the associated clinical manifestations caused by an excessive and unbalanced inflammatory reaction. Endotoxemia is not a disease in its own right but rather a complication of many septic and nonseptic disease processes affecting horses and other animals. Its diagnosis and management must therefore be discussed in the context of underlying primary pathologic conditions.

In its pathophysiologic consequences the innate immune response to endotoxin (LPS) is similar to the response to other stimuli (e.g., bacterial infection, viral infection, severe trauma). Moreover, the clinical presentation and clinical pathologic abnormalities of patients suffering from severe systemic inflammation are consistent regardless of the etiologic cause, and outcome may be predicted more accurately by the severity of the inflammatory response than the nature of the inciting insult.<sup>1</sup> In 1992, therefore, the term *systemic*

*inflammatory response syndrome* (SIRS) was introduced in a consensus statement of chest physicians and critical care physicians to account for these similarities and provide a case definition for clinical and research purposes. Fairly soon thereafter, however, the 1992 SIRS definition was criticized as being too sensitive while providing little specificity,<sup>2</sup> and its usefulness for clinical practice was challenged because it failed to predict outcome and to discriminate patients at a high risk of morbidity and mortality.<sup>3</sup> The definition of *SIRS* may therefore be valuable from a conceptual standpoint, but it has little value in daily clinical practice.

*Sepsis* was defined as the systemic inflammatory response to infection, and *septic shock* as “sepsis-induced hypotension, persisting despite adequate fluid resuscitation, along with the presence of hypoperfusion abnormalities or organ dysfunction.”<sup>1</sup> According to these definitions the diagnosis of *sepsis* requires documentation of infection by culture in addition to two or more of the following findings: hypothermia or hyperthermia; tachycardia; tachypnea or hypocapnia; and leukocytosis, leukopenia, or an increased proportion of immature leukocyte forms.

Organ failure is a common sequela of endotoxic or septic shock, and the term *multiple organ dysfunction syndrome* describes insufficiency of two or more organ systems, as evident by clinical or clinicopathologic changes. In horses the laminae of the feet should be included in the list of organs susceptible to failure.

## ENDOTOXIN

German scientist Richard Pfeiffer (1858–1945), in working with *Vibrio cholerae*, first described endotoxin as a toxin “closely attached to, and probably integral of, the bacterial body.”<sup>4</sup> He observed this toxin to be distinct from the actively secreted, heat-labile, and proteinaceous bacterial exotoxins. Endotoxin later was found to be a heat-stable LPS structure, and the terms *endotoxin* and *LPS* now are often used interchangeably.

LPS is a major structural cell wall component of all gram negative bacteria, including noninfectious species (Figure 15-7). With 3 to 4  $\times 10^6$  molecules per cell, LPS makes up about 75% of the outer layer of the outer cell membrane and is a key functional molecule for the bacterial outer membrane, serving as a permeability barrier against external noxious agents. The LPS molecule consists of four domains, which are essential for

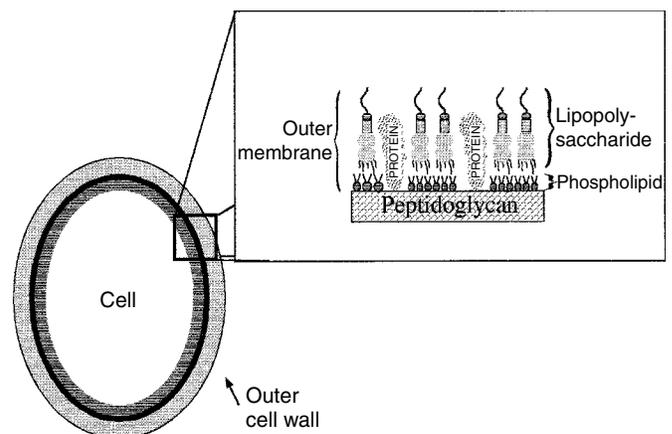

FIGURE 15-7 Lipopolysaccharide.

the virulence of gram negative bacteria.<sup>5</sup> Three of the domains (inner core, outer core, and O-specific chain) represent the hydrophilic polysaccharide portion of the molecule, whereas the lipid A portion represents the hydrophobic lipid portion (Figure 15-8). Combined, these domains confer the overall amphiphilic properties of the molecule that lead to the formation of micellar aggregates in aqueous solutions.

O-specific chains (also called O-antigen polysaccharides or O-chains) are characteristic of any given type of LPS and show enormous structural variability among bacterial serotypes.<sup>6</sup> O-chains are synthesized by addition of preformed oligosaccharide blocks to a growing polymer chain and therefore have a repetitive structure. O-specific chains determine part of the immunospecificity of bacterial cells<sup>5</sup> and, on interaction with the host immune system, serve as antigens for the production of species-specific antibodies.<sup>7</sup> O-specific chains are further responsible for the smooth appearance of gram negative bacterial colonies on culture plates,<sup>5</sup> and LPS molecules containing an O-chain are termed *smooth lipopolysaccharide*.

The inner (lipid A-proximal) and outer (O-chain-proximal) core oligosaccharide portion is more conserved among different strains of gram negative bacteria than the O-specific chain.<sup>6</sup> The core of all LPS molecules contains the unusual sugar KDO (3-deoxy-D-manno-oct-2-ulopyranosonic acid), which links the core region to the lipid A molecule. Synthesis of a minimal core is essential for the survival of bacteria,<sup>5</sup> and the smallest naturally occurring LPS structure consists of lipid A and KDO.<sup>8</sup> In contrast to the S-form colonies, colonies of gram negative bacteria with LPS molecules that lack the O-specific chain but contain a core region show a rough appearance on culture plates. Rough LPS molecules are denoted further as Ra, Rb, and so on to indicate the length of the core region. In Re-LPS (also called *deep rough LPS*), the core region is reduced to a KDO residue. Remutants often are used to raise antibodies against the core region in an attempt to provide cross-protection against a variety of bacterial species. The lipid A portion, which serves to anchor the LPS molecule in the bacterial outer membrane, has been identified as the toxic principle of LPS,<sup>9</sup> and its structure is highly conserved among gram negative bacteria.

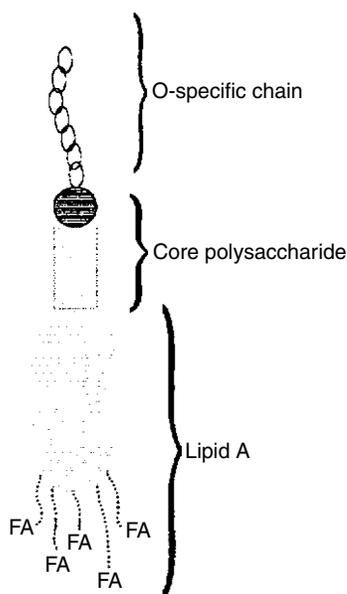

FIGURE 15-8 Three domains of the lipopolysaccharide molecule.

The common structure shared by lipid A molecules is a 1,4'-bisphosphorylated  $\beta$ 1,6-linked D-glucosamine disaccharide backbone (lipid A backbone), which is acylated by up to six fatty acids.<sup>6</sup> Figure 15-9 shows the acylation pattern for *Escherichia coli* LPS. Variation in the lipid A structure between gram negative bacteria affects the number, length, and position of fatty acids and the backbone structure and the substitution of phosphate by other polar groups.<sup>7</sup>

## CAUSES OF ENDOTOXEMIA IN HORSES

According to its nature as a structural cell wall component, the presence of endotoxin implies the presence of gram negative bacteria as a source. Depending on the nature of the underlying disease, these bacteria may circulate in the bloodstream in their intact form (i.e., bacteremia), may be confined to a localized infectious process, or may be part of the endogenous bacterial flora colonizing the gastrointestinal tract. In any of these scenarios endotoxin molecules are released as a by-product of bacterial growth and in large numbers on bacterial cell death.<sup>10</sup> Common infectious conditions associated with endotoxemia in horses include neonatal gram negative sepsis, bacterial pneumonia and pleuropneumonia, endometritis, peritonitis, and infectious colitis with bacteria such as *Salmonella* spp. that are not part of the normal intestinal flora. In one study, for example, endotoxin was detectable in plasma of 50% of foals evaluated for presumed sepsis.<sup>11</sup>

The term *translocation* describes entry of endogenous bacteria and bacterial products from the gastrointestinal tract into tissues and the systemic circulation.<sup>12</sup> The natural intestinal flora of horses consists mainly of gram negative, anaerobic bacteria, and thus large amounts of endotoxin normally exist in the lumen of the equine intestinal tract.<sup>13</sup> Even in healthy horses small amounts of endotoxin probably cross the intact mucosal barrier and reach the portal circulation and the liver.<sup>14</sup> These molecules are cleared, however, by the mononuclear phagocytic system in the liver and lead only to a localized and restricted activation of the host immune system.

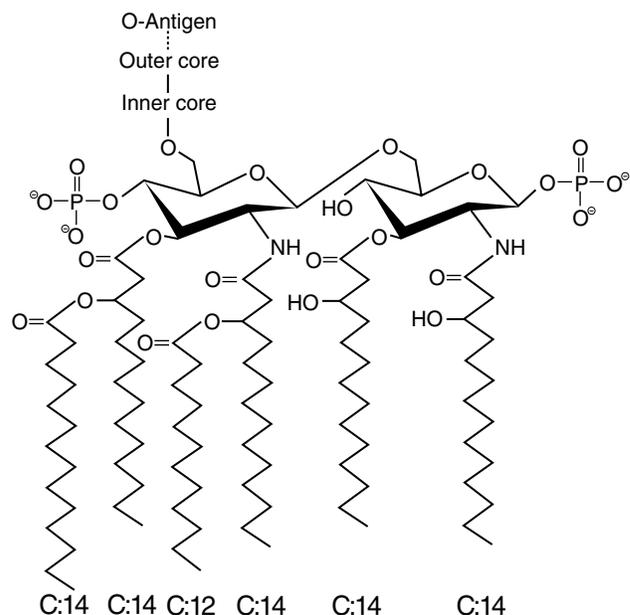

FIGURE 15-9 Acylation pattern for *Escherichia coli* LPS.

For endotoxin translocation to become detrimental, excessive amounts have to cross the intestinal barrier and overwhelm the mononuclear phagocytic system, or the capacity of the liver to detoxify lipopolysaccharide must be compromised. The latter may be a concern in conditions such as hepatitis, cholangiohepatitis, or portosystemic shunting of blood.

Permeability of the intestinal mucosal barrier frequently increases in cases of acute gastrointestinal disease. Colic patients are prime candidates to develop endotoxemia, and plasma endotoxin was detectable in 10% to 40% of colic patients on admission.<sup>15,16</sup> The studies differed in their inclusion criteria, and the higher percentage of horses testing positive for plasma endotoxin was observed when only patients presenting for surgical intervention were evaluated.<sup>16</sup> Aside from gastrointestinal rupture, increased permeability to intact bacteria or free endotoxin molecules is thought to be associated most commonly with ischemic insults such as strangulating obstruction and bowel infarction; severe inflammation, as in proximal enteritis and colitis; bacterial overgrowth; and intraluminal acidosis, which occurs with grain overload.<sup>17,18</sup> One study, however, found no difference in plasma endotoxin detection among disease groups, therefore emphasizing the fact that any disease of the abdominal cavity can induce endotoxemia in horses. In the same study endotoxin was approximately three times more likely to be detected in PF as opposed to plasma samples. Similarly, higher cytokine concentrations have been measured in PF than in plasma. The likely explanation for these findings is a local inflammatory response in the peritoneal cavity elicited by translocated bacteria or LPS molecules before their absorption into the systemic circulation.<sup>15</sup>

Although gastrointestinal disease is likely the most important cause of endotoxin translocation in horses, other conditions may also result in translocation of endotoxin and bacteria. In experimental studies using laboratory animals, entry of gut-associated bacteria into the lymphatic system was demonstrated after hypovolemic shock, burn injuries, trauma, malnutrition, and starvation.<sup>19–21</sup> Furthermore, endotoxin itself caused bacterial translocation into mesenteric lymph nodes after intraperitoneal administration to mice.<sup>22</sup> These findings have received much attention in the literature concerning human patients because they serve to explain cases of endotoxic shock in the absence of demonstrable bacterial infection. The veterinarian should keep in mind the possibility of translocation when evaluating cases of presumed SIRS in horses, in which bacterial infection or gastrointestinal disease cannot be demonstrated. Endotoxin translocation also may be associated with strenuous exercise, which results in reduced splanchnic blood flow, hypoxemia, and a higher body temperature. In fit racehorses a significantly increased mean plasma LPS concentration was found after racing, whereas antilipoplysaccharide immunoglobulin G levels were decreased. Fit horses showed significantly higher antilipoplysaccharide immunoglobulin G concentrations at rest than sedentary controls, suggesting leakage of small amounts of endotoxin from the intestinal lumen during training and racing.<sup>23</sup> A study in endurance horses demonstrated detectable LPS concentration in approximately 50% of horses, and correlation between plasma endotoxin and lactate concentration suggested that plasma endotoxin concentration may be reflective of the vigor of exercise.<sup>24</sup> Surprisingly, the latter study failed to show a correlation between plasma endotoxin concentration and levels of inflammatory mediators such as TNF- $\alpha$  and IL-6,<sup>24</sup> such that the clinical significance of endotoxin translocation during

exercise requires further investigation. At least experimentally, however, alterations in innate immune function during and after strenuous exercise in horses have been demonstrated.<sup>25</sup>

## MECHANISMS OF CELLULAR ACTIVATION BY LIPOPOLYSACCHARIDE

The initiating event in the pathophysiology of endotoxemia is the activation of LPS-responsive cells by endotoxin, resulting in altered cellular functions and increased expression of inflammatory mediators. Immune cells such as macrophages respond to minute amounts of LPS, which usually allows them to eliminate gram negative bacteria and free LPS molecules efficiently. An important factor in the exquisite sensitivity to LPS is the presence of LPS-binding protein (LBP).<sup>6</sup> LBP is an approximately 60-kd plasma glycoprotein<sup>26</sup> that is synthesized primarily by hepatocytes<sup>27</sup> and belongs to the family of lipid transfer/LBPs. LBP is an acute phase protein, and inflammatory agents and cytokines such as IL-1 increase LBP plasma concentration tenfold to 100-fold within 24 to 48 hours of an inflammatory stimulus.<sup>28,29</sup> The main function of LBP is to transfer LPS to endotoxin-responsive cells, which include mononuclear phagocytes, neutrophils, lymphocytes, and endothelial cells. The importance of a highly sensitive response to LPS for protection against gram negative bacterial infection is demonstrated in experiments using LBP knockout mice—that is, mice that lack the LBP gene and are therefore unable to synthesize LBP. Although these animals are resistant to the effects of purified LPS, they are unable to control infection with viable bacteria and rapidly succumb.<sup>30</sup> Despite its crucial importance for an effective host defense, LBP is not essential for LPS-receptor interaction per se, because high concentrations of LPS can activate cells in the absence of LBP.<sup>31</sup>

Aside from its role as a catalyst of cellular activation by LPS, LBP has opsonizing activity<sup>32</sup> and participates in the phagocytosis of LPS by macrophages and neutrophils.<sup>33,34</sup> Although phagocytosis of LPS is receptor dependent, it appears to be uncoupled from intracellular signaling events and occurs in the absence of cell activation.<sup>5</sup> LBP further catalyzes transfer of LPS to lipoproteins such as high-density lipoprotein, which neutralizes LPS activity.<sup>35</sup> This detoxifying effect may become important when large amounts of LPS are present. A protective effect of LBP against LPS challenge and infection has been demonstrated in a murine model of septic shock,<sup>36</sup> and further studies investigating potential therapeutic use of LBP are under way. More recently, LBP has also been investigated as a diagnostic and prognostic indicator in human patients, where it may differentiate between SIRS and sepsis and predict outcome of septic patients.<sup>29</sup> One study investigating serum amyloid A and LBP in horses with colic<sup>37</sup> found no correlation between serum concentration of LBP with outcome, type of disease process, or affected portion of the gastrointestinal tract.

The most important LPS receptors known to date are cluster differentiation antigen 14 (CD14)<sup>31</sup> and Toll-like receptor 4 (TLR-4).<sup>38</sup> Both are classified as pattern recognition receptors,<sup>39</sup> which means that they recognize LPS as a structural motif common to all gram negative bacteria. CD14 is a 53-kd protein that in its membrane-bound form (mCD14) is inserted into the cell membrane via a glycosyl-phosphatidyl-inositol anchor.<sup>40</sup> CD14 is expressed primarily on monocytes and tissue macrophages and to a lesser extent on neutrophils.<sup>41</sup> CD14 also is found in a soluble form (sCD14)<sup>42</sup> that can bind to cell

types lacking CD14, such as endothelial cells, and make them LPS-responsive. In addition to this pro-inflammatory effect, high concentrations of sCD14 can sequester and neutralize LPS.<sup>43</sup> The amount of circulating sCD14 greatly increases during inflammation, which makes it a useful marker of acute and chronic inflammation.<sup>41</sup>

Although CD14 is known to be crucial for cellular activation, it cannot transmit signals to the inside of the cell because it lacks a transmembrane domain. The missing link between CD14 and the cytosolic environment is a Toll-like receptor in association with the molecule MD-2.<sup>44</sup> The name *Toll-like receptor* stems from the homology of the mammalian receptor with a receptor type in *Drosophila* (Toll) that is important for dorsoventral orientation and immune responses in the fly. A number of Toll-like receptors have been identified in mammalian species so far, but TLR4 appears to be the receptor subtype most important for LPS signaling.<sup>38</sup> The importance of CD14 and TLR4 in the cellular response to LPS has been demonstrated in a number of experiments. Mice deficient in CD14 are incapable of mounting a normal inflammatory response to LPS,<sup>43</sup> whereas mutation or deletion of the gene encoding for TLR4 causes LPS hyporesponsiveness.<sup>45-47</sup>

After binding of LPS to cellular receptors, TLR4 undergoes oligomerization and recruits downstream adaptor proteins in order to activate intracellular signaling pathways.<sup>48</sup> Signaling pathways are characterized by sequential phosphorylation and thereby activation of enzymatic activities, and ultimately result in the alterations of cellular metabolism known as *cell activation*. A typical result of intracellular signaling is the activation of transcription factors—that is, proteins that bind to DNA and promote gene transcription. Translational mechanisms are activated in a similar manner.

TLR4-dependent cell signaling pathways can be differentiated according to the use of adaptor proteins that bind to the intracellular domain of TLR4.<sup>48</sup> The MyD88 (myeloid differentiation primary response gene 88)-dependent pathway results in activation of IKK (I $\kappa$ B kinase) and MAPK (mitogen-activated protein kinase) pathways and ultimately in expression of pro-inflammatory cytokine genes. IKK activates the well-described transcription factor NF- $\kappa$ B by phosphorylating an inhibitor protein complex (I $\kappa$ B) that sequesters and inactivates NF- $\kappa$ B in the cytoplasm. On phosphorylation I $\kappa$ B is ubiquitinated and degraded, and NF- $\kappa$ B is translocated to the nucleus, where it unfolds its activity.<sup>49</sup> The MyD88-independent pathway, on the other hand, is activated by interaction of TLR4 with the adaptor protein TRIF (Toll-interleukin-1 receptor domain-containing adaptor inducing interferon- $\beta$ ). While the MyD88-independent pathway also activates MAPK and NF- $\kappa$ B (in addition to a transcription factor called *IRF3*), this pathway primarily results in activation of type I interferons, which are important for antiviral and antibacterial responses.<sup>48</sup> Despite the characterization of seemingly separate and “ordered” pathways, one should recognize that interaction and synergy between pathways is likely to occur. Similarly, inhibitory pathways are required for regulation of the cell response and can target multiple levels of TLR4 signaling.<sup>48</sup> The potential manipulation of signaling pathways for therapeutic use in septic patients is under investigation.

## ☞ INFLAMMATORY MEDIATORS

Although endotoxin can exert some direct effects, cytokines are a primary mediator of LPS effects. Cytokines are glycoprotein molecules that regulate inflammatory and immune responses

by acting as a signal between cells.<sup>50</sup> Cytokines of major interest in the pathogenesis of endotoxemia include TNF- $\alpha$ , the interleukins, chemokines, and growth factors such as granulocyte-monocyte colony-stimulating factor. TNF- $\alpha$  is thought of as the most “proximal” cytokine released in response to LPS. Studies corroborate this by showing that administration of recombinant TNF- $\alpha$  mimics the effects of LPS<sup>51</sup> and that antibodies directed against TNF- $\alpha$  protect against the lethal effects of endotoxin.<sup>52</sup> Increased plasma activity of TNF is associated with increased mortality in equine patients with acute gastrointestinal disease and in septic neonates.<sup>15</sup> Despite being a structurally diverse group of proteins, cytokines share several characteristics that allow them to execute their complex functions in the inflammatory response.<sup>50</sup> Any individual cytokine generally is produced by several different cell types, can act on different cell types, and has multiple effects on any given cell. Furthermore, cytokine effects are redundant, meaning that different cytokines can share the same effect. In endotoxemia this is particularly true for the effects of IL-1 and TNF- $\alpha$ .<sup>53</sup> Many of the biologic activities of cytokines in vivo result from synergistic or antagonistic actions involving two or more cytokines.<sup>54</sup> Within itself the cytokine response is highly regulated: Cytokines induce or suppress synthesis of other cytokines, including their own (feedback regulation); regulate expression of cytokine receptors; and regulate cytokine activities. Additional regulatory mechanisms include the release of specific cytokine inhibitors such as soluble IL-1 and TNF- $\alpha$  receptors; cytokine receptor antagonists such as IL-1 receptor antagonist; and anti-inflammatory cytokines, including IL-10, IL-4, IL-13, and TGF- $\beta$ . Glucocorticoids, which are produced increasingly in response to endotoxin, also inhibit the production of cytokines.<sup>55</sup> During a “controlled” inflammatory response, therefore, cytokine secretion is a self-limited event, whereas excessive stimulation of cytokine production can lead to the perpetuation of the inflammatory response even after the initial stimulus has been removed. Aberrations from the controlled, self-regulated inflammatory response have been described as predominantly pro-inflammatory (SIRS), anti-inflammatory or hypoinflammatory (compensatory anti-inflammatory response syndrome or CARS), or combined (mixed antagonist response syndrome) responses.<sup>56</sup> That these responses may not represent a continuum in response to infection was demonstrated in a recent study investigating cytokine profiles in an experimental model of sepsis.<sup>57</sup> Here, increased plasma concentration of anti-inflammatory mediators such as IL-1 receptor antagonist and IL-10 in the early phase of sepsis predicted early mortality almost as accurately as the typical pro-inflammatory cytokines such as IL-6. Cytokine profiles failed to predict mortality in the later stages of sepsis, thereby suggesting that late outcome is not “preprogrammed” early on in the disease. A progression from pro-inflammatory (SIRS) to anti-inflammatory (CARS), as previously proposed, could not be demonstrated.<sup>57</sup> The authors concluded that use of biomarkers may be helpful in determining the inflammatory status of clinical patients suffering from sepsis and that the success of treatments aimed at suppressing or stimulating immune responses may depend on the individual patient’s inflammatory profile.

Interestingly, tolerance to endotoxin develops after repeated exposure to LPS.<sup>19</sup> Tolerance can be demonstrated in vitro and in vivo and encompasses decreased production of cytokines and a diminished clinical response.<sup>19,58</sup> Tolerance may be a protective mechanism and was shown to reduce

mortality in some experimental models; however, impaired resistance to infectious processes was demonstrated by other investigators.<sup>59</sup> Mechanisms that likely are responsible for the development of endotoxin tolerance include receptor downregulation,<sup>60</sup> downregulation of intracellular signaling pathways,<sup>59,61</sup> and mediators such as glucocorticoids and IL-10.<sup>59</sup> The development of endotoxin tolerance in horses has been reported.<sup>62,63</sup> More recently, the term “cellular reprogramming” has been introduced to describe altered inflammatory cell functions in septic and SIRS patients. This term better accounts for the observation that cellular LPS-sensing ability appears to be maintained while intracellular signaling and thereby cytokine production is modified toward an anti- rather than pro-inflammatory response.<sup>59</sup>

Aside from cytokines, a number of other molecules function as inflammatory mediators in the pathogenesis of endotoxemia, the synthesis and release of which are stimulated by

endotoxin and by cytokines. These mediators include the arachidonic acid metabolites or prostanoids, PAF, oxygen-derived free radicals, nitric oxide, histamine, kinins, and complement components. [Table 15-4](#) summarizes the origins, targets, and effects of the most important inflammatory mediators involved in the pathogenesis of endotoxemia. [Figure 15-10](#) shows the pathways of arachidonic acid metabolism by COX and lipoxygenase. COX products are the prostaglandins (PGs), prostacyclin (PGI<sub>2</sub>) and thromboxanes, and the lipoxygenase produces the leukotrienes.

## ⊞ PATHOGENESIS

The innate immune response to LPS is an efficient defense mechanism that provides maintenance of homeostasis and therefore health in the face of an almost continuous exposure to microorganisms and their products.<sup>5</sup> Detrimental

TABLE 15-4

### Important Mediators of the Systemic Inflammatory Response to Endotoxin

Mediator	Origin	Effects
Tumor necrosis factor	Macrophages	Induces synthesis of TNF, IL-1, IL-6, and GM-CSF
	Monocytes	Activates neutrophils
	Neutrophils	Activates fibrinolysis and coagulation
	CD4+ T cells	Activates contact and complement system
	Natural killer cells	Induces a catabolic state
Interleukin-1		Induces insulin resistance
		Is a pyrogen (direct action and via IL-1 induction)
		Induces synthesis of TNF, IL-1, IL-6, PGI <sub>2</sub> , PAF, and GM-CSF
	Activated macrophages	Activates pyrogen
	Endothelial cells	Induces malaise
	Fibroblasts	Activates neutrophils and chemotaxis
	Dendritic cells	Activates fibrinolysis and coagulation
	Lymphocytes	Activates contact and complement system
	Keratinocytes	Induces acute phase response
		Increases activity of lipoprotein lipase
Interleukin-6		Mobilizes amino acids
		Induces muscle proteolysis
	Activated macrophages	Induces acute phase response
	Fibroblasts	Induces stress response
	Keratinocytes	Is a weak pyrogen
Interleukin-8	T lymphocytes	
	Macrophages	Activates neutrophils and chemotaxis
	Endothelial cells	
Thromboxane A <sub>2</sub>	Platelets	Induces vasoconstriction
Prostaglandin E <sub>2</sub>		Activates platelet aggregation
		Induces vasodilation
		Activates platelet aggregation
		Induces fever
Prostaglandin I <sub>2</sub>	Vascular endothelial cells	Induces vasodilation
		Inhibits platelet aggregation

Continued

TABLE 15-4

**Important Mediators of the Systemic Inflammatory Response to Endotoxin—cont'd**

Mediator	Origin	Effects
Platelet-activating factor	Macrophages	Activates platelet aggregation
	Platelets	Activates macrophages and neutrophils
	Neutrophils	Induces hypotension
	Mast cells	Increases vascular permeability
	Eosinophils	Aids recruitment of leukocytes
		Induces visceral smooth muscle contraction
	Is a negative inotrope and arrhythmogenic	Induces ileus
Prostaglandin F <sub>2α</sub>	Most nucleated cells	Induces vasoconstriction
		Activates luteolysis
Leukotriene B <sub>4</sub>	Most nucleated cells	Is a chemoattractant
		Promotes neutrophil interaction with endothelial cells
Leukotrienes C <sub>4</sub> , D <sub>4</sub> , E <sub>4</sub>	Most nucleated cells	Increase vascular permeability
		Induce bronchoconstriction
		Induce vasoconstriction
Kinins	Produced from serum precursors	Increase vascular permeability
		Induce smooth muscle contraction cause pain
Complement components (C3a, C5a)	—	Activate neutrophils and chemotaxis
		Induce smooth muscle constriction
		Induce mast cell degranulation
		Induce release of histamine and serotonin
		Increase vascular permeability
Oxygen-derived free radicals	Macrophages	Damage cell membranes
	Neutrophils	Inactive enzymes
		Damage tissues
Granulocyte- monocyte colony- stimulating factor	—	Induces rebound neutrophilia

TNF, Tumor necrosis factor; IL, interleukin; GM-CSF, granulocyte-monocyte colony-stimulating factor; PG, prostaglandin; PAF, platelet-activating factor.

consequences of this immune response occur only if excessive and uncontrolled mediator output results in endothelial damage, neutrophil-mediated tissue damage, and uncontrolled activation of the coagulation and fibrinolytic cascades and the complement system. Ultimately, the combination of these events culminates in cardiovascular instability, impaired hemostasis, organ failure, shock, and death. The following discussion addresses the various pathophysiologic events in the development of endotoxemia and shock and the role of inflammatory mediators.

### **ENDOTHELIAL DYSFUNCTION AND DAMAGE**

Normal endothelium plays an important role in regulating blood pressure and regional tissue perfusion and provides an anticoagulant surface. Endothelial dysfunction and damage result in a decreased responsiveness to vasoactive

agents (vasoplegia), increased vascular permeability, and a tendency for clot formation in the microvasculature. If the basement membrane and underlying matrix are compromised, microvascular hemorrhage can occur. Endothelial cell damage is primarily neutrophil-mediated. More specifically, damage is caused by oxygen-derived free radicals, which are produced within endothelial cells through reactions involving neutrophil-derived elastase and hydrogen peroxide molecules, endothelial cell enzymes such as xanthine oxidase, and endothelial cytosolic iron. The hypochloric anion radical (HO<sup>•</sup>) is thought to be responsible most directly for endothelial cell cytotoxicity. Nitric oxide, which is produced by constitutively expressed nitric oxide synthase in endothelial cells and scavenges superoxide radicals in a reaction to form peroxynitrite, may afford protection from oxygen radical-induced endothelial cell damage. Variations in the ability to produce nitric oxide may explain

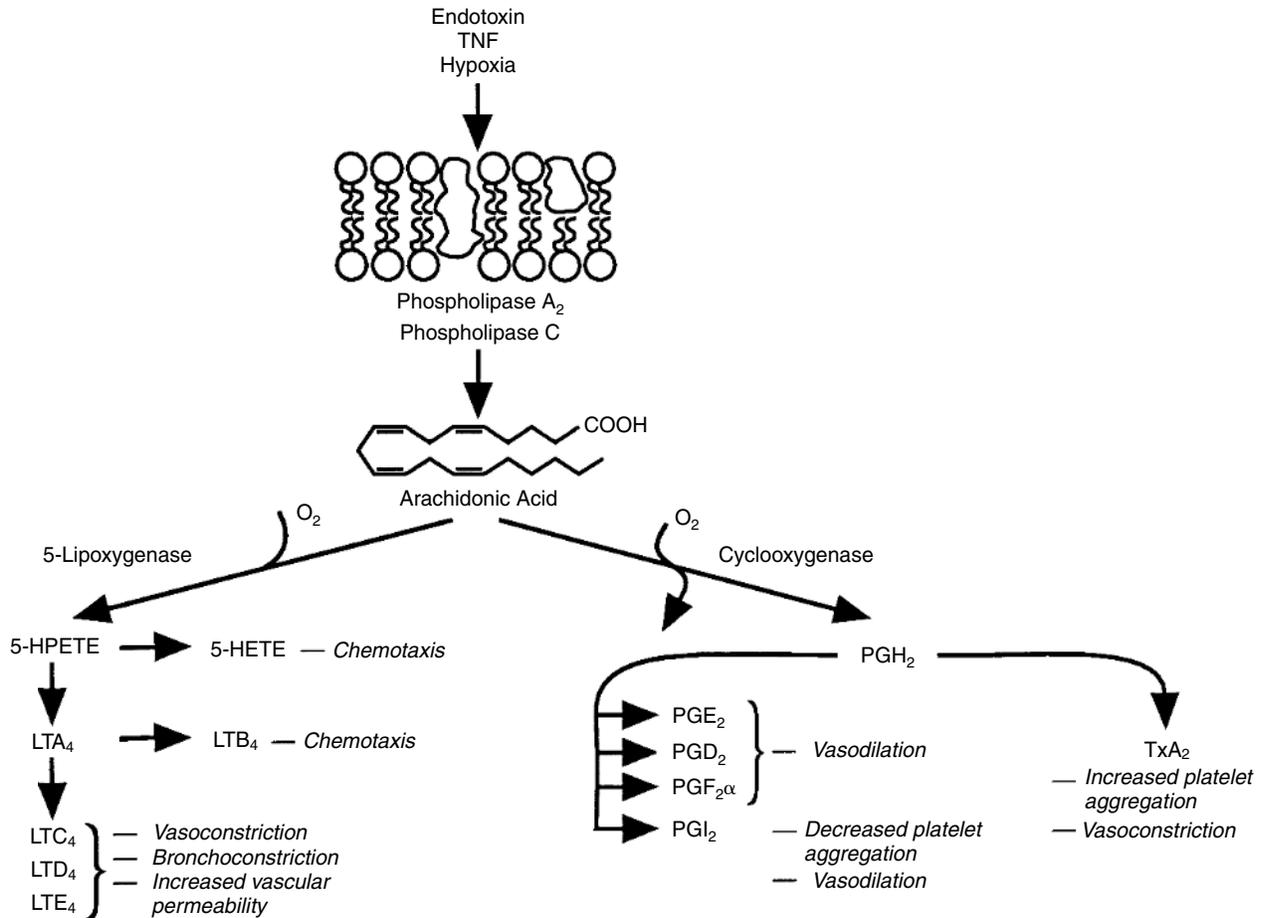

FIGURE 15-10 Pathways of arachidonic acid metabolism by cyclooxygenase and lipoxygenase.

why vascular beds in different organs vary in their susceptibility to neutrophil-mediated damage.<sup>64</sup> Excessive production of nitric oxide by an inducible form of nitric oxide synthase (iNOS), however, contributes to tissue damage, and increased peroxynitrite concentrations may be responsible in part for PAF-induced increases in vascular permeability.<sup>65</sup> In addition to oxygen-derived free radicals, activated neutrophils release matrix metalloproteinases, which contribute to tissue damage.<sup>55</sup> Vascular endothelial cells are further susceptible to direct effects of various cytokines, most prominently TNF- $\alpha$  and IL-1. These cytokines are thought to cause damage via the induction of COX activity and production of prostanoids and through generation of free radicals. Endothelial cell damage in response to endotoxin infusion and the association with leukocyte attachment have been demonstrated in horses.<sup>66</sup>

### NEUTROPHIL ACTIVATION, MARGINATION, AND TRANSMIGRATION

Neutrophil activation by LPS and cytokines results in stimulation of phagocytosis and the respiratory burst, release of lysosomal enzymes and inflammatory mediators, and expression of adhesion molecules. Perhaps the single most specific clinicopathologic indicator of endotoxemia is pronounced neutropenia,<sup>67</sup> which temporally correlates with peak plasma

concentrations of TNF.<sup>68</sup> Neutropenia is caused primarily by margination of neutrophils in the vasculature, especially of the lungs,<sup>69</sup> whereas significant loss through active migration into peripheral tissues likely is limited to the presence of a localized source of infection. In fact, neutrophils exposed to endotoxin or inflammatory mediators exhibit reduced capacity to respond to chemotactic stimuli and extravasate.<sup>69</sup> Margination is made possible by adhesion molecules on endothelial cells and leukocytes that interact and allow sticking of leukocytes to the endothelial lining of blood vessels. The details of neutrophil margination and transmigration are reviewed in several excellent texts.<sup>50,70</sup> Recent evidence demonstrates a role for TLR-4 in neutrophil margination in the lung microvasculature during endotoxemia, and suggests that activation and TLR-4 expression of endothelial cells may be more important than that of circulating neutrophils.<sup>69</sup> While neutrophil activation during infections provides the body with an effective defense system against microbial invaders, margination and reduced migratory ability of neutrophils during endotoxemia results in the accumulation of activated cells at the endothelial surface. These cells are then positioned to effect endothelial injury, increase vascular permeability, and in some cases cause parenchymal cell death and organ dysfunction.<sup>71</sup> In addition, inhibition of transmigration deprives the body of phagocytic cells at sites of infection, resulting in reduced ability to fight bacterial infection.

This latter complication of endotoxemia may have significant clinical impact, because defective neutrophil recruitment has been demonstrated at low endotoxin doses that do not yet result in tissue damage.<sup>71,72</sup> In human patients endotoxemia and impaired neutrophil migration have been associated with infectious complications of surgical procedures.<sup>71</sup> Decreased phagocytic function and oxidative burst activity have also been suggested in sick and septic hospitalized foals,<sup>73,74</sup> where a beneficial effect of plasma transfusion on neutrophil function could be demonstrated. The mechanisms of migration inhibition during endotoxemia are incompletely understood but may include occupation of neutrophil chemotactic receptors by cytokines and complement components, resulting in an inability of activated cells to respond to a chemotactic gradient.<sup>71</sup> Rebound neutrophilia, which is observed frequently following episodes of endotoxemia, is caused by neutrophil release from the bone marrow reserve pool and by stimulation of myeloid cell proliferation via granulocyte-macrophage colony-stimulating factor and is mediated primarily by TNF and IL-1.<sup>53</sup>

### COAGULOPATHY AND DISSEMINATED INTRAVASCULAR COAGULATION

In health coagulation and fibrinolysis underlie stringent control mechanisms that allow appropriate clot formation and their resolution. Coagulopathies frequently are observed in horses with colic<sup>17,75,76</sup> and foals with sepsis<sup>11</sup> and are likely attributable to endotoxemia. In human medicine virtually all septic patients are considered to have some degree of coagulopathy, which may range from subclinical abnormalities of the clotting profile to fulminant disseminated intravascular coagulation (DIC).<sup>77,78</sup> DIC results from a widespread activation of the coagulation and fibrinolytic systems and failure of their control mechanisms. Ultimately, this leads to disseminated fibrin deposition in the microvasculature, consumption of platelets and clotting factors, and accumulation of fibrin degradation products (FDPs). Depending on the underlying disease process and the relative impairment of the coagulation and fibrinolytic systems, DIC can manifest as a diffuse thrombotic syndrome leading to ischemic organ failure, a fibrinolytic syndrome with uncontrolled hemorrhage, or a combination of both.<sup>79</sup> A procoagulant state characterized by clinicopathologic abnormalities of the clotting profile precedes DIC.

The intrinsic and extrinsic arms of the coagulation cascade are activated in endotoxemia. The intrinsic pathway is initiated by activation of coagulation factor XII (HF), prekallikrein, and high-molecular-weight kininogen, which compose the contact system.<sup>19</sup> Although direct activation of coagulation factor XII by endotoxin has been demonstrated,<sup>80</sup> the extrinsic pathway likely is more important for the development of coagulopathy in endotoxemia and sepsis.<sup>19</sup> Activation of the extrinsic pathway depends on the interaction of coagulation factor VII with tissue factor, which is the only coagulation factor not constitutively present in blood. Tissue factor is present in subendothelial tissues and is exposed on vascular injury but also is expressed on endothelial cells and mononuclear phagocytes in response to LPS.<sup>81,82</sup> Increased expression of monocyte tissue factor (also described as increased procoagulant activity) was found to be associated significantly with coagulopathy and poor prognosis in horses with colic.<sup>83</sup> Furthermore, LPS-induced

tissue factor expression by equine peritoneal macrophages may be associated with the development of intra-abdominal adhesions.<sup>62</sup>

Regulatory mechanisms of the coagulation cascade include tissue factor pathway inhibitor, antithrombin III (AT III), and the protein C system.<sup>19</sup> Protein C acts as an anticoagulant by inactivating clotting factors V and VIII and promotes fibrinolysis by inactivating plasminogen activator inhibitor (PAI).<sup>84</sup> Protein C activation by thrombin-thrombomodulin complexes is important for the anticoagulative properties of normal endothelium,<sup>19</sup> and downregulation of endothelial thrombomodulin expression by TNF and IL-1 along with decreased expression of AT III and tissue factor pathway inhibitor by damaged endothelial cells contribute to the procoagulant state in endotoxemia and sepsis.<sup>85-87</sup> In addition, activation of vascular endothelial cells leads to a loss of prostacyclin and nitric oxide production and an increased release of thromboxane A<sub>2</sub> (TXA<sub>2</sub>). As a result, platelets are stimulated to aggregate and release TXA<sub>2</sub> and PAF, thereby further promoting clot formation.<sup>18</sup>

The crucial step in the fibrinolytic cascade is the conversion of plasminogen to plasmin, a fibrin-degrading enzyme.<sup>19</sup> Tissue-type (tPA) and urokinase-type (uPA) plasminogen activator are the major initiators of fibrinolysis, whereas PAI and  $\alpha$ 2-antiplasmin are the main regulatory components.<sup>88,89</sup> TNF and IL-1 have been shown to induce the release of uPA and tPA and the synthesis of PAI.<sup>19</sup> Activation of fibrinolysis leads to consumption of  $\alpha$ 2-antiplasmin and accumulation of FDPs, which if present in high concentrations can interfere with platelet aggregation, fibrin polymerization, and thrombin formation and can promote bleeding. Additionally, FDPs mediate an increase in vascular permeability. LPS infusion in rabbits<sup>90</sup> and human beings<sup>91</sup> resulted in an early increase in plasma tPA activity, followed by a later profound rise in PAI activity and fall in tPA activity. Increased plasma PAI concentrations also were found in horses with colic compared with controls.<sup>92,93</sup> Thus although fibrinolysis may compensate initially for accelerated coagulation, its subsequent inhibition contributes to clot formation.

Cross-activation between the inflammatory and coagulation cascades plays an important role in endotoxemia and sepsis, and presence of coagulopathies has been associated with an increased risk of organ failure and poor outcome in septic human patients.<sup>77,78</sup> Interestingly, activated protein C, an anticoagulant, is the only new treatment shown to reduce mortality in septic human patients.<sup>94</sup> Activated protein C reduces inflammation by inhibiting leukocyte activation and cytokine production and was shown to lower plasma concentration of IL-6.<sup>94</sup> Although bleeding complications were increased in treated patients, incidence of severe bleeding was not increased significantly.

### COMPLEMENT ACTIVATION

Activation of the complement system in endotoxemia occurs via the alternative pathway through interaction with LPS. Increased concentrations of plasmin and kallikrein (caused by activation of the fibrinolytic and contact system) further promote this pathway by directly activating complement factors C3a and C5a. Aside from being key molecules in the complement cascade, C3a and C5a are anaphylatoxins and cause an increase in vascular permeability via mast cell degranulation. C5a further activates the lipooxygenase pathway in

neutrophils and monocytes, acts as a chemotaxin for leukocytes and monocytes, and promotes neutrophil adhesion to endothelial cells.

### ACUTE PHASE RESPONSE

In response to acute inflammation, synthesis and secretion of a number of proteins called the *acute phase proteins* increases in hepatocytes, whereas synthesis of albumin decreases. The primary function of this acute phase response may be to suppress and contain inflammatory processes.<sup>55</sup> IL-6 and IL-1 are the most important cytokines that induce the acute phase response,<sup>95</sup> which typically begins within a few hours of the insult and subsides within 24 to 48 hours,<sup>50</sup> unless the initiating cause persists. In horses fibrinogen (the most commonly evaluated acute phase protein), haptoglobin, transferrin, ferritin, ceruloplasmin, coagulation factor VIII:C, serum amyloid A, C-reactive protein,  $\alpha$ 1-acid glycoprotein, and phospholipase A2 are considered part of the acute phase response.<sup>96</sup> Serum amyloid A has been evaluated in several studies and was found to be a sensitive indicator of experimentally induced inflammation.<sup>97</sup> Although serum amyloid A is a nonspecific indicator of inflammation, its measurement may be helpful in the diagnosis of inflammatory gastrointestinal disease,<sup>37</sup> neonatal weakness and diarrhea,<sup>98</sup> and various infectious diseases. A commercially available turbidometric immunoassay for human serum amyloid A was reliable in measuring equine serum amyloid A in one study.<sup>99</sup>

The effect of acute inflammation on the serum concentration of several coagulation factors must be considered when evaluating coagulation profiles. Serum fibrinogen concentration is determined primarily by the acute phase response, although fibrinogen is consumed increasingly on activation of the clotting cascade.

### HEMODYNAMIC CHANGES, DEVELOPMENT OF SHOCK, AND ORGAN FAILURE

Shock is characterized by a loss of homeostasis attributable to breakdown of hemodynamic control mechanisms, decreases in cardiac output and the effective circulating volume, and inadequate perfusion of vital organs. Shock caused by endotoxemia is classified as distributive shock<sup>100</sup> and is largely initiated by vascular dysfunction in the periphery. Peripheral vascular beds are of major importance for the regulation of local tissue perfusion and affect systemic blood pressure by regulating total peripheral resistance. Normally, vascular smooth muscle tone is regulated by endothelin-1 (vasoconstriction), nitric oxide, and prostacyclin (vasodilation) released from vascular endothelial cells.<sup>19</sup> As mentioned before, detrimental effects of nitric oxide are attributable to overproduction of nitric oxide by iNOS in macrophages and other cell types, rather than endothelial-derived nitric oxide. Peripheral vasomotor effects of endotoxin manifest as vasodilation and vasoplegia and are mediated by PGI<sub>2</sub>, nitric oxide, and mediators such as bradykinin. Widespread vasodilation leads to vascular blood pooling, decentralization of blood flow, decreased venous return, and in effect decreased effective circulating volume and cardiac output.<sup>100</sup> Compensatory responses in the form of an initial hyperdynamic phase include tachycardia, increased cardiac output and central venous pressure, pulmonary hypertension, peripheral vasoconstriction, and increased peripheral vascular resistance.<sup>100-102</sup>

The early vasoconstrictive phase corresponds to an increased serum concentration of TXA<sub>2</sub>,<sup>18</sup> but additional vasoconstrictors such as arginine vasopressin, angiotensin II, serotonin, endothelin, and norepinephrine likely are implicated in the pathogenesis of shock and organ failure.<sup>55</sup> With progression of disease the animal enters a stage of decompensated shock and progressive systemic hypotension, which corresponds to increased plasma concentrations of prostacyclin, PGE<sub>2</sub>, and bradykinin.<sup>18,55</sup> Inadequate blood flow and oxygen delivery to tissues caused by hypotension are confounded by direct myocardial suppression via nitric oxide,<sup>100</sup> increased vascular permeability,<sup>18</sup> intravascular microthrombosis, and impaired tissue oxygen extraction<sup>100</sup> and results in progressive metabolic acidosis and inhibition of normal cellular metabolism.

### CLINICAL SIGNS AND DIAGNOSIS

Quantification of endotoxin in plasma samples is possible. The *Limulus* amebocyte lysate assay is an activity assay based on the endotoxin-sensitive hemolymph coagulation cascade in the horseshoe crab *Limulus polyphemus*. In *Limulus* this reaction is thought to be a defense mechanism against gram negative infection.<sup>103</sup> Although frequently used as a research tool, the assay is not convenient enough to become a routine clinical test. The clinician therefore must appreciate the primary disease processes associated with a high risk of endotoxemia and rely on clinical signs and clinicopathologic data to achieve a diagnosis. In a survey of board-certified internists and surgeons concerning endotoxemia in horses, colitis and enteritis, small intestinal strangulation and obstruction, retained placenta and metritis in mares, grain overload, and pleuropneumonia were among the most frequently cited conditions associated with endotoxemia.<sup>104</sup> In some cases, endotoxemia may be the first indication of disease or may be the most overt of otherwise subtle clinical manifestations. With colitis or proximal enteritis, for example, one may detect signs of endotoxemia before the development of colic, diarrhea, or gastric reflux, which more specifically indicate the nature of the primary illness. Presence of neutropenia should always prompt the clinician to investigate causes of endotoxemia, including septic processes.

In vivo LPS challenge experiments in horses clearly show that many of the clinical signs associated with acute gastrointestinal disease and sepsis are attributable to endotoxemia. On administration of sublethal doses of LPS, the clinical response can be divided into the early hyperdynamic and the later hypodynamic or shock phases. Clinical signs during the first phase, which begins within 15 to 45 minutes after LPS administration, include anorexia, yawning, sweating, depression, evidence of abdominal discomfort, muscle fasciculations, and recumbency. Heart and respiratory rates increase, and decreased borborygmi suggest ileus. Hyperemia of the mucous membranes and an accelerated capillary refill time indicate the hyperdynamic state.<sup>67</sup> If large amounts of LPS are administered or if exposure is ongoing, depression worsens progressively, anorexia persists, and feces develop diarrhetic character. Signs of colic typically abate after the initial stage. Fever develops as a result of direct action of TNF on the thermoregulatory center and IL-1-induced local production of PGE<sub>2</sub> in or near the hypothalamus.<sup>105,106</sup> Because of compromised peripheral perfusion, mucous membrane color changes to brick

red or purple, a dark "toxic" line appears, and capillary refill time is prolonged.<sup>67</sup> Inadequate peripheral perfusion and compromised organ function finally characterize the hypodynamic shock phase. Body temperature may become subnormal, and the skin, especially on extremities, is cool to the touch. The arterial pulse weakens and venous fill is decreased. Vascular endothelial damage and increased capillary permeability result in a muddy mucous membrane color and diffuse scleral reddening. Similar changes are evident in horses suffering from endotoxemia associated with natural disease. In the previously mentioned survey,<sup>104</sup> tachycardia, fever, abnormal mucous membrane color, and increased capillary refill time were named by most specialists as indicating endotoxemia.

Hemostatic abnormalities can manifest in the form of thrombosis, such as of the jugular vein, or increased bleeding tendency with mucosal petechiation or ecchymoses and prolonged bleeding from venipuncture sites.<sup>79</sup> Bleeding also may occur in the form of spontaneous epistaxis or prolonged hemorrhage after nasogastric intubation.<sup>18</sup> Additional clinical signs typically reflect the development of organ failure. Renal failure and laminitis<sup>104</sup> appear to be common complications of endotoxemia in horses, and endotoxemia was identified as the only clinical condition significantly associated with the development of acute laminitis in one retrospective case-control study of horses admitted to a referral center.<sup>107</sup> Other potential complications include liver failure,<sup>79</sup> respiratory failure, colic and ischemia-induced gastrointestinal ulceration,<sup>18</sup> cardiac failure, and abortion in pregnant mares.<sup>108,109</sup> Renal failure results from ischemic cortical necrosis and acute tubular necrosis caused by coagulopathy-induced afferent arteriolar obstruction. Clinical signs may include oliguria, anuria, or hematuria caused by renal infarction. Laminitis may lead to lameness, increased digital arterial pulsation, increased warmth of the hoof wall, and sensitivity to hoof tester pressure. The exact nature of the association between endotoxemia and laminitis is not understood, and, interestingly, experimental endotoxin infusion does not reliably induce laminitis. Studies have shown, however, that endotoxin administration decreases digital blood flow and laminar perfusion<sup>110</sup> coincident with increased plasma concentrations of 5-hydroxytryptamine and thromboxane B<sub>2</sub>.<sup>111</sup> In addition, *in vitro* vascular reactivity of digital vessels is altered following sublethal endotoxin administration to horses.<sup>112</sup> In addition to the response to circulating mediators, LPS exposure also alters the production of vasoactive mediators by digital vascular endothelial cells.<sup>113</sup> Alterations in vascular reactivity are therefore likely responsible for development of laminitis in endotoxemia; however, other mechanisms may apply depending on the underlying clinical disease.

## ☞ CLINICAL PATHOLOGIC TESTING

Alterations in the hemogram and serum biochemical profile mainly reflect the underlying disease process and the occurrence of organ failure. Leukopenia caused by neutropenia may be the most specific indicator of acute bacterial sepsis or endotoxemia.<sup>67</sup> In prolonged cases an increased proportion of immature neutrophil forms (bands), and toxic changes are observed. Toxic changes resulting from neutrophil activation include vacuolation, cytoplasmic granulation, basophilic cytoplasm, and Döhle's bodies. Because neutropenia occurs early in the development of endotoxemia, it also may be a

useful parameter for monitoring horses at risk.<sup>67</sup> On recovery neutropenia typically is followed by a pronounced rebound neutrophilia.

An elevated hematocrit and total serum protein concentration are frequently interpreted as evidence of dehydration; however, splenic contraction caused by increased sympathetic stimulation, increased production of acute phase proteins, or protein losses also influence these parameters. Hyperproteinemia may be observed as a result of increases in the fibrinogen or globulin concentration, and determination of protein fractions, including protein electrophoresis, is indicated in hyperproteinemic patients. Hypoproteinemia and hypoalbuminemia can occur because of loss via the gastrointestinal or urinary tract or with pleural or peritoneal cavity effusion. Increased vascular permeability and edema formation contribute to hypoproteinemia.

Serum electrolyte abnormalities primarily depend on the nature and duration of underlying disease processes and need to be evaluated individually. Common sources of electrolyte loss are gastrointestinal secretions, urine, and sweat; however, severe effusion into body cavities may contribute. In anorexic patients lack of dietary intake is a confounding factor that warrants consideration. In human patients gram negative sepsis frequently is associated with hypocalcemia, more specifically a decrease in serum ionized calcium concentration. Endotoxin is thought to be a causative factor, and proposed mechanisms include acquired parathyroid gland insufficiency, dietary vitamin D deficiency, impaired calcium mobilization, and renal 1-hydroxylase insufficiency leading to decreased 1,25-hydroxylation of vitamin D. Hypocalcemia in septic human patients was associated with hypotension and poor outcome.<sup>114</sup> In horses with surgically managed gastrointestinal disease, decreased serum ionized calcium concentration was a common finding and was most severe in patients with strangulating or nonstrangulating infarctions. In some horses ionized calcium concentration decreased further throughout surgery. Treatment with calcium gluconate resulted in normalization of serum ionized calcium concentrations in all cases.<sup>115</sup>

Septic neonatal patients are frequently hypoglycemic, which may be attributable to decreased oral intake, generally increased metabolism, glucose use by the infecting bacteria, inhibition of gluconeogenesis by endotoxin, and insulin-like activity produced by macrophages.<sup>18</sup> Interestingly, experimental endotoxin administration results in transient hyperglycemia in adult horses,<sup>101</sup> whereas profound hypoglycemia occurs in foals.<sup>116</sup> Because of the high incidence of coagulopathies in endotoxemic and septic patients, clinicians should consider monitoring coagulation parameters. The most significant changes can be expected with severe inflammatory disease such as colitis,<sup>75,76</sup> devitalized intestine as with strangulating obstruction,<sup>76,117</sup> and with increased duration of disease. In 30 horses with acute gastrointestinal disease, coagulation profiles were considered normal in only two horses.<sup>75</sup> Although coagulation times may be shortened during the procoagulant state, commonly observed abnormalities with developing DIC include an increased concentration of FDPs and soluble fibrin monomer, prolonged prothrombin time indicative of factor VII consumption, prolonged activated partial thromboplastin time indicative of factor VIII:C and IX consumption, prolonged thrombin time, decreased AT III activity, thrombocytopenia, and decreased protein C and plasminogen activities. Fibrinogen concentration appears to reflect the acute phase

response rather than coagulation abnormalities in horses and is frequently increased.<sup>83</sup> Some clinicians make a diagnosis of DIC if three or more coagulation parameters (specifically AT III, FDPs, platelet count, prothrombin time, and activated partial thromboplastin time) are abnormal,<sup>117</sup> whereas others require overt clinical signs of hemorrhage and concomitant thrombosis in addition to classic laboratory findings.<sup>76</sup> The prognostic value of coagulation parameters has been evaluated.<sup>17,76,93</sup> Overall, persistence or worsening of abnormalities in the face of treatment appears to be more indicative of poor outcome than alterations in any specific parameter. In one study decreased serum AT III concentration was the parameter most commonly associated with fatal outcome in mature horses with colic.<sup>75</sup>

Clinical pathologic parameters are also helpful in identifying potential underlying diseases and monitoring organ function. Serum creatinine and urea nitrogen concentration in combination with urinalysis parameters are usually monitored as indicators of renal function, whereas serum activity of liver enzymes, serum indirect and direct bilirubin concentration, serum bile acids, and blood ammonia are useful indicators of liver function. One should evaluate arterial blood gases in patients with primary respiratory disease or with clinical evidence of respiratory failure and in profoundly depressed, recumbent patients, especially neonates. Hypoxemia observed in response to endotoxin infusion is thought to be caused by an increase in ventilation-perfusion mismatch rather than pulmonary edema, as occurs in human patients with acute respiratory distress syndrome. Pulmonary edema may occur in patients with associated sepsis or complications such as DIC.<sup>118</sup>

## MANAGEMENT

The ideal treatment for endotoxemia is prevention. Recognition and close monitoring of patients at risk are crucial because doing so allows institution of timely, possibly proactive treatment, which may reverse the effects of endotoxin before the inflammatory response has developed a dynamic of its own. Unfortunately, endotoxemia can develop rapidly, and horses are exquisitely sensitive to the effects of endotoxin; therefore many equine patients are not presented for evaluation until they have reached more severe stages of endotoxemia or shock. Prognosis and patient outcome then frequently depend on the severity of complications associated with endotoxemia.<sup>18</sup>

Treatment of endotoxemia involves multiple aspects, and the following strategies have been proposed:<sup>119</sup>

- Inhibition of endotoxin release into the circulation
- Scavenging of LPS molecules to prevent direct effects and interaction with inflammatory cells
- Inhibition of cellular activation by LPS
- Inhibition of mediator synthesis
- Interference with the effects of inflammatory mediators
- General supportive care

In addition, treatment must also address the primary disease process as well as any complications.

When evaluating reports concerning the efficacy of any one treatment, the clinician should keep in mind differences in underlying disease processes and the complexity of the inflammatory cascade. A “one for all” treatment most likely will not be found; similarly, any one treatment can

address only a few pathophysiologic aspects of endotoxemia at most. In human septic patients many treatments that showed initial promise for improving patient outcome failed to show benefit in larger populations, although benefit for certain subgroups of patients was sometimes demonstrated. Understanding the rationale for different treatment strategies is therefore important to be able to tailor treatment to the needs of the patient. In the following sections discussion will focus on treatments that have been evaluated for use in horses, while mention is also made of studies in other species, where applicable.

## INHIBITION OF ENDOTOXIN RELEASE INTO THE CIRCULATION

Inhibition of endotoxin release requires identification and removal of its source. Therefore whenever endotoxemia is evident, the clinician should strive to reach a diagnosis of the underlying disease and ascertain whether ischemic or inflamed bowel or a gram negative septic process is present. Aside from history, physical examination, and routine laboratory testing, evaluation may include exploratory laparotomy in colic patients, radiographic and ultrasonographic evaluation of the pleural and peritoneal cavity, ultrasonographic evaluation of umbilical remnants in neonatal foals, evaluation of passive transfer and calculation of a sepsis score in foals, and repeated culturing of blood or other specimens. Identification of responsible microorganisms and their antimicrobial sensitivity spectrum is a crucial step toward effective therapy; however, one should not necessarily delay treatment to obtain culture results. Specimen containers with antimicrobial removal devices may be useful in cases for which initiation of treatment precedes specimen collection. Once a diagnosis is reached, appropriate measures to correct the primary disease process must be taken. Examples are removal of devitalized sections of bowel or infected umbilical remnants, drainage of infected pleural or PF, and gastric lavage followed by administration of mineral oil or intestinal adsorbants in cases of grain overload. Di-tri-octahedral smectite (Biosponge™, Platinum Performance Inc., Buellton, California) was shown to remove endotoxin in an *in vitro* assay<sup>120</sup> and may be useful in preventing endotoxemia of intestinal origin. Septic processes must be addressed with appropriate antimicrobial therapy, and principles of antimicrobial therapy should be followed. Regarding endotoxemia specifically, antimicrobial therapy has been suggested to increase the amount of circulating endotoxin by inducing endotoxin release on cell death of gram negative bacteria. An *in vitro* study comparing endotoxin release and inflammatory mediator activity among antimicrobials commonly used to treat *E. coli* septicemia in foals evaluated amikacin, ampicillin, amikacin plus ampicillin, ceftiofur, and imipenem. Although these antimicrobials showed no difference in the ability to kill bacteria, amikacin and the amikacin-ampicillin combination resulted in the lowest, and ceftiofur in the greatest, release of endotoxin. Endotoxin release appeared to be dose dependent in that lesser amounts were released at higher antimicrobial concentrations.<sup>121</sup> On the basis of these results and clinical experience, combining antimicrobial therapy with endotoxin-binding agents such as polymyxin B may be beneficial, especially when using  $\beta$ -lactam antimicrobials.

## SCAVENGING OF LIPOPOLYSACCHARIDE MOLECULES

Endotoxin typically has a short plasma half-life and is removed rapidly by mononuclear phagocytes or neutralized by binding to serum proteins and lipoproteins. Many conditions responsible for the development of endotoxemia in horses, however, may be associated with an ongoing release of endotoxin. Examples include severe gastrointestinal inflammation as in proximal enteritis or colitis, grain overload, or uncontrolled sepsis. Therapy directed against endotoxin itself may be able to interrupt the continuous activation of the inflammatory cascade in these cases. Further benefits of anti-endotoxin treatment may be derived if large amounts of endotoxin have been released before the inciting cause can be addressed.

### IMMUNOTHERAPY

An important consideration regarding the efficacy of immunotherapy is the region of the LPS molecule against which antibodies are raised. The O-chain of LPS acts as a potent antigen on infection with gram negative bacteria;<sup>7</sup> however, antibodies directed against the O-chain are serotype specific and cannot afford significant cross-protection against heterologous bacterial strains. The core and lipid A region, both of which show a much higher degree of homology between LPS derived from different bacterial strains, offer a more promising target for immunotherapy. Active immunization against endotoxin has been reported for horses. Vaccination with a bacterin-toxoid vaccine prepared from rough mutants of *Salmonella typhimurium* or *S. enteritidis* protected horses against homologous and heterologous endotoxin challenge<sup>122,123</sup> and carbohydrate overload.<sup>132</sup> Despite these encouraging results and the current availability of a vaccine for use in horses (Endovac-Equi, Immvac Inc., Columbus, Missouri), active immunization against endotoxin does not appear to be a common practice. In comparison, passive immunization with antilipoplysaccharide antibodies is used widely. Rough bacterial mutants, most commonly J5 of *E. coli* O111:B4 and *S. minnesota* Re595, are used to immunize donor horses and subsequently prepare serum or plasma products. Proposed mechanisms of action after binding of the antibodies to LPS include steric blockade of lipid A interaction with cellular receptors and enhanced bacterial clearance by opsonization.<sup>124-126</sup> Studies concerning the efficacy of antibody administration in equine patients vary in their results. Beneficial effects have been described in experimental models of endotoxemia, acute gastrointestinal disease, and neonates with sepsis,<sup>123,127-130</sup> whereas in other studies antibodies failed to protect foals and horses against endotoxin effects.<sup>131-133</sup> Furthermore, administration of a *S. typhimurium* antiserum to foals was associated with an increased respiratory rate and higher serum activities of IL-6 and TNF.<sup>131</sup>

Various equine serum and plasma products are commercially available. An antiserum raised against the LPS-core of *S. typhimurium* (Endoserum®, Immvac Inc., Columbus, Missouri) is available for administration to endotoxemic horses at a recommended dose of 1.5 ml/kg body mass. Diluting the serum tenfold to 20-fold in crystalloid intravenous solutions, administering it slowly over 1 to 2 hours, and monitoring the patient for adverse reactions is advisable. Although the product is marketed for use in foals with failure of passive transfer, adverse effects have been reported,<sup>131</sup> and one should use caution when administering it to neonates. Plasma from donors

inoculated with J5 (*E. coli*) and *S. typhimurium* (Re mutant) is available under a California license (Equiplas J®, Plasvacc USA Inc, Templeton, California). The manufacturer recommends administration of at least 1 to 2 L in cases of endotoxemia. In addition, hyperimmune plasma, which has a guaranteed minimum immunoglobulin G content but does not contain specific antiendotoxin antibodies (Hi-Gamm Equi, Lake Immunogenics, Inc., Ontario, New York; Equiplas and Equiplas Plus, Plasvacc USA Inc.), is marketed for treatment of failure of passive transfer, and many clinicians use it to treat endotoxemia and sepsis. In addition to antibodies and protein, plasma contains active constituents such as complement components, fibronectin, clotting factors, and AT III<sup>128</sup> and therefore may be particularly useful in patients with endotoxemia-induced coagulopathy. Volumes of 2 to 10 ml/kg body mass of hyperimmune plasma have been recommended for use in endotoxemic patients.<sup>55,134</sup>

### POLYMYXIN B

Polymyxin B is a cationic polypeptide antibiotic that binds to the anionic lipid A portion of LPS and neutralizes its endotoxin capacity.<sup>135</sup> At dosages required for antimicrobial activity, polymyxin B carries the risk of respiratory paralysis and ototoxic, nephrotoxic, and neurotoxic side effects; however, a much lower dose is required for endotoxin-binding activity. The effects of polymyxin B in horses have been evaluated in different experimental models.<sup>131,135,136</sup> In an in vivo study in foals, treatment with polymyxin B at a dosage of 6000 U/kg body mass before infusion with *S. typhimurium* LPS resulted in significantly less severe elevations of body temperature, respiratory rate, and serum activities of TNF and IL-6 compared with untreated controls.<sup>131</sup> Similarly, polymyxin B treatment of adult horses given endotoxin significantly ameliorated clinical signs and decreased plasma TNF activity.<sup>137</sup> In the latter study benefits of treatment were also evident at lower dosages of polymyxin B (1000 and 5000 U/kg body mass) and administration of polymyxin B 1 hour after the start of endotoxin infusion. Conversely, polymyxin B failed to ameliorate clinical signs of endotoxemia or prevent the development of coagulopathy, acidosis, lameness, and shock in experimental carbohydrate overload.<sup>138</sup> Side effects suggestive of neurotoxicity appeared after repeated administration of 5 mg/kg body mass (36,000 U/kg) and in milder form 2.5 mg/kg body mass (18,000 U/kg) polymyxin B. Nephrotoxicity was not observed. Currently, use of polymyxin B in equine patients is recommended at dosages of 1000 to 6000 U/kg body mass every 8 to 12 hours.<sup>139,140</sup> Treatment should be initiated as early in the disease process as possible because the beneficial effects of LPS scavenging may be limited to the first 24 to 48 hours after the onset of endotoxemia, before endotoxin tolerance develops. Side effects in the form of neuromuscular blockade and apnea, which necessitate slow infusion of the drug in human patients, have not been observed in horses. Therefore the entire dose can be administered as a slow bolus. If treating horses with hypovolemia, dehydration, or azotemia, the clinician should attempt to improve peripheral tissue perfusion, minimize the polymyxin B dose, and closely monitor patients for nephrotoxicity. Close monitoring is also important if medications such as aminoglycoside antibiotics, which share a similar spectrum of potential side effects, are administered concurrently. Azotemic neonates have been reported to be more susceptible to the nephrotoxic effects of polymyxin B than adult horses.<sup>137</sup>

In an attempt to decrease the risk for adverse effects while preserving LPS-neutralizing ability, a conjugate of polymyxin B with dextran has been developed.<sup>141</sup> In conjugated form, polymyxin B is prevented from extravasation into tissues, where it exerts toxic effects by interaction with cell membranes. In addition, conjugation increases the residence time of polymyxin B in the circulation and therefore should prolong the anti-endotoxic effect. The polymyxin B–dextran combination was evaluated at a total dose of 5 mg/kg body mass of polymyxin B in 6.6 g/kg body mass dextran given 15 minutes before administration of endotoxin in horses.<sup>142</sup> Treatment was found to block the development of tachycardia, tachypnea, fever, and neutropenia completely and to prevent increases in serum concentrations of TNF, IL-6, TXB<sub>2</sub> (a TXA<sub>2</sub> metabolite), and the prostacyclin metabolite 6-keto-PGF<sub>1</sub>α. Although mild adverse effects in the form of tachypnea, sweating, and increased systolic blood pressure were observed, these were transient and could be prevented by pretreatment with ketoprofen. To the author's knowledge, the polymyxin B–dextran combination is not commercially available at this time.

### NATURAL ENDOTOXIN-BINDING SUBSTANCES

Natural endotoxin-binding proteins such as LBP, lipoproteins, and sCD14 have been evaluated experimentally. Results of these studies are somewhat contradictory, and detrimental effects occurred in some cases.<sup>143</sup> A protein receiving much attention regarding potential therapeutic efficacy is the bactericidal permeability-increasing protein (BPI). This protein is structurally similar to LBP but is expressed exclusively in myeloid precursors of polymorphonuclear leukocytes.<sup>144</sup> BPI is stored in primary granules of mature neutrophils and during inflammation is expressed on their cell membranes and secreted into the extracellular environment.<sup>145</sup> BPI has an even higher affinity for LPS than LBP<sup>146</sup> and shows antibacterial activity specific for gram negative bacteria.<sup>5</sup> Binding of BPI to the gram negative bacterial membrane results in growth arrest and is an important factor in the antibacterial activity of intact neutrophils. Furthermore, BPI binding disrupts normal membrane organization and makes bacteria more susceptible to hydrophobic substances, including antimicrobials.<sup>147</sup> Experimentally, recombinant BPI protects against the toxic and lethal effects of isolated LPS and intact gram negative bacteria, and clinical trials in human patients show promising results regarding its therapeutic use.<sup>148</sup> The biology and potential use of BPI in horses has not been evaluated.

Phospholipid emulsions have recently been evaluated for treatment of experimentally induced endotoxemia in horses. Phospholipid infusion improved clinical parameters, ameliorated neutropenia, and reduced inflammatory mediator production in response to an endotoxin challenge.<sup>149,150</sup> Because hemolysis was a complication of phospholipid infusion in some horses in these studies, optimization of dose and time of administration will be necessary before evaluating this treatment for potential clinical use.

### INHIBITION OF CELLULAR ACTIVATION BY LIPOPOLYSACCHARIDE

Treatments aimed at inhibiting LPS interaction with cells or turning off intracellular signaling pathways are under investigation. Nontoxic LPS or lipid A structures can act as endotoxin antagonists, if they competitively inhibit binding to LBP or cellular receptors or inhibit cellular activation by other

mechanisms. Of the potential antagonists that have been evaluated experimentally, LPS and lipid A of the phototrophic bacterium *Rhodobacter sphaeroides* and the synthetic compounds E5531 and E5564 have been most promising.<sup>150-156</sup> Unfortunately, species differences exist regarding cellular response to these structures, and *R. sphaeroides* LPS as well as E5531 have been found to have agonist activity in equine cells.<sup>157,158</sup> In cell transfection experiments, TLR4 was shown to be responsible for this phenotypic variation with regard to *R. sphaeroides* LPS.<sup>159</sup> Given these results, any future potential LPS antagonists must be evaluated in equine systems.

## INHIBITION OF MEDIATOR SYNTHESIS

### NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

NSAIDs are probably the most commonly used drugs to treat endotoxemia in horses. The rationale for their use is inhibition of COX and thereby inhibition of prostanoid production (see Figure 15-10). Additional beneficial effects may include scavenging of oxygen-derived free radicals and iron chelation; however, side effects may occur at dosages required to achieve these effects.<sup>160</sup> Prostanoids have been identified as important mediators in the inflammatory response in a number of studies, and inhibition of their synthesis is associated with beneficial effects. Generally speaking, two COX isoforms are recognized: constitutively expressed COX-1 and inducible COX-2. Upregulation of COX-2 expression results from various pro-inflammatory stimuli, including LPS, TNF α, and IL-1.<sup>161</sup> Constitutively expressed COX products are likely important for maintenance of homeostasis, whereas increased production of prostanoids by COX-2 is thought to be responsible for detrimental effects during inflammation and shock. Research has focused on the development of selective COX-2 inhibitors, and firocoxib (Equioxx®, Merial Ltd., Duluth, Georgia) has been approved for treatment of osteoarthritis in horses. This drug has not been evaluated critically for treatment of endotoxemia.

In horses the most commonly used NSAID to treat endotoxemia is flunixin meglumine. Beneficial effects of flunixin meglumine have been described in experimental models of endotoxemia<sup>162-164</sup> and in clinical cases. In equine colic patients treatment with flunixin meglumine before exploratory surgery resulted in reduced plasma concentrations of TXB<sub>2</sub> and PGE<sub>2</sub> and had a favorable effect on cardiovascular parameters.<sup>165</sup> Flunixin meglumine was shown further to maintain cardiac output and systemic arterial blood pressure, improve blood flow to vital organs, reduce pulmonary endothelial damage, and improve survival on endotoxin challenge.<sup>66,166-168</sup> Conversely, in vitro studies have suggested that flunixin meglumine impairs recovery of intestinal barrier function in intestinal segments subjected to ischemia-reperfusion injury and may increase mucosal permeability to LPS.<sup>169,170</sup> This effect may be reduced or eliminated by concurrent administration of continuous-rate infusion of lidocaine.

NSAID use in horses carries the risk of side effects, the most significant of which is the development of gastrointestinal ulceration and renal papillary necrosis (renal crest necrosis). Differences may exist among NSAIDs in their propensity to induce adverse effects,<sup>171</sup> but all NSAIDs must be used cautiously. A concern about NSAID use specifically in colic patients is the masking of cardiovascular effects of endotoxin, which are used to determine the necessity of surgical exploration.<sup>172</sup> For these reasons a reduced dose of flunixin

meglumine (0.25 mg/kg body mass thrice daily) has been suggested and is used widely in horses.<sup>104</sup> At this dosage flunixin meglumine inhibits eicosanoid synthesis efficiently in an *in vivo* model of endotoxemia.<sup>173</sup> Reduction of clinical signs, however, was dose dependent, and lower doses provide minimal, if any, analgesia (see Chapter 4 for further discussion of NSAID therapy in horses). Therefore the veterinarian should choose the appropriate dose of any NSAID after carefully considering the circumstances of each case.

Some researchers have suggested that ketoprofen offers superior effects because of a proposed dual inhibitory effect on COX and lipoxygenase and may carry a decreased risk of adverse effects compared with flunixin meglumine and phenylbutazone. A comparison of cytokine and eicosanoid production by LPS-stimulated isolated monocytes *in vitro*, however, showed no significant difference between horses pretreated with flunixin meglumine (1.1 mg/kg body mass) or ketoprofen (2.2 mg/kg body mass), respectively.<sup>174</sup>

Eltenac has been evaluated in an experimental endotoxemia model in horses.<sup>175</sup> Given 15 minutes before LPS infusion, eltenac at a dose of 0.5 mg/kg protected against changes in clinical, hemodynamic, and hematologic parameters and blunted the LPS-induced rise in plasma cytokine concentrations in comparison with controls. Some parameters, however, including heart rate, leukocyte count, lactate concentration, and plasma TNF activity, were not improved. Ibuprofen may have beneficial effects superior to those of the other NSAIDs because it may be possible to achieve tissue concentrations safely that allow iron chelation to occur. According to a study in healthy foals, dosages of ibuprofen up to 25 mg/kg every 8 hours can be given safely for up to 6 days.<sup>160</sup>

### CORTICOSTEROIDS

The use of corticosteroids for anti-inflammatory therapy in sepsis and endotoxemia has been controversial in human and equine patients, and beneficial effects superior to the ones achieved by NSAIDs have not been demonstrated consistently. Corticosteroids inhibit the activity of phospholipase A<sub>2</sub> and the release of arachidonic acid from cell membrane phospholipids, as well as the production of TNF, IL-1, and IL-6 in response to a LPS stimulus. Experimentally, beneficial effects of dexamethasone in equine endotoxemia have been demonstrated.<sup>176,177</sup> To inhibit TNF production by equine peritoneal macrophages, however, the required concentration of dexamethasone was high and corresponded to an *in vivo* dosage (approximately 3 mg/kg body mass) greatly exceeding current recommendations.<sup>176</sup> Although single doses of corticosteroids are unlikely to carry a disproportionate risk of adverse effects, the clinician should consider the suggested association of laminitis with corticosteroid use in horses. In cases of sepsis immunosuppressive effects could also be detrimental.

In human patients with certain types of septic shock, dysfunction of the hypothalamic-pituitary-adrenal axis has been recognized and successfully treated with hydrocortisone replacement therapy.<sup>178</sup> Hypothalamic-pituitary-adrenal axis dysfunction has been suggested to occur in septic foals;<sup>179</sup> however, the use of low-dose corticosteroids for this indication remains to be investigated in horses.

### PENTOXIFYLLINE

Pentoxifylline, a methylxanthine derivative and phosphodiesterase inhibitor, has been suggested for use in endotoxemia because of its effects on neutrophil function and its ability to

inhibit the production of various cytokines, interferons, and thromboplastin. Decreased production of TNF, IL-6, TXB<sub>2</sub>, and thromboplastin in response to endotoxin was shown in an equine *ex vivo* model.<sup>180</sup> In horses given endotoxin followed by treatment with pentoxifylline (7.5 mg/kg body mass followed by continuous infusion of 3 mg/kg/hr for 3 hours), however, only minimal beneficial effects were observed.<sup>181</sup> Treatment significantly improved body temperature, respiratory rate, and whole blood recalcification time, but no effect was observed regarding heart rate, blood pressure, leukocyte count, plasma fibrinogen concentration, and serum cytokine concentrations. The conclusion was that benefits of treatment with pentoxifylline might be restricted to administration of high bolus doses or continuous infusion early in the pathophysiologic process. In an *in vivo* endotoxemia model in horses, the combination of pentoxifylline (8 mg/kg body mass) and flunixin meglumine (1.1 mg/kg body mass) was found to have greater benefit than each treatment on its own.<sup>182</sup> Because of its rheologic properties (i.e., the ability to increase erythrocyte deformability and microvascular blood flow), pentoxifylline has been suggested for use in endotoxemic patients showing evidence of laminitis; however, no effect on blood flow to the hoof was demonstrated after administration to healthy horses.<sup>183</sup> An intravenous preparation of pentoxifylline is not commercially available.

### ANTIOXIDANTS

Dimethyl sulfoxide (DMSO) is used by some clinicians in an attempt to scavenge oxygen-derived radicals. The treatment may be most appropriate in cases of ischemia-induced intestinal damage and associated reperfusion injury. However, DMSO failed to show beneficial effects in an experimental model of intestinal ischemia when administered on reperfusion of the ischemic intestine.<sup>184</sup> DMSO at a dose of 1 g/kg body mass was shown to increase mucosal loss after ischemia and reperfusion of the large colon,<sup>185</sup> and hence a reduced dose of 0.1 g/kg body mass has been proposed for cases of intestinal ischemia. DMSO failed to show significant benefit in an experimental model of endotoxemia in horses, although it ameliorated the effect on fever.<sup>186</sup> For intravenous administration, DMSO should be diluted in polyionic solutions to a concentration not exceeding 10%. Oral administration of a 10% to 20% solution via nasogastric intubation is also possible. Aside from DMSO the xanthine oxidase inhibitor allopurinol has been suggested as a treatment to prevent oxygen radical-induced tissue damage. During periods of ischemia tissue xanthine dehydrogenase is converted to xanthine oxidase, which on reperfusion catalyzes the generation of superoxide radicals.<sup>187,188</sup> Evaluation in horses showed beneficial effects of 5 mg allopurinol per kilogram body mass administered 12 hours before endotoxin challenge.<sup>189</sup> In another study mucosal damage attributable to oxygen-derived free radicals was not attenuated by allopurinol in an experimental ischemia-reperfusion model.<sup>185</sup>

### LIDOCAINE

Lidocaine given intravenously has been suggested as an anti-inflammatory, analgesic, and prokinetic agent, and some clinicians use it to treat colic and laminitis in horses. In an experimental endotoxemia model in rabbits, lidocaine inhibited hemodynamic and cytokine responses to endotoxin profoundly if given immediately after LPS infusion.<sup>190</sup> Lidocaine further ameliorated the inhibitory effects of flunixin

on recovery of mucosal barrier function following ischemic injury in equine small intestine.<sup>191</sup> Use of lidocaine therefore may have merit in endotoxemic patients. A common regimen for lidocaine use in horses is administration of an initial bolus (1.3 mg/kg body mass) followed by continuous infusion at a rate of 0.05 mg/kg/min. The veterinarian should monitor patients for toxic neurologic effects associated with a lidocaine overdose.

### **ω-3 FATTY ACIDS**

High concentrations of ω-3 fatty acids can alter the phospholipid composition of cellular membranes toward a decreased ratio of ω-6 to ω-3 and thereby can affect membrane functions such as phagocytosis, receptor binding, and activities of membrane-bound enzymes.<sup>67</sup> Most important for the treatment of endotoxemia, ω-3 fatty acid incorporation into cell membranes decreases the availability of arachidonic acid (an ω-6 fatty acid) for eicosanoid synthesis<sup>192</sup> and provides alternative substrates. Metabolism of ω-3 fatty acids via the COX and lipoxygenase pathway leads to the production of 3-series prostaglandins and 5-series leukotrienes, which have less biologic activity than their 2-series and 4-series counterparts derived from arachidonic acid. Aside from these mechanisms, ω-3 fatty acids prevent LPS-induced upregulation of CD14 in monocytic cells and therefore may be able to block transmembrane signaling of LPS.<sup>193</sup> Cells from horses given linseed oil (high in ω-3 fatty acids) for 8 weeks before blood collection showed significantly decreased expression of procoagulant activity, TXB<sub>2</sub>, and TNF in response to LPS stimulation.<sup>194,195</sup> In an *in vivo* experimental model of endotoxemia in horses, treatment resulted in prolonged activated partial thromboplastin time and whole blood recalcification time, suggesting an anticoagulant effect; however, a significant beneficial effect on clinical response and serum eicosanoid concentrations was not observed.<sup>196</sup> Because dietary addition of ω-3 fatty acids requires several weeks of treatment, intravenous infusion was evaluated and shown to alter the composition of cell membrane phospholipids rapidly.<sup>197</sup> Further evaluation of this treatment for use in horses is necessary before specific dosage recommendations can be made.

## **INTERFERENCE WITH THE EFFECTS OF SPECIFIC INFLAMMATORY MEDIATORS**

### **ANTIBODIES DIRECTED AGAINST TUMOR NECROSIS FACTOR**

Monoclonal and polyclonal antibodies against equine TNF have been evaluated in horses.<sup>198-200</sup> Administration of a monoclonal antibody preparation before LPS infusion resulted in significantly reduced plasma TNF activity, improved clinical abnormality scores, lower heart rate, and higher leukocyte count compared with controls.<sup>199</sup> Furthermore, plasma concentrations of lactate and 6-keto-PGF1 $\alpha$  were reduced significantly, whereas TXA<sub>2</sub> production was not affected.<sup>198</sup> In another study<sup>200</sup> administration of a rabbit polyclonal antibody against recombinant human TNF did not improve clinical and hematologic parameters when given shortly (15 minutes) after LPS infusion, although inhibition of TNF activity was present *in vitro*.<sup>200,201</sup> Findings in horses are in agreement with studies in other species and suggest that beneficial effects of TNF inhibition may be limited to administration before LPS exposure. Widespread clinical use therefore

is unlikely to become feasible. Clinical trials in septic human patients have not shown significant benefits of TNF antibody treatment.<sup>202,203</sup>

### **PLATELET-ACTIVATING FACTOR RECEPTOR ANTAGONISTS**

The effects of selective PAF receptor antagonists have been evaluated. PAF is implicated in the development of systemic hypotension,<sup>204</sup> LPS-induced platelet aggregation,<sup>205</sup> ileus,<sup>206</sup> and increased vascular permeability<sup>207</sup> and may mediate recruitment of leukocytes to inflamed tissues.<sup>208,209</sup> A study in horses using the PAF receptor antagonist SRI 63-441 before LPS infusion showed significant decreases in heart rate and shorter elevation of lactate concentrations in response to the treatment. Although not statistically significant, additional beneficial effects included delayed onset of fever, a shortened period of neutropenia, and reduced maximal platelet aggregation.<sup>210</sup>

## **SUPPORTIVE CARE**

### **FLUID THERAPY AND CARDIOVASCULAR SUPPORT**

Fluid therapy is a mainstay of therapy of most endotoxemic patients suffering from the cardiovascular effects of systemic inflammation. Many endotoxemic equine patients will further require fluid therapy for treatment of the underlying disease process and correction of dehydration and electrolyte and acid-base abnormalities. Principles of fluid therapy are discussed elsewhere in this text.

Patients with severe hypovolemia and shock present management challenges, especially because increased vascular permeability in endotoxemic patients requires careful consideration of fluid therapy plans. A rapid increase in total body fluid volume may be detrimental in patients with compromised cardiac and peripheral vasomotor function and may increase the severity of vascular pooling in peripheral organs. In these patients hypertonic solutions or colloids may be more appropriate means of stabilization than large volumes of crystalloid solutions. Hypertonic saline solution (7.5% sodium chloride) is the most commonly used hypertonic solution in horses and has beneficial effects in endotoxemic patients.<sup>211</sup> A dose of 4 ml/kg is recommended, which should be given as a bolus infusion over 10 to 15 minutes, followed by administration of an isotonic solution to restore total body fluid volume. The clinician should use hypertonic saline with caution in patients with sodium or chloride derangements and should monitor serum electrolyte concentrations in the case of repeated administration. Improvement of the cardiovascular status in response to fluid therapy is indicated by normalization of heart rate, mucous membrane color, and capillary refill time. Failure of urination to occur despite appropriate fluid resuscitation should result in critical evaluation of renal function. In one recent study small volume resuscitation with hypertonic saline plus hetastarch failed to alleviate hemodynamic responses in experimental endotoxin infusion in horses.<sup>212</sup>

Plasma is an ideal colloid and should be administered to maintain a serum total protein concentration above 4.2 g/dl.<sup>134</sup> To raise plasma protein concentration and colloid osmotic pressure significantly, however, horses often require large volumes of plasma (7 to 10 L or more in a 450-kg horse), and alternative colloids should be considered. High-molecular-weight polymers are thought to provide superior oncotic effects in

cases of sepsis and endotoxemia, when vascular permeability is increased. Hetastarch, or hydroxyethyl starch (Hespan), is commercially available as a 6% solution in 0.9% sodium chloride. Hetastarch molecules have very high molecular weight, and degradation must occur before renal excretion.<sup>213</sup> These properties result in a longer plasma half-life and prolonged oncotic effects compared with other colloids; persistence of the oncotic effect for 24 hours was observed in hypoproteinemic horses.<sup>214</sup> A dosage of 5 to 15 ml/kg given by slow intravenous infusion along with an equal or greater volume of crystalloid fluids has been recommended.<sup>213,215</sup> In human patients prolonged activated partial thromboplastin time, decreased factor VIII activity, and decreased serum fibrinogen concentration have been described in association with hetastarch use.<sup>216</sup> In the limited number of equine studies, bleeding times were not affected,<sup>217,218</sup> however, patients treated with hetastarch should be monitored for coagulopathy.

Metabolic acidosis in endotoxic shock is attributable to lactic acidemia and inadequate tissue perfusion.<sup>219</sup> Acid-base balance often improves considerably after fluid resuscitation (preferably with alkalizing solutions such as lactated Ringer's solution) alone; however, additional sodium bicarbonate may be required in cases in which serum bicarbonate concentration remains below 15 mEq/L.

Foals with sepsis are frequently hypoglycemic, and 5% dextrose solutions are useful as initial resuscitation fluids. The clinician should reduce the glucose concentration of intravenous solutions according to the blood glucose concentration to avoid prolonged hyperglycemia. Administration of hyperimmune plasma (20 to 40 ml/kg body mass) is highly recommended in foals with evidence of partial or complete failure of passive transfer.

One should consider positive inotropic and vasomotor agents in patients with persistently inadequate tissue perfusion. Lower dosages of dopamine (0.5 to 2  $\mu\text{g}/\text{kg}/\text{min}$ ) result in vasodilation of the renal, mesenteric, coronary, and intracerebral vasculature via dopaminergic effects, whereas higher dosages (up to 10  $\mu\text{g}/\text{kg}/\text{min}$ ) also exert stimulation of  $\alpha_1$ -adrenergic receptors, resulting in increased myocardial contractility and heart rate.<sup>220</sup> Dobutamine is a direct  $\alpha_1$ -adrenergic agonist and does not appear to have significant vasodilator properties. Dosages for dobutamine of 1 to 5  $\mu\text{g}/\text{kg}/\text{min}$  as a continuous intravenous infusion have been recommended for use in horses. In addition, norepinephrine was evaluated in hypotensive critically ill foals that were refractory to the effects of dopamine and dobutamine.<sup>221</sup> At dosages up to 1.5  $\mu\text{g}/\text{kg}/\text{min}$  administered concurrently with dobutamine, six out of seven foals showed an increase in mean arterial pressure, and all foals had increased urine output. Because of the risk of cardiac side effects, close monitoring of heart rate and rhythm should accompany infusion of inotropes. Indirect blood pressure measurements using a tail cuff may be used to monitor the effects of treatment.

### MANAGEMENT OF COAGULOPATHY

More frequently than overt thrombosis or bleeding attributable to DIC, hemostatic abnormalities occur in the form of alterations in the coagulation profile. A procoagulant state with shortened bleeding times or prolonged bleeding times caused by consumption of clotting factors may be evident. One should address abnormalities in the coagulation profile as early as possible but especially if they persist more than 24 hours after initiation of therapy. Because of the complex

interactions of coagulation and fibrinolysis during endotoxemia, it might be necessary to combine anticoagulant therapy with the administration of fresh frozen plasma to replace clotting and fibrinolytic factors. Heparin acts as an anticoagulant by activation of AT III and subsequent inhibition of thrombin, release of tissue factor pathway inhibitor from endothelial cells, and inhibition of platelet aggregation.<sup>222</sup> Because endogenous AT III levels frequently are decreased in patients with coagulopathy, addition of heparin to fresh frozen plasma may be the most effective route of administration. An initial dose of 100 IU/kg body mass followed by 40 to 80 IU/kg body mass thrice daily has been recommended.<sup>134</sup> Anemia caused by erythrocyte agglutination occurs in some patients during therapy with unfractionated heparin<sup>223,224</sup> but typically resolves within 96 hours if therapy is discontinued.<sup>134</sup> Because of the risk of microthrombosis associated with erythrocyte agglutination, use of low-molecular-weight heparin (50 IU/kg body mass subcutaneously every 24 hours) has been recommended<sup>225</sup> but may be cost prohibitive. Aspirin can be given orally (10 to 20 mg/kg body mass, every 48 hours), which irreversibly inhibits platelet COX activity, to inhibit platelet aggregation and microthrombosis. Platelet hyperaggregability has been implicated in the pathogenesis of carbohydrate-induced laminitis,<sup>226</sup> and heparin and aspirin have been recommended to prevent development of laminitis. In an *in vitro* study, however, aspirin did not inhibit endotoxin-induced platelet aggregation.<sup>227</sup>

### OTHER CONSIDERATIONS

Luteolysis caused by increased concentrations of  $\text{PGF}_2\alpha$  may lead to pregnancy loss in endotoxemic mares before day 55 of pregnancy (see Chapter 18).<sup>228</sup> Daily administration of altrenogest (Regu-Mate, Hoechst-Roussel Agri-Vet, Somerville, New Jersey) at a dose of 44 mg orally consistently prevented fetal loss in mares if administered until day 70 of pregnancy.<sup>108</sup> Treatment with flunixin meglumine, by blockade of  $\text{PGF}_2\alpha$  release,<sup>109</sup> also may contribute to the maintenance of pregnancy in endotoxemic mares. The pathogenesis of fetal loss and abortion caused by endotoxemia, surgery, or systemic disease later in gestation is not understood completely. Proposed mechanisms include direct effects on the fetus, placental function, or placental progesterone production.<sup>229</sup>

Decreased nitric oxide production by vascular endothelial cells in response to endotoxin has been suggested as a mechanism for vasoconstriction and decreased blood flow leading to laminitis (see Chapter 11);<sup>230</sup> however, use of nitric oxide donors remains controversial. Maintenance of adequate peripheral perfusion and anticoagulant and anti-inflammatory therapy may be helpful in preventing and treating laminitis caused by endotoxemia.

### ☞ SUMMARY

Although the innate immune response to endotoxin (LPS) is crucially important for the preservation of homeostasis and health, large amounts of endotoxin can evoke an excessive and uncontrolled inflammatory response and result in a dysfunction of hemostatic and circulatory control mechanisms, loss of vascular integrity, and finally tissue damage and organ failure. Conditions commonly associated with the development of endotoxemia in horses are acute gastrointestinal diseases, especially of ischemic and severe inflammatory nature, and localized or generalized infections. Although measuring

endotoxin concentrations in equine plasma is possible, a diagnosis of endotoxemia is typically based on clinical signs and clinicopathologic data. Successful treatment of endotoxemia requires resolution of the primary disease process in addition to neutralization of circulating endotoxin, interference with the activities of inflammatory mediators, and general supportive care. Newer treatments, such as blockade of endotoxin interaction with cells or interruption of cell signaling pathways, are under investigation. Possible sequelae of endotoxemia include DIC, multiple organ failure, circulatory failure, and death. Frequently, the outcome of conditions associated with endotoxemia in horses depends on the severity of associated complications (e.g., renal compromise and laminitis).

## ORAL DISEASES\*

L. Chris Sanchez

The word *mouth* is used commonly to signify the first part of the alimentary canal or the entrance to it.<sup>1</sup> The mouth is bounded laterally by the cheeks, dorsally by the palate, and ventrally by the body of the mandible and by the mylohyoid muscles. The caudal margin is the soft palate. The mouth of the horse is long and cylindrical, and when the lips are closed, the contained structures almost fill the cavity. A small space remains between the root of the tongue and the epiglottis and is termed the *oropharynx*. The cavity of the mouth is subdivided into sections by the teeth. The space external to the teeth and enclosed by the lips is termed the *vesicle of the mouth*, and in the resting state the lateral margins of the vesicle (i.e., the buccal mucosa) are in close contact with the cheek teeth. Caudally, the external space communicates with the pharynx through the *aditus pharyngis*. The mucous membrane of the mouth is continuous at the margin of the lips with the skin and during life is chiefly pink but can be more or less pigmented, depending on the skin color and the breed type.

## ☞ MORPHOLOGY AND FUNCTION

The lips are two muscular membranous folds that unite at angles close to the first cheek teeth. Each lip presents an outer and an inner surface. The upper lip has a shallow median furrow (philtrum); the lower lip has a rounded prominence or chin (mentum). The internal surface is covered with a thick mucous membrane that contains small, pitted surfaces that are the openings of the ducts of the labial glands. Small folds of the mucous membrane called the *frenula labii* pass from the lips to the gum.

The free border of the lip is dense and bears short, stiff hairs. The arteries of the mouth are derived from the maxillary, mandibular, labial, and sphenopalatine arteries of the major palatine artery. The veins drain chiefly to the lingual facial vein. Sensory nerves originate from the trigeminal nerve (cranial nerve V) and the motor nerves from the facial nerve (VII). The cheeks spread back from the lips and from both sides of the mouth and are attached to the alveolar borders of the bones of the jaws. The cheeks are composed of skin and

muscular and glandular layers and then the internal mucous membrane. The skin is thin and pliable. In contrast, the oral mucous membrane is dense and in many areas of the oral cavity is attached firmly to the periosteum so that construction of oral mucosal flaps can be achieved only by horizontal division of the periosteal attachment. Such a feature is important in reconstructive techniques applied to the oral cavity. The blood supply to the cheeks comes from the facial and buccal arteries and the sensory nerves from the trigeminal and motor nerves from the facial nerve.

The hard palate (*palatum durum*) is bounded rostrally and laterally by the alveolar arches and is continuous with the soft palate caudally. The hard palate has a central raphe that divides the surface into two equal portions. From the line of the rostral cheek tooth, the hard palate is concave to the line of the caudal cheek tooth. Paired transverse ridges (approximately 18) traverse the concavity and have their free edges directed caudally. The incisive duct is a small tube of mucous membrane that extends obliquely through the palatine fissure. The dorsal component communicates by a slitlike opening in the rostral portion of the ventral nasal meatus, and its palatine end is blind and lies in the submucosa of the palate. When stallions display their flehmen response, watery secretions enter the nose from the glands of the vomeronasal duct. To what extent these secretions aid in pheromone reception is not known.<sup>2</sup>

That portion of the palatine mucosa immediately behind the incisor teeth frequently is swollen (*lampas*) during eruption of the permanent teeth. This swelling is physiologic and not pathologic.

The tongue is situated on the floor of the mouth between the bodies of the mandible and is supported by the sling formed by the mylohyoid muscles. The root of the tongue is attached to the hyoid bone, soft palate, and pharynx. The upper surface and the rostral portion of the tongue are free; the body of the tongue has three surfaces. The apex of the tongue is spatulate and has a rounded border. The mucous membrane adheres intimately to the adjacent structure and on the dorsum is dense and thick. From the lower surface of the free part of the tongue, a fold of mucous membrane passes to the floor of the mouth, forming the lingual frenulum. Caudally, a fold passes on each side of the dorsum to join the soft palate, forming the palatoglossal arch. Dorsally from the soft palate, the palatopharyngeal arch attaches and circumvents the *aditus laryngis* and attaches to the roof of the nasopharynx. The mucous membrane of the tongue presents four kinds of papillae:

1. Filiform papillae are fine threadlike projections across the dorsum of the tongue. They are absent on the root of the tongue and are small on the rostral portion of the tongue.
2. The fungiform papillae are larger and easily seen at the rounded free end. They occur principally on the lateral portion of the tongue.
3. Vallate papillae are usually two or three in number and are found on the caudal portion of the dorsum of the tongue. The free surface bears numerous small, round secondary papillae.
4. Foliate papillae are situated rostral to the palatoglossal arches of the soft palate, where they form a rounded eminence about 2 or 3 cm in length marked by transverse fissures.

Foliate, vallate, and fungiform papillae are covered with taste buds and secondary papillae.

\*Previous version by Samuel L. Jones.

The lingual and sublingual arteries supply the tongue from the linguofacial trunk and matching veins. The linguofacial trunk drains into the linguofacial vein. The lingual muscles are innervated by the hypoglossal nerve (XII), and the sensory supply is from the lingual and glossopharyngeal (IX) nerves.

## ☞ EQUINE DENTITION

The formula for the deciduous teeth of the horse is 2 times I3-3 C0-0 P3-3 for a total of 24. The permanent dental formula is 2 times I3-3 C1-1 P3-3 or P4-3 M3-3 for a total of 40 or 42. In the mare the canine teeth are usually small or do not erupt, hence reducing the number to 36 or 38. The first premolar tooth (wolf tooth) is often absent and has been reported as occurring in only 20% of the upper dentition of Thoroughbreds.<sup>3</sup> The teeth of the horse are complex in shape and are compounded of different materials (dentin, cementum, and enamel). They function as grinding blades to masticate and macerate cellulose food in the important first stage of the digestive process. The cheek teeth in the horse are a well-documented feature of the evolution of *Equus caballus*.

### DECIDUOUS TEETH

The first incisor is present at birth or the first week of life. The second incisor erupts at 4 to 6 weeks of age; the third incisor, at 6 to 9 months of age; the first and second premolars, at birth to 2 weeks of age; and the third premolar, 3 months of age.

### PERMANENT TEETH

The eruption times for the permanent teeth are as follows: first incisor, 2 ½ years of age; second incisor, 3 ½ years of age; third incisor, 4 ½ years of age; the canine tooth, 4 to 5 years of age; the first premolar (wolf tooth), 5 to 6 months of age; the second premolar, 2½ years of age; the third premolar, 3 years of age; the fourth premolar, 4 years of age; the first molar, 10 to 12 months of age; the second molar, 2 years of age; and the third molar, 3½ to 4 years of age. This eruption sequence clearly indicates that the eruption of the second and third permanent premolar teeth gives the potential for dental impaction.

The modern horse has six incisor teeth in each jaw that are placed close together so that the labile edges form a semi-circle. The occlusal surface has a deep enamel invagination (infundibulum) that is filled only partially with cementum. As the incisor teeth wear, a characteristic pattern forms in which the infundibulum is surrounded by rings of enamel, dentin, enamel, and crown cementum in a concentric pattern. Each incisor tooth tapers from a broad crown to a narrow root so that as the midportion of the incisor is exposed to wear, the cross-sectional diameters are about equal; that is, at 14 years of age, the central incisor tooth of the horse has an occlusal surface that is an equilateral triangle. Observations on the state of eruption, the angles of incidence of the incisor teeth, and the pattern of the occlusal surfaces are used as guides for aging of horses. The canine teeth are simple teeth without complex crowns and are curved. The crown is compressed and is smooth on its labial aspect but carries two ridges on its lingual aspect. No occlusal contact occurs between the upper and lower canine teeth.

When erupted, the six cheek teeth of the horse function as a single unit in the mastication of food. Each arcade consists

of three premolar and three molar teeth. The maxillary arcade is slightly curved, and the teeth have a square occlusal surface. The occlusal surfaces of the mandibular teeth are more oblong, and each arcade is straighter. The horse is anisognathic; that is, the distance between the mandibular teeth is narrower (one third) than the distance between the upper cheek teeth. This anatomic arrangement affects the inclination of the dental arcade as the jaws slide across each other in the food preparation process. The unworn upper cheek tooth presents a surface with two undulating and narrow ridges, one of which is lateral and the other medial. On the rostral and lingual side of the medial style is an extra hillock. The central portion of these surfaces is indented by two depressions that are comparable with, but much deeper than, the infundibula of the incisor teeth. When the teeth have been subjected to wear, the enamel that closed the ridges is worn through and the underlying dentin appears on the surface. Thus after a time the chewing surface displays a complicated pattern that may be likened to the outline of an ornate letter *B*, the upright stroke of the *B* being on the lingual aspect. Dentin supports the enamel internally, cementum supports the enamel lakes, and the peripheral cementum fills in the spaces between the teeth so that all six teeth may function as a single unit (i.e., the dental arcade). Transverse ridges cross each tooth so that the whole maxillary arcade consists of a serrated edge. The serrations are formed so that a valley is present at the area of contact with adjacent teeth. These serrations match fitting serrations on the mandibular arcade. One should note that the mediolateral mandibular motion that occurs while the horse is chewing pellets does not provide full occlusal contact as it does when the horse is chewing hay.<sup>4</sup>

The true roots of the cheek teeth are short compared with the total length of the tooth. Cheek teeth have three roots: two small lateral roots and one large medial root. By custom, that portion of the crown embedded within the dental alveolus is referred to as the *reserve crown*, and the term *root* is confined to the area of the tooth that is comparatively short and enamel free. Wear on the tooth gradually exposes the reserve crown, and the roots lengthen. In an adult 1000-lb horse, the maxillary cheek teeth are between 8 and 8.5 cm in length. Dental wear accounts for erosion and loss of tooth substance at a rate of 2 mm annually. The pulp chambers of the teeth are also complex. The incisors and canines have a single pulp chamber. The mandibular cheek teeth have two roots and two separate pulp chambers. The maxillary cheek teeth, although they have three roots, have in fact five pulp chambers.

As occlusal wear proceeds, deposition of secondary dentin within the pulp chambers protects the chambers (e.g., the dental star, medial to the infundibulum on the incisor teeth). In the mandibular cheek teeth, the transverse folding of the enamel anlage (during morphogenesis of the tooth) does not take place, and the occlusal surface is a simple surface of central dentin surrounded by enamel. Each tooth then is conformed to a single arcade by the presence of peripheral crown cementum.

## ☞ MOUTH DISEASES

The oral cavity and oropharynx are subject to a variety of diseases. However, many conditions affecting the first portion of the alimentary system produce the same clinical signs, regardless of their cause. The clinical signs may include inappetence or reluctance to eat, pain on eating or swallowing,

From Baker GJ: Diseases of the teeth. In Colohan PT, Mayhew IG, Merritt AM, et al, editors: *Equine medicine and surgery*, ed 4, vol 1, Goleta, Calif, 1991, American Veterinary Publications.

oral swelling, oral discharge, and fetid breath. Affected animals may show some interest in food but hesitate to eat it. Salivation may be excessive and contaminated with purulent exudate or blood. The occurrence of bruxism (i.e., grinding of teeth) can indicate discomfort in other areas of the alimentary tract; for example, bruxism and frothing oral saliva are characteristic features of gastric ulceration in the foal. The clinician should be aware that considerable weight loss can occur rapidly with the inability to feed and swallow. Diseases that result in denervation of the pharynx and inappropriate swallowing can have the complication of aspiration pneumonia.

### EXAMINATION AND CLINICAL SIGNS

After performing a complete physical examination and ascertaining the history, the clinician should approach examination of the mouth systematically in all cases. One can examine a considerable portion of the mouth and teeth from the outside by palpation of the structures through the folds of the cheek. Most horses allow a cursory oral examination without sedation or the use of an oral speculum. In many cases, however, a detailed oral examination is best achieved by sedation and the use of an oral speculum and a light source. The clinician should irrigate the mouth to wash out retained food material before inspecting and palpating the lips, cheeks, teeth, and gums.

The classic signs of dental disease in the horse include difficulty and slowness in feeding, with a progressive unthriftiness and loss of body condition. In some instances the horse may quid (i.e., drop poorly masticated food boluses from the mouth), and halitosis may be obvious. Additional problems reported by owners include biting and riding problems and headshaking or head shyness. Facial or mandibular swelling may occur. Nasal discharge can result from dental disease

associated with maxillary sinus empyema. Mandibular fistulae frequently are caused by lower cheek tooth apical infections. Some correlation exists between the age of the animal and clinical signs (Table 15-5).

### ANCILLARY DIAGNOSTIC TECHNIQUES

Ancillary aids for a complete examination of the oral cavity of the horse include radiology, endoscopic examination, fluoroscopy, biopsy, and culture. The clinician always should take care during endoscopic evaluation of the oral cavity using a flexible endoscope. The author recommends sedation and the use of an oral speculum to prevent inadvertent mastication of the endoscope. If general anesthesia is used as part of the diagnostic workup, then endoscopic evaluation of the oral cavity is much easier. In selected cases advanced imaging technologies such as computed tomography, magnetic resonance imaging, or nuclear scintigraphy may be beneficial.

### ☞ DYSPHAGIA

#### CLINICAL SIGNS AND DIAGNOSIS

The lips of the horse are mobile and prehensile. In many ways they function like the tip of the elephant's trunk in that they test, manipulate, and sample the environment for potential nutritive value. Consequently, loss of motor function (e.g., facial palsy) affects the efficiency of the prehensile system. The lips grasp food in grazing or browsing, and the incisor teeth section the food. With mastication and lubrication with saliva, the bolus of food forms and is manipulated from side to side across the mouth, assisted by the tight cheeks of the horse and the palatine ridges. Swallowing begins as the food

bolus contacts the base of the tongue and the pharyngeal walls. During swallowing the soft palate elevates to close the nasopharynx, the base of the tongue elevates, and the hyoid bone and the larynx move rostrally following contraction of the hyoid muscles. During this process the rima glottidis closes, and the epiglottis tilts dorsally and caudally to protect the airway so that food is swept through lateral food channels around the sides of the larynx into the laryngoesophagus. Fluoroscopic studies in nursing foals in the dorsoventral view showed that contact occurs between the lateral food channels in the midline so that in outline the food bolus achieves a bow-tie shape.<sup>5</sup>

*Dysphagia* is defined as the difficulty or inability to swallow. Anatomic classifications for dysphagia include prepharyngeal, pharyngeal, and esophageal (postpharyngeal) dysphagias. The site of the cause for dysphagia influences the clinical signs. Prepharyngeal dysphagia is characterized by dropping food (quidding) or water from the mouth, reluctance to chew, hypersalivation, or abnormalities in prehension. Pharyngeal and esophageal dysphagias are characterized by coughing; nasal discharge containing saliva, water, or food material; gagging; anxiousness; and neck extension during attempts to swallow. The following section describes esophageal dysphagia in more detail. Causes of dysphagia can be divided into four types: painful, muscular, neurologic, or obstructive (Table 15-6). Pain and obstruction cause dysphagia by interfering with the mechanics of prehension, bolus formation and transfer to the pharynx, and deglutition. Muscular and neurologic causes of dysphagia impede prehension and swallowing by affecting the motor function of the lingual or buccal musculature, muscles of mastication (temporal and masseters), and pharyngeal and cranial esophageal muscles. Sensory loss to the lips, buccal mucous membranes, pharynx, or tongue also may cause dysphagia. Neurologic causes of dysphagia may affect the forebrain, brainstem, or peripheral nerves that control prehension (cranial nerves Vm, Vs, VII, and XII), transfer of the food bolus to the pharynx (cranial nerves Vs and XII), and swallowing (cranial nerves IX and X). The latter point was classical thinking, but recent evidence suggests that although stimulation of cranial nerve IX stimulates swallowing, bilateral blockade of that nerve is not necessary for normal swallowing of either liquid or solid material.<sup>6</sup>

Diagnosis of the cause of dysphagia is based on physical examination, including a careful oral examination; neurologic examination; clinical signs; and endoscopy of the pharynx, esophagus, and guttural pouches. Radiology may be useful to assess the bony structures of the head and throat. Ultrasonography is valuable for examining the retropharyngeal space and esophagus to detect and evaluate masses. One may detect pharyngeal or esophageal causes of dysphagia with routine endoscopic examination or with contrast radiography. Although endoscopy can also be used to assess deglutition, it is important to remember that sedation adversely affects the deglutition mechanism. One may assess deglutition using fluoroscopy<sup>7</sup> or manometry,<sup>8</sup> but these techniques require specialized equipment. Specific diagnostic procedures for nonalimentary causes of dysphagia are covered elsewhere in this text (see Chapter 3).

## MANAGEMENT

Specific treatments aimed at resolving the underlying disorder causing dysphagia are discussed in detail elsewhere. Most horses with dysphagia should not eat roughage with long

fiber length (hay or grass). Dietary modifications that promote swallowing, such as feeding slurries made from complete pelleted feeds, may be sufficient to manage some cases of partial dysphagia. Care must be taken to prevent or avoid aspiration pneumonia in horses with pharyngeal or esophageal dysphagia. Affected foals can be managed by feeding mare's milk or a suitable substitute through a nasogastric tube. The clinician also may administer pelleted slurries or formulated liquid diets through a nasogastric tube to older horses. Prolonged nutritional management of dysphagic horses may require extraoral feeding using a tube placed through an esophagostomy.<sup>9</sup>

Formulated pelleted diets are often easy to administer through a tube as slurry and are balanced to meet the nutritional requirements for healthy horses. Sufficient quantities must be fed to deliver adequate calories (16 to 17 Mcal/day for a 500-kg horse). Adjustments may be necessary for horses that are cachectic or have extra metabolic demand (e.g., pregnancy). Adding corn oil to the ration (1 cup every 12 or 24 hours) is a common method of increasing fed calories. Liquid diets also have been used for enteral feeding<sup>10</sup> but may not be tolerated as well as pelleted diets. Regardless of the method of nutritional management, the clinician must monitor and replace salivary losses of electrolytes. Saliva contains high concentrations of Na, K, and Cl. A group of ponies with experimental esophagostomies<sup>11</sup> and a horse with esophageal squamous cell carcinoma<sup>12</sup> were fed a complete pelleted diet through esophagostomy tubes but developed metabolic acidosis, hyponatremia, and hypochloremia, apparently because of salivary losses. Surprisingly, salivary losses of potassium did not result in hypokalemia in these cases, presumably because of replacement in the diet. However, if the diet is deficient in potassium, hypokalemia may result. Electrolyte replacement often can be accomplished by adding NaCl and KCl to the diet. Horses can be maintained for months with frequent feedings through an esophagostomy tube.<sup>12</sup> Parenteral nutrition (total or partial) may be useful in the short term but is not often feasible for long-term management.

## ☞ DENTAL DISEASES

### ERUPTION DISORDERS

Tooth eruption is a complex phenomenon involving the interplay of dental morphogenesis and those vascular forces responsible for creating the eruption pathway. These changes are responsible for osteitis and bone remodeling within the maxilla and mandible. Young horses frequently show symmetric bony swelling resulting from these eruption cysts. In some cases additional clinical signs of nasal obstruction with respiratory stridor or nasal discharges may be apparent.

Pathologic problems associated with maleruption include a variety of dental diseases.<sup>13</sup> Oral trauma can displace or damage erupting teeth or the permanent tooth buds. As a result, teeth may be displaced and erupt in abnormal positions or may have abnormal shapes. Supernumerary teeth, incisors and molars, can develop as well as palatal displacement of impacted teeth (maxillary P3-3, or third cheek tooth). In almost all of these conditions, some form of surgical treatment is necessary, but depending on the number and location, conservative therapy can be successful.<sup>14</sup>

Significant evidence from the location of apical osteitis in diseased teeth confirms that dental impaction is a major cause of dental disease in the horse. In a series of 142 extracted teeth,

63 were P3-3 or P4-4 (cheek tooth 2 or 3, respectively).<sup>15</sup> Early observations had indicated that the first molar (M1, or cheek tooth 4) was the most commonly diseased tooth, and an “open infundibulum” in this tooth has been suggested as the cause.<sup>16</sup> In a later study the mandibular cheek teeth 2 and 3 were the most commonly affected, whereas cheek teeth 2 and 4 were most commonly affected in the maxillary arcade, which was the more commonly affected arcade.<sup>17</sup> Studies on cementogenesis of the maxillary cheek teeth have shown, however, that in fact most maxillary cheek teeth have a greater or lesser degree of hypoplasia of cementum within the enamel lakes and that this “lesion” rarely expands into the pulp. The central infundibular hole is the site of its vascular supply to the unerupted cement lake. On those occasions in which caries of cementum occurs (i.e., secondary inflammatory disease and acid necrosis of the cementum), apical osteitis may develop.

## **DENTAL DECAY**

Pulpitis is key to the pathogenesis of dental decay in the horse. The initiation of inflammatory pulp changes may be a sequela to dental impaction or dental caries or may result from fracture of a tooth. If the onset of the inflammatory process is slow, then formation of secondary dentin within the pulp chambers may protect the pulp and the tooth. Secondary dentin formation occurs from stimulation of odontoblasts within the pulp chamber. Such changes are the normal process of protection during dental wear and attrition as crown substances wear away and the reserve crown comes into wear. In acute disease,

however, this defense mechanism is ineffective, and the changes that occur and that are sequelae to pulpitis reflect the location of each affected tooth. For example, pulpitis and apical osteitis of the third mandibular cheek tooth most commonly results in the development of a mandibular dental fistula. Pulpitis of the third maxillary cheek tooth, however, results in an inflammatory disease within the rostral maxillary sinus and in development of chronic maxillary sinus empyema.

Oblique radiographs greatly assist the diagnosis of dental decay by demonstrating sinus tract formation, sequestration of bone, mandibular osteitis, hyperplasia of cementum, and new bone formation (so-called alveolar periosteitis).<sup>18</sup> Nuclear scintigraphy and computed tomography can aid in an accurate diagnosis.<sup>19,20</sup> The management of dental decay in the horse usually involves surgical extraction of the diseased tooth. In some cases one can use apicoectomy and retrograde endodontic techniques to save the diseased tooth. The clinician must take care, however, in selection of patients. In most cases of apical osteitis in the horse that result from dental impaction, immature root structures make achieving an apical seal of the exposed pulp difficult.

## **☞ PERIODONTAL DISEASE**

Gingival hyperemia and inflammation occur during the eruption of the permanent teeth and are common causes of a sore mouth in young horses (particularly 3-year-olds as the first dental caps loosen). Such periodontal changes usually resolve as the permanent dental arcade is established. During normal

mastication the shearing forces generated by the occlusal contact of the cheek teeth essentially clean the teeth of plaque and effectively inhibit deposition of dental calculus. Wherever occlusal contact is ineffective, periodontal changes and calculus buildup occur; for example, the deposition of calculus on the canine teeth of mature geldings and stallions is common. Routine dental prophylaxis forms an important component of maintaining normal occlusal contact, and for this reason arcade irregularities that result in enamel point formation on the buccal edges of the maxillary cheek teeth and the lingual edges of the mandibular cheek teeth should be removed. The clinician should remove these edges annually in horses that are at grass and twice yearly in young horses, aged horses, and stabled horses. Horses at grass have been shown to have a greater range of occlusal contact and therefore better periodontal hygiene than stabled horses. In stabled horses the range of occlusal contact is narrower, and the formation of enamel points occurs more frequently with subsequent buccal ulceration and the initiation of a cycle of altered occlusal contact and hence irregular arcade formation. This process leads to severe forms of periodontal disease and wave mouth formation.

Periodontal disease occurs with abnormal occlusal contact and initiation of the cycle of irregular wear and abnormal contact. Such changes progress to loss of alveolar bone, gross periodontal sepsis, and loss of tooth support. In this sense periodontal disease truly is the scourge of the equine mouth and results in tooth loss.<sup>21</sup>

## ☞ CONGENITAL AND DEVELOPMENTAL ABNORMALITIES

### CLEFT PALATE

Palatine clefts may result from an inherited defect and are caused by failure of the transverse palatal folds to fuse in the oral cavity. Harelip accompanies few palatine clefts in the horse. The degree of palatine clefting depends on the stage at which interruption in the fusion of the palatopalatal folds occurs. Toxic or teratogenic effects are documented in other species, but little data are available in the horse.

In recent years treatment for repair of uncomplicated palatine defects has been recommended, but the prognosis is generally poor because of the considerable nursing care required and the high incidence of surgical failures. One should emphasize early surgery and the use of mandibular symphysiotomy in affording surgical exposure. The combination of mandibular symphysiotomy and transhyoid pharyngotomy to approach the caudal margins of the soft palate affords surgical access, and mucosal flaps can be constructed to repair the defects. However, the incidence of surgical breakdown is high, and healing by first intention is the exception rather than the rule. A recent surgical report documented the successful closure of a median cleft of the lower lip and mandible in a donkey.<sup>22</sup>

### CAMPYLORHINUS LATERALIS

Foals born with a severely deviated premaxilla and palate have a wry nose. Good functional and cosmetic outcome can be achieved with surgical correction.<sup>23</sup> Circumstantial evidence indicates that such a defect has a genetic cause, and the defect occurs most frequently in the Arabian breed.

## CYSTS

Other developmental abnormalities are subepiglottic cysts resulting from cystic distortion of remnants of the thyroglossal duct, which may cause dyspnea and choking in foals. Surgical removal of these cysts results in normal function.

## PARROT MOUTH

The most significant developmental defect of dental origin is a maxilla that is longer than the mandible (i.e., parrot mouth). An overbite of 2 cm in the incisor arcade may be present in a horse with a mismatch of less than 1 cm between the first upper and lower cheek teeth. Parrot mouth and monkey or sow mouth are thought to be inherited conditions. Some correction of minor incisor malocclusion occurs up to 5 years of age. Recognition and detection of parrot mouth are important in the examination of potential breeding stock. Surgical attempts to inhibit overgrowth of the premaxilla by wiring or by the application of dental bite plate procedures have been documented.<sup>24</sup>

## ORAL WOUNDS

As has been indicated, the horse is by nature a curious animal that uses its lips as a means of exploring a variety of objects. Wounds of the lips, incisive bone, and the mandibular incisor area occur commonly in the horse and usually result from the horse getting the lips, jaw, or teeth caught in feeding buckets, in fence posts, or in halters or having a segment of tongue encircled with hair in tail chewing. As the horse panics and pulls away from its oral entrapment, considerable trauma can occur to the lips, teeth, and gums.

Most wounds heal satisfactorily, provided one finds them early and observes the basic principles of wound hygiene, excision of necrotic tissue, and wound closure. One must ensure that oral mucosal defects are closed and that effective oral seals are made before external wounds are closed. In some cases offering specially constructed diets or even feeding the horse by nasogastric tube or esophagostomy during the healing processes may be necessary.

## ☞ STOMATITIS AND GLOSSITIS

Foreign body penetration of the tongue, cheek, or palate has been reported in grazing and browsing horses, particularly horses that have certain hay sources containing desiccated barley awns or yellow bristle grass.<sup>25</sup> Other plant material and grass awns also occasionally may penetrate the tongue, gingiva, or cheek, causing inflammation or abscesses. Metallic foreign bodies have been reported in the tongue, and a history of feeding hay or the use of cable-framed tractor tires was often reported as part of the history.<sup>26</sup> Ulcerative stomatitis also results from the toxicity of phenylbutazone therapy.<sup>27</sup> Vesicular stomatitis is a highly contagious viral blistering disease described in more detail elsewhere. Treatment of glossitis and stomatitis primarily aims at removing the inciting cause. *Actinobacillus lignieresii*, the causative agent of actinobacillosis, has been isolated and identified from ulcers on the free border of the soft palate and oral and laryngeal granulomata. The bacterium also was reported in a sublingual caruncle in a horse with a greatly swollen tongue.<sup>28</sup> Therapy with 150 ml of 20% sodium iodide and 5 g of ampicillin every 8 to 12 hours effected a clinical cure.

## ☞ SALIVARY GLANDS

### FUNCTION

Saliva is important for lubricating and softening food material. The horse has paired parotid, mandibular, and polystomatic sublingual salivary glands. The parotid gland is the largest of the salivary glands in the horse and is situated in the space between the ramus of the mandible and the wing of the atlas. The parotid duct is formed at the ventral part of the gland near the facial crest by the union of three or four smaller ducts. The duct leaves the gland above the linguofacial vein, crosses the tendon of the sternocephalicus muscle, and enters the mouth obliquely in the cheek opposite the third upper cheek tooth. The parotid duct orifice is small, but some dilation of the duct and a circular mucous fold (the parotid papillae) exist at this point. The mandibular gland is smaller than the parotid gland and extends from the atlantal fossa to the basihyoid bone. For the most part the mandibular gland is covered by the parotid gland and the lower jaw. The mandibular duct is formed by the union of a number of small duct radicles that emerge along the concave edge of the gland and run rostral to the border of the mouth opposite the canine tooth.

The orifice is at the end of a sublingual caruncle. The mandibular gland possesses serous, mucous, and mixed alveolar glandular components. The parotid gland is a compound alveolar serous gland. The parotid salivary gland can secrete saliva to yield rates of 50 ml/min, and a total daily parotid secretion can be as much as 12 L in a 500-kg horse. Parotid secretion occurs only during mastication, and administration of atropine or anesthesia of the oral mucosa can block secretion. Parotid saliva is hypotonic compared with plasma, but at high rates of flow, concentrations of sodium, chloride, and bicarbonate ions increase.

### SALIVARY GLAND DISORDERS

Parotid saliva of the horse has a high concentration of calcium, and occasionally calculi (sialoliths) form within the duct radicles of the parotid salivary gland.<sup>29</sup> Congenital parotid duct atresia, acquired stricture from trauma to the duct, or obstruction by plant material (e.g., sticks or foxtails and other seeds) also may occur. The clinical signs of sialolithiasis or other forms of ductule obstruction include a fluid swelling in the form of a mucocele proximal to the stone and occasionally inflammation of the parotid gland. Ultrasonography is useful to diagnose salivary mucoceles and to detect foreign bodies or sialoliths. Measurement of electrolyte concentrations in aspirates from suspected mucoceles might be helpful to distinguish them from hematomas. Salivary potassium and calcium concentrations are higher than those in plasma. Treatment may require surgical removal of the stone or plant material in the case of sialolithiasis or foreign body obstructions. Other causes of obstruction may require resection of the affected portion of the duct or chemical ablation of the gland.<sup>30</sup>

Primary sialoadenitis is unusual but can occur in one or both glands. The condition is painful and may be associated with a fever and anorexia. Secondary sialoadenitis is more common and usually is associated with trauma. Infectious sialoadenitis resulting from *Corynebacterium pseudotuberculosis*<sup>31</sup> or other bacterial pathogens also may occur. Diagnosis is by physical examination and identification of an enlarged

edematous parotid gland tissue on ultrasonographic examination. Culture and cytologic examination of aspirates may be useful for diagnostic purposes. Treatment is usually palliative, consisting of NSAIDs. Appropriate antibiotic therapy is indicated as directed by culture and sensitivity results.

Chemical irritation, glossitis, stomatitis, or other causes of prepharyngeal dysphagia cause ptyalism, or excessive salivation, in horses. Specific therapy for the ptyalism usually is not required as long as salivary losses are not excessive, resulting in dehydration and electrolyte imbalances. Ingestion of the fungal toxin slaframine also causes hypersalivation in horses.<sup>32</sup> The fungus *Rhizoctonia leguminicola*, which produces slaframine, causes black patch disease in red clover. Slaframine is a parasympathomimetic compound that stimulates exocrine secretion in the parotid gland. Slaframine toxicosis most commonly occurs in the spring or early summer and rarely requires treatment other than removal from the pasture. Mowing removes the source in most cases because regrowth in pastures often has less fungal contamination.<sup>33</sup>

## ESOPHAGEAL DISEASES

L. Chris Sanchez

### ☞ ANATOMY AND FUNCTION

The esophagus is a musculomembranous tube that originates from the pharynx dorsal to the larynx and terminates at the cardia of the stomach.<sup>1</sup> In adult Thoroughbreds the esophagus is approximately 120 cm long. The cervical portion is approximately 70 cm long; the thoracic portion, approximately 50 cm long; and the short abdominal portion, only approximately 2 cm long. The cervical esophagus generally lies dorsal and to the left of the trachea in the cervical region. In the thorax the esophagus courses through the mediastinum lying dorsal to the trachea and crosses to the right of the aortic arch dorsal to the heart base.

The esophagus has no digestive or absorptive functions and serves as a conduit to the stomach for food, water, and salivary secretions. The esophageal mucosa is a keratinized stratified squamous epithelium.<sup>1</sup> The submucosa contains elastic fibers that contribute to the longitudinal folds of the esophagus and confer elasticity to the esophageal wall. A transition occurs in the muscle type composing the tunica muscularis from striated skeletal muscle in the proximal two thirds of the esophagus to smooth muscle in the distal third. In the proximal esophagus the skeletal muscle layers spiral across one another at angles. Within the smooth muscle layers of the distal esophagus the outer layer becomes more longitudinal, whereas the inner layer thickens and becomes circular. The wall of the terminal esophagus can be 1 to 2 cm thick. Deep cervical fascia, pleura, and peritoneum contribute to the thin fibrous tunica adventitia of the esophagus. Motor innervation to the striated skeletal muscle of the esophagus includes the pharyngeal and esophageal branches of the vagus nerve, which originate in the nucleus ambiguus of the medulla oblongata. Parasympathetic fibers of the vagus nerve supply the smooth muscle of the distal esophagus. Sympathetic innervation of the esophagus is minimal.

Passage of ingesta through the esophagus can be considered part of the swallowing process, which consists of oral,

pharyngeal, and esophageal stages. The oral stage is voluntary and involves transport of the food bolus from the mouth into the oropharynx. During the involuntary pharyngeal stage, the food bolus is forced through the momentarily relaxed upper esophageal sphincter by simultaneous contractions of the pharyngeal muscles. In the esophageal phase of swallowing, the upper esophageal sphincter closes immediately, the lower esophageal sphincter opens, and esophageal peristalsis propels the bolus into the stomach.<sup>2</sup> Unlike a food bolus, liquids do not require peristalsis to reach the lower esophageal sphincter and may precede the food bolus during swallowing.

The upper esophageal sphincter prevents esophagopharyngeal reflux during swallowing and air distention of the esophagus during inspiration. Upper esophageal pressure increases in response to pressure from a food bolus and to increased intraluminal acidity, as would occur with gastroesophageal reflux. The lower esophageal sphincter is a smooth muscle located at the gastroesophageal junction that is morphologically ill defined but forms an effective functional barrier.<sup>2</sup> The lower esophageal sphincter is normally closed in response to gastric distention to restrict gastroesophageal reflux. Relaxation of the lower esophageal sphincter permits passage of ingested material from the esophagus to the stomach. Distention of the stomach with ingesta mechanically constricts the lower esophageal sphincter. Gastric distention also triggers a vagal reflex that increases lower esophageal sphincter tone, a safety mechanism against gastroesophageal reflux. The mechanical and vagal mechanisms that promote lower esophageal sphincter tone prevent spontaneous decompression of the stomach, which, along with a lack of a vomiting reflex in the horse, increases the risk of gastric rupture during episodes of severe distention.

A wide variety of congenital and acquired disorders of the esophagus have been described in horses. These are summarized in [Table 15-7](#) and discussed in detail in the next sections.

## ☉ ESOPHAGEAL OBSTRUCTION

Esophageal obstruction has many causes ([Table 15-8](#)) and most often is manifested clinically by impaction of food material and resulting esophageal dysphagia. Esophageal obstruction may be caused by primary impactions (simple choke) of roughage, particularly leafy alfalfa hay, coarse grass hay, bedding, and even grass.<sup>3</sup> Prior esophageal trauma or poor mastication caused by dental abnormalities may predispose horses to primary esophageal impaction.<sup>16</sup> Wolfing or gulping food may precipitate primary impactions, particularly if the horse is exhausted or mildly dehydrated after a long ride or is weakened from chronic debilitation. Impactions also may result from disorders that physically impede the passage of food material and fluid by narrowing the luminal diameter, reduce the compliance of the esophageal wall, or alter the conformation of the esophageal wall such that food material accumulates in a pocket or diverticulum. Foreign bodies, intramural or extramural masses, or acquired or congenital anomalies cause these so-called secondary impactions. Intramural causes of esophageal obstruction include tumors (squamous cell carcinoma), strictures, diverticula, and cysts.<sup>6,16,26,34,42,53-56</sup> Mediastinal or cervical masses (tumors or abscesses) may cause extramural obstructions. Congenital anomalies are covered in detail later.

## CLINICAL SIGNS AND DIAGNOSIS

The clinician must perform a thorough physical examination, including a complete oral and neurologic examination, to help rule out causes of dysphagia and nasal discharge other than esophageal obstruction. The clinical signs associated with esophageal obstructions are related to dysphagia.<sup>57</sup> Horses with esophageal obstruction are often anxious and stand with their neck extended. They may gag or retch, particularly with acute proximal obstructions. Bilateral frothy nasal discharge containing saliva, water, and food material; coughing; odynophagia; and ptyalism are characteristic clinical signs, the severity of which varies with the degree and location of the obstruction. Distention in the jugular furrow may be evident at the site of obstruction. Other clinical signs related to regurgitation of saliva, water, and food material may be observed, such as dehydration, electrolyte or acid-base imbalances, weight loss, and aspiration pneumonia. In extreme cases pressure necrosis from the impaction or trauma to the esophagus may cause esophageal rupture. If the rupture is in the cervical esophagus, crepitus or cellulitis may be evident along with signs of systemic inflammation. Thoracic auscultation is important to determine whether aspiration pneumonia is present. Intrathoracic esophageal rupture may result in pleuritis and its associated clinical signs.

Passage of a nasogastric tube is an effective way to detect and localize an obstruction but provides little information about the nature of the obstruction or the condition of the esophagus. The most direct method for diagnosis of esophageal obstructions is endoscopic examination. Most cases of esophageal obstruction occur at sites of natural narrowing of the esophageal lumen, such as the cervical esophagus, the thoracic inlet, base of the heart, or the terminal esophagus; thus an endoscope longer than 1 m may be necessary for complete evaluation. Endoscopic evaluation is useful before relief of an impaction to localize the obstruction and to investigate the nature of the impaction if a foreign body is suspected. Foreign bodies may be retrievable through transendoscopic tethering.<sup>58</sup> The veterinarian can obtain critical diagnostic and prognostic information after resolution of the impaction. Assessing the affected esophagus for mucosal ulceration, rupture, masses, strictures, diverticula, and signs of functional abnormalities is important ([Figures 15-11 and 15-12](#)).

Ultrasonography of the cervical region is useful not only to confirm a cervical esophageal impaction but also to provide critical information about the location and extent of the impaction and esophageal wall thickness and integrity. Ultrasonography may provide information about the cause.<sup>35</sup> Radiographic assessment of the esophagus can confirm the presence of esophageal obstruction when the affected area cannot be adequately viewed using endoscopy. Impacted food material in the esophagus can be detected by its typical granular pattern, and gas accumulation is often visible proximal to the obstruction. Air or barium contrast radiographic studies are most useful for evaluating the esophagus after relief of the impaction if a stricture is suspected. It is often easier to detect esophageal dilation, diverticula, rupture, functional disorder (megaesophagus), or luminal narrowing caused by extraluminal compression by using contrast radiographic studies instead of endoscopy ([Figure 15-13](#)).<sup>59-61</sup> One should take care when interpreting radiographic studies in sedated horses, particularly after passage of a nasogastric tube or other esophageal manipulations that may contribute to esophageal dilation.<sup>62</sup>

TABLE 15-7

<b>Esophageal Disorders of Horses</b>				
<b>Disorder</b>	<b>Presenting Complaints</b>	<b>Diagnosis</b>	<b>Treatment</b>	<b>Selected References</b>
<b>ACQUIRED DISORDERS</b>				
Choke	Nasal discharge of saliva and food; retching; excessive salivation; cough; sweating; extension of head and neck	Passage of a nasogastric tube; endoscopy	Medical and surgical treatment options as described in text	3-5
Foreign bodies	Acute or recurrent choke	Endoscopy; radiography	Manual retrieval or removal; endoscopic removal; surgery	6-10
External compression	Acute or recurrent choke.	Endoscopy; radiography; ultrasound	Removal of the obstructive mass	11
Muscular hypertrophy	No clinical signs observed in most affected horses; may predispose to esophageal diverticula	Incidental finding at necropsy	None	12
Gastroesophageal reflux disease	Inappetence; bruxism; ptyalism; colic; gastric reflux; weight loss; exercise intolerance	Esophageal and gastric endoscopy	Correct primary problem; decrease gastric acidity; gastric protectants; surgery	13-15
Stricture	Recurrent choke; weight loss	Endoscopy; contrast radiography	Bougienage; surgery	16-25
Diverticula*	Recurrent choke; weight loss	Endoscopy; contrast radiography	Surgery	24,26-29
Perforation, trauma	Salivation; bruxism; cough; nasal discharge; sepsis	Endoscopy	Enteral feeding; supportive care	30,31
Megaesophagus*	Recurrent choke; intermittent food and saliva from nares; pneumonia; weight loss; colic	Endoscopy; contrast radiography	Nutritional modification as described in text	32, 33
Neoplasia	Recurrent choke; weight loss	Endoscopy; biopsy	Surgical resection	34,35
Granulation tissue	Recurrent choke; swelling in the region of the cervical esophagus	Endoscopy; biopsy	Laser surgical resection	36
<b>CONGENITAL DISORDERS</b>				
Tubular duplication of the esophagus	Young horse; mass caudal to mandible; dyspnea; dysphagia; nasal regurgitation of food and saliva	Radiography and ultrasonography of mass; endoscopy; contrast radiography	Surgical excision	37,38
Cystic duplication of the esophagus	Young horse; mass in cervical or throatlatch area; recurrent choke; bruxism; excessive salivation; nasal regurgitation of saliva and feed; weight loss	Endoscopy; ultrasonography; aspiration of cyst; contrast radiography	Surgical excision; marsupialization of cyst	39-41
Vascular ring anomaly	Cervical swelling after introduction to solid feed; chronic respiratory disease	Endoscopy; contrast radiography; computed tomography; magnetic resonance imaging	Surgical correction	42-49
Congenital stenosis	Nasal regurgitation of milk; cough	Endoscopy; contrast radiography	Dietary management as described in text	50
Ectasia	Nasal regurgitation of milk	Histologic evaluation	None described	51,52

\*May occur as congenital or acquired lesions.

TABLE 15-8

Causes of Complete or Partial Esophageal Obstruction in the Horse		
Category	Differential	Examples
Intraluminal	Foreign body	Apples, potatoes
	Feed material	
Extramural	Neoplasia	Squamous cell carcinoma, lymphoma
	Vascular ring anomaly	Persistent right aortic arch
	Granuloma	
Intramural	Esophageal abscess	
	Granuloma	
	Neoplasia	Squamous cell carcinoma, leiomyosarcoma
	Cysts	Intramural cysts, duplication cysts
	Diverticula	
Functional disorders	Stenosis	
	Dehydration	
	Exhaustion	
	Pharmacologic	Acepromazine, detomidine
	Primary megaesophagus	Congenital ectasia
	Esophagitis	
	Autonomic dysautonomia	
	Vagal neuropathies	

## TREATMENT

The primary goal of treatment for esophageal impaction is to relieve the obstruction. A variety of approaches have been described, ranging from minimal conservative therapy to aggressive intervention. Parenteral administration of acepromazine (0.05 mg/kg intravenously), xylazine (0.25 to 0.5 mg/kg intravenously) or detomidine (0.01 to 0.02 mg/kg intravenously), oxytocin (0.11 to 0.22 IU/kg intramuscularly), and esophageal instillation of lidocaine (30 to 60 ml of 1% lidocaine) may reduce esophageal spasms caused by pain or may decrease esophageal tone.<sup>4,62,63</sup> Some clinicians advocate parasympatholytic drugs such as atropine (0.02 mg/kg intravenously) to reduce salivary secretions and lessen the risk of aspiration. However, undesirable effects of atropine, including excessive drying of the impaction and inhibition of distal gastrointestinal motility, may preclude its use.

In many horses with esophageal obstruction secondary to a feed impaction, the problem may be resolved with conservative management. To facilitate examination, relieve anxiety, and relax the esophagus, the clinician should begin by sedating the horse. Then, the clinician passes a stomach

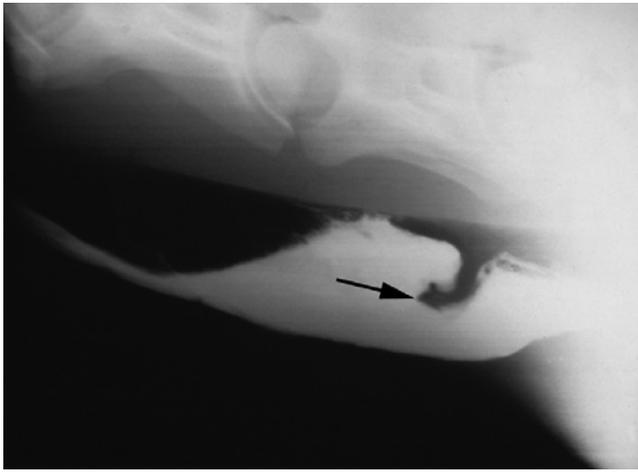

**FIGURE 15-11** Endoscopic view of the cervical esophagus in an adult horse 6 months after an episode of choke that caused circumferential ulceration of the esophageal mucosa. The area of luminal narrowing (stricture) is at the upper right of the image, and the proximal dilation forms an outpouching of the esophageal wall. A contrast esophagram revealed that the outpouching was a pulsion diverticulum.

**FIGURE 15-12** Endoscopic view of the proximal esophagus in a yearling filly with recurrent esophageal obstruction. Circumferential mucosal ulceration is evident proximal to incomplete stricture formation.

tube to confirm the diagnosis. When an obstruction is encountered, gentle pressure is applied in an attempt to dislodge and move distally the offending feed material. If the choke is not easily dislodged with gentle pressure, the tube is removed. Appropriate sedatives (e.g., xylazine, detomidine, acepromazine), anti-inflammatory-analgesic (e.g. flunixin, butorphanol), and smooth muscle-relaxing drugs (e.g., oxytocin) are administered. The horse is moved to an unbedded stall with absolutely no food or water within reach and is muzzled if

**FIGURE 15-13** Contrast esophagram in a horse with circumferential esophageal stricture (*arrow*) and a pulsion diverticulum proximal to the stricture.

necessary. The horse is left alone in the stall for several hours. If there is evidence of dehydration, appropriate intravenous fluid therapy is provided. If there is evidence of aspiration pneumonia, appropriate intravenous antimicrobial therapy is provided. Upon re-examination, a stomach tube is passed and gentle pressure is again applied to the area of obstruction. In most horses the impaction will have softened and can be easily dislodged, if it has not resolved already, with minimal pressure from the stomach tube.

Some clinicians prefer a more interventional approach to resolution of an impaction, and some impactions are severe enough to require physical dispersal of the material.<sup>4</sup> A nasogastric tube can be used to displace the impacted material along with external massage if the obstruction is in the cervical region. Often, carefully lavaging the esophagus with water using an uncuffed or a cuffed nasogastric tube while the head is lowered is necessary to aid in breaking up the impaction. Some clinicians advocate a dual tube method, whereby a tube is placed through each nasal passage into the esophagus for ingress and egress of the lavage fluid. Because of the risk of aspiration of water and food material, esophageal lavage sometimes is done under general anesthesia with a cuffed nasotracheal tube.

In refractory cases intravenous administration of isotonic fluid containing 0.9% NaCl and KCl (10 to 20 mEq/L) for 24 hours at a rate of 50 to 100 ml/kg/day along with esophageal relaxants such as oxytocin may promote hydration and softening of the impaction and help prevent or alleviate any electrolyte or acid-base imbalances resulting from salivary losses of chloride, sodium, and potassium.<sup>64</sup> Oxytocin may or may not provide a direct effect for the resolution of an esophageal obstruction. Oxytocin reduced area under the curve for esophageal smooth muscle strip contractions but had no effect on skeletal muscle strips *in vitro*.<sup>65</sup> In one *in vivo* report, oxytocin administration resulted in decreased esophageal tone in the proximal esophagus (aboral to larynx and thoracic inlet).<sup>63</sup> However, in another study oxytocin administration did not affect esophageal manometric recordings.<sup>66</sup> Rarely, esophageal obstruction ultimately may require esophagotomy to relieve the impaction. Strict restriction of food and water, including access to bedding material, must be

enforced until the obstruction is resolved and the esophagus has regained function. Surgical removal of esophageal foreign bodies can be considered if the size or orientation of the object is such that transendoscopic retrieval is considered unlikely to be successful.<sup>6,7</sup> In one report an intraluminal mass composed of exuberant granulation tissue was removed through serial transendoscopic ND:Yag laser ablation.<sup>36</sup>

Systemic effects of dysphagia associated with esophageal impaction include dehydration, hyponatremia, hypochloremia, and metabolic alkalosis from prolonged loss of salivary free water and electrolytes.<sup>64</sup> If the duration of a complete esophageal obstruction is 48 hours or longer, the clinician should correct dehydration and electrolyte and acid-base imbalances. One can restore fluid and electrolyte balance with oral electrolyte solutions if the patient is less than 6% to 7% dehydrated and the esophageal obstruction is resolved. In horses that are greater than 6% to 7% dehydrated or those that have a refractory obstruction or moderate to severe electrolyte imbalances, intravenous fluid therapy with solutions containing 0.9% NaCl and KCl (10 to 20 mEq/L) may be required.

The clinician should perform esophageal endoscopy after relief of the impaction to determine whether any complications of the impaction have developed or if a primary cause of the obstruction is present. Endoscopic examination is critical to determine the postobstruction treatment plan and for follow-up evaluation of esophageal healing. One should re-evaluate the horse every 2 to 4 weeks after resolution of the impaction if esophageal dilation or mucosal injury is evident. Additional evaluation using radiography may be warranted to assess motility and transit times.

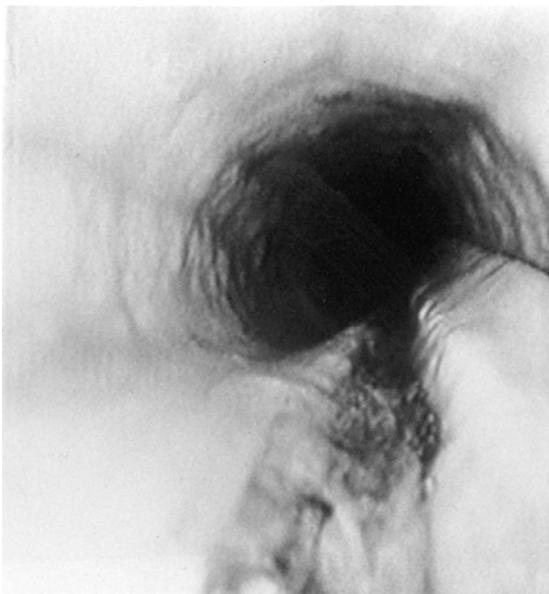

Dilation proximal to the site of obstruction, mucosal injury from trauma, stricture formation, formation of a diverticulum, megaesophagus, and esophagitis are sequelae to esophageal obstruction that predispose patients to re-obstruction. Underlying functional or morphologic abnormalities were much more likely in cases of recurrent, relative to first time, obstruction in a retrospective study.<sup>3</sup>

The rate of re-obstruction may be as high as 37%. Depending on the duration of the obstruction and the degree of trauma or dilation, the risk of re-obstruction is high for 24 to 48 hours or longer; thus food should be withheld for at least 24 to 48 hours after resolution of the obstruction. Sucralfate (20 mg/kg orally every 6 hours) may hasten healing if esophageal ulceration is evident, but the efficacy of sucralfate for this purpose is not established. Some clinicians suggest that administration of an NSAID such as flunixin meglumine (1 mg/kg orally or intravenously every 12 hours) or phenylbutazone (1 to 2 mg/kg orally or intravenously every 12 to 24 hours) for 2 to 4 weeks after resolution of the impaction may reduce the development of strictures. Judicious use of NSAIDs is recommended to prevent NSAID-induced worsening of esophageal mucosal injury. Orally administered NSAIDs are not recommended if esophagitis is present. After 48 to 72 hours or when the esophageal mucosa has recovered as assessed by endoscopy, the horse can be fed soft food (e.g., moistened pellets and bran mashes). One can return the patient gradually to a high-quality roughage diet over 7 to 21 days, depending on the degree of esophageal damage induced by the impaction and the nature of any underlying disease. The prognosis for survival is good (78% to 88%), but some horses may require permanent dietary modification if chronic obstruction persists.<sup>3,16</sup>

Aspiration pneumonia is a potential complication in every case of esophageal obstruction, and perforation is possible with severe or prolonged obstruction. In one report duration of obstruction before presentation was a good predictor of pneumonia, whereas endoscopic evidence of tracheal food contamination was not.<sup>3</sup> Thus administration of broad-spectrum antibiotics that are effective against gram positive and gram negative organisms, including metronidazole for anaerobes, is highly recommended if the duration of obstruction is either unknown or prolonged or if aspiration is at all suspected. A subsequent section describes treatment of esophageal perforation or rupture.

## ESOPHAGITIS

*Esophagitis* refers to a clinical syndrome of esophageal inflammation that may or may not be ulcerative. The major protective mechanisms of the esophageal mucosa include salivary and food material buffers, normal peristaltic motility, and the barrier formed by the gastroesophageal sphincter. Reflux esophagitis is caused by repeated episodes of gastric fluid regurgitation into the distal esophagus and subsequent chemical injury to the mucosa.<sup>67</sup> Esophageal mucosal ulceration also can occur if the clearance of gastric fluid from the esophagus is delayed, such as in functional disorders of the esophagus. Like ulceration of the squamous portion of the stomach in horses, gastric acid and bile salt chemical injury is a major mechanism of esophageal squamous epithelial ulceration.<sup>67,68</sup> Reflux esophagitis may occur along with gastric ulcer disease, motility disorders, increased gastric volume from gastric outflow obstructions, gastric paresis, intestinal ileus, or impaired lower esophageal sphincter function.<sup>55,67</sup> Other causes of esophagitis in horses include trauma (e.g., foreign bodies, food impactions, nasogastric tubes), infection (e.g., mural abscesses), or chemical injury (e.g., pharmaceuticals, cantharidin) (Figure 15-14).<sup>7,8,30,69</sup>

**FIGURE 15-14** Endoscopic view of the cervical esophagus of a horse that had repeated passages of a stiff nasogastric tube. The deep, linear ulceration of the esophageal mucosa is notable.

## CLINICAL SIGNS AND DIAGNOSIS

The clinical signs of esophagitis are nonspecific and similar to those of esophageal obstruction and gastric ulceration. Gagging or discomfort when swallowing may be evident, along with hypersalivation and bruxism. Esophageal (postpharyngeal) dysphagia may be evident. Partial or complete anorexia may occur, such that horses with chronic esophagitis may have significant weight loss. Esophageal hypomotility dysfunction caused by the inflammatory process may result in esophageal impaction. Clinical signs of underlying diseases that predispose to esophagitis may predominate or mask the signs of esophagitis. Horses with gastrointestinal motility disorders such as proximal enteritis or gastric outflow obstruction are at a high risk of developing reflux esophagitis because of the presence of gastric acid and bile salts in the fluid reflux. Foals with obstructive gastroduodenal ulcer disease commonly have reflux esophagitis.

Diagnosis requires endoscopic examination of the esophagus. Diffuse, patchy, linear, or coalescing erosion or ulcerations may be evident (see Figure 15-14), as well as significant edema or hyperemia. It is important to determine whether an underlying disease, such as infection, neoplasia, esophageal strictures, or diverticula, is present. In addition, the clinician must examine the stomach to determine whether the esophagitis is associated with gastritis, gastric outflow obstruction, or gastric ulcer disease. Contrast radiography may be helpful to detect esophageal ulceration and is useful to assess esophageal motility and transit time.<sup>60</sup>

## TREATMENT

The principles of therapy for reflux esophagitis include control of gastric acidity, mucosal protection, and correction of any underlying disorder contributing to gastroesophageal reflux. Reduction of gastric acid production with proton pump antagonists such as omeprazole or H<sub>2</sub> histamine receptor blockers such as ranitidine is critical for resolution of esophagitis. Some clinicians advocate using sucralfate to promote healing of ulcerated esophageal mucosa. However, the ability of sucralfate to bind ulcerated esophageal mucosa and hasten esophageal ulcer healing has not been established.

Horses with reflux esophagitis following delayed gastric outflow caused by gastroduodenal ulcer disease, gastric paresis, or proximal enteritis may benefit from prokinetic drugs that act on the proximal gastrointestinal tract. Metoclopramide (0.02 to 0.1 mg/kg subcutaneously every 4 to 12 hours) reduces gastroesophageal reflux by increasing lower esophageal sphincter tone, gastric emptying, and gastroduodenal coordination. The clinician should exercise caution when giving metoclopramide to horses because they are prone to extrapyramidal neurologic side effects of the drug. Cholinergic drugs such as bethanechol (0.025 to 0.035 mg/kg subcutaneously every 4 to 24 hours or 0.035 to 0.045 mg/kg orally every 6 to 8 hours) may improve gastric emptying and are effective for treating reflux esophagitis. The clinician should take care to rule out a physical obstruction before using prokinetic drugs. For esophagitis from trauma or pressure injury after esophageal impaction, judicious use of NSAIDs may be warranted to reduce esophageal inflammation and pain.

Dietary modification may be necessary for patients with esophagitis, depending on the degree of ulceration or if motility is impaired. Horses with mild esophagitis should be fed

frequent small meals of moistened pellets and fresh grass. Severe esophagitis may necessitate withholding food and imposing complete esophageal rest for several days. Although the prognosis for esophagitis is good in the absence of underlying disease, the risk of stricture formation is high if severe circumferential or coalescing ulcerations are present. Esophagitis from severe trauma or infection may lead to stricture formation.

## ☞ MOTILITY DISORDERS

Motility dysfunction of the equine esophagus most commonly is caused by hypomotility resulting in esophageal dilation (ectasia) or megaesophagus. Although megaesophagus in horses usually is acquired, reports indicate that idiopathic megaesophagus in young horses may be congenital.<sup>32,33,51,52,70</sup> Acquired megaesophagus in horses may be a consequence of chronic or recurrent esophageal obstruction.<sup>16,55</sup> Esophageal impactions of a short duration cause a proximal dilation of the esophagus that is generally reversible.<sup>60</sup> However, if the duration of the obstruction is long enough, the motility of the esophagus proximal to the site of obstruction may be impaired permanently. Other causes of acquired megaesophagus include extra-esophageal obstruction by tumors or abscesses, pleuropneumonia, and vascular ring anomalies.<sup>16,42</sup> A retrospective report of horses with megaesophagus reveals an overrepresentation of Friesian horses (14 of 18 cases), suggesting the possibility of a predisposition for esophageal disorders in this breed.<sup>32</sup> The authors state that preliminary pedigree analyses suggest the possibility of a recessive pattern of inheritance.<sup>32</sup>

Megaesophagus also may result from neurologic, neuromuscular, and muscular disorders. Neurologic diseases that cause vagal neuropathy (e.g., equine protozoal myeloencephalitis, equine herpesvirus myeloencephalitis, idiopathic vagal neuropathy) have been associated with megaesophagus in horses. Pleuropneumonia may be associated with a vagal neuropathy resulting in megaesophagus. Megaesophagus is an early sign of equine dysautonomia<sup>71</sup> and may be observable in patients with botulism. Myasthenia gravis is a well-known cause of megaesophagus in nonequine species but has not been reported in horses. Also in other species electrolyte disorders, cachexia, primary myopathies, myositis, and Addison's disease may affect esophageal motility but have not been associated with megaesophagus in horses. One can induce iatrogenic megaesophagus by the  $\alpha_2$ -adrenergic agonist detomidine, but this is transient and reversible.<sup>62,72</sup> Acepromazine, detomidine, and a combination of xylazine and butorphanol can alter proximal esophageal motility by disrupting coordinated peristalsis and decreasing spontaneous swallowing, but only acepromazine affected the manometric profile of the distal esophagus.<sup>66</sup> None of these drugs altered contractility of isolated esophageal smooth or striated muscle strips *in vitro*.<sup>65</sup> Nonetheless, the use of these drugs may complicate clinical evaluation of esophageal motility. Esophageal disorders, including megaesophagus, esophageal diverticulum, and esophageal rupture, appear to be more common in young Friesian horses, suggesting the possibility of a genetic predisposition in this breed.

Esophageal inflammation, particularly reflux esophagitis, may affect motility and cause megaesophagus. However, because esophageal hypomotility affects the tone and function of the lower esophageal sphincter, reflux esophagitis also may be a complication of a primary functional disorder. Thus

assessing esophageal motility in horses with esophagitis that is not responding appropriately to treatment is important.

## CLINICAL SIGNS AND DIAGNOSIS

Along with a complete physical examination, the clinician should perform a careful neurologic examination to help rule out primary neurologic causes of megaesophagus. Because esophageal hypomotility is a functional obstruction, the clinical signs of esophageal hypomotility or megaesophagus are similar to those of esophageal obstruction. Unlike mechanical obstruction the onset of clinical signs is insidious rather than acute. The clinical signs include those associated with esophageal dysphagia.<sup>33,42,51,52,55,70</sup> The cervical esophagus may be dilated enough to be evident externally. Weight loss is a common sign. Signs attributable to an underlying disease may be evident.

Diagnosis of esophageal hypomotility requires transit studies. One can measure the transit time of a bolus from the cervical esophagus to the stomach by fluoroscopy or contrast radiography.<sup>60,71</sup> Other signs of esophageal hypomotility and megaesophagus include pooling of contrast material and an absence of peristaltic constrictions.<sup>55,60,70,71</sup> Endoscopy may reveal a dilated esophagus and an absence of peristaltic waves.<sup>55,70</sup> Evidence of underlying disease causing obstruction or esophageal dilation may be apparent.<sup>16,55</sup> One should evaluate the esophagus for evidence of esophagitis that is causing esophageal motility dysfunction or is a result of impaired esophageal clearance of gastric fluid. Esophageal manometry may be useful to document abnormal postdeglutition contraction pressures, contraction time, and propagation times but is not often available for routine clinical application.<sup>70,73</sup> One should perform other diagnostic tests, such as a complete blood count and chemistry, to help determine a possible underlying cause. Cerebral spinal fluid analysis may be indicated to rule out neurologic disorders. Specialized testing such as electromyography may also be indicated to detect neuromuscular disorders.

## TREATMENT

Treatment of esophageal hypomotility or megaesophagus should aim at treating the underlying cause. Dietary modification should aim at improving esophageal transit of food. The horse should be fed slurries of pellets from an elevated position to promote transit by gravity flow. Metoclopramide or bethanechol may benefit patients with reflux esophagitis associated with megaesophagus by increasing lower esophageal tone, gastric emptying, and reducing gastroesophageal reflux. The prognosis depends on the underlying cause and the degree of dilation. Although many cases of megaesophagus associated with reflux esophagitis respond well to treatment, many other forms of megaesophagus, including congenital megaesophagus, have a poor prognosis.

## ☞ ESOPHAGEAL STRICTURE

Strictures most commonly are caused by pressure necrosis from esophageal impactions that induce circumferential erosion or ulceration of the esophageal mucosa, although esophageal injury caused by oral administration of corrosive medicinal agents and trauma to the neck may also result in stricture formation.<sup>17</sup> Congenital strictures also have been reported.<sup>74</sup>

Strictures caused by mucosal and submucosal trauma are termed *esophageal webs* or *rings*. Strictures may also originate in the muscular layers and adventitia of the esophagus (mural strictures) or in all of the layers of the esophagus (annular stenosis).<sup>18,74</sup> Horses with these lesions have a presentation similar to those with simple obstructions, because strictures result in partial obstruction and impaction of food material in the lumen. Endoscopy can be used to detect esophageal webs or rings (see *Figures 15-11 and 15-12*), whereas identification of mural strictures or annular stenosis may require a double-contrast esophogram (see *Figure 15-13*). In a retrospective study of horses with esophageal stricture following simple obstruction, maximal reduction in esophageal lumen diameter occurred within 30 days of the esophageal obstruction. Although surgery has been used to relieve such strictures, initial medical management is warranted because strictures may resolve with conservative therapy, and the esophagus continues to remodel for up to 60 days following ulceration. In one report seven horses with esophageal obstruction-induced stricture were treated conservatively by feeding a slurry diet and administering anti-inflammatory and antimicrobial medications, and five of seven were clinically normal within 60 days.<sup>17</sup> One of the five successfully treated horses had a 10-cm area of circumferential ulceration, suggesting that the potential exists for extensive mucosal injury to resolve without permanent stricture formation.

If resolution of strictures within 60 days is insufficient, the veterinarian should investigate other methods to increase esophageal diameter. Bougienage and balloon dilation have been used successfully in small animal patients and human beings and with variable results in horses.<sup>19-21</sup> The technique involves passage of a tubular dilatable instrument down the esophagus and stretching of the stricture. One may perform the technique by passing a nasogastric tube with an inflatable cuff. However, the procedure must be performed frequently to have any success, and horses may not tolerate it well.<sup>74</sup> Alternatively, a number of surgical techniques have been used to resolve strictures, including resection and anastomosis,<sup>75,76</sup> temporary esophagostomy with fenestration of the stricture,<sup>18</sup> esophagomyotomy for strictures of the muscularis and adventitia,<sup>22,77</sup> and patch grafting with local musculature.<sup>23</sup> However, such surgeries are fraught with complications, largely because of the propensity of the traumatized esophagus to restricture.<sup>16,17</sup> The esophagus lacks a serosal layer and does not rapidly form a fibrin seal as does the remainder of the intestinal tract, so anastomoses tend to leak.<sup>76</sup> In addition, tension on the esophagus during swallowing and movement of the neck impairs healing of anastomoses.<sup>18,75</sup> In spite of these difficulties, the long-term prognosis for horses with chronic esophageal strictures treated surgically is better than for those treated nonsurgically.<sup>16</sup> Two recent reviews describe surgical approaches to the esophagus in detail.<sup>24,78</sup>

## ESOPHAGEAL DIVERTICULA

Two types of diverticula are traction (true) diverticula and pulsion (false) diverticula. Traction diverticula result from wounding and subsequent contraction of periesophageal tissues, with resultant tenting of the wall of the esophagus. Pulsion diverticula arise from protrusion of esophageal mucosa through defects in the muscular wall of the esophagus and usually result from trauma or acute changes in intraluminal

pressure.<sup>74</sup> Traction diverticula appear as a dilation with a broad neck on contrast esophagography, whereas pulsion diverticula typically have a flask shape with a small neck on an esophagram (see *Figure 15-13*).<sup>26,27</sup> Although traction diverticula are usually asymptomatic and of little clinical significance, pulsion diverticula may fill with feed material, ultimately leading to esophageal obstruction and rupture.<sup>9,27,28</sup>

A movable mass in the midcervical region may be noticeable before onset of complete obstruction.<sup>74</sup> Pulsion diverticula may be corrected surgically by inverting or resecting prolapsed mucosa and closing the defect in the wall of the esophagus.<sup>26-28</sup> Inversion of excessive mucosa may reduce the diameter of the esophageal lumen and predispose horses to esophageal obstruction and therefore should be reserved for small diverticula.<sup>26</sup>

## CONGENITAL DISORDERS

Congenital disorders of the esophagus are rare. Reported congenital abnormalities include congenital stenosis,<sup>50</sup> persistent right aortic arch,<sup>42-47</sup> other vascular anomalies,<sup>48</sup> esophageal duplication cysts,<sup>37,39,40</sup> intramural inclusion cysts,<sup>41,56</sup> and idiopathic megaesophagus.<sup>33,51,52</sup> In the one report of congenital stenosis, double-contrast radiography revealed concentric narrowing of the thoracic esophagus in the absence of any vascular abnormalities at the base of the heart. Successful treatment included having the foal stand with the forelimbs elevated off the ground following each feeding.<sup>50</sup>

Persistent right aortic arch is a congenital anomaly in which the right fourth aortic arch becomes the definitive aorta instead of the left aortic arch, which results in constriction of the esophagus by the ligamentum arteriosum as it extends between the anomalous right aorta and the left pulmonary artery.<sup>49</sup> Clinical signs may include those associated with esophageal (postpharyngeal) dysphagia, drooling, and distention of the cervical esophagus resulting from partial obstruction of the thoracic esophagus.<sup>42,43</sup> Endoscopic examination typically reveals dilation of the esophagus cranial to the obstruction, with evidence of diffuse esophagitis. Surgical treatment of persistent right aortic arch has been reported in foals, with varying degrees of success.<sup>43,45,47</sup> In one report, preoperative computed tomography was used to identify the exact anatomic location of the offending lesion and guide the surgical approach.<sup>47</sup>

Esophageal duplication cysts and intramural inclusion cysts cause typical signs of esophageal obstruction, including salivation, esophageal dysphagia, and swelling of the cervical esophagus as the cysts enlarge.<sup>37,39,41</sup> Such signs can make them difficult to differentiate from other forms of esophageal obstruction (choke). Endoscopic examination may reveal compression of the esophageal lumen and communication with the esophageal lumen if it exists.

Ultrasonographic examination may be the most useful method of antemortem diagnosis if the cyst is in the cervical esophagus. Examination of an aspirate of the mass may aid in the diagnosis by revealing the presence of keratinized squamous cells.<sup>39,41</sup> Surgical treatments have included complete surgical resection and surgical marsupialization.<sup>37,39,41</sup> The latter appears to be more successful and results in fewer complications.<sup>37,41</sup> Complications of surgical resection include laryngeal hemiplegia following surgical trauma to the recurrent laryngeal nerve in the region of the esophagus and esophageal fistula formation.<sup>41</sup>

## ESOPHAGEAL PERFORATION

Perforation typically occurs in the cervical region in response to external trauma, necrosis of the esophageal wall caused by a food impaction, or rupture of an esophageal lesion such as an impacted diverticulum. The esophagus is particularly vulnerable to external trauma in the distal third of the neck because only a thin layer of muscle covers it at this point.<sup>79</sup> Iatrogenic perforation may occur in response to excessive force with a stomach tube against an obstruction or a compromised region of the esophagus.<sup>30</sup> Esophageal perforations may be open or closed and tend to cause extensive cellulitis and necrosis of tissues surrounding the wound because of drainage of saliva and feed material within fascial planes. Systemic inflammation resulting from septic cellulitis may occur. Closed perforations of the esophagus are particularly troublesome because food material, water, saliva, and air may migrate to the mediastinum and pleural space via fascial planes.<sup>30,79</sup> Because of the leakage of air into the tissues surrounding the rupture, extensive subcutaneous and fascial emphysema frequently develops and is usually evident clinically and on cervical radiographs. Pneumomediastinum and pneumothorax are potentially fatal complications of esophageal ruptures. If the esophagus ruptures into the mediastinum, horses usually exhibit signs of acute systemic inflammatory response syndrome that may be mistaken for colic.

Treatment should include converting closed perforations to open perforations if possible,<sup>80</sup> extensive débridement and lavage of affected tissues, broad spectrum antibiotics, tetanus prophylaxis, and esophageal rest. The clinician may achieve the latter by placing a feeding tube into the esophagus via the wound. Alternatively, one may place a nasogastric tube using a small tube (12-F diameter).<sup>30</sup> For open perforations, once the wound has granulated and contracted to a small size, peroral feeding may be attempted.<sup>79</sup> Extensive loss of saliva via esophageal wounds may lead to hyponatremia and hypochloremia. In addition, transient metabolic acidosis occurs because of salivary bicarbonate loss, followed by progressive metabolic alkalosis.<sup>64</sup> Although reports of esophageal wounds healing well by second intention exist, healing time is prolonged.<sup>81</sup> In addition, some perforations never completely heal and form permanent esophagocutaneous fistulae that may require surgical correction. The development of esophageal strictures is not common because wounds are usually linear and not circumferential. However, traction diverticula may develop. Other complications of esophageal wounds include Horner's syndrome and left laryngeal hemiplegia.<sup>79</sup>

In a retrospective study on esophageal disorders, only 2 of 11 horses with esophageal perforations survived over the long term;<sup>16</sup> in a report of esophageal trauma following nasogastric intubation, four of five horses were euthanized.<sup>30</sup> The prognosis is therefore poor in horses with esophageal perforations, largely because of the extent of cellulitis, tissue necrosis, shock, and local wound complications.

## DISEASES OF THE STOMACH

L. Chris Sanchez

The availability of specialized endoscopic equipment allowing visual inspection of the entire adult equine stomach and proximal duodenum is now commonplace for veterinarians in referral

and select ambulatory settings. Thus veterinarians, owners, and trainers are increasingly aware of gastric disease in horses.

## GASTRODUODENAL ULCERATION

*Peptic ulcer disease* is defined as erosions or ulcers of any portion of the gastrointestinal tract normally exposed to acid.<sup>1</sup> Mucosal damage can include inflammation, erosion (disruption of the superficial mucosa), and ulceration (penetration of the submucosa). In severe cases full-thickness ulceration can occur, resulting in perforation. The proximal (orad) portion of the equine stomach is lined by stratified squamous mucosa similar to that lining the esophagus. This proximal portion is also commonly termed the *nonglandular region* of the stomach. The distal (aborad) portion of the stomach is lined with glandular mucosa, and the distinct junction between the two regions is deemed the *margo plicatus*. Ulceration can occur in either or both gastric regions, although different clinical syndromes and pathophysiologic mechanisms apply. As a result, the broad term *equine gastric ulcer syndrome* (EGUS) has been used to encompass the wide array of associated clinical syndromes.<sup>2</sup> EGUS develops in horses of all ages and is arguably the most clinically and economically important disorder of the equine stomach.

## PREVALENCE

The prevalence of gastric ulceration has been reported for a variety of breeds and usages; however, most current data involve Thoroughbreds or Standardbreds in race training. The prevalence of squamous ulceration in horses in race training varies between 70% to 95%<sup>3-11</sup> and can be as high as 100% when limited to animals actively racing.<sup>7</sup> In recent years horses performing in other disciplines have also been evaluated, including active show horses (58% prevalence),<sup>12</sup> endurance horses (67%),<sup>13</sup> western performance horses (40%),<sup>14</sup> Thoroughbred broodmares (67% pregnant; 77% nonpregnant),<sup>15</sup> and nonracing performance horses (17% precompetition; 56% postcompetition).<sup>16</sup> In one large retrospective study (3715 adult horses from 1924-1996) evaluating incidence of gastric ulceration identified at necropsy, an overall prevalence of 10.3% was found, with the highest prevalence in Thoroughbreds (including Arabians) and Standardbred trotters (19%).<sup>17</sup> Horses in a university riding program also demonstrated a low squamous ulceration prevalence (11%).<sup>18</sup> Approximately 49% of horses seen in a referral hospital for colic had evidence of gastric ulceration.<sup>19</sup> The reported prevalence of gastric ulceration in foals varies between 25% to 57%.<sup>20-22</sup>

Many earlier studies investigating the prevalence of gastric ulceration do not differentiate between nonglandular and glandular lesions, and many evaluate only the nonglandular region of the stomach, but this trend is changing. In a recent study of 162 horses in a hospital setting, 58% had antral or pyloric erosions or ulcerations, 58% had squamous mucosal lesions, and 8% had lesions involving the glandular body.<sup>23</sup> In other studies 56% of Thoroughbreds in which the pylorus was examined had glandular ulceration,<sup>9</sup> and 47% of racehorses (Thoroughbred and Standardbred) in which the pylorus was evaluated had ulceration in that location.<sup>11</sup> In the former study<sup>9</sup> all horses with glandular lesions also had squamous disease, whereas such an association was not seen in the latter study.<sup>11</sup> In endurance horses with a 67% overall lesion prevalence, 57% had squamous ulceration, whereas 27% had

glandular disease.<sup>13</sup> In a postmortem evaluation, lesions were most commonly located in the squamous mucosa along the margo plicatus, followed by the glandular body, proximal squamous mucosa, and antrum.<sup>17</sup>

## PATHOPHYSIOLOGY

An imbalance between inciting and protective factors in the mucosal environment can result in ulcer formation.<sup>24,25</sup> The major intrinsic factors promoting ulcer formation include hydrochloric acid (HCl), bile acids, and pepsin, with HCl the predominant factor. Various intrinsic factors protect against ulcer formation, such as the mucus-bicarbonate layer, maintenance of adequate mucosal blood flow, mucosal prostaglandin E<sub>2</sub> and epidermal growth factor production, and gastroduodenal motility. In humans extrinsic ulcerogenic factors include NSAIDs; *Helicobacter pylori*; stress; changes in diet; and gastrointestinal disorders, especially those resulting in delayed gastric emptying.<sup>1</sup> In human neonates physiologic stress associated with a major primary illness seems to be strongly associated with gastric ulcers.<sup>26</sup> Many of the other factors mentioned previously are believed to be important in horses, but clear evidence of an infectious agent has not yet been identified in horses or foals with EGUS.<sup>27,28</sup> Recently, the possibility of *Helicobacter* infection in horses has re-emerged with the identification of polymerase chain reaction (PCR) products consistent with *Helicobacter*-like bacteria in horses with and without gastric lesions<sup>29,30</sup> and a new species, *Helicobacter equorum*, identified in horse feces.<sup>31</sup> Serum antibodies against *H. pylori* appear common in postsuckling foals and their dams.<sup>32</sup> However, *H. equorum* did not colonize the equine stomach in an experimental model,<sup>33</sup> and a true link between *Helicobacter* infection and any form of EGUS remains elusive.

The specific factors involved in injury as well as protective mechanisms vary among regions of the proximal gastrointestinal tract, and a thorough review of mucosal injury and repair is presented elsewhere in this chapter. The pathophysiology of squamous mucosal ulceration in the horse appears similar to that seen in gastroesophageal reflux disease (GERD) in human beings and ulceration of the nonglandular mucosa in pigs. Excessive acid exposure is the predominant mechanism responsible for squamous mucosal ulceration, although many details remain unclear.<sup>34</sup> Hydrochloric acid is secreted by parietal cells in the gastric glands via a hydrogen-potassium adenosine triphosphatase (H<sup>+</sup>, K<sup>+</sup>-ATPase) pump on the luminal side. Horses secrete acid continuously, and measured pH of equine gastric contents is variable from less than 2 to greater than 6, depending on the horse's dietary state (fed versus fasted).<sup>35,36</sup> A protocol of repeated 24-hour periods of fasting and feeding induces squamous erosion and ulceration.<sup>37</sup> Because this protocol results in periods of prolonged gastric acidity (pH < 2.0) and concurrent administration of the histamine<sub>2</sub> (H<sub>2</sub>) receptor antagonist ranitidine reduces lesion severity, it supports the role of acid exposure in the pathogenesis of squamous ulcer disease.

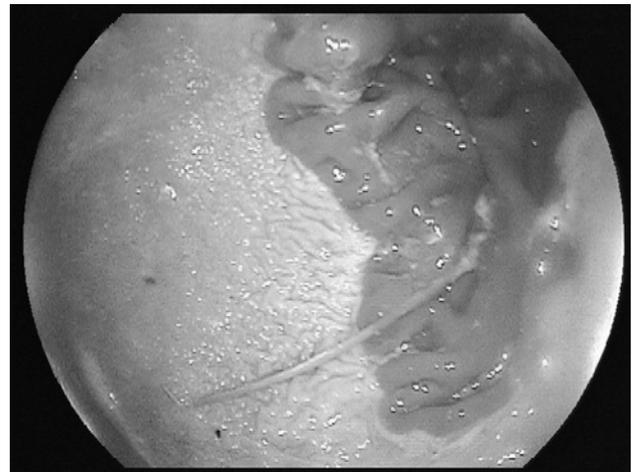

Several peptides can stimulate or inhibit the secretion of acid by the parietal cell. The predominant stimuli to hydrochloric acid secretion are gastrin, histamine, and acetylcholine via the vagus nerve.<sup>1</sup> Gastrin is released by G cells within the antral mucosa, and histamine is released by mast cells and ECL cells in the gastric gland. Histamine binds to type 2 receptors on the parietal cell membrane, causing an increase in cyclic adenosine monophosphate (cAMP), resulting in phosphorylation of enzymes that activate the proton

pump. Gastrin and acetylcholine can act via calcium-mediated intracellular pathways and also stimulate histamine release directly.<sup>38</sup> Isolated equine parietal cells respond maximally to histamine stimulation and only minimally to carbachol and pentagastrin.<sup>39</sup> In vivo, histamine or pentagastrin infusion can stimulate similar maximal acid output.<sup>40</sup> Interestingly, pentagastrin stimulation also induces a marked duodenal secretion of a sodium chloride-rich fluid, which can reflux back into the stomach under fasting conditions.<sup>40</sup> Gastrin release is primarily controlled by gastrin-releasing peptide (GRP), which is stimulated by gastric distention and increased luminal pH, but the interaction between gastrin and histamine has not been fully elucidated in the horse.

Gastric acid secretion by parietal cells is primarily inhibited by somatostatin, released by fundic and antral D cells. The inhibitory effect of somatostatin is primarily paracrine, but plasma levels of somatostatin negatively correlate with gastric luminal acidity.<sup>41</sup> Gastric acid secretion also is inhibited by epidermal growth factor (EGF), a peptide produced in saliva.<sup>42</sup>

Foals can produce significant amounts of gastric acid by the second day of life, with consistent periods of acidity (pH < 2.0) in clinically normal animals.<sup>43,44</sup> In one study foals tended to have a high gastric pH at day 1 of age,<sup>43</sup> but in a study of critically ill foals, some foals demonstrated periods of gastric acidity on the first day of life.<sup>45</sup> Suckling was associated with an immediate rise in gastric pH, whereas periods of rest during which foals did not suck for more than 20 minutes were associated with prolonged periods of acidity.<sup>44</sup> Premature human infants are capable of gastric acid production at 28 weeks of gestation.<sup>46</sup> In sheep abomasal pH begins to drop at approximately 125 days of gestation but does not reach values normal for adult sheep (2.5) until after birth, which corresponds to the presence of H<sup>+</sup>/K<sup>+</sup>/ATPase mRNA, present in the fetal fundus by 125 days of gestation and rising to adult levels until after birth.<sup>47</sup> This observed increase in acid secretion corresponds to an increase in bioactive serum gastrin. Only one of seven premature foals demonstrated an acidic pH recording in a study of gastric pH profiles in critically ill foals.<sup>45</sup> Although multiple factors were likely involved in those foals, the true ontogeny of gastric acid production in foals is currently unknown.

Equine squamous mucosa is very thin at birth but becomes hyperplastic and parakeratotic within days (Figure 15-15).<sup>48</sup>

**FIGURE 15-15** Endoscopic image of the greater curvature of the stomach in a 3-day-old Thoroughbred colt.

The parallel between decreasing pH and proliferation of squamous epithelium correlates with that seen in other species.<sup>49</sup> The combination of a relatively thin gastric epithelium with a high acid output may leave neonatal foals susceptible to ulcer formation at a very young age. In addition, one must remember the difference in normal appearance of the squamous mucosa when interpreting gastric endoscopy in a neonatal population.

In esophageal squamous mucosa, intercellular tight junctions and bicarbonate secretion are the major factors involved in protection against acid injury in other species, although squamous bicarbonate secretion has not been documented in the horse.<sup>50-52</sup> The principal barrier is a glycoconjugate substance secreted by cells in the *stratum spinosum*, with a contribution from the tight junctions in the *stratum corneum*.<sup>52</sup> This barrier function is considered weak at best, and thus a functioning lower esophageal sphincter, normal salivary flow, and salivary mucins contribute to the prevention of acid injury in human GERD. In horses a mechanical barrier like the lower esophageal sphincter is not available to protect the gastric squamous mucosa from acid exposure. The squamous mucosa adjacent to the margo plicatus, especially along the lesser curvature, likely receives regular exposure to acidic gastric contents. Recently, surface mucus demonstrating cross-reactivity to a mixture of anti-human MUC5AC (a mucin gene) antibodies has been identified in both the glandular and nonglandular regions of healthy equine gastric mucosa.<sup>53</sup>

Bile salts and pepsin have been implicated as contributing factors to ulcer disease in many species. In rabbit esophageal mucosa, bile salt absorption occurs and is directly correlated with mucosal barrier disruption.<sup>54</sup> The unconjugated bile salts cholate and deoxycholate have a  $pK_a$  of 5 and 5.3, respectively, and therefore cannot remain in solution and cause mucosal damage in the presence of acid. Alternatively, the conjugated bile salt taurocholate ( $pK_a$  1.9) can cause mucosal injury in either the ionized salt form at pH 7 or the nonionized acid form at pH 1-2.<sup>54</sup> In the pig bile salts or acid alone causes squamous mucosal damage, whereas a combination of the two result in extensive damage in vitro.<sup>55</sup> In the horse a similar synergistically damaging effect was found with the addition of bile salts and acid (pH 2.5) to stratified squamous mucosa in vitro in one study.<sup>56</sup> In addition, the investigators were able to document levels of both bile salts and acid sufficient to cause mucosal damage in gastric contents within 14 hours of feed deprivation. This is not surprising, given that duodenogastric reflux occurs normally in the horse.<sup>40</sup> In a separate in vitro study of equine squamous mucosa, prolonged exposure to acid alone (pH 1.5) had a damaging effect, and synergism with exposure to a combination of acid and pepsin or taurocholate was not found.<sup>57</sup> The lack of synergism is likely due to the lower pH used in this study and stresses the importance of acid exposure in squamous ulcer disease. The effect of acid has been consistent among studies. In addition, several volatile fatty acids (acetic, butyric, and propionic), which had previously been documented in gastric contents of horses fed hay or hay and grain diets, decreased nonglandular mucosal barrier function.<sup>58,59</sup> Lactic acid exposure alone does not appear to alter nonglandular mucosal bioelectric properties.<sup>60</sup>

Pepsinogens are secreted primarily by chief cells, although secretion by neck cells, cardiac glands, and antral pyloric glands also occurs.<sup>61</sup> In an acidic environment (pH <3.0), pepsinogen is converted to the active pepsin. Although the proteolytic

activity of pepsin is normally directed toward dietary protein, it can also act on the gastric mucosa.<sup>62</sup>

Several mechanisms help protect the glandular mucosa from acid injury. The mucus-bicarbonate layer serves to titrate  $H^+$  ion from the gastric lumen to  $CO_2$  and  $H_2O$ . Cellular restitution and prostaglandins of the E series, which enhance mucosal blood flow and mucus-bicarbonate secretion in the glandular mucosa, have not been documented in squamous epithelium.<sup>34,51</sup> Of these mechanisms mucosal blood flow is likely the most important contributor to overall gastric mucosal health. Nitric oxide is a key regulator of mucosal blood flow and prostaglandin synthesis and thus may play a role in mucosal protection.<sup>63</sup>

Overall, acid remains the major contributing factor to nonglandular mucosal damage, although other factors, such as pepsin and bile salts, may play an important role as well, either in the initiation or perpetuation of disease.

## RISK FACTORS

Many aspects of diet and management have been associated with the development of nonglandular ulceration in adult horses, several of which have already been discussed with reference to pathophysiology. These include diet, feeding patterns, exercise, stall confinement, transportation, and administration of NSAIDs.

Horses in race training have a high incidence of gastric ulceration and are frequently fed high-concentrate, low-roughage diets. A diet high in concentrate and either high or low in forage, in conjunction with stall confinement but no exercise, was shown to induce nonglandular ulceration within 2 weeks.<sup>64</sup> In one study higher volatile fatty acid concentrations, higher gastric juice pH, and lower number and severity of nonglandular ulceration were documented after feeding an alfalfa hay-grain diet when compared to a bromegrass hay diet.<sup>58</sup> However, many factors differed between the diets, such as digestible energy, bulk, crude protein, and mineral content (especially calcium). These findings were recently supported by a study in which an alfalfa hay/pelleted concentrate diet significantly reduced ulcer severity scores and prevented ulcer development relative to a coastal hay-concentrate diet in horses managed with dry lot housing and regular exercise.<sup>65</sup> Intermittent feeding has clearly been shown to induce nonglandular ulceration and is a consistent model of ulcer induction.<sup>36,37,66</sup>

The pathophysiologic correlation between exercise and squamous ulcer disease has not yet been defined, despite the high prevalence of ulceration in performance horses. Nonglandular ulceration can develop within 8 days of exercise varying from light halter to active race training<sup>67</sup>, and time in work was found to be a risk factor for squamous ulceration in racing Thoroughbreds.<sup>68</sup> Elevations in postfeeding serum gastrin concentration have been demonstrated after treadmill exercise.<sup>69</sup> During treadmill exercise at gaits faster than a walk, proximal gastric size decreases in conjunction with an increase in intra-abdominal pressure, resulting in a simultaneous decrease in proximal gastric pH.<sup>70</sup> Both proximal gastric size and pH return to baseline levels as soon as the horse returned to a walk, and the resultant theory was that gastric contraction could result in increased acid exposure to the squamous mucosa by raising the level of liquid gastric contents.

Stall confinement<sup>66</sup> and transport<sup>71</sup> have been shown to induce nonglandular ulceration. However, a distinct mechanism for either of these factors has not been definitively

determined. A recent study did not detect a difference in pH in the proximal or ventral stomach in response to three different environmental situations (stall confinement alone in a barn, stall confinement with a horse in an adjacent stall, and pad-dock turnout with a companion horse), each for 24 hours.<sup>72</sup> This work suggests that increased acid exposure to the proximal stomach alone is not causative.

Several studies have failed to document a correlation between NSAID administration and naturally occurring ulcer disease.<sup>3,4,6,7,17</sup> However, NSAID administration is a well-known cause of gastric ulceration under experimental conditions.<sup>73-77</sup> NSAID-related ulceration is typically described as predominantly glandular in nature, although nonglandular ulceration can also occur by a mechanism that has not yet been fully characterized. NSAIDs cause a decrease in prostaglandin E<sub>2</sub> synthesis caused by inhibition of the COX pathway. Therefore a resultant decrease in glandular mucosal protection, most notably by way of decreased mucosal blood flow and mucus production, is the most likely mechanism of action. In one study, however, phenylbutazone administration resulted in ulceration of the glandular mucosa at the pyloric antrum but did not significantly alter mucosal prostaglandin E<sub>2</sub> concentration.<sup>75</sup>

Other risk factors associated with gastric ulceration include gender and age, and the reported prevalence of gastric ulcers has increased over time. In one study the frequency of gastric ulceration increased from less than 6% before 1945 to approximately 18% after 1975.<sup>17</sup> The association between sex or age and ulceration has not been consistent among studies.<sup>7,9,10,17,78</sup> Crib biting has also been discussed as a risk factor.<sup>68,79</sup> In one study difficulty maintaining weight and playing of a radio were also associated with risk of ulceration.<sup>68</sup> Although the former is easily explained, the latter certainly requires further investigation. In foals risk factors are less clearly defined and will be discussed along with the clinical syndrome in each age group.

### **CLINICAL SYNDROME: NEONATAL FOALS**

Clinical signs typically associated with gastric ulceration in foals include poor appetite, diarrhea, and colic. Many foals probably never exhibit clinical signs, and some do not exhibit clinical signs until ulceration is severe or fatal perforation has occurred. Glandular ulceration is typically considered the most clinically significant type of disease in this population.

The physiologic stress of a concurrent illness has been associated with gastric ulceration in foals. Retrospectively, 14 (23%) of 61 foals up to 85 days of age with a clinical disorder were found to have lesions in the gastric glandular mucosa,<sup>22</sup> and prospectively 8 (40%) of 20 foals up to 30 days of age with a clinical disorder had glandular ulceration.<sup>80</sup> By contrast, only 4% to 9% of clinically normal foals examined in endoscopic surveys had lesions observed in the gastric glandular mucosa.<sup>21,81</sup>

Critically ill neonatal foals can have a markedly different pH profile compared with that seen in clinically normal foals, possibly because of alterations in gastric motility and acid secretion.<sup>45</sup> Gastric ulceration was not identified in any animals at necropsy in that study; however, ulceration has been documented in a similar population.<sup>20</sup> Thus factors other than acid exposure, most notably mucosal perfusion, may play an important role in the so-called stress-related ulceration seen in neonates. Gastric ulceration and rupture in the hospitalized

neonatal population appears to occur less often now than in previous reports, despite a decline in the use of ulcer prophylaxis in one hospital.<sup>82</sup> Advances in overall neonatal care, especially supportive care, have likely contributed to this decline.

One recent report evaluated the use of gastric tonometry as a measurement of mucosal perfusion in neonatal foals.<sup>83</sup> However, despite investigations into the effect of age, feeding, and omeprazole administration, the reference interval in foals appears too wide to warrant clinical application of this tool to evaluate the relationship between ulceration and mucosal perfusion in foals.

### **CLINICAL SYNDROME: SUCKLINGS AND WEANLINGS**

In suckling foals younger than 50 days old, lesions typically originate in the squamous mucosa adjacent to the margo plicatus along the greater curvature. Such lesions can be seen in foals as young as 2 days of age and have been observed in 50% of foals younger than 50 days old. Histologic examination of these lesions has revealed disruption of the epithelial layers of the mucosa and a neutrophilic infiltration. Another phenomenon that occurs in young foals is the shedding, or desquamation, of squamous epithelium, which appears as flakes or sheets of epithelium. Desquamation occurs without ulceration in up to 80% of foals less than 35 days of age, and this process is not typically associated with clinical signs.<sup>21,22,81</sup>

In older foals lesions become more prevalent in the squamous mucosa, particularly along the lesser curvature.<sup>80</sup> Lesions also are found in the squamous mucosa of the fundus and adjacent to the margo plicatus. These lesions can be very severe and are often associated with clinical signs such as diarrhea, poor appetite, and poor growth and body condition. Diarrhea is the most frequent sign in symptomatic foals with squamous mucosal lesions and is associated with more diffuse erosion or ulceration of the squamous mucosa than occurs in asymptomatic foals. In some foals poor growth, rough hair coat, a potbelly appearance, or all of these occur in conjunction with moderate to severe squamous mucosal ulceration. In cases with severe or diffuse squamous ulceration, bruxism or colic may occur.

Gastroduodenal ulcer disease (GDUD) occurs almost exclusively in suckling and early weanling foals. Clinical signs of duodenal ulceration are similar to that described for gastric ulceration (bruxism, colic, ptyalism, diarrhea), but the consequences are often more severe. Lesions occur primarily in the proximal duodenum, ranging from diffuse inflammation to severe ulceration, but affected foals typically have severe squamous or glandular ulceration as well (Figure 15-16). Foals with duodenal ulceration often have delayed gastric emptying and may have gastroesophageal reflux. Potential complications include gastric or duodenal rupture, pyloric or duodenal stricture (Figure 15-17), and ascending cholangitis. Severe squamous and esophageal ulceration and aspiration pneumonia can occur secondary to gastroesophageal reflux.<sup>24,84-87</sup>

The GDUD syndrome can occur in outbreaks and is most commonly identified in intensive breeding operations. The cause of duodenal lesions in foals is not known. One theory is that the problem begins with diffuse duodenal inflammation that can coalesce down to a focal area of ulceration.<sup>88</sup> A temporal relationship between GDUD and rotaviral diarrhea has been suggested, but an infectious etiology remains unproven. Although lesion location and severity associated with rotaviral

**FIGURE 15-16** Endoscopic image of the lesser curvature in a 3-month-old foal diagnosed with gastroduodenal ulcer disease and a gastric outflow obstruction.

infection varies among species, duodenal ulceration has not been reported.<sup>89</sup>

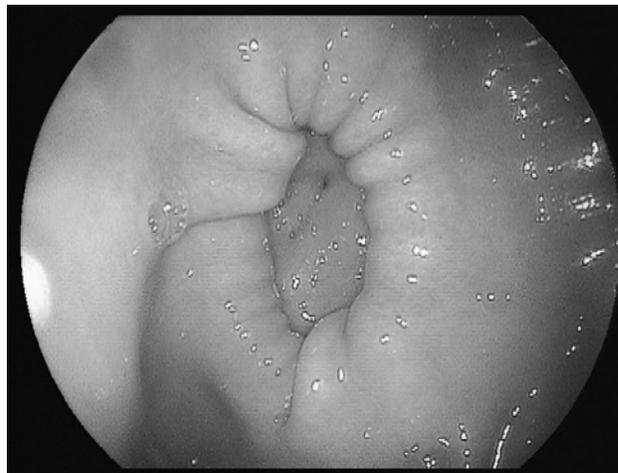

### CLINICAL SYNDROME: YEARLINGS AND ADULT HORSES

Clinical signs attributable to EGUS in older horses are variable and classically include anorexia and chronic or intermittent colic of varying severity.<sup>90</sup> Many horses with endoscopic evidence of disease may appear to be clinically normal or have vague signs that include decreased consumption of concentrates, postprandial episodes of colic, poor performance or failure to train up to expectations, poor hair coat, and decreased condition or failure to thrive. Diarrhea is not typically associated with gastric ulceration in adult horses, although ulceration can occur concurrently with other causes of diarrhea. Neither presence nor type of clinical signs was correlated with prevalence or severity of ulceration.<sup>9</sup> Horses actively racing appear more likely to have squamous ulceration than those solely in training.<sup>7,10</sup> In some studies of horses in race training, neither prevalence nor severity of ulceration was associated with age or sex,<sup>9,10,78</sup> whereas in others ulcer severity increased with age.<sup>7,91</sup>

Lesions occur predominantly in the squamous mucosa, particularly adjacent to the margo plicatus, but glandular and antral involvement has become increasingly apparent.<sup>9,23</sup> In severe cases lesions can extend dorsally into the squamous fundus. Clinically relevant lesions typically affect a greater portion of the squamous mucosa and can be deep enough to cause bleeding, but a correlation between lesion severity and clinical signs is often not apparent. Bleeding from ulcers in the gastric squamous mucosa is typically not associated with anemia or hypoproteinemia.

### DIAGNOSIS

Although a diagnosis of EGUS can be suspected on the basis of clinical signs and response to treatment, the only current method of confirmation is gastroendoscopy, which can easily be performed in the standing horse or foal with mild sedation. In adult horses a 3-meter endoscope allows for visual

**FIGURE 15-17** Endoscopic image of the pylorus in the foal depicted in Figure 2, 2 months after surgery. Note the extremely small pyloric opening, which had formed a mechanical obstruction to gastric outflow.

**TABLE 15-9**

#### Equine Gastric Ulcer Syndrome Lesion Scoring System<sup>2</sup>

Lesion Grade	Description
Grade 0	Intact epithelium with no appearance of hyperemia or hyperkeratosis
Grade 1	Intact mucosa with areas of reddening or hyperkeratosis (squamous)
Grade 2	Small single or multifocal lesions
Grade 3	Large single or multifocal lesions or extensive superficial lesions
Grade 4	Extensive lesions with areas of deep ulceration

inspection of the entire stomach, pylorus, and proximal duodenum. Shorter scopes will permit examination of the gastric body and fundus but not the pyloric antrum in most cases. Recent work detailing the prevalence of glandular and antral disease, often in the absence of squamous disease, underscores the importance of performing a thorough examination. A maximum external diameter of 9 mm should be used for neonatal foals. Numerous scoring systems for lesion severity have been described, but a recent consensus has been published by the Equine Gastric Ulcer Council<sup>2</sup> (Table 15-9). This system appears to be accurate and more user-friendly than previous systems.<sup>92</sup> Urine<sup>93</sup> and blood<sup>94</sup> sucrose absorption testing have recently been evaluated as a measure of gastric mucosal permeability in horses with EGUS. Also, serum  $\alpha_1$ -antitrypsin was detectable more frequently in foals with gastric ulceration than normal foals.<sup>95</sup> These blood tests may provide economical, less invasive screening tools, but further evaluation of sensitivity and specificity is necessary before widespread use.

Duodenal ulceration can be difficult to confirm. Duodenoscopy is the most specific means of diagnosis, although the procedure is more difficult than gastroscopy. Additionally, an

endoscope at least 200 cm in length is needed for foals up to 5 to 7 months old, and a longer endoscope usually is required for older animals. Diffuse reddening or inflammation may be the only recognizable lesion in cases of early duodenal disease. In older foals with GDUD, detection of gastric outflow obstruction is critical to the therapeutic plan and appropriate prognosis. Abdominal radiography without contrast in foals with outflow obstruction typically reveals a distinctly enlarged, gas-filled stomach. Liquid barium contrast will either have markedly delayed (with incomplete obstruction) or no (complete obstruction) outflow. Clinically, foals with outflow obstruction will develop reflux after suckling or marked reflux even with limited to no suckling if the duodenal obstruction is distal to the common bile duct.

## TREATMENT

Multiple pharmacologic treatments have been suggested for the treatment of EGUS. Because acid has been implicated as the most important pathophysiologic component of squamous ulcer disease, most anti-ulcer therapy centers on suppression or neutralization of gastric acid. Severity and location of gastric lesions and severity and duration of clinical signs as well as medication cost can play a role in the therapeutic management of EGUS (Table 15-10).

If gastroendoscopy is unavailable, some guidelines to therapy can be employed, but the efficacy of the treatment will be based on clinical signs, which are often vague or nonspecific. Signs of colic or diarrhea that result from gastric ulcers often resolve within 48 hours. Improvements in appetite, bodily condition, and attitude can be noted within 1 to 3 weeks. If improvement in clinical signs is not observed, either treatment has not been effective or gastric ulceration was not the primary problem. Typically, a treatment period of at least 2 to 4 weeks, followed by prophylaxis depending on the animal's exercise and environmental status, is recommended.

The principal therapeutic options for ulcer treatment include H<sub>2</sub> antagonists (cimetidine, ranitidine, famotidine, nizatidine), proton pump inhibitors (PPIs; omeprazole,

pantoprazole, rabeprazole, esomeprazole), the mucosal adherent sucralfate, and antacids.

The H<sub>2</sub> antagonists suppress hydrochloric acid secretion through competitive inhibition of the parietal cell histamine receptor that can be partially overcome with exogenous penta-gastrin.<sup>96</sup> Use of H<sub>2</sub> antagonists has been successful in raising gastric pH and resolving gastric lesions in both foals and adult horses.<sup>44,85,97</sup> Clinical and experimental evidence has demonstrated greater individual variability with lower dosages of H<sub>2</sub> antagonists.<sup>98</sup> Thus dosage recommendations are based on levels necessary to increase gastric pH and promote ulcer healing in a majority of horses. Commonly recommended dosages are 20 to 30 mg/kg orally every 8 hours or 6.6 mg/kg intravenously every 6 hours for cimetidine and 6.6 mg/kg orally every 8 hours or 1.5 to 2 mg/kg intravenously every 6 hours for ranitidine. Famotidine has been used less extensively in the horse, but a dose of 10 to 15 mg/kg/day has been recommended. Although clinically normal foals respond predictably to ranitidine,<sup>44</sup> sick neonates have shown variability in pH response to intravenous ranitidine, with a much shorter duration of action and, in some cases, no noticeable response.<sup>45</sup> Currently, cimetidine and ranitidine are available in injectable, tablet, and liquid forms. Famotidine and nizatidine are available in tablets. Omeprazole appears more effective for ulcer healing than either ranitidine or cimetidine.<sup>99,100</sup>

PPIs block secretion of H<sup>+</sup> at the parietal cell membrane by irreversibly binding to the H<sup>+</sup>, K<sup>+</sup>-ATPase proton pump of the cell. These agents have a prolonged antisecretory effect, which allows for once-daily dosing. Omeprazole, the first PPI to be developed, is the only currently approved agent for the treatment of EGUS. Several studies have documented the safety of oral omeprazole in foals and adult horses.<sup>101,102</sup> Omeprazole has demonstrated efficacy in the healing of NSAID-induced ulcers in horses as well naturally occurring cases of EGUS.<sup>103,104</sup> Omeprazole has been shown to eliminate or reduce the severity of gastric ulcers in Thoroughbreds maintained in race training.<sup>105</sup> The available equine preparation of omeprazole (GastroGard™, Merial, Ltd., Duluth, GA) is recommended at a dose of 4 mg/kg orally every 24 hours for ulcer healing (Figures 15-18 to 15-20). An increase in gastric pH and a decrease in acid output are evident 5 to 8 hours after omeprazole paste

TABLE 15-10

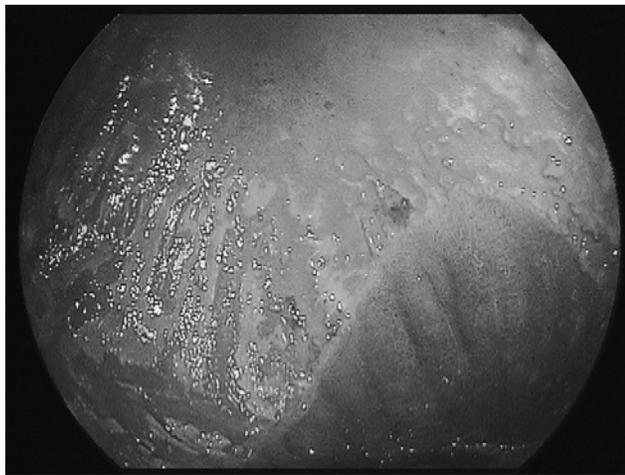

### Therapeutic Options for the Treatment of Equine Gastric Ulcer System

Drug	Dose (mg/kg)	Dosing Interval (hours)	Route of Administration
Ranitidine	6.6	8	PO
Ranitidine	1.5-2	6	IV, IM
Cimetidine	20-25	8	PO
Cimetidine	6.6	6	IV, IM
Omeprazole	0.5	24	IV
Omeprazole	1-2 (prevention)	24	PO
Omeprazole	4 (treatment)	24	PO
Pantoprazole	1.5	24	IV, PO
Sucralfate	20-40	8	PO

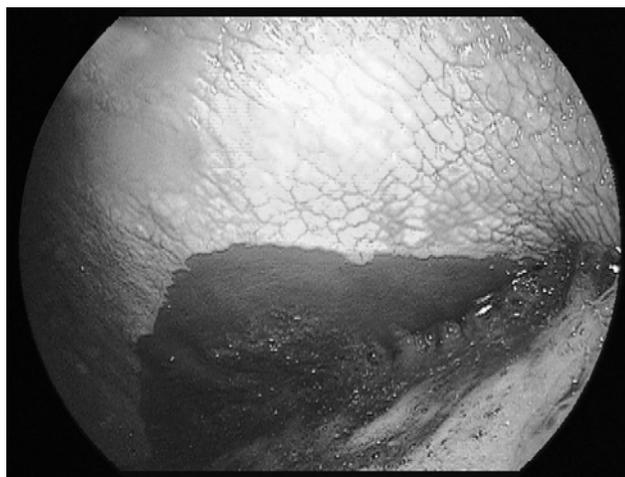

PO, Per os (by mouth); IV, intravenous; IM, intramuscular.

**FIGURE 15-19** Greater curvature viewed endoscopically in the horse depicted in Figure 15-18.

**FIGURE 15-20** Endoscopic image of the greater curvature in the horse depicted in Figures 15-18 and 15-19 after 1 week of omeprazole (4 mg/kg PO every 24 hours) therapy.

administration.<sup>106</sup> Treatment with 1, 2, or 4 mg/kg orally every 24 hours has been shown to decrease or prevent disease or the recurrence of disease in animals maintained in training.<sup>67,107-109</sup> Omeprazole (4 mg/kg) also has demonstrated efficacy in raising intragastric pH in clinically normal<sup>110</sup> or critically ill<sup>111</sup> foals and in ulcer healing in foals.<sup>103</sup>

Because the powder form of omeprazole is rapidly degraded in an acidic environment, an enteric-coated capsule (as used in the human preparation) or a specially formulated paste must be used to allow delivery of the active drug to the small intestine for absorption. Compounded preparations have shown limited to no efficacy in pharmacodynamic and clinical trials,<sup>112,113</sup> and the proprietary formulation of omeprazole was the only product (including buffers, H<sub>2</sub>-receptor antagonists, sucralfate, and compounded preparations) that decreased the odds of gastric ulceration in a population of racehorses.<sup>114</sup> Omeprazole appears to be more effective in ulcer healing than either ranitidine or cimetidine.<sup>99,100</sup> A compounded intravenous preparation of omeprazole (0.5 mg/kg) increases gastric juice pH and

decreases the number of nonglandular lesions in horses.<sup>115</sup> From a regulatory standpoint, omeprazole (4 mg/kg/day orally) does not appear to affect quantitative measurements of performance in Standardbreds.<sup>116</sup>

Other PPIs have been recently developed for use in humans, including rabeprazole, lansoprazole, esomeprazole, and pantoprazole. In the treatment of GERD in humans, esomeprazole has demonstrated a higher rate of healing at 4 and 8 weeks when compared with omeprazole, but rabeprazole, lansoprazole, and pantoprazole have similar efficacy.<sup>117</sup> Pantoprazole given by either intravenous or intragastric routes (1.5 mg/kg) raised intragastric pH in clinically normal neonatal foals.<sup>118</sup>

Sucralfate is effective in the treatment of peptic ulcers and prevention of so-called stress-induced ulcers in humans. The mechanism of action likely involves adherence to ulcerated mucosa, stimulation of mucus secretion, enhanced prostaglandin E synthesis, and increased concentration of growth factor at the site of ulceration, although the prostaglandin effects may not play an important role in ulcer healing.<sup>119</sup> These are all factors relevant to glandular mucosa, and the efficacy of sucralfate in treating ulcers in the equine gastric squamous mucosa remains undetermined. In one study sucralfate did not promote subclinical ulcer healing in foals, relative to corn syrup.<sup>120</sup> In another, simultaneous sucralfate administration significantly reduced the total area of oral ulceration and gastric epithelial necrosis experimentally induced by phenylbutazone but did not significantly reduce the number of squamous or glandular ulcers in foals.<sup>121</sup> In humans sucralfate provides protection against stress-induced ulcers with a decreased risk of pathogenic gastric colonization.<sup>122</sup> Sucralfate should be given at a dosage of 10 to 20 mg/kg every 6 to 8 hours. The efficacy of sucralfate in an alkaline pH is controversial but appears likely.<sup>123-125</sup>

The use of antacids in the treatment of gastric ulcers has not been critically examined in the horse. Research in horses has shown that 30g aluminum hydroxide/15 g magnesium hydroxide will result in an increase in gastric pH above 4 for approximately 2 hours.<sup>126</sup> Thus, although antacids may be useful for the treatment of ulcers in horses, a dose of approximately 180 to 200 ml at least every 4 hours is necessary for a standard adult horse.

The use of synthetic prostaglandin E<sub>1</sub> analogs, such as misoprostol, has been effective in the treatment of gastric and duodenal ulcers in humans, and the proposed mechanism of action involves both inhibition of gastric acid secretion and mucosal cytoprotection.<sup>127</sup> In horses misoprostol (5 µg/kg) increases gastric pH<sup>128</sup> and ameliorates deleterious effects of flunixin on mucosal recovery after ischemic injury in vitro.<sup>129</sup> Misoprostol is contraindicated in pregnant mares.

Prokinetic drugs should be considered in foals with duodenal disease, gastroesophageal reflux, and when delayed gastric emptying without a physical obstruction is suspected. Bethanechol and erythromycin increase the rate of gastric emptying in horses.<sup>130</sup> In cases of acute gastric atony, bethanechol 0.025 to 0.030 mg/kg, administered subcutaneously every 3 to 4 hours, has been effective in promoting gastric motility and emptying, followed by oral maintenance dosages of 0.35 to 0.45 mg/kg three to four times daily. Adverse effects can include diarrhea, inappetence, salivation, and colic, but at the dosages stated, adverse effects have been infrequent and mild. A complete review of ileus and prokinetic therapy is available elsewhere in this chapter.

For foals with severe GDUD that have developed duodenal stricture, surgical therapy is necessary.<sup>84,131</sup> These animals

require a serious financial commitment because intensive perioperative medical therapy is critical for a successful outcome. Prognosis in two recent abstracts has improved over that previously reported. In one, 98% of surgically treated foals survived to discharge from the hospital, with 68% survival 8 months following discharge from the hospital.<sup>132</sup> In that study, of the surviving Thoroughbreds of racing age, 71% had started a race. In another, short-term survival was reported as 80% for those foals treated surgically and 50% for those treated medically.<sup>133</sup> A variety of nutraceuticals are currently marketed for the treatment and prevention of EGUS, but as of this writing no objective data are available regarding their efficacy.

## PREVENTION

Because gastric perforation resulting from glandular ulcer disease has been reported in hospitalized neonates, many clinicians routinely use prophylactic anti-ulcer therapy in this population. Because some critically ill foals have a predominantly alkaline gastric pH profile, and because gastric acidity may be protective against bacterial translocation in neonates, the need for prophylactic ulcer therapy is controversial. In critically ill human neonates, although intravenous ranitidine therapy raises gastric pH and gastric bacterial colonization, it does not increase the risk of sepsis.<sup>134</sup> In a retrospective study of 85 hospitalized foals younger than 30 days of age, no difference in the frequency of gastric ulceration at necropsy was found between those foals that received prophylactic treatment for gastric ulcers and those that did not.<sup>82</sup> Because of the retrospective nature of that study, specific details regarding lesion location and severity were not available; however, none of the foals in the study died as a result of gastric ulcer disease. Thus many clinicians no longer recommend routine ulcer prophylaxis in all ill neonates. Possible exceptions include foals requiring significant doses of NSAIDs for painful orthopedic disorders.

In adults dietary and environmental management can help prevent gastric ulceration. Pasture turnout and continuous access to high-quality forage, especially alfalfa, are currently recommended. For horses at high risk, the best proven pharmacologic approach to prevention involves administration of omeprazole (1 to 2 mg/kg orally every 24 hours).<sup>100,107-109</sup>

## ☞ OTHER DISORDERS OF THE STOMACH

### PYLORIC OBSTRUCTION AND DELAYED GASTRIC EMPTYING

Pyloric stenosis is a structural resistance to gastric outflow. Congenital pyloric stenosis has been reported in foals and one yearling and results from hypertrophy of the pyloric musculature.<sup>135-137</sup> Acquired pyloric stenosis can result from neoplasia or duodenal ulceration.<sup>138-141</sup> Clinical signs depend on the degree of obstruction but include abdominal pain, salivation, and teeth grinding. Complete or near-complete obstruction can result in gastric reflux and reflux esophagitis. In foals with congenital pyloric hypertrophy, clinical signs may begin with the consumption of solid feed. In foals a presumptive diagnosis can be made using gastric endoscopy and radiography (plain and contrast studies). Depending on the cause and severity of disease, gastric endoscopy may provide a presumptive

diagnosis in the adult horse. Measurement of gastric emptying can aid the diagnosis. Several methods of measurement are currently available, including nuclear scintigraphy, acetaminophen absorption, and postconsumption [<sup>13</sup>C]-octanoic acid blood or breath testing.<sup>130,142,143</sup> During an exploratory laparotomy, a distended stomach and thickened pylorus are accompanied by a relatively empty intestinal tract.

If complete obstruction is not present, medical therapy with a prokinetic such as bethanecol can increase the rate of gastric emptying.<sup>130</sup> Phenylbutazone and cisapride have also been shown to attenuate the delay in gastric emptying caused by endotoxin administration.<sup>142,144</sup> Surgical repair is necessary for definitive treatment of complete or near-complete obstruction and consists of either gastroenterostomy or pyloroplasty.<sup>84,131</sup> Pyloric-duodenal intussusception has been reported in an adult horse with colic.<sup>145</sup>

### GASTRIC DILATION AND RUPTURE

Gastric dilation can be classified as primary, secondary, or idiopathic. Causes of primary gastric dilation include gastric impaction, grain engorgement, excessive water intake after exercise, aerophagia, and parasitism.<sup>141,146</sup> Secondary gastric dilation is more common and can result from primary intestinal ileus or small or large intestinal obstruction. Time to development of gastric reflux is proportional to the distance to the intestinal segment involved, with duodenal obstruction resulting in reflux within 4 hours.<sup>147</sup> Clinical signs of gastric dilation include those associated with acute colic and, in severe cases, ingesta appearing at the nares. Associated laboratory abnormalities include hemoconcentration, hypokalemia, and hypochloremia.<sup>141</sup>

The most common cause of gastric rupture in horses varies between reports. In a retrospective study of 54 horses, gastric rupture occurred most commonly as a secondary phenomenon (65%), usually caused by small intestinal obstruction, with primary gastric dilation and idiopathic rupture occurring almost equally (15% and 17%, respectively).<sup>146</sup> In another retrospective study of 50 horses in combination with a search of the Veterinary Medical Database, 60% of the gastric rupture cases were classified as idiopathic.<sup>148</sup> Risk factors for gastric rupture include feeding grass hay, not feeding grain, gelding, and a nonautomatic water source.<sup>146,148</sup> Nasogastric intubation does not preclude the possibility of gastric rupture, and the amount of reflux obtained before rupture is highly variable.<sup>146</sup> Because of the retrospective nature of these reports, one cannot rule out confounding factors with certainty.

Regardless of the initiating cause, gastric rupture usually occurs along the greater curvature. In horses with rupture resulting from gastric dilation, tears in the seromuscular layer are frequently larger than the corresponding tears in the mucosal layer, indicating that the seromuscularis likely weakens and tears before the mucosa.<sup>146,148</sup> In contrast, horses with gastric rupture secondary to gastric ulceration usually demonstrate full-thickness tears of equal size in all layers. Gastric rupture is usually fatal because of the widespread contamination of the peritoneal cavity, septic peritonitis, and septic shock. Initial clinical signs vary with the primary disease; however, when rupture occurs, horses that had been in pain may exhibit signs of relief. Subsequent signs, including tachypnea, tachycardia, sweating, and muscle fasciculations are consistent with peritonitis and shock. Surgical repair is thus limited but has been reported for partial-thickness tears<sup>149</sup> and, in one case

of a combined tear of the mucosa and muscularis with only a focal serosal tear, a full-thickness repair was performed with a favorable outcome.<sup>150</sup>

## GASTRIC IMPACTION

Gastric impaction can result in either acute or chronic signs of colic in the horse. Although a specific cause is not always evident, ingestion of coarse roughage (e.g., straw bedding, poor-quality forage), foreign objects (e.g., rubber fencing material), and feed that may swell after ingestion or improper mastication (e.g., persimmon seeds, mesquite beans, wheat, barley, sugar beet pulp) have been implicated.<sup>151-154</sup> Possible predisposing factors include poor dentition, poor mastication and rapid consumption of feedstuffs, and inadequate water consumption. Clinical signs vary, from anorexia and weight loss to those consistent with severe abdominal pain. In severe cases spontaneous reflux may occur, with gastric contents visible at the nares. If the horse suffers from acute severe abdominal pain, a diagnosis is often made during exploratory celiotomy. In horses that do not exhibit signs of colic warranting surgical intervention, an endoscopic finding of a full stomach after a normally adequate fast (18 to 24 hours) can often confirm the diagnosis. Abdominal radiographs are reserved for smaller horses and ponies. In addition to pain management, specific treatment consists of gastric lavage via nasogastric intubation or massage and injection of fluid to soften the impaction during laparotomy.<sup>151-153</sup>

## MISCELLANEOUS CAUSES OF GASTRITIS

Nonulcerative gastritis rarely appears to be a clinical problem in the horse, but it has been reported at necropsy in a large retrospective study.<sup>17</sup> Emphysematous gastritis caused by *Clostridium perfringens*<sup>155</sup> and *Clostridium septicum*<sup>156</sup> has been reported.

## DUODENTITIS-PROXIMAL JEJUNITIS

Laura H. Javscas

Duodenitis-proximal jejunitis (DPJ) is an inflammatory condition affecting the upper small intestine and resulting in distention, abdominal pain, gastric reflux caused by excessive fluid and electrolyte secretion, and increased PF protein concentration without a significant elevated nucleated cell count. Other terms for this condition are *anterior enteritis* and *proximal enteritis*. Clinical signs of DPJ mimic those of a small intestinal obstruction; thus distinguishing between the two syndromes is important. The clinical syndrome of DPJ was well described in the 1980s,<sup>1-4</sup> but the severity of clinical signs, especially duration of disease, is variable. Although not typical, DPJ can occur in conjunction with gastritis, ileitis, typhlitis, and colitis.

## ∞ PATHOPHYSIOLOGY

Typical pathologic findings in horses with DPJ include involvement of the duodenum and usually the proximal jejunum.<sup>4</sup> The ileum and large colon usually are determined to be grossly normal. Gastric distention is a common finding and is thought to be caused by hypersecretory mechanisms in the proximal

small intestine and a functional ileus of affected enteric segments. The small intestine may be 5 to 7 cm in diameter because of fluid distention with malodorous, red to brown-red intraluminal fluid accumulation. Duodenal (and jejunal) serosal surfaces may have varying degrees and distribution of bright red to dark red petechial and ecchymotic hemorrhages and yellow to white streaks. The enteric mucosal surfaces are usually hyperemic and have varying degrees of petechiation and ulceration.

Microscopically, the most severe lesions have been located in the duodenum and proximal jejunum but may extend proximally to the gastric mucosa and aborally to the large intestinal mucosa and submucosa.<sup>4</sup> Microscopic lesions consist of varying degrees of mucosal and submucosal hyperemia and edema. More severe lesions include villous degeneration with necrosis and, more severely, sloughing of villous epithelium. The lamina propria, mucosa, and submucosa may have varying degrees of granulocyte infiltration (predominantly neutrophils), and the muscular layers and serosal surfaces contain small hemorrhages. Proximal small intestinal serosal fibrinopurulent exudate is a common finding in the more severe cases; therefore the term *hemorrhagic fibrinonecrotic duodenitis-proximal jejunitis* has been suggested as a more descriptive name for this syndrome.

Horses with DPJ often have evidence of multiple organ involvement and can have hepatic changes including hepatocellular vacuolization, cholestasis, inflammatory infiltrate (either in association with centrilobular necrosis or periportal), and biliary hyperplasia.<sup>5</sup> Hepatic disease is thought to result from ascending infection by way of the common bile duct, local absorption of endotoxin via the portal circulation, systemic consequences of endotoxin absorption, metabolic imbalances such as acidemia, and hypoperfusion or hypovolemia.

In most cases an underlying etiology cannot be determined. In some cases *Salmonella* spp. or *Clostridium* spp. can be isolated from culture of gastric reflux. Salmonellosis has never been consistently identified in a majority of cases, and many horses with documented infections by these organisms do not develop DPJ. Recently, toxigenic strains of *Clostridium difficile* were isolated from the reflux of five out of five horses with DPJ and none of six control horses with other causes of nasogastric reflux.<sup>6</sup> Further investigation of this organism is clearly warranted. Another suspected infectious agent is *Fusarium* spp.<sup>7</sup> A recent dietary change with an abrupt increase in dietary concentrate level has been suggested to predispose a horse to developing DPJ because of intraluminal microbial imbalances. Feeding and grazing practices have been shown to be different between horses with DPJ and those with other forms of colic or lameness. In one report horses with DPJ were fed significantly more grain and were more likely to have grazed pasture, but these associations were not deemed strong enough to allow clinical application to differentiate DPJ from other causes of colic.<sup>8</sup>

Two intracellular processes control intestinal secretion: the cyclic nucleotide (cyclic adenosine monophosphate and cyclic guanosine monophosphate) and calcium systems.<sup>9</sup> Inflammatory mediators, microorganisms, and toxins can activate adenyl cyclase (vasoactive intestinal peptide, prostaglandin E<sub>2</sub>) or guanyl cyclase (bacterial enterotoxins) and induce increases in cyclic adenosine monophosphate and cyclic guanosine monophosphate, respectively. This reaction causes phosphorylation of specific protein kinases, which induce the actual mucosal

membrane transport events. Increases in intracellular free calcium may arise from cyclic nucleotide-dependent release of stored calcium within the cell or from increased calcium entry across the cell membrane. Calcium may act through calmodulin, which then can activate membrane-phosphorylating protein kinases. The net effect is increased movement of sodium and chloride into the mucosal cell from the interstitium, with secretion of sodium and chloride into the intestinal lumen. Water follows the directional flux of sodium and chloride through highly permeable intercellular spaces. Several bacterial toxins and endogenous mediators can cause active secretion and contribute to a synergistic mucosal secretory response. Passive secretion of protein-rich fluid into the lumen occurs after damage to the mucosal epithelium, capillary endothelium, and submucosal inflammation in the proximal small intestine. The clinically relevant events that result from active and passive fluid secretion are proximal small intestinal distention and nasogastric reflux, dehydration, and circulatory shock.<sup>10</sup>

The concentration of protein in the PF from horses with DPJ is usually higher than in horses with small intestinal obstruction. A disproportionate increase in total protein concentration relative to nucleated cell count occurs, probably by leakage of blood or plasma into the peritoneal cavity without a significant stimulus for leukocyte chemotaxis. Suggested mechanisms for increased abdominal fluid protein concentration include serositis associated with inflamed intestine and small intestinal distention causing passive congestion and increased capillary hydrostatic pressure of visceral peritoneal vessels.<sup>11</sup> Small intestinal ileus is another hallmark sign of DPJ, and the pathophysiology is complicated, involving primary and secondary dysfunction of the central, autonomic, and enteric nervous systems and their purported roles in governing intestinal motility. Primary role players in DPJ-associated ileus include peritoneal inflammation, inflammatory cell migration/activation within the muscularis, small intestinal mechanical distention, and endotoxin absorption. Further detail regarding the effect of inflammation on small intestinal motility is provided elsewhere in this chapter.

## CLINICAL AND CLINICOPATHOLOGIC SIGNS

The veterinarian has the challenge of differentiating horses with DPJ from horses with small intestinal obstructive lesions so as to avoid surgical intervention. Although there are differences between DPJ and small intestinal obstructive lesions, there is no single distinguishing feature and all information must be considered collectively. Horses with obstructive lesions of the small intestine usually show consistent signs of abdominal pain until the affected viscus is repaired surgically or ruptures. In contrast, signs of acute abdominal pain typically subside after gastric decompression and volume replacement in horses with DPJ. They are replaced by signs of lethargy and general malaise. On rectal examination the degree of small intestinal distention may be subjectively less with DPJ than with obstructive lesions, particularly following gastric decompression. Although the color and odor of gastric reflux can be similar, horses with DPJ tend to have a larger volume ( $\geq 4$  to 20 L with each decompressive effort) of reflux than horses with obstructive lesions. Horses with DPJ often have a temperature of 38.6° to 39.1° C (101.5° to 102.5° F), whereas horses with

obstructive lesions are typically normothermic or hypothermic. DPJ-affected horses typically are dehydrated and have brick-red mucous membranes, lethargy, decreased to absent borborygmi, prolonged capillary refill time, tachycardia ( $\geq 60$  beats/min), and tachypnea.

Typical clinical laboratory findings include an increased packed cell volume and total plasma protein reflective of volume depletion and a normal, decreased, or increased peripheral white blood cell count.<sup>1,4</sup> Abnormalities in the leukogram are more common in horses with DPJ than with an acute obstructive lesion. In addition, hyponatremia, hypochloremia, hypokalemia, prerenal azotemia, and elevated hepatic enzymes ( $\gamma$ -glutamyl transferase [GGT], alanine transaminase [AST], and alkaline phosphatase [AP]) are often evident.<sup>5</sup> The loss of enteric bicarbonate through evacuation of enterogastric reflux and hyperlactemia from poor tissue perfusion and hypovolemia can lead to metabolic acidosis with a high anion gap.

PF analysis may be helpful in distinguishing DPJ from an obstructive lesion. The typical findings with DPJ include an increased PF protein concentration (often  $\geq 3.5$  g/dl) and a mild to moderate elevation of the peritoneal white blood cell count, although the count usually is less than 10,000 cells per microliter. The disproportionate increase in PF total protein compared with peritoneal nucleated cell count may be due to leakage of blood or plasma without a marked leucocytic response.<sup>4</sup> The PF is usually yellow and turbid, but in severe cases diapedesis can occur, resulting in a serosanguinous color. Strangulating lesions typically result in more severe changes in the PF. Serosanguinous PF with increased protein, white blood cells, and red blood cells is typical. Horses with intraluminal obstructions such as ileal impactions typically have grossly normal PF with a mildly elevated protein resulting from intestinal distention.<sup>1,4,10</sup>

Abdominal ultrasound findings can help support a diagnosis of DPJ and allow evaluation of the small intestinal diameter and wall thickness as well as the PF volume and character. Ultrasonographic findings in horses with DPJ typically include gastric distention, duodenal distention, and segments of small intestine containing hypoechoic to anechoic fluid. The wall of the small intestine can be normal or thickened with time. Peristalsis can be decreased, normal, or increased. Differentiation from a small intestinal obstructive lesion remains difficult. More long-standing obstructions typically result in increased wall thickness, sedimentation of ingesta within the small intestinal lumen, and distended small intestine proximal to the lesion with collapsed intestine distally.<sup>12,13</sup>

A definitive diagnosis of DPJ is made in most cases by gross examination of the duodenum and proximal jejunum at surgery or at necropsy, but the diagnosis is typically suspected on the basis of clinical and clinicopathologic signs and response to therapy.

## TREATMENT

Horses with DPJ appear to share a common characteristic clinical presentation, and the mechanisms leading to electrolyte imbalances, fluid loss, ileus, and endotoxemia and septicemia are similar. Treatment regimens are supportive and provide plasma volume replacement, analgesic and anti-inflammatory therapy, gastric decompression, anti-endotoxin therapy, antimicrobial therapy if indicated, nutritional support, and nursing care.

## GASTRIC DECOMPRESSION

Although the signs of abdominal pain usually resolve after gastric decompression, most horses remain severely lethargic. Without periodic removal of fluid that accumulates in the proximal intestinal tract, signs of abdominal pain usually recur. Horses with DPJ often require gastric decompression at 2-hour intervals, with 2 to 10 L of fluid recovered each time. Nasogastric tubes left in place for long periods cause varying degrees of pharyngitis (Figure 15-21), laryngitis, and esophagitis, and maintenance of an indwelling nasogastric tube may further delay gastric emptying.<sup>10,14,15</sup>

## FLUID SUPPORT

Aggressive intravenous polyionic fluid therapy should be instituted immediately in a horse with suspected DPJ. The veterinarian should calculate the total fluid deficit on the basis of clinical assessment of dehydration (e.g., for 8% or moderate dehydration,  $0.08 \times 450 \text{ kg body mass} = 36 \text{ L}$ ) and should administer replacement fluids rapidly (up to 6 to 10 L per hour for a 450-kg adult horse). Placement of a second, large-bore (10- or 12-gauge) intravenous catheter can aid in rapid administration of large volumes of fluid during the initial resuscitation. Administering intravenous hypertonic saline (7%) may be useful to treat hypovolemic shock in horses with severe circulatory shock. The use of 1 to 2 L of hypertonic saline (7% NaCl) improved cardiac output in horses with hemorrhagic shock and in a model of equine endotoxemia.<sup>16,17</sup> If this treatment option is chosen, intravenous administration of replacement isotonic fluids must follow immediately to maintain tissue integrity. Horses with significant volumes of gastric reflux should not be allowed to ingest foodstuffs or liquids orally.

Once replacement fluids have been administered and the horse is well hydrated, one should administer maintenance fluid amounts, which may be as high as 120 ml/kg/day. Unfortunately, the intravenous fluid therapy itself may accelerate

**FIGURE 15-21** Endoscopic image from a 15-year-old Quarter Horse gelding. The horse was diagnosed with duodenitis-proximal jejunitis (DPJ) and developed mild respiratory stridor and gagging and writhing behavior after an indwelling nasogastric tube had been in place for 48 hours to allow for intermittent drainage of gastric reflux. The horse responded well to medical therapy for DPJ and pharyngitis-esophagitis.

the flux of fluid from the vasculature into the intestinal lumen because of a reduction in intravascular oncotic pressure and an increased capillary perfusion pressure, which can result in an increased volume of gastrointestinal reflux. However, the veterinarian should not consider reducing the volume of intravenous fluid therapy because excessive fluid losses continue to occur. One should monitor plasma protein concentration, overall hydration, and the volume of reflux and then determine the rate of intravenous fluid administration. Ongoing fluid losses should be calculated by measuring the volume of net reflux in a graduated bucket. Close monitoring of “ins and outs” allows adjustment of the rate of fluid administration to ensure that adequate volumes are given to account for correction of the initial fluid deficit, maintenance requirements, and ongoing losses from reflux. The clinical response, as measured by improved hydration status, decreased nasogastric reflux, improved attitude, and improvement in values reflecting kidney function (decreased blood urea nitrogen and creatinine), correlates with improvement of intestinal damage.

## ONCOTIC SUPPORT

Horses with DPJ that continue to reflux large volumes of enterogastric fluid frequently for more than 36 to 48 hours may experience protein loss from the inflamed and disrupted intestinal mucosal barrier and from systemic protein catabolism. Decreased colloid oncotic pressure leads to decreased effective circulating fluid volume and edema. Total plasma protein may decline to below 4 g/dl, and the albumin may decrease to below 2.0 g/dl. Fresh or thawed frozen plasma is ideal for replacement of functional proteins. One should consider treatment with intravenous plasma therapy or a combination of plasma and synthetic colloid (e.g., hydroxyethyl starch [Hetastarch [6%], Abbott Laboratories, North Chicago, Illinois) as soon as a consistent decline in total plasma protein or albumin is evident or if the horse is developing dependent edema. Fresh plasma (preferred) or fresh frozen plasma is the treatment of choice if coagulation disorders accompany protein loss. An average-size horse (450 kg) requires 6 to 10 L of plasma (albumin 3.0 g/dl) or synthetic colloid to improve plasma oncotic pressure. Administration of additional aliquots of 2 to 10 L of a balanced colloidal solution may be necessary if the DPJ crisis continues. In addition to albumin (the major colloid component), plasma contains other components that provide overall systemic support (e.g., fibronectins, complement inhibitors, elastase and proteinase inhibitors, antithrombin III). One may administer a 6% solution of hydroxyethyl starch at 5 to 10 ml/kg/day. Because of the large size of the starch molecules, this solution is an effective plasma volume expander, resulting in sustained dose-dependent decreases in packed cell volume and plasma protein concentration with increased oncotic pressure. The cost of an appropriate amount of commercial plasma or synthetic colloid solution for treatment of adult horses with DPJ may be prohibitive but can be life saving.

## ANTI-ENDOTOXIN

Horses with enteritis frequently absorb large amounts of endotoxin from the disrupted intestinal mucosal barrier, thereby putting these horses at a high risk for laminitis. One should monitor digital pulses frequently until systemic signs of enteritis have abated (e.g., fever, leukopenia) and even for several days beyond this point. Treatment to combat endotoxemia

is critical, and several therapeutic approaches are available. Choice of treatment options is based on severity of disease, renal function, hydration status, and economics. Endotoxemia and systemic inflammatory response syndrome are discussed elsewhere in this chapter.

### ANTI-INFLAMMATORY AND ANALGESIC

NSAIDs are the most frequently used group of drugs for treatment of abdominal pain in horses (flunixin meglumine 0.25–1.1 mg/kg intravenously every 8–12 hours, with the higher dose given only at the least frequent interval). These agents also have beneficial anti-inflammatory and anti-endotoxic effects. The clinician must weigh the benefit of these drugs against their negative effects on gastrointestinal mucosa and renal function. Another popular analgesic option is butorphanol, an opioid agonist-antagonist, given at 0.02 to 0.1 mg/kg intramuscularly every 6 to 8 hours or as a constant-rate infusion at 13 µg/kg/h.<sup>18</sup> This route appears to have minimal effects on gastrointestinal motility.

### ANTIMICROBIAL

Because *Clostridium* spp. are suspected as a causative agent of DPJ, penicillin, metronidazole, or both are often administered to affected horses. However, the veterinarian should consider broad spectrum antimicrobial coverage for horses with DPJ and significant leukopenia. An aminoglycoside or enrofloxacin can be added to the penicillin therapy, although the potential adverse effects of aminoglycosides on renal function should be noted.

### NUTRITIONAL SUPPORT

The veterinarian should consider the nutritional needs of horses with DPJ. Most horses have a total body protein loss on account of cachexia and a protein-losing enteropathy. Total parenteral nutrition may be indicated in horses that remain anorectic for more than 3 to 4 days. Parenterally administered solutions containing glucose, balanced amino acid solutions, lipid emulsions, balanced electrolyte and trace minerals, and vitamins have been administered to adult horses with small intestinal ileus or enterocolitis. Based on a small number of horses, this therapy has proved promising in terms of minimizing protein losses and decreasing the duration of illness. Postoperative parenteral nutrition ameliorates clinicopathologic evidence of starvation following small intestinal resection and anastomosis in adult horses.<sup>19</sup> Providing for part of the nutritional requirements of the horse (8000 to 12,000 kcal/day) is possible with glucose–amino acid solutions, which are of moderate cost. It is reasonable to suppose that providing nutritional support to an anorectic, severely ill horse will facilitate healing and even shorten the duration of illness. Thus the overall cost of providing parenteral nutritional supplementation to horses with DPJ may be offset by quicker recovery and diminished requirements for other, expensive treatments, but further data are necessary to accurately assess this point.

### PROKINETICS

Normal (healthy) intestine is necessary for optimal performance of most prokinetic agents in horses. Many motility-modifying agents likely are ineffective in cases of DPJ. Inflamed

jejunal tissue has been shown to have downregulation and decreased production of motilin receptors, which may alter the prokinetic response to erythromycin.<sup>20</sup> However, some benefit may come of the judicious use of prokinetic agents in inflammatory conditions of the equine intestine, particularly if the agent provides additional effects such as analgesia. Lidocaine has shown particular promise for this use. Although the exact mechanism of action is unknown, the beneficial effects in horses with ileus are likely due to anti-inflammatory effects because a direct prokinetic effect has not been demonstrated.<sup>21</sup> In horses with nasogastric reflux attributable to postoperative ileus or enteritis, a constant-rate infusion of lidocaine was shown to reduce the hourly volume of reflux and shorten the time to cessation of reflux compared with saline.<sup>22</sup> A 2 mg/kg loading dose over 15 minutes followed by 50 µg/kg/min has been recommended.<sup>23</sup> Prokinetic therapy with erythromycin lactobionate, metaclopramide, or bethanechol can also be considered.<sup>24,25</sup> Motility-modifying agents and the influence of inflammation on their effects are discussed elsewhere in this chapter.

### SURGICAL THERAPY

Medical therapy is sufficient in most cases of DPJ, but in those cases in which the horse continues to produce copious enterogastric reflux despite aggressive medical treatment, or when a mechanical obstruction cannot be satisfactorily ruled out, surgery may be considered as an option. Refractory cases have improved with surgical intervention; however, some horses with refractory DPJ have been observed to recover after prolonged (up to 20 days) supportive care and gastric decompression. The decision as to when to intervene surgically often is difficult. Surgery may be necessary to determine the extent of gross pathologic condition and intestinal distention and to perform intestinal bypass so as to direct enterogastric reflux toward the cecum and colon. For a horse exhibiting abdominal discomfort with small intestinal distention palpable per rectum that produces more than 2 L of gastric reflux, the veterinarian should recommend referral to an appropriate surgical facility. Typically, the main determinants for surgical intervention are degree and duration of abdominal pain, PF analysis, and results of (often repeated) rectal palpation and ultrasonography.

Short-term mortality rates have been reported to be 37% for horses in which manual evacuation of the small intestine into the cecum was performed surgically, compared with 40% for horses that received medical treatment.<sup>26</sup> A 95% recovery rate was reported in horses with DPJ that underwent laparotomy and manual evacuation of the small intestine into the cecum, combined with treatment for *Clostridium perfringens* consisting of intravenous metronidazole and intramuscular procaine penicillin.<sup>27</sup> Drawbacks of surgery include the expense, risks of anesthesia, prolonged return to training, and risk of incisional complications. However, when an obstruction cannot be ruled out, these concerns are of minor consequence.<sup>10</sup>

### ☞ PROGNOSIS

Survival rates for DPJ range between 25%<sup>2</sup> to 94%.<sup>1,4</sup> At present the survival of horses with DPJ that undergo surgery is much greater than previously described, and certainly greater than that of horses with small intestinal obstruction that do not have surgery.<sup>26,27</sup> Horses with DPJ that receive appropriate

therapy have a reasonably good chance of making a full recovery, and recurrence is rare. Horses that continue to have frequent episodes of voluminous nasogastric reflux and systemic signs of endotoxemia and septicemia have a poorer prognosis for recovery. Frequent complications of DPJ include laminitis, thrombophlebitis, and weight loss. In one study, survival was significantly less (45.5%) in horses that developed laminitis than in horses without laminitis (68.7%).<sup>24</sup> There appears to be geographic variation in the severity and prognosis for DPJ, with horses in the southeastern United States most severely affected.

## DISEASES ASSOCIATED WITH MALABSORPTION AND MALDIGESTION

*L. Chris Sanchez*

Malabsorption and maldigestion are commonly recognized clinical problems in humans and small animals and documented clinical entities in horses. The term *malabsorption* implies impairment of digestive and absorptive processes arising from functional or structural disorders of the small intestine and related organs, including the pancreas, liver, and biliary tract. The condition can affect absorption of carbohydrates; proteins; fats; vitamins; minerals; and, to a lesser extent, water and electrolytes. In horses the resulting pathophysiologic changes may influence large intestinal function adversely through alterations in the substrate presented for fermentation or through direct infiltration of the large colon.

Differentiation among carbohydrate, protein, or fat malabsorption is not possible in the horse because of its herbivorous diet and the contribution of large intestinal functions. The rarity of pancreatic problems, such as exocrine pancreatic insufficiency, in horses along with their herbivorous diet makes maldigestion less problematic. However, maldigestion can certainly contribute to chronic weight loss in horses with severe infiltrative small intestinal disease and exacerbate diarrhea in the suckling foal through reduced intestinal bile salt concentrations from hepatic or ileal dysfunction.

Malabsorption is not synonymous with diarrhea, although diarrhea may be a feature. Adult horses rarely exhibit diarrhea with small intestinal problems unless large intestinal involvement is concomitant. Chronic diarrhea is predominantly a large intestinal disorder that reflects an overload of water and electrolytes and thus may be considered a state of impaired absorption. Primary small intestinal disease is more likely in neonates and young foals. For example, acquired small intestinal brush border lactase deficiency may result in increased lactose fermentation in the large intestine and induction of osmotic diarrhea.<sup>1</sup>

## CLINICAL ASSESSMENT

### PHYSICAL EXAMINATION

The principal concern of the owner is weight loss and poor condition of the horse. Many clinical examination findings, except for body condition, may appear within normal limits. Investigation of weight loss, with clinical pathologic findings,

helps eliminate other, more commonly encountered causes of wasting.

Malabsorption is associated with pathologic conditions of the small intestine characterized by substantial reduction of the available absorptive surface area. By virtue of the extent of the morphologic changes, interference with digestive processes occurs, although maldigestion may be difficult to confirm in the absence of assessment measures. The small bowel problem may alter the composition and availability of substrate presented for fermentation in the large intestine. Clinical signs may be modified or accentuated if involvement of the large intestine is concomitant. Diarrhea indicates significant alterations in bidirectional fluid and electrolyte fluxes and in large intestinal transit.

## CLINICAL PATHOLOGY

No characteristic clinical pathologic profile of malabsorption exists. The syndrome tends to cause anemia (normocytic, normochromic) and neutrophilia. Hemolytic or macrocytic anemia and thrombocytopenia have been observed in alimentary lymphosarcoma. Lymphocytosis (leukemia) rarely is encountered. Peripheral eosinophilia is uncommon even with widespread tissue eosinophilia. Many animals are hypoalbuminemic and hypoproteinemic; horses with alimentary lymphosarcoma may exhibit hyperproteinemia and hypergammaglobulinemia. Serum or plasma may be lipemic. The clinician may find elevated hepatic and biliary tract enzymes ( $\gamma$ -glutamyltransferase and alkaline phosphatase) in multisystemic conditions such as multisystemic eosinophilic epitheliotropic disease (MEED). Abdominocentesis can aid in the diagnosis of alimentary lymphosarcoma but rarely in the granulomatous conditions.

Table 15-11 lists the clinical and clinicopathologic features of the diseases most commonly associated with malabsorption.

## ULTRASONOGRAPHY

Ultrasonographic examination of the abdomen can yield information on intestinal distention, wall thickness, and unexplained masses detected on rectal palpation. This can be helpful in the determination of small and large intestinal involvement. One should also note the amount and character of free PF and examine all abdominal organs in an effort to detect evidence of multisystemic involvement.

## GROSS AND MICROSCOPIC PATHOLOGY

Rectal biopsy is easy to perform and may reveal cellular infiltration that could be present at more proximal locations. However, interpretation is frequently equivocal. In one retrospective study inflammatory bowel disease was diagnosed on the basis of rectal biopsy specimens in approximately 50% of cases.<sup>2</sup> In that report simple proctitis (neutrophils in the crypt or surface epithelium) was associated with inflammatory disorders, whereas only mild scattered neutrophil infiltration was seen in controls. Rectal biopsy aided in the diagnosis of three of seven horses with lymphocytic-plasmacytic enterocolitis<sup>3</sup> and one of two horses with eosinophilic enterocolitis.<sup>4</sup>

Table 15-12 presents the pathologic features of the diseases most commonly associated with malabsorption. In the same animal the extent and severity of pathologic changes vary in

TABLE 15-11

**Predominant Clinical and Clinicopathologic Features of Horses with Proliferative and Inflammatory Bowel Diseases**

Condition	Breed	Age Range	Clinical Signs	Dermatitis/ Coronitis	Hematology	Chemistry	Absorption Tests
Alimentary lymphosarcoma	None	2 yr to aged; Majority ≤4 yr	Weight loss, poor appetite, edema, depression, occasional fever, occasional diarrhea or colic	+ /- Scurfy skin	Anemia, neutrophilia; lymphocytosis rare	Decreased albumin; TP normal to increased; increased globulin	Reduced absorption; partial to complete mal-absorption
Granulomatous enteritis	Standardbred	1-6 yr; Majority ≤3 yr	Severe wasting, edema, variable appetite, depression, infrequent diarrhea, occasional slight fever	+ /- Scurfy skin; severe lesions rare	Anemia; Leukocytes normal to slightly increased or decreased	Decreased albumin; TP normal to decreased; GGT normal, ALP normal to increased	Reduced absorption; partial to complete mal-absorption
Multisystemic eosinophilic epitheliotropic disease	Standardbred, Thoroughbred	1 yr to aged; Majority ≤4 yr	Severe wasting, edema, appetite poor to ravenous, slight fever, diarrhea or soft feces common, rare colic, depression, oral ulcers	+ +++ Severe skin lesions and ulcerative coronitis prominent	Anemia rare to slight; neutrophilia and eosinophilia rare	Decreased albumin; TP normal to decreased; GGT and ALP normal to increased	Delayed absorption (peak shifted to right); reduced or normal peak concentration
Lymphocytic-plasmacytic enterocolitis	None	3 yr to aged	Inappetence, depression, colic, edema		Normal	Decreased albumin and TP; increased fibrinogen	Inadequate absorption or delayed peak
Proliferative enteropathy	None	3-8 months; sporadic reports older	Depression, colic, diarrhea, edema, appetite often normal, concurrent infection	+ /- Scurfy skin	Anemia, leukocytosis	Decreased albumin and TP; Increased CPK	Often normal

\*GGT,  $\gamma$ -Glutamyltransferase; ALP, alkaline phosphatase; CPK, creatine phosphokinase; none, no predominant breed.

TABLE 15-12

Pathologic Features of Proliferative and Inflammatory Bowel Diseases of Horses				
Condition		Small Intestine	Large Intestine	Other Organs/Systems
Alimentary lymphosarcoma	G	<b>Constant</b> ; extensive thickening, thickened mucosa, fissures, serosal plaques, nodules, congestion	<b>Infrequent</b> ; unremarkable to thickened segments	MLNs massively enlarged; occasional enlargement of other LN
	H	Villous atrophy (partial to total); crypts disappear with hyperplasia; infiltrate of pleomorphic lymphoid cells, plasma cells; transmural	Nothing evident to diffuse mucosal infiltration	Extensive infiltration of MLNs; moderate in other LNs (liver, spleen, stomach rare)
Granulomatous enteritis	G	<b>Constant</b> ; thickened wall and mucosa, fissures, widespread ulceration (tiny ulcers)	<b>Common</b> , generally discrete	MLNs enlarged, edematous; stomach commonly affected (generally discrete); liver/pancreas rare
	H	Villous atrophy (partial to total), crypt hyperplasia and abscesses, diffuse granulomatous inflammation; mononuclear cells (lymphoid), giant cells, epithelioid foci; lymphangiectasia	Similar infiltrate usually discrete; mucosa, submucoa	Similar infiltrate; stomach discrete; MLNs discrete to florid macrophage infiltration; diffuse cortical hyperplasia
Multisystemic eosinophilic epitheliotropic disease	G	<b>Common</b> ; diffusely thickened, especially proximal duodenum and distal ileum; serosal nodules or granularity; ulceration	<b>Constant</b> ; severe; segmental or multifocal granuloma; mucosal (predominantly) and transmural thickening; extensive ulcers	MLNs and other LNs enlarged; stomach and esophagus commonly affected; liver/pancreas commonly affected; may be hyperkeratotic; Skin: exudative dermatitis, ulcerative coronitis
	H	Villous atrophy rare; lymphocytic and eosinophilic infiltration most severe in cranial duodenum, ileum, ileocecal junction; infiltrate more widespread than gross lesions	Segmental/multifocal lesions, severe infiltration, reactive fibrosis, tissue eosinophilia, walled-off granulomata, central necrotic core of eosinophilic material	Similar infiltration with fibrosis of MLNs, liver, pancreas; skin: acanthosis, hyperkeratosis, diffuse infiltrate of eosinophils, lymphocytes in dermis; focal eosinophilic accumulations
Lymphocytic-plasmacytic enterocolitis	G	<b>Constant</b> ; mucosal/ submucosal edema; prominent folds	<b>Common</b> ; edema, congestion, areas of mucosal ulceration	MLNs enlarged
	H	Villous blunting to atrophy; moderate to severe infiltration of lymphocytes, plasma cells; edema, dilated lymphatics	Similar infiltrate, less remarkable	Minimal evidence
Proliferative enteropathy	G	<b>Constant</b> ; significant mucosal thickening, corrugated appearance from proximal jejunum to distal ileum	<b>Uncommon</b> ; submucosal edema	MLNs unremarkable
	H	Villous shortening, severe hyperplasia of crypt epithelium, small curved bacteria in apical cytoplasm, mononuclear infiltrate	No evidence	No evidence

G, Gross pathologic findings; H, histopathologic findings; MLNs, mesenteric lymph nodes; LNs, lymph nodes

different regions of the small and large intestines, thus influencing the severity of clinical signs and abnormalities present, if any, in tests of intestinal function. Early diagnosis remains a challenge, and even multiple intestinal biopsies taken at exploratory laparotomy may prove unhelpful.

Biopsies of skin, liver, lymph node, or lung may reveal evidence of multisystemic disease and can easily be obtained in the standing horse, with organ biopsies typically obtained with ultrasonographic guidance. One can obtain intestinal and lymph node biopsies during a standing laparotomy.

Exploratory laparotomy facilitates rigorous inspection of the gastrointestinal tract and associated organs to obtain multiple biopsies from intestinal sites and lymph nodes. Cost and potential postoperative complications may limit surgical procedures for diagnosis. Laparoscopy may provide an alternative means to facilitate biopsy of certain tissues but is typically more helpful from a diagnostic rather than a therapeutic standpoint. From this perspective, the veterinarian should consider surgical exploration as an option early in the process rather than as a last resort.

## ☞ TESTS OF INTESTINAL FUNCTION

Intestinal function tests are a practical and inexpensive means to assess the absorptive capability of the small intestine. For clinical practice purposes this is limited to carbohydrate absorption tests, which are easy to perform. The noninvasive breath hydrogen test used to assess carbohydrate malabsorption in human beings has not proved reliable in equine studies.<sup>5</sup> Abnormality of carbohydrate absorption has become an important precept on which to base a diagnosis of malabsorption in the horse. However, results of the oral glucose tolerance test (OGTT) or D-xylose absorption test require cautious interpretation. Pathologic changes in the mucosa and submucosa must be extensive and widely distributed to greatly affect the peak plasma concentration and shape of the curve. Many commercial laboratories conduct xylose assays, and glucose concentrations are routinely monitored in most referral and many primary care facilities.

### ORAL GLUCOSE TOLERANCE TEST

The OGTT is typically performed by administering 1 g of glucose per kg of body weight as a 20% solution through a nasogastric tube following an overnight fast (14-16 hours).<sup>6</sup> Blood is collected into heparinized tubes before glucose administration and at 30-minute intervals for 180 minutes; if possible, the test is continued at 60-minute intervals until 360 minutes have elapsed. An alternative protocol is to continue sampling at 30-minute intervals for 240 minutes. Food is withheld during the sampling period, but water is allowed at all times. Maximum plasma glucose level (>85% baseline) is reached by 120 minutes in healthy horses.<sup>6,7</sup>

The immediate dietary history, gastric emptying rate, intestinal transit, age, and hormonal effects of the horse influence glucose peak and curve shape. Prolonged fasting ( $\geq 24$  hours) results in a delayed and slightly lower peak plasma glucose concentration.<sup>8</sup> Higher glucose peaks are recorded from healthy animals eating grass or hay than from those eating concentrates<sup>9</sup> and from horses fed a pasture (clover and kikuyu) versus stable (oat hay, complete feed, and alfalfa/oat chaff) diet.<sup>10</sup> Results from the OGTT can also be affected by the content of nonstructural carbohydrate and fat in the diet<sup>11</sup> and other disorders, such as polysaccharide storage myopathy.<sup>12</sup>

In one report of 42 mature horses with chronic weight loss, a normal OGTT (peak glucose concentration at 120 minutes >85% baseline) was not associated with abnormal small intestinal morphology in any of the five horses in which it was documented. When peak glucose concentration was between 15% and 85% of baseline at 120 minutes (considered partial malabsorption), approximately 72% had small intestinal infiltrative disease, and when peak concentration at 120 minutes was less than 15% above baseline (total malabsorption), all had severe small intestinal infiltrative disease.<sup>7</sup> However, other reports have documented horses with flat OGTT curves that subsequently showed more normal OGTT responses and resolved clinical condition<sup>13</sup> and poor diagnostic sensitivity of carbohydrate absorption tests to detect small intestinal involvement in horses with chronic diarrhea and predominantly large intestinal problems.<sup>14</sup> Thus an abnormal absorption test and weight loss can occur in the horse as a transient event and without significant morphologic changes in the small intestine.

### D-XYLOSE ABSORPTION TEST

The D-xylose absorption test is performed in the same manner as the OGTT, except 0.5 g D-xylose per kilogram of body weight is administered as a 10% solution through a nasogastric tube. The pretest period of fasting and timing of sample collection is identical. Before collecting the samples, the veterinarian should contact the laboratory to ensure that heparinized plasma is acceptable. Plasma D-xylose should peak between 20 and 25 mg/dl between 60 and 90 minutes after administration, with occasional peaks as late as 120 minutes.<sup>15,16</sup>

D-xylose absorption testing is not confounded by hormonal effects or mucosal metabolism, as is glucose, but is altered by diet, length of fasting (which could also be influenced by recent appetite or degree of cachexia), and age. Horses fed a high-energy (e.g., oat chaff, oats, and corn) diet had a lower mean peak plasma D-xylose concentration (14.1 versus 24.9 mg/dl) than those consuming a low-energy (alfalfa chaff) diet.<sup>10</sup> Healthy mares fasted for up to 96 hours had flatter curves and a slower decrease in plasma xylose than when fasted for 12 to 36 hours.<sup>15</sup> Kinetic analysis indicates that prolonged food deprivation does not alter renal or nonrenal excretion of D-xylose; thus the effect of fasting on the curve is likely related to intestinal transit, small intestinal absorption, or both.<sup>17,18</sup> Ponies may have lower peak D-xylose concentrations than horses, although the range is wide and diagnostic discriminatory cutoff points for peak plasma xylose concentrations have not been determined. Foals normally have a higher mean peak xylose concentration at 1 and 2 months of age, but mean peak falls to a level similar to that seen in adults by 3 months of age.<sup>19</sup> Gastric emptying rate, intestinal motility, intraluminal bacterial overgrowth, and renal clearance can affect curve shape.

D-Xylose, a pentose sugar, is absorbed unchanged by the duodenum and jejunum in other species. The intestinal sugar active transport system has a low affinity for D-xylose in the equine jejunum *in vitro*; hence D-xylose absorption likely occurs primarily by convection or diffusion.<sup>20</sup> Thus an abnormal D-xylose absorption test likely indicates abnormal mucosal surface area or permeability. Such an abnormality, represented by a flat curve or delayed absorption, has been observed with most examples of chronic inflammatory bowel disease, parasitism, and idiopathic villous atrophy.<sup>21,22</sup> Abnormal absorption curves have been detected in the absence of small intestinal histologic changes,<sup>23</sup> and interpretation is clouded further by findings from small intestinal resection studies in healthy ponies. One study demonstrated a progressive decline in mean peak xylose concentration after 70% distal small intestinal resection in ponies, despite their normal clinical appearance and absence of diarrhea.<sup>24</sup> In another study a similar decline in peak xylose concentration following extensive ( $\geq 60\%$ ) small intestinal resection was accompanied by weight loss, diarrhea, and ill thrift.<sup>25</sup>

Peak xylose concentrations were much lower in horses with granulomatous enteritis than those with eosinophilic granulomatosis (EG), whereas in EG the absorption curve shifted to the right, with the peak occurring at 240 minutes.<sup>26</sup> This is not surprising given the typical lesion distribution with these disorders. As with the OGTT, results of the xylose absorption test can improve after therapy.<sup>27</sup>

## LACTOSE ABSORPTION

Milk intolerance is well documented in children and can result from primary or secondary lactase (neutral  $\beta$ -galactosidase) deficiency. Secondary lactase deficiency can occur when a small intestinal disorder, typically rotavirus, damages the epithelial cells, resulting in decreased brush border disaccharidase activity. Such an association has been reported secondary to clostridial enteritis in the foal.<sup>28</sup> In horses lactase activity peaks at birth and declines slowly, such that activity is approximately 50% at 2 years of age and rapidly decelerates after 3 years of age; it is barely detectable by 4 years of age.<sup>29</sup> The oral lactose tolerance test is performed in foals after a 4-hour fast, with a standard dose of 1 g/kg lactose monohydrate given through a nasogastric tube as a 20% solution. Blood sampling is performed in the same manner as for the OGTT. Plasma glucose typically peaks 1 hour after lactose administration, with a range from 30 to 90 minutes, with a mean increase of 77 mg/dl and a 35 mg/dl increase covering two standard deviations.<sup>30</sup> It should be noted that older foals (12 weeks) had a more significant increase in plasma glucose relative to 1-week-old foals.

## NUCLEAR MEDICINE

Scintigraphy with radiolabeled leukocytes (technetium-99m-labeled hexamethyl-propyleneamine oxime (<sup>99m</sup>Tc-HMPAO)) was recently used to evaluate 17 horses with suspected intestinal malabsorption.<sup>31</sup> In that report the investigators were able to detect intestinal inflammation in 12 of 17 horses, and increased intestinal uptake was not evident in any of the control horses. Corroborating histopathologic results were not available for all cases; this technique was not able to differentiate between type or location of disease, nor did it indicate prognosis.

## ☞ DISEASES ASSOCIATED WITH MALABSORPTION AND MALDIGESTION

The clinical signs of chronic wasting and poor body condition, although nonspecific for a diagnosis of malabsorption ante mortem, can be attributed to proliferative or inflammatory intestinal disorders, often collectively referred to as *chronic inflammatory bowel diseases* (CIBD).<sup>22</sup> Summaries of the characteristic clinicopathologic and pathologic findings for each disease are presented in Tables 15-11 and 15-12, respectively.

## ALIMENTARY LYMPHOSARCOMA

Alimentary lymphosarcoma of the horse may represent a primary neoplasia of the gut-associated lymphoid tissue with significant cellular infiltration of the small intestine and associated lymph nodes with minimal large intestinal or systemic involvement. Case series and pathology reports indicate that young horses 2 to 4 years of age primarily are affected, although the age range can be broad.<sup>32-34</sup> No breed or sex predilection has been documented, and disease prevalence is unknown. Despite the progressive nature of lymphomata, onset of clinical signs can be rapid, and the animal may become acutely ill. As with all adult cases of CIBD, ante-mortem diagnosis is by a process of exclusion and usually

is confirmed post mortem. Frequent abnormalities include anemia, thrombocytopenia, neutrophilia or neutropenia, and hypoalbuminemia with hyperglobulinemia, resulting in either a normal or elevated serum protein. Lymphocytosis is rare. Intra-abdominal masses, mainly enlarged mesenteric lymph nodes, may be rectally palpated. Abdominocentesis and rectal biopsy can provide a diagnosis but are not sensitive indicators of disease. Carbohydrate absorption tests usually reveal partial to total malabsorption indicative of the severely reduced surface area resulting from significant villous atrophy and the extensive mucosal or transmural infiltration. Early confirmation of a suspected diagnosis necessitates exploratory laparotomy to obtain multiple intestinal and lymph node biopsies if the results of rectal biopsy or abdominocentesis are normal. Prognosis is poor, especially insofar as most horses are presented in an advanced state of disease. Immunosuppressive drugs or chemotherapy may afford temporary improvement, but long-term outcome is unaffected. A detailed discussion of lymphosarcoma is included in Chapter 14.

## GRANULOMATOUS ENTERITIS

Granulomatous enteritis was first described as a chronic wasting condition in 1974<sup>35</sup>; 9 of 10 horses were young Standardbreds. Most affected horses are 2 to 3 years of age. Case reports from many countries revealed a predominance of Standardbred over Thoroughbreds by three to one.<sup>26,36</sup> Some of the Standardbreds were related, implicating a genetic predisposition, but this has not been proved. Prevalence is low. The condition is sporadic and has an insidious onset, and the course can be protracted. Significant diagnostic features include anemia, slight increases or decreases in white blood cell counts, hypoalbuminemia, normal serum protein or hypoproteinemia, occasional increases in serum alkaline phosphatase activity, normal serum  $\gamma$ -glutamyltransferase activity, and enlarged mesenteric lymph nodes on rectal palpation. Partial or complete malabsorption is typically documented by carbohydrate absorption testing. The low proportion of horses exhibiting diarrhea can be attributed to the preferential distribution of inflammatory infiltration in the small intestine.<sup>37</sup> Rectal biopsy can be a useful aid to diagnosis.<sup>2</sup>

The cause of granulomatous enteritis is unknown. Several infectious agents have been implicated, including *Mycobacterium avium*.<sup>38</sup> The condition may represent a granulomatous hypersensitivity reaction. Immune-mediated responses to dietary, parasitic, or bacterial antigens may be important initiating factors.<sup>22</sup> Six cases purported to represent granulomatous enteritis were linked to environmental contamination with aluminum,<sup>39</sup> although problems existed regarding the case definition, data, and interpretation.<sup>40</sup>

Treatment of horses with granulomatous enteritis with a variety of drugs, particularly corticosteroids, has not affected the long-term outcome in the majority of cases.<sup>41</sup> Prolonged (i.e., 5 months) corticosteroid administration produced clinical remission and a favorable athletic outcome in a 6-year-old Standardbred gelding based on improvement in clinical signs and in D-xylose absorption.<sup>27</sup> Surgery may be indicated with localized disease. Two young horses underwent resection of the thickened terminal small intestine; one horse died 4 months after surgery, and the other remained clinically normal for at least 10 years.<sup>36</sup>

## MULTISYSTEMIC EOSINOPHILIC EPITHELIOTROPIC DISEASE

MEED encompasses disorders characterized by a predominant eosinophilic infiltrate in the gastrointestinal tract, associated lymph nodes, liver, pancreas, skin, and other structures and accompanied by some degree of malabsorption and enteric protein loss. The disorders include chronic eosinophilic gastroenteritis,<sup>42</sup> eosinophilic granulomatosis,<sup>26</sup> chronic eosinophilic dermatitis,<sup>43</sup> and probably basophilic enterocolitis.<sup>44</sup>

Although prevalence is low, MEED appears to be more common than granulomatous enteritis. Most affected horses are 2 to 4 years of age, and Standardbreds and Thoroughbreds are reported to predominate. The condition is sporadic and has an insidious onset and often a protracted course (i.e., 1 to 10 months). Diarrhea is common. Severe skin lesions with exudative dermatitis and ulcerative coronitis are prominent and frequently are the principal presenting complaint. Despite extensive tissue eosinophilia, systemic eosinophilia is rare and hematologic values are usually unremarkable. Notable features include hypoalbuminemia and elevations in serum  $\gamma$ -glutamyltransferase and alkaline phosphatase activities. Most reports of carbohydrate absorption test findings indicate a reduced or normal peak concentration delayed to at least 180 minutes. Morphologic changes are less pronounced in the small intestine than in the large intestine,<sup>26</sup> and small intestinal lesions predominate segmentally in the proximal duodenum and distal ileum. Furthermore, significant hyperkeratosis of the fundic region may contribute to gastric muscle contractile disruption. Diarrhea can be a consequence of the severe segmental or multifocal granulomatous lesions in the large intestine, with mucosal and transmural thickening and extensive ulceration. Abundant fibrosis is a feature of all affected tissues.

The cause of MEED is unknown and could represent a chronic, ongoing, immediate hypersensitivity reaction against undefined antigens ingested or excreted into the lumen from parasitic, bacterial, or dietary sources. Infectious agents have not been identified.<sup>42,43</sup> Eosinophilia is a feature of parasitism in the equine intestinal tract, although nematodes rarely have been identified in any lesions of MEED.<sup>42,45</sup> However, failure to detect larval structures in these lesions may be attributable to the chronicity of the disease and destruction of the parasites in tissue.<sup>36</sup> Biopsies of the rectal mucosa<sup>2</sup> or of the skin, liver, intestinal tract, and lymph nodes may assist in diagnosis. Unlike the other conditions, MEED has definitive liver and pancreatic involvement; thus maldigestion may contribute to the wasting disease.

Treatment has been attempted with a variety of drugs, including antibiotics, corticosteroids, and anthelmintics with larvicidal activity. Although some horses improve briefly, the long-term prognosis is poor.

## EOSINOPHILIC ENTEROCOLITIS

Idiopathic eosinophilic enterocolitis affects segmental lesions in the small or large intestine, inducing signs of colic, and often requires surgical intervention.<sup>36,46,47</sup> This problem may not involve evidence of malabsorption and does not have multisystem involvement. Because the problem is often associated with signs of colic and not signs of malabsorption, eosinophilic enterocolitis differs from the other conditions discussed in this section and is often diagnosed at the time of surgery. It

carries a much better prognosis than the other inflammatory bowel diseases.

## LYMPHOCYTIC-PLASMACYTIC ENTEROCOLITIS

The morphologic findings in lymphocytic-plasmacytic enterocolitis reflect the predominant infiltrative cellular elements of this rarely encountered condition. No specific clinical or clinicopathologic features differentiate this condition ante mortem from other inflammatory diseases of adult horses. In a retrospective study of 14 horses, carbohydrate absorption was abnormal or delayed in 9 of 12 horses, consistent with the predominance of small intestinal pathologic changes.<sup>3</sup> Rectal biopsies were abnormal in three of seven horses, two of which were reported as having lymphocytic-plasmacytic proctitis. Prognosis is poor. Treatment has been unsuccessful, probably because of the advanced nature of the condition at the beginning of treatment.

## PROLIFERATIVE ENTEROPATHY

Proliferative enteropathy (PE) typically affects weanling foals between 3 to 8 months of age and has been reported in North America, Europe, and Australia, causing disease in individuals or outbreaks of multiple affected animals on the same premise.<sup>48-59</sup> PE has been reported uncommonly in yearlings and adult horses.<sup>57,60</sup> The disease affects many other species, especially swine, and is caused by *Lawsonia intracellularis*, an obligate intracellular bacterium found in the cytoplasm of proliferative crypt epithelial cells of the jejunum and ileum.<sup>51,57,59</sup> The condition in a foal was described first as intestinal adenomatosis,<sup>61</sup> but later work confirmed that intestines from an affected foal contained *L. intracellularis*.<sup>51</sup>

Clinical signs include depression, rapid and significant weight loss, edema, diarrhea, and colic.<sup>57</sup> Poor body condition, a rough hair coat, and potbelly appearance are also reported. It is important to remember that not all clinical signs are present in all cases, and diarrhea has been noted in only approximately half of reported cases. Other problems often were concurrent, including respiratory tract infection, dermatitis, intestinal parasitism, and gastric ulceration. The most significant laboratory finding is profound hypoproteinemia, predominantly characterized by hypoalbuminemia, but panhypoproteinemia can also occur.<sup>48,52,57</sup> Leukocytosis and hyperfibrinogenemia are also common, with occasional alterations in electrolytes (hyponatremia, hypokalemia, hypochloremia) and elevated serum creatine kinase concentrations. Abdominal ultrasound commonly reveals increased small intestinal mural thickness.<sup>48,52</sup> Colloid oncotic pressure is typically low, if measured.<sup>48</sup>

One can suspect PE based on clinical signs and severe hypoalbuminemia in a weanling foal with exclusion of common enteric infections. Fecal PCR for bacterial DNA or serum immunofluorescence assay or immunoperoxidase monolayer assay (IMPA) for antibodies against the organism can provide additional support for the diagnosis. The IMPA may be more sensitive, and typically titers greater than or equal to 1:60 are considered positive.<sup>60</sup> Submission of both tests is recommended; although both tests are quite specific, both also lack sensitivity, especially early in the course of disease (serology) or with prior antimicrobial therapy (fecal PCR).<sup>48,57</sup> Notably, fecal PCR can become negative in affected foals within 4 days

of antimicrobial therapy.<sup>58</sup> PE is not typically associated with abnormal carbohydrate absorption test results.<sup>57,58</sup> In cases with diarrhea, infectious causes should be ruled out. A definitive postmortem diagnosis can be confirmed by identifying characteristic mural thickening and intracellular bacteria within the apical cytoplasm of proliferating crypt epithelial cells using silver stains, PCR, or immunohistochemical testing.<sup>57</sup>

Reported antimicrobial therapy includes erythromycin, alone or with rifampin, azithromycin, clarithromycin, oxytetracycline, doxycycline, metronidazole, or chloramphenicol.<sup>48,57,62</sup> Recent reports appear to favor the use of intravenous oxytetracycline, followed by oral doxycycline, with apparent success.<sup>48,62</sup> Duration of therapy is typically 2 to 4 weeks. Affected foals often need supportive therapy, including crystalloid fluid and electrolyte replacement and often colloid support with either hydroxyethyl starch or plasma. NSAID therapy can be used as needed for significant pyrexia. Corticosteroid therapy is not indicated because inflammation is not a significant pathologic finding. Response to therapy has been good, with reported survival rates between 82% and 93%.<sup>48,57,62</sup> Rapid improvement in clinical signs, even within 24 hours, preceded the rise in plasma protein concentration.

The source of infection is typically not determined. In some epidemiological investigations, close proximity to swine operations was apparent, but in most such an association was not evident.<sup>52,57</sup> Comparisons of epidemiologic findings from the swine disease indicated that overcrowding, feed changes, antibiotic usage, and mixing and transportation were potential risk factors at two of the farms in one study, and recent weaning appears to be a common risk factor.<sup>57</sup>

## OTHER CONDITIONS

Abnormal D-xylose absorption has also been noted in association with AA amyloid-associated gastroenteropathy in an 18-year-old Morgan stallion<sup>63</sup> and a horse with a gastric mass and secondary small intestinal villous atrophy.<sup>64</sup>

## MANAGEMENT, THERAPY, AND OUTCOME

The chronic wasting horse with suspected malabsorption and probable enteric protein loss has at best a guarded to poor prognosis, with the exception of those suffering from PE. Prognosis may be improved through early and aggressive investigation to achieve a diagnosis. In the short term intravenous infusion of plasma or colloids, with or without fluids and electrolytes, may be necessary to stabilize the profoundly hypoalbuminemic patient. Prognosis is much worse for the horse that is inappetent. Prolonged intensive total parenteral nutrition, oral alimentation, or both may not be a realistic course of action. The owner must be cognizant from the start that the outcome may not be altered, even after protracted therapy; only a few case reports of successful responses with long-term follow-up have been documented.

## NUTRITION

Some level of digestive and absorptive capability remains in the diseased small intestine. Interval feeding of small quantities of easily digestible food may be beneficial. Diet should include feeds with a high fiber content to favor large intestinal fermentation, including grass hay and access to pasture

complemented by high-fiber rations based on beet pulp and soybean hulls, which are commercially available in many complete pelleted feeds. Energy intake can be increased through feeding high-energy dense fats that provide 2.25 times more calories than carbohydrates. Most affected horses should tolerate high fat (5% to 10%) processed feeds containing vegetable oils or rice bran (up to 20% of the concentrate mix, equivalent to 8% vegetable oil) to achieve the higher-fat composition. The transition to a higher-fat concentrate should be gradual. Even in healthy animals that can eat up to 20% added fat, appetite may decrease as the percentage increases, and fecal consistency may change. Clearly, the objective for the horse with suspected malabsorption is to sustain, and preferably increase, dietary intake, value, and efficiency.

The owner of an affected horse must be prepared to experiment with feeds, be patient, and keep records. Exposure to a feed component may contribute to the problem as an allergen eliciting a hypersensitivity reaction. Identifying the potential allergen through immunologic testing or by stepwise removal and outcome assessment over a longer period may be difficult. The clinician should give immunosuppressive drugs early in the process.

## DRUG THERAPY

Immunosuppressive agents have produced the most promising responses to ameliorate the effects of conditions associated with malabsorption, particularly CIBD. Short-duration, and in some cases more prolonged and sustained, improvements in body condition, weight gain, demeanor, energy, and activity levels have occurred following corticosteroid administration. Treatment should begin as early as possible. The clinician should follow initial parenteral (intramuscular or intravenous) loading doses of dexamethasone (sodium phosphate) with a series of depot injections or orally administered prednisolone on a tapered-dose protocol over a period of months. Interval low-dose therapy may be necessary if clinical signs return after treatment ends. The clinician should use the lowest dose that effectively controls the clinical signs for alternate-day therapy. Clinical benefits far outweigh concerns over potential adverse effects. Chemotherapeutic agents such as vincristine, cytosine, cyclophosphamide, and hydroxyurea have been tried in a few cases of CIBD or lymphosarcoma with no apparent success, probably because of the advanced stage of the disease when treatment was initiated and the dose selected.

## SURGERY

Resection of a segment of intestine that is edematous, hemorrhagic, or constricted is an option in localized forms of CIBD,<sup>46,47</sup> particularly if gross changes are not discernible in adjacent or distant parts of the intestinal tract—that is, malabsorption is not a feature. Long-term outcome has been favorable. Removal of a substantial proportion of the diseased small intestine may be indicated in a horse with malabsorption, considering that resection of 70% distal small intestine was performed in healthy animals without inducing adverse effects.<sup>24</sup> However, because pathologic changes may exist in normal-appearing small or large intestine that is not resected or biopsied, the prognosis remains guarded. Two young horses with granulomatous enteritis had the thickened terminal small intestine resected with positive outcomes; one survived 4 months, the other has a follow-up extending more than 10 years.<sup>36</sup>

## INFLAMMATORY DISEASES OF THE GASTROINTESTINAL TRACT CAUSING DIARRHEA

Samuel L. Jones

Acute diarrhea caused by colitis in adult or young horses is a potentially life-threatening disorder with a variety of possible etiologies (Table 15-13) characterized by hypersecretion of fluid, motility disturbances, and an impaired mucosal barrier resulting from direct injury or inflammation. Many of the clinical and clinicopathological features are similar regardless of the underlying cause. Severe dehydration with profound electrolyte abnormalities is common, as is systemic inflammation secondary to absorption of endotoxin or other bacterial products through compromised gastrointestinal mucosa. Severe cases may be complicated by serosal inflammation and mural ischemia and infarction as a direct extension of mucosal inflammation or secondary to coagulopathies. The diagnostic approach for horses with acute diarrhea is aimed at determining the underlying etiology but must be accompanied by clinical and laboratory assessment of hydration, electrolyte and acid base balance, organ function, and evaluation of the degree of systemic inflammation and the integrity of the intestinal wall. The therapeutic approach for horses with colitis, regardless of cause, consists primarily of controlling local and systemic inflammation, maintaining fluid and electrolyte balance, and promoting mucosal repair. In addition, some horses with acute colitis require specific therapy aimed at the underlying etiology.

### INFECTIOUS DISEASES

#### SALMONELLOSIS

##### PATHOGENESIS

*Salmonella enterica* is a species of gram negative facultatively anaerobic bacteria that is a common gastrointestinal pathogen in horses. Many serovars of *S. enterica* have been reported to infect horses, but those classified in group B appear to be more commonly associated with disease than those in other groups. Group B includes *S. enterica* var. *typhimurium* and *S. enterica* var. *agona*, two of the species most frequently isolated from horses.<sup>1-3</sup> *S. enterica* var. *typhimurium* is the most pathogenic serotype in horses and is associated with a higher case fatality rate than other serovars of *S. enterica*.<sup>1</sup> The number of horses that are inapparently infected with and actively shed *S. enterica* in their feces has been reported to be as high as 10% to 20%, but actual prevalence of *S. enterica* shedding in the general horse population is likely to be much lower, less than 2%.<sup>4</sup> Horses shedding *S. enterica* are a potential source of infection to susceptible horses,<sup>1,5</sup> as are environmental reservoirs.<sup>6-8</sup> For these reasons salmonellosis is one of the most common nosocomial diseases in horses. Nosocomial salmonellosis significantly affects morbidity and mortality in hospitalized horses.<sup>9</sup> The emergence of multidrug resistance in equine *S. enterica* isolates has been a cause of concern because of the importance of salmonellosis as a nosocomial disease and because a number of serovars of *S. enterica* are significant zoonotic pathogens.<sup>7,10,13</sup>

TABLE 15-13

#### Differentials and Diagnosis of Some Causes of Acute Diarrhea in Adult Horses

Category	Differentials	Diagnosis
Infectious	Salmonellosis	Fecal culture (5 consecutive) Fecal PCR
	<i>Clostridium perfringens</i>	Quantitative fecal culture Fecal toxin immunoassay or PCR
	<i>Clostridium difficile</i>	Fecal culture Fecal toxin immunoassay or PCR
	<i>Lawsonia intracellularis</i>	Serology Fecal PCR Small intestinal ultrasound Histopathology
	<i>Neoristicii risticii</i>	Fecal or blood PCR Serology
Parasitic	Strongylosis	Fecal egg counts Cranial mesenteric artery palpation Serum IgG(T)
	Cyathostomiasis	Fecal egg count Rectal biopsy Cecal or colonic biopsy
Toxic	NSAID	History and clinical signs Right dorsal colon ultrasonography Laparoscopy or laparotomy
	Cantharidin	History of exposure Fecal or urine cantharidin concentrations
	Arsenic	History of exposure Fecal, blood, urine, or tissue arsenic concentrations
Miscellaneous	Carbohydrate overload	History of inappropriate ingestion of carbohydrate Blood lactate concentration
	Sand enteropathy	Auscultation of ventral colon Fecal sand content Abdominal radiography

PCR, Polymerase chain reaction; NSAID, nonsteroidal anti-inflammatory drug.

The virulence of the bacteria varies tremendously with serotype and even among strains of the same serotype. In part, this is due to the important role of host susceptibility in the pathogenicity of particular organisms. The infective dose is generally on the order of millions of organisms inoculated orally, but various environmental and host factors can reduce the infective dose to a few thousand or even hundreds of organisms.<sup>14-16</sup> Environmental factors or stresses that increase susceptibility to *S. enterica* infection are not well defined, but it is known that high ambient temperature, for example, can greatly increase the prevalence of salmonellosis in horses.<sup>6,15,16</sup> Indeed, the peak incidence of salmonellosis

in horses occurs in late summer and fall.<sup>6,15,16</sup> Other environmental and host factors that increase the risk of or are associated with salmonellosis or shedding of *S. enterica* organisms in feces include transportation, antibiotic administration before or during hospitalization, gastrointestinal or abdominal surgery, general anesthesia, preexisting gastrointestinal disease (e.g., colic, diarrhea), presence of leukopenia or laminitis during hospitalization, prolonged hospital stay, change in diet, and immunosuppression.<sup>1,8,16-18</sup> Interestingly, foals with gastrointestinal disease are more likely to shed *S. enterica* organisms than are adult horses with gastrointestinal disease.<sup>17</sup>

Host factors that restrict gastrointestinal colonization and invasion by pathogens include gastric pH, commensal gastrointestinal flora, gastrointestinal motility, the mucosal barrier, and mucosal immunity.<sup>1,19</sup> Gastric acidity is an important defense mechanism for preventing live organisms from reaching the intestine.<sup>19</sup> Altering the gastric pH, with histamine H<sub>2</sub> receptor antagonists, for example, may increase susceptibility to infection. Gastrointestinal flora inhibit the proliferation and colonization of *S. enterica* by secreting bacteriocins, short-chain fatty acids (SCFAs), and other substances that are toxic to *S. enterica*.<sup>19</sup> In addition, elements of the normal flora compete for nutrients and space, especially on the mucosa.<sup>19</sup> Being predominantly anaerobic, the normal flora maintain a low oxidation-reduction potential in the environment of the large intestine, which inhibits the growth of many bacterial pathogens.<sup>20</sup> The importance of normal host gastrointestinal ecology is illustrated by the fact that disturbances of the colonic flora with antibiotics, changes in feed, ileus, or other underlying gastrointestinal disease markedly increases the susceptibility of the host to infection by *S. enterica*, often resulting in serious disease.

The immune status of the host may be one of the most important factors determining not only the susceptibility to *S. enterica* infections but also the degree of invasion and subsequent outcome of the infection. Local immunity, such as mucosal antibody secretion and enterocyte-derived cationic peptides, prevents colonization of the mucosa.<sup>19,21,22</sup> Opsonizing antibodies and activation of the complement cascade are important in fighting systemic invasion by *S. enterica* by increasing the efficiency of phagocytosis and by direct bactericidal activity. Humoral immunity, however, is often ineffective in preventing disease and dissemination once invasion occurs and *S. enterica* has established in its intracellular niche. Following invasion, *S. enterica* is capable of surviving and multiplying within macrophages, rendering humoral (non-cellular) immune systems ineffective.<sup>23,24</sup> Specific cellular immunity may be the most effective defense mechanism in the host arsenal against dissemination and systemic infection by *S. enterica*.<sup>20,24</sup> Protective immunity in horses and calves may be induced by oral inoculation with small numbers of virulent organisms, but the duration of the immunity is not known.<sup>25,26</sup> Oral and parenteral vaccines using killed or attenuated organisms and bacterial products have been promising but are effective only against homologous organisms and are usually not cross-protective among different serogroups.<sup>25-27</sup>

In adult horses *S. enterica* primarily infects the cecum and proximal colon, causing enterocolitis, with limited likelihood of dissemination beyond the intestine. In foals, however, salmonellosis is often associated with septicemia. The ability of *S. enterica* to cause enterocolitis depends on the ability of the bacteria to invade the gastrointestinal mucosa.<sup>19,23</sup> Invasion of the gastrointestinal mucosa occurs preferentially through

specialized enterocytes called *M cells* that overlay intestinal lymphoid tissues such as Peyer's patches in nonequine species. *M cells* are exploited by a variety of enteric pathogens during infection of intestinal tissue.<sup>28</sup> Invasion of the epithelium occurs by self-induced uptake via the apical membrane of the *M cell*, often killing the cell in the process.<sup>23</sup> *S. enterica* then invades neighboring cells via the basolateral membrane, eventually spreading the destruction of the epithelium beyond the principal area of attack. Virulent *S. enterica* have a well-developed invasion mechanism that involves the generation of an apparatus called a Type III secretory system that enables virulence gene products to be injected directly into enterocytes.<sup>29</sup> Virulence proteins injected by *S. enterica* into enterocytes engage the cellular machinery and induce the cell to engulf the bacteria by macropinocytosis. *S. enterica* virulence gene products also induce enterocyte chloride and fluid secretion and upregulate enterocyte transcription of inflammatory cytokines (TNF- $\alpha$  and IL-1 $\beta$ ) and chemokines that trigger a mucosal inflammatory response.<sup>23,29,30</sup>

Once *S. enterica* has invaded the mucosa, the organisms are quickly phagocytosed by macrophages and dendritic cells in the lamina propria and in lymphoid tissues. The ability of *S. enterica* to disseminate systemically and cause enteric fever is associated with the ability to survive and proliferate in macrophages. Indeed, phagocytes have an important role in dissemination to blood, lymph nodes, liver, and spleen.<sup>31</sup> The majority of *S. enterica* in the blood and tissues of animals infected with a strain of *S. enterica* that is competent to cause enteric fever are within phagocytic cells.<sup>31</sup> In adult horses with salmonellosis, dissemination appears to be limited to the intestine and mesenteric lymph nodes, and *S. enterica* is rarely cultured from blood. However, in foals and in some adults, *S. enterica* causes an enteric fever-like disease with dissemination to mesenteric lymph nodes, liver, spleen, and blood.

Specific virulence gene clusters called *pathogenicity islands* encoded on the chromosome or on plasmids confer the main virulence traits of *S. enterica*: invasion, enteropathogenesis, intracellular survival, and proliferation.<sup>23</sup> Some of the genes encoded within these islands or virulence factors are sensors that signal to the bacteria that it has entered an intracellular environment and turn on other genes required for intracellular survival. Others, such as invasion genes, are transported from the bacteria and injected into macrophage cytosol by a Type III secretory system apparatus to prevent phagosome-lysosome fusion and subvert other essential macrophage-killing mechanisms. Virulent *S. enterica* may also possess multiple genes that enable adhesion to target cells or confer resistance to reactive oxygen and nitrogen metabolites, perhaps the most lethal antimicrobial mechanisms of macrophages.<sup>32</sup>

Diarrhea associated with salmonellosis has multiple causes. A *S. enterica* cytotoxin inhibits protein synthesis in mucosal cells, causing morphologic damage and altered permeability.<sup>34</sup> Virulent *S. enterica* also produce an enterotoxin that is similar to the heat-labile (LT) toxin produced by *E. coli*.<sup>34,35</sup> This enterotoxin contributes to, but is not required, in the pathogenesis of diarrhea.<sup>36,37</sup> *S. enterica* enterotoxin increases secretion of chloride and water by colonic mucosal cells in many species, including horses, by increasing intracellular cAMP concentrations.<sup>34,35,38</sup>

The ability of virulent *S. enterica* to cause diarrhea appears to be most closely associated with the ability to invade

enterocytes and to trigger an inflammatory reaction in the intestinal tissue.<sup>23,39</sup> Gene products injected into enterocyte cytosol by the Type III secretory system of invading *S. enterica* stimulate chloride and fluid secretion.<sup>29</sup> *S. enterica* invasion of enterocytes is also a potent activator of inflammatory chemokine and cytokine production, resulting in the recruitment of leukocytes, particularly neutrophils, and activation of resident macrophages and mast cells. Products of these activated leukocytes, including prostaglandins, leukotrienes, reactive oxygen metabolites, and histamine, are potent stimulators of chloride secretion in the colon of many species.<sup>19,40-42</sup> The enteric nervous system integrates the diverse processes of pathogen recognition, triggering of the inflammatory response, and induction of enterocyte fluid secretion.<sup>42</sup>

Many of the inflammatory mediators studied stimulate colonic secretion by prostaglandin-dependent mechanisms, resulting in either increased intracellular cAMP or calcium concentrations, or both, in mucosal cells.<sup>40</sup> In addition, these mediators and the enteric nervous system may stimulate secretion by prostaglandin-independent mechanisms, inhibit sodium and water absorption, cause motility disturbances, and potentiate tissue injury, all of which enhance the pathogenicity and dissemination of *S. enterica* and contribute to the pathogenesis of diarrhea.<sup>40,42</sup> Neutrophils recruited to the mucosa by signals generated by the infected enterocytes physically contribute to mucosal injury by producing a variety of products that are lethal to pathogens but are also toxic to host cells.<sup>43,44</sup> Moreover, neutrophils attracted to infected epithelial cells accumulate beneath the monolayer, lifting it off the basement membrane in sheets. Neutrophils also migrate across the epithelial monolayer in potentially massive numbers—enough to be detectable in feces as a marker of inflammatory diarrhea. Although the transepithelial migration of neutrophils has a benefit, positioning the host defense cell at the apical membrane to ward off attacks by invading bacteria, the mechanical disruption to the epithelial barrier may be significant enough to increase the permeability to macromolecules, bacterial products, and even bacteria.<sup>44</sup> Potentially massive losses of electrolytes, water, and protein can occur, depending on bacterial and host factors. Perhaps most devastatingly, mucosal injury and altered permeability allow systemic absorption of bacterial products and dissemination of bacteria, resulting in life-threatening sepsis.

### CLINICAL SIGNS AND DIAGNOSIS

Four clinical syndromes of *S. enterica* infection have been documented clinically and reproduced experimentally in horses: (1) inapparent infections with latent or active carrier states; (2) depression, fever, anorexia, and neutropenia without diarrhea or colic; (3) fulminant or peracute enterocolitis with diarrhea; and (4) septicemia (enteric fever) with or without diarrhea.<sup>45</sup> Inapparent infections can be activated to clinical disease in compromised horses, such as horses with colic or horses being treated with antibiotics, causing mild to severe enterocolitis. In addition, latent infections (non-shedding) can become active infections (shedding) under certain conditions, such as transportation stress and antibiotic treatment. Horses with depression, anorexia, fever, and neutropenia without diarrhea generally have a good prognosis and recover in several days without specific treatment.<sup>45</sup> The septicemic form is mostly restricted to neonatal foals and is uncommon in adult horses. The focus of this discussion is acute enterocolitis.

Acute enterocolitis is characterized by severe fibrinonecrotic typhlocolitis, with interstitial edema and variable degrees of intramural vascular thrombosis that may progress to infarction.<sup>1</sup> Severe ulceration of the large intestinal mucosa may occur, with serosal ecchymoses and congestion. The earliest signs of enterocolitis are usually fever and anorexia.<sup>1,16</sup> Signs of colic may be seen early in the course of the disease, especially if ileus is present. Clinical signs of endotoxemia are common, and range from fever, elevated heart and respiratory rates, poor peripheral perfusion, and ileus to fulminant and rapidly progressive signs of endotoxemic shock. Oral mucous membranes are often pale with perigingival hyperemia (a toxic rim) but may be brick red or cyanotic, with prolonged capillary refill time. Weakness, muscle fasciculations, cold extremities, and other signs suggestive of hypotensive shock; synchronous diaphragmatic flutter; abdominal pain; and marked metabolic and electrolyte abnormalities may be noted in severe cases of enterocolitis. Signs of mild dehydration may be observed before diarrhea is seen. Once diarrhea is evident, dehydration may rapidly become severe. Occasionally, horses die peracutely, without developing diarrhea.

Diarrhea may not occur for several days, but usually is evident by 24 to 48 hours after the onset of fever.<sup>1,16</sup> The duration of diarrhea may be days to weeks. The character of the first diarrheal feces is usually watery, with particles of roughage, but may rapidly become fluid without solid material. Finding frank blood and fibrin in the feces is unusual. The volume of feces is often large, with frequent defecation. Straining or signs of colic may be observed when the patient is defecating, and rectal prolapse may occasionally occur. Persistent straining and rectal prolapse may be a sign of colonic infarction. Abdominal borborygmi are often absent early in the course of the disease because of ileus but become evident later, usually when diarrhea begins. Fluid and gas sounds are commonly auscultated, but normal progressive motility is less frequently heard than normally. Transrectal palpation may reveal edematous rectal and colonic mucosa and fluid-filled colon and cecum. Gastric reflux may be obtained, especially early in the course, when ileus is evident.

Hematologic abnormalities early in the course of the disease include moderate to severe neutropenia, lymphopenia, and leukopenia, a mild to moderate left shift, and toxic changes in the neutrophils.<sup>1,16</sup> Thrombocytopenia, moderate to severe hemoconcentration, and hyperfibrinogenemia are also common. Neutropenia is an early but nonspecific indicator of salmonellosis, often occurring concurrently with the onset of fever.<sup>1</sup> Later in the course of disease, neutrophilic leukocytosis may be seen, indicating recovery. A degenerating left shift, with metamyelocytes and myelocytes seen in the peripheral blood, is a poor prognostic sign.

Serum biochemical analysis may reveal azotemia, increases in serum sorbitol dehydrogenase and  $\gamma$ -glutamine aminotransferase activity, and increased blood lactic acid concentration. Azotemia is often prerenal, but acute hemodynamic renal failure may be seen in severely dehydrated, endotoxemic, or septic patients. Indeed, elevation of creatinine concentration is a poor prognostic indicator in horses with acute colitis.<sup>46</sup> Hemodynamic renal disease may be complicated by toxic injury caused by administration of nephrotoxic drugs. Hyponatremia may also contribute to prerenal azotemia. Elevations in hepatocellular enzymes are usually mild and reflect damage to the hepatocytes from absorbed toxins such as endotoxin and from poor perfusion resulting from hypotensive shock,

dehydration, or both. Lactic acidemia may be present, reflecting poor tissue perfusion. Plasma protein rapidly drops, as protein is lost in the gastrointestinal tract, causing moderate to severe hypoalbuminemia and hypoglobulinemia. Peripheral or organ edema (vascular leak syndrome) may occur if hypoproteinemia is severe, coupled with systemic inflammation-induced increases in endothelial permeability.

Hypokalemia, hyponatremia, hypochloridemia, and hypocalcemia are common electrolyte abnormalities in patients with enterocolitis. Metabolic acidosis may also be present and DIC is common. Urinalysis may reveal isosthenuria, proteinuria, hematuria, cylindruria, or glucosuria if hemodynamic or toxic renal injury is present. The number of leukocytes in the feces is usually elevated, and occult blood may be detected. PF is usually normal except when severe mural inflammation or colonic infarction occurs.

*S. enterica* in feces is routinely detected by analyzing five daily cultures of large samples (10-30 g) of feces using enrichment techniques.<sup>1,47,48</sup> However, the sensitivity of fecal culture can be as low as 30% to 50%, even if several fecal samples collected daily are cultured.<sup>48</sup> Concurrent culture of rectal biopsy specimens and feces increases the sensitivity of culture techniques to 60% to 75%.<sup>48</sup> Currently, the PCR test is the most sensitive and rapid way to detect *S. enterica* in feces. A single PCR test applied early in the course of disease is a more sensitive test for the presence of *S. enterica* than repeated fecal cultures,<sup>49,50</sup> with as high as 100% sensitivity and 98% specificity for detection of organisms in some reports.<sup>51</sup> Although detection of *S. enterica* organisms in feces does not prove a diagnosis of salmonellosis, the positive predictive value of either a positive PCR or culture result is high in horses with compatible clinical signs. Culture of peripheral blood may allow isolation of the organism if bacteremia or septicemia is present, but blood cultures are not a sensitive test for salmonellosis in adult horses. However foals are more likely than adults to become septicemic and culture of blood is recommended in all foals with signs of sepsis. Increased numbers of fecal leukocytes suggest an invasive process in the colon but are not specific for salmonellosis.

Early in the course of the disease, dehydration, electrolyte and acid-base imbalances, endotoxemia, and sepsis may be life threatening. Aggressive treatment during the acute stages to replace fluids lost in the diarrhea and to control sepsis and endotoxemia is often effective in controlling the primary disease. Weight loss and hypoproteinemia are often severe. Possible complications include multiorgan dysfunction, vascular leak syndrome with peripheral and organ edema, laminitis, acute renal failure, venous thrombosis and septic phlebitis, irreversible protein-losing enteropathy or chronic malabsorption, pulmonary aspergillosis, and gastrointestinal infarction. The reader is referred to Chapter 7 and the section on endotoxemia in this chapter for additional information regarding treatment of horses with severe endotoxemia and SIRS.

In many instances horses recover from acute salmonellosis with aggressive treatment, only to succumb to complications of the disease, which partially explains the high fatality rate of equine salmonellosis compared with that of human salmonellosis. Chronic, mild to moderate diarrhea is occasionally seen in horses after a bout of severe salmonellosis, usually with protein-losing enteropathy. If the chronic diarrhea persists beyond 4 to 5 weeks after the onset of signs, the prognosis for recovery is poor.<sup>16</sup>

## POTOMAC HORSE FEVER

### PATHOGENESIS

Potomac horse fever is caused by the obligate intracellular rickettsial organism *Neorickettsia risticii* (formerly called *Ehrlichia risticii*).<sup>52,53-56</sup> The disease is most common from late summer to early fall, with a peak incidence in July and August.<sup>53,54</sup> Potomac horse fever was first described in the Northeastern United States but has since been described now in most areas of the continental United States, with a particularly high prevalence in the Northeast and Midwest. The geographical distribution is characterized by a significantly higher percentage of cases found along waterways and rivers.<sup>53,54</sup> The disease occurs sporadically, both temporally and geographically, and can affect any age group of horses. The case fatality rate ranges between 5% to 30%.<sup>53</sup>

Transmission of *N. risticii* has been reproduced experimentally by oral, intramuscular, intradermal, subcutaneous, and intravenous routes.<sup>53,57</sup> Attempts to transmit the disease experimentally with ticks (*Dermacentor variabilis*) or biting flies (*Stomoxys calcitrans*) were unsuccessful.<sup>58,59</sup> Recently, *N. risticii* was found to infect virgulate cercariae, larval stages of trematodes that use operculate freshwater snails of the family *Pleuroceridae* (*Juga* spp. in California and *Elimia* spp. in Ohio and Pennsylvania), as intermediate hosts in their life cycle.<sup>60-63</sup> Infected virgulate cercariae have been identified in aquatic snails collected in other parts of the world as well.<sup>64</sup> Although the trematode species infected with *N. risticii* remain to be definitively identified, at least two species have been identified as potential vectors,<sup>65</sup> and at least two potential definitive hosts were identified when *N. risticii* DNA was detected in the blood, liver, or spleen of 23 of 53 little and big brown bats harboring gravid trematodes in their intestinal tracts.<sup>66</sup>

Aquatic snails release large numbers of infected cercariae into water, where they seek their next intermediate host—any of a variety of aquatic insects.<sup>63,67</sup> Successful transmission of *N. risticii* to horses was accomplished experimentally using trematode stages collected from *Juga yrekaensis* snails.<sup>68</sup> The number of PCR-positive snails in endemic regions corresponds to the seasonal incidence of Potomac horse fever and may be as high as 26%.<sup>69</sup> However, preliminary studies suggest that *N. risticii* may in fact be naturally transmitted to horses through the ingestion of caddisflies and mayflies.<sup>63,70</sup>

The pathogenesis of *N. risticii* is not completely understood. The organism infects and survives in monocytes and monocyte-derived leukocytes and can be found in blood monocytes during natural infections, but the sequence of events resulting in enterocolitis remains open to speculation. The organism appears first to infect blood monocytes in experimentally infected horses, which may be the vehicle of organ infection.<sup>55,71</sup> However, it is unclear whether leukocytes of the monocytic lineage or epithelial cells are infected first in naturally infected horses. The target organ is the gastrointestinal mucosa, with the most severe lesions found in the large intestine.<sup>71,72</sup> Infection of human colonic cells in vitro does not cause major cytopathologic effects for several days.<sup>73</sup> Disruption of the microvilli in the region of the plasma membrane where sodium chloride channels are located has been observed in human colonic cell cultures.<sup>73</sup> Infection in horses is associated with variable degrees of morphologic damage.<sup>71,72</sup> Mild morphologic damage and mononuclear cell infiltration of the lamina propria occur early during the infection, but fibrinous,

necrotizing typhlocolitis with severe mucosal ulceration and inflammation of the lamina propria may occur later in the disease. Vasculitis and intravascular coagulation are consistent features in the large intestine, with perivascular edema.<sup>72</sup> *N. risticii* can be observed in mucosal cells and macrophages and mast cells of the lamina propria.<sup>71,72</sup> *N. risticii* can survive and multiply in macrophages by inhibiting the production of reactive oxygen intermediates and avoiding lysosomal digestion by blocking phagosome-lysosome fusion.<sup>74-76</sup>

Some researchers have suggested that impaired sodium chloride absorption in the colon contributes to diarrhea in infected horses and may be related to destruction of the enterocyte membrane structure in the region of sodium chloride channels.<sup>73,77</sup> Direct injury to the mucosa by *N. risticii* and colonic inflammation are likely to be prominent features leading to diarrhea, especially later in the disease.<sup>72</sup> Loss of fluid, protein, and electrolyte is likely due to mucosal injury and effects on enterocyte fluid secretion caused by the inflammatory response. Like other inflammatory conditions of the colon, systemic inflammation caused by absorption of bacteria and bacterial products is a potential complication of *N. risticii* infections if mucosal injury is severe, which contributes to the clinical signs seen during the disease.

### CLINICAL SIGNS AND DIAGNOSIS

*N. risticii* infection is clinically similar to other forms of enterocolitis and is characterized by anorexia, depression, and fever.<sup>53,72,78</sup> Experimental infections produce a biphasic fever wherein the second febrile phase occurs 6 to 7 days after the first.<sup>78,79</sup> Decreased gastrointestinal motility, manifested as reduced borborygmi, occurs during the early stages, before the onset of diarrhea. Diarrhea is seen in 75% of cases, and occurs 2 days after the second fever episode during experimental infections.<sup>78,79</sup> The diarrhea can be moderate to severe and dehydrating. Ileus can develop at any stage of the disease and can cause signs of moderate to severe colic. Systemic signs of endotoxemia, shock, and peripheral edema may occur and are similar to those described for salmonellosis. Experimental and natural infection with *N. risticii* can cause abortion of infected fetuses in pregnant mares.<sup>80,81</sup> Laminitis is a complication in 20% to 30% of naturally occurring cases and is often severe.<sup>54</sup> Other complications include protein-losing enteropathy, thrombosis, and renal failure, as described for salmonellosis.

Hematologic abnormalities reflect endotoxemia, dehydration, and sepsis and are essentially identical to those described for salmonellosis. Neutropenia with a left shift is a consistent feature and occurs concurrently with or soon after the onset of diarrhea.<sup>79</sup> Thrombocytopenia is common and often severe.<sup>79</sup> Neutrophilic leukocytosis occurs later in the course of the disease. Hyperfibrinogenemia is usually more pronounced than that seen with salmonellosis. Serum electrolyte, acid-base, and biochemical abnormalities are also similar to those described for salmonellosis. Coagulopathies are commonly seen during *N. risticii* infection and reflect activation of coagulation pathways. DIC is not uncommon and may be the cause of the high frequency of laminitis associated with *N. risticii* infection.<sup>82</sup>

Diagnosis of *N. risticii* infection cannot be based solely on clinical signs because the disease is clinically similar to other forms of enterocolitis. However, in endemic areas, acute colitis is likely to be caused by *N. risticii*, and thus the clinical signs of acute inflammatory colitis may in fact have a high predictive value in these areas. Serologic evidence of infection, such as rising antibody titers to *N. risticii* detected by indirect

immunofluorescence (IFA) or enzyme-linked immunosorbent assay (ELISA) in paired serum samples, may be helpful in establishing a diagnosis.<sup>54,83</sup> Care should be taken when interpreting the IFA serologic test for *N. risticii* because the test appears to have a high false-positive rate.<sup>84</sup> Culture of the organism from blood is possible but difficult and is generally useful only in the research laboratory. Recently developed PCR tests for *N. risticii* DNA are rapid, highly sensitive (as sensitive as culture), and specific tests for *N. risticii* infection that can be applied to blood or feces.<sup>85-87</sup>

### PREVENTION

Prevention of the disease by reducing exposure to the etiologic organism is difficult because the mode of transmission is not known. A killed vaccine has been developed that is relatively effective in preventing clinical illness other than fever in 80% of experimentally challenged horses using the vaccine strain. However, field studies suggest the vaccine has limited benefit for preventing natural infection or decreasing its severity.<sup>88,89</sup> Vaccine failures have been attributed to strain differences in antigenicity or to poor antibody responses to the vaccine.<sup>88,89</sup>

## EQUINE INTESTINAL CLOSTRIDIOSIS

### PATHOGENESIS

Clostridiosis is an important cause of acute enterocolitis in foals and adult horses. *Clostridium perfringens* and *Clostridium difficile* are most commonly associated with intestinal clostridiosis in horses, but other clostridial species, including *Clostridium septicum*, *Clostridium cadaveris*, and *Clostridium sordelli* have also been isolated from horses with enterocolitis.<sup>90-95</sup> In horses of all ages, clostridial enterocolitis appears to be a common antibiotic-associated and nosocomial cause of enterocolitis.<sup>94,96,97</sup> Hemorrhagic enterocolitis caused by *C. perfringens* in neonatal foals is a distinct clinical entity and will be discussed in more detail elsewhere. This discussion focuses on adult intestinal clostridiosis. The reader is referred to Chapter 21 for information regarding the disease in foals.

*Clostridium* organisms are obligate anaerobic to aerotolerant spore-forming gram positive rods that are ubiquitous in the environment in the spore form.<sup>95</sup> They are elements of the normal flora of horses of all ages and are among the first bacteria acquired after birth. However, *Clostridium* organisms inhabiting the gastrointestinal tract are normally found in very low numbers and do not produce enterotoxins. Clostridiosis is associated with an increase in the number of a particular species of *Clostridia* in the gastrointestinal tract and, perhaps most important, exotoxin production. Although the conditions resulting in exotoxin production are not fully understood, several factors increase clostridial numbers in the gastrointestinal tract. Dietary factors affect the numbers of *Clostridium* species shed in horse feces.<sup>90</sup> Experimental induction of colic has been shown to increase fecal shedding of *Clostridium* species in the absence of diarrhea.<sup>98</sup> Antibiotics, particularly those administered orally or recycled via the enterohepatic system, have been shown to increase the recovery of *Clostridia* colony-forming units in equine feces and clinical clostridiosis.<sup>91,93,99-101</sup> Indeed, clostridiosis associated with *C. difficile* is likely to be the most important cause of antibiotic-induced enterocolitis in the horse.

**Clostridium perfringens** *C. perfringens* includes many genetically distinct strains of variable virulence that produce one or more of a large group of exotoxins. The pattern of

exotoxin production is used to classify *C. perfringens* into five types: A, B, C, D, and E. *C. perfringens* type A is the most common clostridial isolate from healthy and diarrheic horses of all ages. *Clostridium perfringens* types A, B, C, and D have all been associated with hemorrhagic enteritis in foals younger than 10 days of age, with type C being the most common cause in North America.

The primary toxin produced by *C. perfringens* type A is  $\alpha$ -toxin (phospholipase C), which interferes with glucose uptake and energy production and activates arachidonic acid metabolism and signaling pathways in enterocytes.<sup>95</sup> Oral administration of  $\alpha$ -toxin does not cause tissue necrosis but causes increased secretion by small intestinal mucosal cells.<sup>24,102</sup> The  $\beta$  toxin of types B and C is a cytotoxin that causes enterocyte necrosis, ulceration, and ultimately severe intestinal inflammation and hemorrhage.<sup>24,95</sup> A novel toxin designated  $\beta_2$  may also have a role in *C. perfringens* enterocolitis.<sup>103</sup> The biologic activity of the  $\beta_2$  toxin is similar to that of  $\beta$  toxin, but  $\beta_2$  toxin is not related to  $\beta$  toxin in its genetic sequence. The  $\beta_2$  toxin was prevalent in two groups of horses with acute enterocolitis but not in healthy horses.<sup>104</sup> The  $\beta_2$  toxin is predominantly associated with *C. perfringens* that would have otherwise been classified as type A but that may in fact represent a previously undescribed type.

Virulent strains of *C. perfringens* type A and, to a lesser extent, type C may produce enterotoxin. Enterotoxin is a cytotoxin that inserts into cell membranes to form pores, which alter permeability to water and macromolecules and ultimately lead to cellular necrosis.<sup>105</sup> Massive desquamation of the intestinal mucosa that is a result of enterotoxin cytotoxicity triggers an inflammatory response, intestinal edema, mural hemorrhage, and systemic inflammation.<sup>106</sup> Enterotoxin also alters tight junction integrity, resulting in increased paracellular permeability by a noncytotoxic mechanism.<sup>107</sup>

**Clostridium difficile** *C. difficile* produces several toxins, only two of which, toxin A and toxin B, have been studied in detail. Toxin B is a potent cytotoxin in vitro, but its role in enterocolitis is less clear than that of toxin A. Toxin B does not induce fluid secretion, inflammation, or characteristic alterations in intestinal morphology. *C. difficile* toxin A is an enterotoxin that induces an inflammatory response with hypersecretory diarrhea.<sup>108</sup> Toxin A induces neutrophil influx into intestinal tissue, mast cell degranulation, and secretion of prostaglandins, histamine, cytokines, and 5-HT by these activated leukocytes.<sup>108-110</sup> The products of neutrophils and mast cells have a significant role in the vasodilatory and secretory responses in the intestine during *C. difficile* infection.

The enteric nervous system (ENS) is central to the induction of intestinal inflammation and mucosal secretion by toxin A. A model for toxin A-induced secretory diarrhea has emerged in which toxin A stimulates substance P-containing afferent sensory nerve fibers, which in turn stimulate mast cell degranulation, recruitment and activation of polymorphonuclear leukocyte (PMN), and vasodilation.<sup>111-113</sup> Toxin A-induced stimulation of enterocyte secretion can occur via secretomotor neuronal stimulation by substance P-containing sensory neurons or products of mast cells and PMN. Mast cell degranulation, PMN influx, and enterocyte secretion are all abolished by neural blockade or depletion of substance P. How toxin A triggers the sensory component of the ENS remains unknown, but it is likely that toxin A-induced necrosis of enterocytes exposes afferent neurons to the noxious milieu of the intestinal contents.

## CLINICAL SIGNS AND DIAGNOSIS

Equine intestinal clostridiosis is clinically similar to other forms of acute enterocolitis in horses.<sup>90,95</sup> Although the clinical course is usually acute, peracute colitis with rapid death may occur. Occasionally, a milder, more prolonged clinical course is seen. Fever, anorexia, and depression may be observed before the onset of gastrointestinal signs, but the absence of prodromal signs is more common. Signs of endotoxemia and shock may accompany acute signs of colic and severe, dehydrating diarrhea. Diarrhea may not be profuse but is usually dark and foul. Like the clinical signs, hematologic and serum biochemical abnormalities are similar to those associated with other forms of enterocolitis and reflect fluid, protein, and electrolyte loss and systemic inflammation resulting from endotoxemia. Neutropenia, leukopenia, and hemoconcentration are common. Hypoproteinemia may be profound. Hyponatremia, hypokalemia, hypochloremia, hypocalcemia, and a mixed prerenal-renal azotemia are often noted, as well as metabolic acidosis and coagulopathies. Serum concentrations of hepatocellular enzymes, such as sorbitol dehydrogenase, may be elevated, and liver function may be reduced.

Preliminary diagnosis of equine intestinal clostridiosis caused by *C. perfringens* is based on the isolation of greater than 100 colony-forming units (CFU) of *C. perfringens* type A per gram of feces from patients with diarrhea and signs suggestive of toxemia.<sup>90,114</sup> Similar criteria are used to screen human patients for *C. perfringens* type A infection. Normal horses shed less than 100 CFU/g of feces, and usually horses with intestinal clostridiosis shed greater than 10<sup>6</sup> CFU/g.<sup>90,114</sup> However, identification of high numbers of *Clostridium* organisms in the feces does not prove infection. Detection of *C. perfringens* toxins in feces or intestinal contents in horses with high numbers of fecal CFU and clinical signs of enterocolitis is more conclusive evidence of an enterotoxigenic infection than that based on culture alone.<sup>95</sup> Immunoassays are available that are primarily designed to detect *C. perfringens* enterotoxin.<sup>95</sup> However, the reliability (specificity) of some immunoassays for diagnosis of *C. perfringens* infection has come into question. Recently, PCR multiplex and gene probe assays have been developed for detection of the major lethal toxins in bacterial isolates or fecal samples to determine the pattern of toxin production and are currently the preferred methods of detection.<sup>115-117</sup>

Like *C. perfringens*, diagnosis of *C. difficile* infection depends on culture of the organism from feces and identification of toxins in the feces. Bacterial culture of *C. difficile* may be difficult, and therefore it is an insensitive diagnostic test in horses.<sup>118,119</sup> Enrichment techniques and culture of multiple fecal samples may be required.<sup>119,120</sup> Detection of toxin A or B (or both) in feces by cell cytotoxicity assay or immunoassay is the preferred test for diagnosis of *C. difficile* infection in humans.<sup>95</sup> These tests are more sensitive than bacterial culture for identifying *C. difficile* infection in adult horses.<sup>118,119</sup> Sensitive PCR methods may also be used to identify genes for toxins A and B in fecal samples from diarrheic horses.<sup>95</sup>

## PROLIFERATIVE ENTEROPATHY

### PATHOGENESIS

Proliferative enteropathy is a chronic hyperplastic disorder of the small intestine that has been described in a wide variety of mammalian and avian species.<sup>121,122</sup> The only etiologic agent identified to date that induces PE is the obligate intracellular

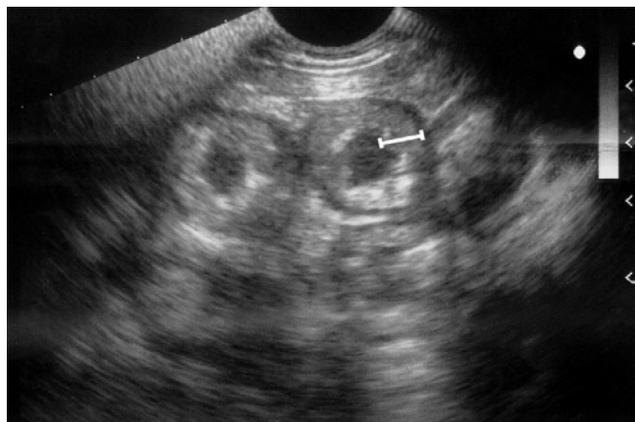

pathogen *Lawsonia intracellularis*.<sup>122,123</sup> The pig is the most frequently naturally affected species. However, reports of equine PE associated with *L. intracellularis* have increased in recent years.<sup>124-127</sup> The relatedness of the strains of *L. intracellularis* causing PE in pigs and horses or even among other affected species is not known. There appears to be no host restriction because hamsters and other rodents can be infected with porcine strains of *L. intracellularis*. Before 2000 there were sporadic reports of PE in the literature describing isolated cases in horses.<sup>125-127</sup> Since 2000 outbreaks on breeding farms have been described in Canada and anecdotally reported in the U.S.<sup>128</sup>

Although the epidemiology of PE is not known specifically for horses, in other species the mode of transmission is fecal-oral, and large numbers of organisms can be shed in feces of infected animals.<sup>122</sup> Affected animals shedding the organism in the feces serve as a source of infection for herd mates. It is possible that nonequine species serve as reservoirs contributing to outbreaks on horse farms. Factors that increase the risk of PE in pigs include overcrowding, ration changes, transport, and weaning.<sup>122,123</sup> Like pigs, horses are affected as weanlings. Factors associated with weaning and other stresses may affect immunity and increase susceptibility to infection. The incubation period is 2 to 3 weeks in nonequine species and is presumed to be similar in horses.

Experimental *L. intracellularis* infection produces characteristic pathologic lesions in pigs and hamsters that are identical to lesions in horses with PE.<sup>122,123</sup> A profound hyperplasia of the mucosa associated with proliferation of crypt epithelium and crypt hyperplasia is induced locally in infected islands of tissue that eventually extend to the entire distal jejunum and ileum. *L. intracellularis* preferentially infects proliferating cells, thus the tropism for the crypt epithelium. Infected cells proliferate far more rapidly than uninfected cells, suggesting that *L. intracellularis* directly induces the proliferative response. However, the molecular basis for enhanced proliferation is not known. *L. intracellularis* penetrates epithelial cells in a membrane-bound vesicle but eventually escapes the vacuole and is found free in the cytoplasm, concentrated at the apical pole of the cell.

The gross pathologic lesions of equine PE are quite characteristic.<sup>124-127</sup> Lesions may be segmental and are most commonly found in the ileum and terminal jejunum in horses. However, the duodenum may also be affected. Severe mucosal hypertrophy is often observed but may wane during the chronic stages of the disease. The mucosa may become corrugated with focal erosions or ulcers. Submucosal edema is often easily identified on cut sections of affected segments. Moderate to severe crypt hyperplasia with atrophy of intestinal villi is a consistent feature. Hyperplastic crypts are branched and may herniate into the submucosa. Necrosis, edema of the submucosal and lamina propria, hemorrhage, mononuclear inflammation, and muscular hypertrophy have been reported in affected intestinal segments but are not consistent. Special stains such as silver stain are required to detect intracellular organisms. The organisms are curved or comma-shaped rods found clustered in the apical cytoplasm of hyperplastic crypt epithelium.

The proliferative response of the intestinal mucosa alters absorption of nutrients and fluid secretion by disrupting the architecture of the villi and by altering the maturation of epithelial cells into absorptive cells, accounting for the secretory diarrhea and often severe weight loss.<sup>121,123</sup> The combined effects of the inflammatory response and malabsorption

**FIGURE 15-22** Ultrasonogram of the small intestine in a weanling foal with weight loss, diarrhea, and hypoproteinemia. Note the extreme mural thickening of the small intestine (bar) typical of proliferative enteropathy.

may account for the clinically observed protein-losing enteropathy.

#### CLINICAL SIGNS AND DIAGNOSIS

Weanling foals 4 to 6 months of age are most commonly affected.<sup>124-127</sup> The clinical signs of PE include ill thrift, weight loss, peripheral edema, diarrhea, and colic.<sup>124-127</sup> The diarrhea is usually in the form of soft feces but may be profuse and watery. Some foals with mild diarrhea have black, tarry feces. Secondary complications such as gastric ulceration, bronchopneumonia, and parasitism may occur concurrently with the PE. Clinicopathologic features include mild to moderate anemia, moderate to severe hypoalbuminemia (often <2 g/dl), hypoglobulinemia, neutrophilic leukocytosis, and hyperfibrinogenemia. Creatine kinase activities may be elevated in affected foals. Prerenal azotemia and electrolyte imbalances such as hyponatremia may be associated with diarrhea. PF analysis is usually unremarkable. Ultrasonographic examination of the small intestine often reveals marked thickening of the intestinal wall (Figure 15-22). Intestinal edema may be evident as a hypoechoic appearance to one or more layers of the intestinal wall.

Methods for antemortem diagnosis include serologic analysis of *L. intracellularis* antibodies and PCR analysis of feces.<sup>124</sup> Serologic analysis using an indirect immunofluorescent antibody test may be the most useful single test available. The PCR test is very specific, but the sensitivity may be low as a result of sporadic shedding of organisms at the time clinical signs are evident. By the time clinical signs appear, 90% of pigs are serologically positive for anti-*L. intracellularis* IgG.<sup>129</sup> In contrast, only 37% of pigs had positive fecal PCR tests.<sup>129</sup> Of the seven foals tested in an outbreak of equine PE,<sup>124</sup> four foals with confirmed disease and three with suspected PE had serologic titers against *L. intracellularis* of 1:30 or greater. In contrast, serum samples collected from 72 foals before the outbreak were negative for *L. intracellularis* antibodies. Fecal PCR for *L. intracellularis* was positive in 6 of 18 foals tested, and half of the serologically positive foals had negative fecal PCR tests. Many clinicians combine serologic analysis with fecal PCR testing to increase the sensitivity and specificity of these diagnostic methods. Isolation and culture of the organism require cell culture techniques that are not widely available. Thus no

practical method for culturing the organism from feces or tissues is available for clinical use.

Definitive diagnosis requires histopathologic examination of affected tissues.<sup>121</sup> Diagnosis is based on typical histopathologic findings of mucosal hypertrophy and submucosal edema and identification of small, curved, rod-shaped intracellular bacteria at the apical pole of epithelial cells in affected segments of intestine. Special stains such as Warthin-Starry silver stain are required to detect the bacteria in histopathologic specimens. PCR analysis of affected intestinal tissue is a very specific test for the presence of *L. intracellularis* and, unlike fecal PCR analysis, appears to be quite sensitive.<sup>130</sup>

## STRONGYLOSIS

### PATHOGENESIS

Strongyle infections in horses are caused by two groups of nematodes: large and small strongyles (see the section on cyathostomiasis). Large strongyles that are pathogenic in horses include *Strongylus vulgaris*, *Strongylus edentatus*, and *Strongylus equinus*. Of these species *S. vulgaris* is by far the most important cause of disease in the large intestine and in fact is the most pathogenic parasitic infection in horses.<sup>131</sup> *S. vulgaris* infection in horses is manifested clinically by two forms, causing acute and chronic disease.<sup>131</sup> The age and resistance of the host, the infective dose, and the size and function of the affected arteries influence the type and degree of disease that occurs. Sudden ingestion of large numbers of infective larvae by a naive host causes acute strongylosis, whereas ingestion of fewer infective larvae over a long period of time by an older, more resistant host causes chronic strongylosis. Acute strongylosis is more likely to cause colic than diarrhea and may be rapidly fatal. Chronic strongylosis tends to cause debilitation and signs of colic but may also cause diarrhea.

Diarrhea associated with acute strongylosis occurs within several days of infection and is likely to be caused by migration of the larvae through the intestinal wall. Fourth-stage larvae migrate through the mucosa and submucosa into the arterioles of the intestine, causing mural edema, hemorrhage, and infiltration of inflammatory cells.<sup>131,132</sup> Increased secretion and decreased absorption of fluid and electrolytes, stimulated by inflammatory mediators such as prostaglandins and histamine, may play a role in the diarrhea induced by *S. vulgaris*. Interstitial edema and damage to the interstitial matrix and mucosa may occur as a result of inflammation and migration of the parasites, causing increased secretion of fluid and albumin loss. Abnormal gastrointestinal motility may also play a role in the development of diarrhea. Migration of larvae through the intestinal wall early in the course of infection affects myoelectrical activity and motility in the large intestine and may affect retention of ingesta and absorption of fluid.<sup>133,134</sup> The cause of death in acute strongylosis has not been addressed, but it may be related to massive migration through the vasculature, causing thrombosis with ischemia and infarction of the intestine.

Chronic strongylosis causes typical verminous arteritis and is more commonly associated with natural infections in horses than acute strongylosis.<sup>131</sup> Lesions of the large intestinal vasculature caused by migration of larvae through the intima are characterized by thrombus formation, narrowing of the arterial lumen, fibrosis, and thickening of the arterial wall.<sup>131,132</sup> Embolization may occur, causing acute segmental infarction of the large intestine, but more commonly, reduced

blood flow without embolization causes ischemia and occasionally infarction.<sup>132,135</sup> Postmortem examination of horses with colonic infarction failed to reveal embolization as the cause in the majority of cases.<sup>135</sup> Reduced blood flow in the tissues of the intestine usually results from narrowing of the arterial lumen by the thrombus and formation of microthrombi at sites independent of the parasites. Release of vasoconstrictive inflammatory mediators, such as leukotrienes, from platelets, neutrophils, and eosinophils, as well as elaboration of parasitic antigens or toxins, may cause vasoconstriction and ischemia.<sup>136</sup> Horses with experimental strongylosis had a 50% reduction of blood flow in the colonic vasculature.<sup>137</sup>

Clearly, reduced blood flow is an important effect of chronic strongylosis, but the relationship between blood flow and diarrhea is unclear. Disrupted motility resulting from ischemia may lead to diarrhea by reducing the retention of ingesta and absorption of fluid. Acute infarction and mucosal ulceration cause severe, chronic diarrhea in naturally infected horses.<sup>138</sup> Release of inflammatory mediators, such as prostaglandins, histamine, and kinins, from inflammatory cells associated with thrombi and inflamed intestine may also affect secretion, absorption, and motility, leading to diarrhea.

### CLINICAL SIGNS AND DIAGNOSIS

The clinical signs of acute strongylosis caused by *S. vulgaris* infection include depression, moderate to severe colic, and fever.<sup>139</sup> Diarrhea is less often a feature of acute strongylosis than colic.<sup>131</sup> Most cases of acute strongylosis occur in young naive horses that are introduced to an infested environment or are inoculated experimentally with infective larvae. This form of strongylosis is not often recognized naturally. Chronic strongylosis, however, is most commonly observed as a natural syndrome. Weight loss or poor weight gain; chronic, intermittent colic; fever; poor appetite; and diarrhea are frequently observed.<sup>131,132</sup> Diarrhea may be profuse and watery, or the feces may be soft but of normal volume. Transrectal palpation may reveal thickening and fremitus in the cranial mesenteric artery. Young horses are most commonly affected, but older horses may also be affected. Horses with acute infarction or large intestinal ulceration secondary to chronic strongylosis may have signs of severe abdominal pain, sepsis, and endotoxemia, and profuse, watery diarrhea is common.

Hematologic abnormalities associated with strongylosis include neutrophilic leukocytosis and eosinophilia.<sup>139-141</sup> Neutrophilia appears to be an early event during the course of the disease, and eosinophilia tends to appear later.<sup>139,141</sup> Hyperfibrinogenemia may also occur, especially later in the course of the disease. Serum  $\alpha$ - and  $\beta$ -globulin and IgG(T) concentrations are characteristically elevated.<sup>140-142</sup> Horses with chronic ulcerative colitis secondary to strongylosis may develop severe hypoalbuminemia.<sup>138</sup> PF analysis may reveal an elevated protein concentration and eosinophilia.<sup>140,141</sup> Tentative diagnosis is based on clinical signs, hematologic abnormalities, and PF analysis. Elevated serum  $\alpha$ - and  $\beta$ -globulin concentrations and IgG(T) concentration support the diagnosis.<sup>142</sup> Fecal analysis may reveal strongyle eggs, but fecal egg counts are often unreliable because nonpatent larvae cause the disease.

### PREVENTION

Appropriate preventive measures are important in controlling this disease, including such management procedures as preventing overcrowding, reducing exposure of susceptible individuals, and instituting proper deworming schedules. Ivermectin

is the preferred anthelmintic used to control strongylosis in horses. Monitoring fecal egg counts as a means of evaluating the efficacy of parasite control measures is recommended.

## CYATHOSTOMIASIS

### PATHOGENESIS

Infection with small strongyles (cyathostomiasis) is well recognized as a cause of diarrhea and large intestinal disease in horses of all ages.<sup>143-148</sup> Clinical disease is caused by intramural larval stages of more than 50 species of small strongyles (cyathostomes). The cyathostome life cycle requires migration by fourth-stage larvae through the mucosa of the large intestine and may include a period of hypobiosis, during which the larvae remain encysted within the mucosal layer of the large intestine.<sup>143</sup> After a period of hypobiosis, the larvae emerge in response to a largely unknown stimulus. Most cases occur when larval emergence takes place, classically in the late winter and spring in the northern temperate zones and in the late fall or winter months in the southeastern U.S. and subtropical regions.<sup>143</sup> Sudden emergence of encysted larvae causes mucosal injury, ulceration, and an inflammatory reaction that are largely responsible for the clinical disease.<sup>143,149</sup> However, migration of the larvae as they penetrate the mucosa affects motility patterns and can cause inflammation that may contribute to diarrhea.<sup>149</sup> Chronic, eosinophilic, granulomatous colitis and diarrhea with histopathologic evidence of hypobiotic cyathostome larvae in the large intestine has been reported in two horses during a period in which emergence of larvae would not be expected to occur (early winter).<sup>143</sup>

Natural emergence of cyathostome larvae causes fibrinous inflammation of the large intestine, focal necrosis, mural hemorrhage, and ulceration of the large intestinal mucosa, which may even result in bleeding into the lumen.<sup>132,149</sup> Mild to moderate eosinophilic and mononuclear inflammation of the lamina propria is seen.<sup>132,149</sup> Moderate to severe interstitial edema is frequently observed.<sup>132,149</sup> Colonic inflammation and interstitial edema may contribute to diarrhea, in conjunction with the loss of the mucosal barrier, by causing increased active and passive secretion of fluid, electrolytes, and protein. Protein loss is often significant, resulting in profound hypoalbuminemia and interstitial edema of skin and other organs. Chronic granulomatous colitis has been reported to occur in response to encysted larvae and may cause diarrhea by increased secretion secondary to granulomatous inflammation or disruption of the interstitium by granulomatous infiltration. Administration of an anthelmintic to horses with a heavy load of encysted larvae may also cause rapid larval death and acute and often severe inflammation similar to natural emergence.

### CLINICAL SIGNS AND DIAGNOSIS

Cyathostomiasis may be the most commonly identified cause of chronic diarrhea in the horse.<sup>150-152</sup> However, an acute syndrome has also been associated with cyathostomiasis.<sup>148</sup> Clinical signs of cyathostomiasis characterized by moderate to severe weight loss or poor weight gain, ill thrift, ventral edema, intermittent fever, and intermittent mild colic.<sup>143-148,152</sup> Acute onset of diarrhea is typically profuse and progresses to chronic diarrhea that is often mild and the consistency of bovine feces and may be intermittent.<sup>143-148,152</sup> Appetite is usually normal, but some affected horses have a ravenous appetite. Transrectal palpation usually does not reveal any abnormalities. Horses of

any age may be affected, and clinical signs are more common during periods of emergence of larvae, corresponding to late winter and spring in northern temperate zones. The deworming history may appear to be adequate.

Neutrophilic leukocytosis is typically evident, but the white blood cell count may be normal.<sup>143-148</sup> Profound hypoalbuminemia is a characteristic feature of cyathostomiasis, manifested clinically by ventral edema. Plasma  $\alpha$ - and  $\beta$ -globulin concentrations may be elevated, which can result in a normal total plasma protein concentration in spite of hypoalbuminemia.<sup>144-146</sup> The serum IgG(T) concentration, however, has been reported to be normal, which may help distinguish cyathostomiasis from *S. vulgaris* infection.<sup>143,145,146</sup> PF analysis does not usually reveal any abnormalities, in contrast to horses with *S. vulgaris* infection. Fecal analysis may be unrewarding because the infection is often not patent when clinical signs are apparent. Measurement of plasma fructosamine may provide a measure of protein catabolism or protein loss in the absence of hypoalbuminemia.<sup>152,153</sup> Plasma fructosamine concentrations are significantly lower in horses with experimental cyathostomiasis than in normal controls,<sup>152,153</sup> suggesting that this test may be a useful diagnostic tool. However, the test has not yet been validated in naturally occurring cases, and neither the specificity nor the sensitivity is known. Rectal scrapings or rectal mucosal biopsies may reveal evidence of cyathostome larvae.<sup>143,146</sup> Definitive diagnosis usually requires microscopic examination of biopsy specimens of the cecum and ascending colon, collected by laparotomy. Examination of biopsy specimens collected from the small intestine is recommended to rule out other causes of weight loss and diarrhea. Appropriate diagnostic tests, such as culture of feces for pathogenic bacteria, should be included in the workup to further rule out other causes.

### PREVENTION

Preventive measures are appropriate for other horses on the premises known to have a problem with cyathostomiasis. These include frequent deworming (every 6 weeks) during times of high infectivity (spring and summer in the north and fall, winter, and early spring in the south) to eliminate parasites before they become patent.<sup>143</sup> Because of high levels of resistance to benzimidazoles, avermectins (ivermectin or moxidectin) are often the drugs of choice for cyathostome control.<sup>154-156</sup> Resistance to ivermectin has been demonstrated, but the prevalence of ivermectin resistance appears to remain low.<sup>154</sup> Although daily pyrantel pamoate administration has also been reported to effectively reduce worm burdens and pasture infectivity in young and mature horses,<sup>157</sup> cyathostome resistance has been reported and is a concern for the use of this drug as a routine preventive anthelmintic.<sup>155,158,159</sup> Because of the rapid emergence of resistant strains to even ivermectin, targeted treatment, based on fecal egg counts and careful monitoring for the development of resistance to any anthelmintics used for cyathostome control, is warranted.<sup>159</sup>

## ☞ TOXICOLOGIC DISEASES

### ANTIBIOTIC-ASSOCIATED DIARRHEA

#### PATHOGENESIS

Antibiotic-associated diarrhea has been reported in many species, including horses.<sup>160</sup> Certain antibiotics, such as trimethoprim-sulfonamide combinations, erythromycin, penicillins, tetracyclines, clindamycin, and lincomycin, are

associated with naturally occurring and experimental enterocolitis syndromes in horses.<sup>91,160-163</sup> In some cases, such as those seen with trimethoprim-sulfonamide combinations, the geographical incidence of antibiotic-associated diarrhea appears to differ markedly.

*C. perfringens*, *C. difficile*, and serovars of *S. enterica* are apparently the most common causes of antibiotic-associated diarrhea in horses. Outbreaks of *C. difficile* have been reported in hospitalized horses being treated with antibiotics.<sup>93,97</sup> In Sweden accidental erythromycin ingestion has been associated with *C. difficile* enterocolitis in mares in which their foals were being treated for *R. equi*.<sup>100,162,164</sup> Tetracycline administration has been associated with an increase in the numbers of gram negative enteric bacteria and *C. perfringens* in the feces of horses as well as reactivation of salmonellosis and prolongation of fecal shedding of serovars of *S. enterica*.<sup>90,165</sup>

The most common mechanism by which antibiotics cause diarrhea is disruption of the gastrointestinal flora. The normal large intestinal flora, composed of mainly obligate anaerobes and streptococci, protects the host from pathogenic bacteria by colonization resistance.<sup>20</sup> Ecologic factors play an important role in colonization resistance. For example, surface bacteria in the large intestine interact with receptors on the mucosal cells, facilitating adherence to the mucosa.<sup>20,166</sup> In doing so, the normal organisms compete more successfully for this important niche. Competition for space and nutrients is an important means of preventing colonization and proliferation of pathogenic bacteria.<sup>19,20,166</sup> In addition, anaerobic bacteria produce short-chain fatty acids and other metabolites that are toxic to facultative anaerobic bacteria, especially in the conditions of the large intestine.<sup>19,20,166</sup> Organisms of the normal flora produce bacteriocins that inhibit growth of potential pathogens.<sup>19</sup>

Antibiotics that deplete the population of obligate anaerobes and streptococci efficiently decrease colonization resistance.<sup>19</sup> Production of fatty acids is diminished, and competition for space and nutrients is reduced. As a result, gram negative enteric bacteria, such as *S. enterica var typhimurim*, are able to proliferate. In addition, pathogenic anaerobes normally found in low numbers can proliferate. Antibiotic-resistant strains of bacteria, especially gram negative enteric bacteria and possibly clostridia, may be selected by antibiotic administration, allowing proliferation of pathogenic bacteria resistant to many antibiotics.<sup>167</sup> Obligate anaerobic commensal organisms, perhaps the most critical group of microbes for maintaining colonization resistance, are usually susceptible to macrolides, tetracyclines,  $\beta$ -lactams, and lincomamides, which may explain the high incidence of diarrhea associated with the administration of these antibiotics.<sup>95</sup>

In addition to reduction of colonization resistance, depletion of the normal anaerobic microbial population in the intestine decreases carbohydrate fermentation and production of SCFAs, which contributes to the pathogenesis of antibiotic-associated diarrhea by decreasing absorption of sodium and water by the colonic mucosa.<sup>168</sup> Ampicillin decreases colonic fermentation of carbohydrates in humans.<sup>169</sup> Human patients with antibiotic-associated diarrhea have markedly impaired colonic fermentation and very low production of SCFAs.<sup>170</sup> Erythromycin, ampicillin, or metronidazole treatment is associated with decreased production of SCFA in patients with and without diarrhea.<sup>170</sup> Absorption of sodium and water is stimulated by absorption of SCFA in the equine colon, suggesting that reduction of colonic SCFA content by antibiotic-induced

depletion of anaerobic flora has similar effects in horses as in humans.<sup>168</sup>

Broad spectrum antibiotics exert a more profound effect on the gastrointestinal flora than narrow-spectrum antibiotics.<sup>171</sup> Antibiotics administered orally, especially those that are poorly absorbed, are more likely to cause diarrhea than parenterally administered antibiotics.<sup>171</sup> For instance, clindamycin is less likely to cause diarrhea in humans when administered intravenously than when administered orally.<sup>171</sup> Antibiotics with extensive enterohepatic circulation, such as tetracyclines and erythromycin, are excreted in high concentrations in the bile and are more commonly associated with diarrhea than antibiotics that do not undergo enterohepatic circulation.<sup>171</sup>

Antibiotics may cause diarrhea by other means than by disrupting the normal flora. Direct toxic effects may play a role in producing irritation, increasing secretion, and disrupting motility patterns. Tetracyclines are irritating to the gastrointestinal mucosa and may cause inflammation and increase secretion.<sup>171</sup> Erythromycin has been shown to interact with smooth muscle cells, stimulating gastrointestinal motility.<sup>171,172</sup> Normal peristalsis plays an important role in suppressing the population size of potentially pathogenic bacteria. Normally, bacteria that are prevented from adhering to the mucosa by colonization resistance are swept aborally by peristalsis and excreted in the feces. Disruption of normal motility patterns may prevent clearance of pathogenic bacteria, contributing to the colonization of mucosal surfaces.

## CLINICAL SIGNS AND DIAGNOSIS

Diarrhea induced by antibiotics usually occurs within 7 days of initiation of antibiotic administration but may occur several days after cessation of antibiotic treatment. The clinical syndrome of antibiotic-associated diarrhea varies from mild diarrhea to fulminant enterocolitis with severe diarrhea. Mild diarrhea is common, especially in foals receiving erythromycin, trimethoprim-sulfa combinations, or rifampin<sup>162,173</sup> and are usually not clinically significant. However, acute, severe enterocolitis can occur in horses of all ages receiving antibiotics and can be life threatening. Clinical signs are identical to those resulting from other causes of acute enterocolitis. Severe, dehydrating diarrhea; endotoxemia; sepsis; and shock may occur. Hemoconcentration, neutropenia, hypoproteinemia, and electrolyte and acid-base imbalances are common. Severe hyponatremia may occur in foals with antibiotic-associated diarrhea, especially if trimethoprim-sulfa and rifampin combinations are the cause.<sup>173</sup> More detailed descriptions of the clinical and laboratory findings were given earlier. Diagnosis is presumptive because definitive diagnosis of antibiotic-associated diarrhea is impossible. Fecal culture or PCR testing may reveal *S. enterica* or *Clostridium* spp. infection.

## NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

### PATHOGENESIS

Toxicity resulting from NSAID administration has been well documented in several species, including horses, and is discussed in Chapter 4.<sup>174-180</sup> In horses and humans NSAID toxicity is manifested by renal and gastrointestinal disease. Foals are considered to be more susceptible than adult horses to gastrointestinal disease secondary to NSAID administration, and ponies may be more susceptible than horses. NSAID toxicity

varies primarily as a result of properties that influence distribution to sensitive tissues and relative selectivity for COX-1 or COX-2. All nonselective NSAIDs are capable of inducing gastrointestinal and renal damage at toxic concentrations. Aspirin has been suggested to be more toxic than other NSAIDs because it irreversibly inactivates COX by acetylation, whereas other NSAIDs reversibly inhibit COX.<sup>174</sup> Phenylbutazone is the drug most commonly reported to cause gastrointestinal toxicity in horses, perhaps because of its widespread usage by veterinarians and horse owners or perhaps because of bona fide differences in toxicity in horses compared with other nonselective NSAIDs. Acute phenylbutazone toxicity in horses resulting from overdose is characterized by mucosal ulceration throughout the gastrointestinal tract, oral ulceration, renal papillary necrosis, vasculopathy, thrombosis, and protein-losing enteropathy with hypoalbuminemia.<sup>176-178</sup> COX-2-selective NSAIDs appear to be much less toxic in the equine gastrointestinal tract.<sup>181,182</sup> The focus of this discussion is on the toxic effects of NSAIDs on the large intestine, but this necessarily includes elements of upper gastrointestinal and renal disease.

Horses with large intestinal disease resulting from NSAID toxicity generally are receiving inappropriately large doses or have underlying disorders that predispose the large intestine to the toxic effects of NSAIDs even at appropriate dosages. The dosage regimen recommended for phenylbutazone (4.4 mg/kg every 12 hours for 1 day, and then 2.2 mg/kg every 12 hours) is considered safe. Experimental studies in horses, however, have shown toxicity to occur when amounts exceeding the recommended dosage (6.6 mg/kg/day) is administered for several days.<sup>176,177</sup> Most reported cases of phenylbutazone toxicosis occurred in horses receiving higher-than-recommended dosages.<sup>178,180,183</sup> Regardless, administration of phenylbutazone at the recommended dosage has been reported to cause a significant decrease in plasma protein concentration and gastrointestinal disease.<sup>177,184</sup> Moreover, signs of NSAID toxicity have been reported in normovolemic horses treated with appropriate doses of phenylbutazone.<sup>184,185</sup> Dehydration, sepsis, endotoxemia, and other conditions that alter hemodynamic homeostasis exacerbate renal and gastrointestinal toxicity of NSAIDs.<sup>174</sup> Underlying inflammation of the intestinal tissues may increase the likelihood of gastrointestinal ulceration resulting from NSAIDs.

Gastrointestinal disease induced by NSAIDs is manifested by mucosal ulceration, inflammation, bleeding, and protein-losing enteropathy.<sup>176,177,180,184</sup> In addition to direct effects on the mucosal barrier, NSAID administration causes an acute relapse of preexisting colonic inflammatory disease and worsens colonic inflammation in humans with inflammatory bowel disease.<sup>174,186,187</sup>

It is not clear whether the aforementioned NSAID effects occur in horses. The mechanism by which NSAIDs induce mucosal damage is probably multifactorial. Direct irritation may play a role in oral and gastric irritation and ulceration; however, parenteral administration of NSAIDs produces oral and gastric ulceration as well. Inhibition of prostaglandin synthesis by inhibition of both COX-1 and COX-2 appears to be the most important mechanism of mucosal injury. Prostaglandins, particularly PGE<sub>2</sub> and PGI<sub>2</sub>, are critical for mucosal health and repair after injury.<sup>188,189</sup> PGE<sub>2</sub> increases mucosal blood flow; increases secretion of mucus, water, and bicarbonate; increases mucosal cell turnover rate and migration; stimulates adenyl cyclase activity; and exerts other protective effects in

the gastric mucosa of several species.<sup>174,188,189</sup> Perhaps most important, PGE<sub>2</sub> and PGI<sub>2</sub> have roles in maintaining epithelial tight junction integrity, which is indispensable for mucosal barrier function and repair after mucosal injury.<sup>188</sup>

In spite of the overwhelming amount of information about the role of prostaglandins in maintaining the mucosal barrier in other species and clear clinical and experimental evidence that NSAIDs injure the equine colonic mucosa, the role of prostaglandins in mucosal protection in the equine colon is not yet well defined. Inhibition of COX-1 and COX-2 in equine colonic mucosa with flunixin meglumine results in reduced electrical resistance of the mucosa and increased permeability to macromolecules *in vitro*,<sup>190</sup> suggesting that flunixin treatment disrupts the epithelial tight junctions in the equine colon. This was correlated with a profound inhibition of PGE<sub>2</sub> and PGI<sub>2</sub> concentrations in the treated tissues. Administration of a PGE<sub>2</sub> analog prevents the gastrointestinal manifestations of phenylbutazone-toxicosis in ponies.<sup>177</sup>

Recent development of NSAIDs that specifically inhibit COX-2 have markedly reduced the frequency and severity of gastrointestinal side effects in humans taking NSAIDs for chronic musculoskeletal conditions.<sup>191</sup> COX-2-specific NSAIDs such as firocoxib hold promise for use in horses to treat arthritis<sup>192</sup> and other conditions, with reduced incidence of toxicity. For example, the relatively COX-2-specific inhibitors meloxicam and firocoxib are less harmful to equine intestinal mucosa than flunixin meglumine *in vitro*.<sup>181,182</sup> Moreover, COX-2-selective inhibitors are significantly more permissive than flunixin for recovery of the mucosa in equine ischemic-injured intestinal tissues; in fact, recovery is no different than that for control tissues.<sup>181,182</sup>

NSAID-induced mucosal injury is associated with a marked inflammatory response to microbial products exposed to the lamina propria.<sup>193</sup> This inflammation exacerbates mucosal dysfunction and injury associated with NSAID toxicity. For example, depletion of neutrophils or blockade of neutrophil influx into gastrointestinal tissues or inhibition of neutrophil activation and release of toxic products prevents many of the pathophysiologic effects of NSAID toxicity in the gastrointestinal tract.<sup>194-197</sup> The inflammatory response alone may result in moderate to severe gastrointestinal ulceration, mural vascular thrombosis and edema, fluid secretion, protein-losing enteropathy, and mucosal hemorrhage.

## CLINICAL SIGNS AND DIAGNOSIS

NSAID colitis manifests as two clinical syndromes: right dorsal ulcerative colitis (RDUC) and generalized NSAID toxicity. As its name implies, RDUC is a disorder isolated to the right dorsal segment of the large intestine.<sup>179,180,185</sup> The most prominent clinical signs of RDUC are anorexia, lethargy, and colic. Anorexia, depression, diarrhea, fever, and signs of endotoxemia may also be features. If RDUC is chronic, weight loss, intermittent colic, lethargy, anorexia, and ventral edema are common clinical signs with soft and unformed feces. Ulceration of the right dorsal colonic mucosa results in protein-losing enteropathy and significant hypoproteinemia attributable mainly to hypoalbuminemia. Hypoproteinemia may be one of the earliest clinical manifestations of RDUC and can be sufficiently severe to cause peripheral (usually ventral) edema. In some cases, dehydration, electrolyte abnormalities, neutropenia or anemia, azotemia, and biochemical abnormalities may be noted if the ulceration and diarrhea are severe or if systemic inflammation is present.

Clinical signs of generalized NSAID toxicity vary from mild diarrhea with no systemic signs to severe dehydrating diarrhea with anorexia, fever, depression, peripheral edema, oral ulceration, and colic.<sup>177,178,183</sup>

Clinical signs of systemic inflammation caused by endotoxemia may occur, manifested as poor peripheral perfusion, tachycardia and tachypnea, weakness, trembling, and cyanotic or hyperemic oral mucous membranes. Hematuria or oliguria may be present with renal involvement. Complications associated with other forms of severe enterocolitis, such as laminitis, thrombophlebitis, and severe weight loss, may occur.

Although phenylbutazone has been associated specifically with bone marrow depression resulting in abnormalities in one or more blood cell lines,<sup>198</sup> hematologic abnormalities of generalized NSAID toxicity are usually nonspecific and include neutropenia with a left shift or leukocytosis and hemoconcentration. Serum biochemical analysis is characterized by profound hypoproteinemia, hyponatremia, and metabolic acidosis.<sup>183,184</sup> Hypocalcemia, hypokalemia, hypochloremia, and elevated hepatocellular enzyme activities may also be seen. Hypoproteinemia may occur without signs of diarrhea. Azotemia may be prerenal as a result of dehydration, but it is frequently caused by renal failure that results from a combination of hemodynamic effects of NSAIDs and direct toxic renal injury. Urinalysis frequently reveals hematuria, proteinuria, cylindruria, and isosthenuria. Fecal occult blood is frequently detected.

Diagnosis of either form of NSAID colitis is often presumptive, with a history of overdose of NSAIDs being strong evidence of NSAID toxicity. But as discussed earlier, toxicity may occur with dosage regimens that are not considered inappropriate, particularly if the horse experiences a concurrent period of dehydration. Ultrasonographic examination of the right dorsal colon can be used to confirm a diagnosis of RDUC, but the sensitivity of this method appears to be low.<sup>199</sup> Ultrasonography (3.5-5 MHz transducer at the right twelfth through fifteenth intercostal spaces below the margin of the lung axial to the liver) may reveal a thickened right dorsal colon (>0.5 cm) and evidence of colonic edema in horses with RDUC.<sup>199,200</sup> Nuclear scintigraphy of horses after infusion with technetium-99–labeled white blood cells can be used to document inflammation of the right dorsal colon.<sup>201</sup> Laparotomy or laparoscopic examination of the right dorsal colon may be required for definitive diagnosis of RDUC. Other causes of enterocolitis, such as salmonellosis, Potomac horse fever, clostridiosis, and antibiotic-associated diarrhea, must be ruled out.

## CANTHARIDIN TOXICITY

### PATHOGENESIS

Cantharidin is the toxic substance found in beetles of the genus *Epicauta*, commonly known as *blister beetles*.<sup>202-204</sup> Ingestion of the beetles causes release of the toxin and absorption through the gastrointestinal tract. Transcutaneous absorption may occur but appears to be rare in horses.<sup>203</sup> Blister beetles feed on the flowers of alfalfa and may be incorporated into processed alfalfa hay if the hay is cut and processed simultaneously, as by crimping.<sup>202-204</sup> The beetles often swarm, and large numbers of beetles may be found in relatively small portions of hay. The lethal dose of cantharidin is less than 1 mg/kg, but the concentration of cantharidin varies among species of blister beetles and between sexes.<sup>202,203</sup> As many as

100 to as few as six beetles may be lethal. Usually, only one or a few horses fed contaminated hay will ingest beetles because the beetles are concentrated in a small portion of the hay. However, outbreaks involving many horses on a farm have occurred. Most cases have occurred in Texas and Oklahoma, but horses in other states may be affected as well, especially if hay is imported from states where blister beetles are common. Peak incidence is in late summer and fall.<sup>205</sup> The fatality rate may be 50% or greater,<sup>202,206</sup> but if the patient survives several days, recovery is probable.

Cantharidin is absorbed from the gastrointestinal tract and excreted by the kidneys. Cantharidin is a potent irritant, causing acantholysis and vesicle formation when applied topically.<sup>202,204,206</sup> The chemical is thought to disrupt oxidative metabolism in the mitochondria, causing mitochondrial swelling, plasma membrane damage, and changes in membrane permeability.<sup>202</sup> The mucosa of the gastrointestinal tract is most commonly affected in horses because they ingest the toxin. Cell swelling and necrosis occur, resulting in mucosal ulceration. Oral, esophageal, gastric, and small and large intestinal ulceration have been observed in natural and experimental cantharidiasis.<sup>202,204,206</sup> Severe fibrinous to pseudomembranous inflammation and submucosal edema of the intestine have also been reported. Diarrhea probably results from the severe ulceration and inflammation of the large intestine, causing increased secretion of water, electrolytes, and protein and decreased absorption of fluid. Large volumes of fluid and protein are lost in the gastrointestinal tract, causing hemoconcentration and profound hypoalbuminemia in some affected horses.<sup>202,203,206</sup>

Cystitis and myocarditis occur in natural and experimentally induced cases of cantharidin toxicity.<sup>202,204,206</sup> The toxin is excreted by the kidneys, and high concentrations of cantharidin in the urine induce cystitis. Occasionally, hemorrhagic cystitis may occur, resulting in hematuria or frank hemorrhage into the bladder.<sup>202</sup> The cause of myocarditis and myocardial necrosis is unknown but may be a direct effect of toxin on the myocardium. Increased plasma creatine kinase activity is often observed and has been postulated to arise from the damaged myocardium.<sup>202,203</sup> Affected horses have a characteristically stiff gait, but histopathologic evidence of skeletal muscle injury that explains the elevated plasma creatine kinase activity has not been observed.<sup>203</sup> The kidneys are often pale, swollen, and moist, with occasional infarcts.<sup>204</sup>

Hypocalcemia and hypomagnesemia are biochemical features of cantharidin toxicity in horses that have not been explained.<sup>202,203,206</sup> Hypocalcemia may result from hypoalbuminemia, but the ionized calcium concentration is often decreased, indicating that hypoalbuminemia is not responsible for the hypocalcemia.<sup>203</sup>

### CLINICAL SIGNS AND DIAGNOSIS

Cantharidin toxicity can cause a range of clinical signs, from mild depression and abdominal discomfort to fulminant signs of toxemia and rapid death, depending on the ingested dose of toxin.<sup>202,203,206</sup> Most commonly, clinical signs include depression, sweating, irritability, abdominal pain, elevated heart and respiratory rates, fever, polyuria, polydipsia, and profuse diarrhea.<sup>202,203,206</sup> Blood is rarely seen in the feces. Stranguria and pollakiuria are common.<sup>202</sup> Signs of hypocalcemia include synchronous diaphragmatic flutter and tremors. A stiff and stilted gait may be evident. Neurologic signs such as head

pressing, swaying, and disorientation may be noted.<sup>206</sup> Signs of systemic inflammation resulting from endotoxemia may be seen in severe cases. Some horses develop severe depression and toxemia and may die within hours of ingesting cantharidin without developing diarrhea.<sup>202,206</sup>

Hematologic abnormalities include hemoconcentration and neutrophilic leukocytosis.<sup>202,203</sup> Occasionally, neutropenia and leukopenia may accompany endotoxemia. Serum biochemical analysis usually reveals increased creatine kinase activity, hypocalcemia, and hypoalbuminemia.<sup>202,203</sup> Biochemical abnormalities include hypocalcemia (both ionized and total calcium concentrations), hypomagnesemia, and azotemia.<sup>202,203,206</sup> Urine specific gravity is characteristically in the hyposthenuric range.<sup>202,203</sup> Microscopic hematuria and mild proteinuria may be evident. Fecal occult blood is often present, but hematochezia is unusual.

A tentative diagnosis can be made on the basis of clinical signs and identification of blister beetles in the hay. Determining the species of the insects may be necessary to estimate the amount of cantharidin ingested. All species of *Epicauta* contain cantharidin, but some have small amounts. Definitive diagnosis requires the measurement of the cantharidin concentration in gastric or intestinal contents and urine.<sup>202,205</sup>

## ARSENIC TOXICOSIS

### PATHOGENESIS

Arsenic toxicosis is an unusual cause of diarrhea in horses, resulting from ingestion of arsenic-containing herbicides, insecticides, and other pest-control products contaminating water or roughage used as a food source.<sup>207</sup> The toxicity of arsenic depends on the valence of the element.<sup>207,208</sup> Arsenate may be reduced to arsenite in mammalian systems.<sup>208</sup> Arsenite is thought to be more toxic than arsenate and less rapidly excreted in urine.<sup>208</sup> Arsenate and arsenite uncouple oxidative phosphorylation, leading to breakdown of energy metabolism in the cells of many tissues.<sup>208</sup> Widespread cellular injury and death occur rapidly during acute arsenic toxicosis. Multiorgan failure is usually the result. In fact, cardiomyopathy and pulmonary disease are common causes of death in humans.<sup>209</sup> Damage to the large intestine is probably due in part to direct cellular toxicity and corrosion by the compound. However, vasculitis is a hallmark of the disease in humans and horses and is thought to be the most important mechanism of large intestinal disease in humans.<sup>207,210</sup> Acute hemorrhagic colitis is a feature of arsenic toxicosis, with severe mural edema and mucosal ulceration.<sup>207</sup> Profuse hemorrhagic diarrhea and abdominal pain result. Chronic arsenic toxicity can occur but appears to be rare in horses.

### CLINICAL SIGNS AND DIAGNOSIS

Depression, weakness, abdominal pain, hemorrhagic diarrhea, and shock are characteristic of acute arsenic toxicosis in horses.<sup>207</sup> Death may occur before diarrhea is evident. Initial clinical signs may be difficult to distinguish from other peracute forms of colitis and are related to endotoxic shock, metabolic disturbances, and dehydration. Later, cardiac arrhythmias, pulmonary edema, acute renal failure, and neurologic deficits (ataxia and stupor) may develop.<sup>207</sup> Anuria or polyuria may be observed. Hemolytic anemia caused by preferential binding of arsenic compounds to red blood cells is a feature of arsenic poisoning in humans.<sup>209</sup> Hematologic abnormalities resulting

from injury to bone marrow cells and ongoing hemolysis may be seen after the peracute stage. Leukopenia and thrombocytopenia have been described in human patients.<sup>209</sup> Serum biochemical analysis may reveal azotemia, hepatocellular enzyme activities higher than generally attributed to endotoxemia, and increased creatine kinase activity.<sup>207</sup> Urine specific gravity may be in the isosthenuric range, with hematuria, cylindruria, and proteinuria evident by urinalysis.

Diagnosis may be possible by measuring blood and urine arsenic concentration, but these tests may not be diagnostic. Postmortem diagnosis is confirmed by measuring arsenic concentrations in liver and kidney samples.<sup>207</sup> History of exposure and clinical signs remain the primary means of diagnosis.

## MISCELLANEOUS DISORDERS OF THE LARGE INTESTINE

### INTESTINAL ANAPHYLAXIS

#### PATHOGENESIS

Severe intestinal anaphylaxis is a syndrome in horses characterized by peracute, rapidly fatal colitis.<sup>211</sup> The severe syndrome is clinically and pathologically similar to other known causes of peracute colitis, such as salmonellosis, clostridiosis, and antibiotic-associated diarrhea. Some cases are less severe and manifest as mild to moderate diarrhea or colic (or both). The syndrome of intestinal anaphylaxis can be produced by either an IgE-mediated Type I hypersensitivity or an IgE-independent anaphylactoid reaction.<sup>212,213</sup> Intestinal anaphylaxis is usually induced by local gastrointestinal exposure to a food, environmental, drug, or other allergen<sup>212,214</sup> but may also occur with systemic exposure to an allergen.<sup>215-217</sup> Massive mast cell degranulation, secretion of inflammatory mediators, and activation of enteric neural reflexes in the intestine causes profound alterations in blood flow, increased vascular permeability and interstitial edema, recruitment of neutrophils, altered motility, mucosal injury, absorption of microbial products, and mucosal hypersecretion.<sup>218-222</sup> Systemic signs may be caused by the anaphylactic reaction or may be associated with systemic inflammation triggered by microbial products (endotoxin) absorbed through the injured and hyperpermeable mucosa.

Intestinal anaphylaxis in horses may be a peracute, fulminant enterocolitis with endotoxemia that may be fatal.<sup>211,223</sup> This form is characterized by severe intramural edema and hemorrhagic inflammation of the large intestine, often producing submucosal thickening on the order of many centimeters. Vascular thrombosis may be widespread, with mucosal and serosal petechia and ecchymoses. Less severe forms of intestinal anaphylaxis may manifest as patchy areas of intestinal edema and congestion.<sup>215</sup> Diarrhea results from intestinal inflammation initiated by the type I hypersensitivity response. Many of the mediators of type I hypersensitivity, such as histamine and 5-HT, have well-documented stimulatory effects on mucosal secretory activity, vascular and epithelial permeability, and motility<sup>218-220</sup> in the intestine. Systemic inflammation resulting from endotoxemia may be overwhelming once the mucosal barrier breaks down. Infarction of intestinal segments and other organs may result from intravascular coagulation. Ileus, abdominal distention, and moderate to severe abdominal pain may result from motility disturbances and infarction of the large intestine.

## CLINICAL SIGNS AND DIAGNOSIS

The clinical signs are similar to those described for other forms of peracute colitis. However, the severity may be variable, manifesting as colic or moderate diarrhea. Characteristically, severe shock, signs of systemic inflammation resulting from endotoxemia, and severe metabolic disturbances are observed.<sup>211,223</sup> Heart and respiratory rates may be markedly elevated, with other signs of cardiovascular collapse, such as weak and thready peripheral pulses and peripheral vasoconstriction. However, peripheral vasodilation may be seen later in the course of disease. Dark red, muddy, or cyanotic mucous membranes with a prolonged capillary refill time are consistent with sepsis. Borborygmi are usually absent, and abdominal tympany may be heard on percussion, secondary to ileus. Moderate to severe colic may accompany ileus. Severe diarrhea is possible, but death may occur before diarrhea is evident. Multiorgan failure resulting from DIC is not unusual. The rapid onset of weakness, staggering, and trembling commonly precedes death. The syndrome may cause death in 4 to 24 hours.

Hematologic abnormalities include severe neutropenia and leukopenia, thrombocytopenia, and hemoconcentration.<sup>211</sup> Serum biochemical alterations include hyponatremia, hypokalemia, hypocalcemia, and severe metabolic acidosis. Blood urea nitrogen and creatinine may be elevated from prerenal or renal azotemia. If acute renal failure occurs, hyperkalemia may result. Hepatocellular enzyme activity may be increased on account of endotoxemia. Severe coagulopathies are common, resulting in prolonged coagulation times, decreased antithrombin III activity, and increased plasma concentration of fibrin degradation products. Analysis of PF may be valuable because infarction of the large intestine is not unusual. Protein concentration and the white blood cell count may be elevated. Red blood cell counts are less likely to be elevated because infarction, rather than strangulation, of the intestine occurs.

Diagnosis is based on clinical signs, postmortem findings, and exclusion of other causes. Cultures and toxicologic analysis of fecal samples and gastrointestinal tissues fail to demonstrate a clear cause. Other diagnostic tests are also inconclusive. If an antigen is suspected as the trigger of the anaphylaxis, a Prausnitz-Kustner passive cutaneous anaphylaxis sensitization test can confirm the presence of antigen-specific IgE in the patient serum.<sup>215</sup>

## CARBOHYDRATE OVERLOAD

### PATHOGENESIS

Overeating of soluble carbohydrates, especially so-called hot grains such as corn, overwhelms the digestive capability of the small intestine, resulting in a high percentage of soluble carbohydrates entering the large intestine. The amount of soluble carbohydrates that will produce diarrhea varies according to the previous dietary history of the individual. Horses fed diets higher in soluble carbohydrates are more resistant to the deleterious effects of carbohydrate overload. Gradual accommodation to a diet high in carbohydrates can be accomplished over several weeks. However, horses fed an unusually large amount of grains or other form of soluble carbohydrates often develop diarrhea and may, depending on the amount ingested, develop severe colitis, systemic inflammation resulting from endotoxemia, metabolic acidosis, and laminitis.<sup>224-227</sup>

The pathogenesis of colitis from carbohydrate overload is primarily due to the toxic effects on the microbial flora in the large intestine.<sup>225</sup> A sudden delivery of soluble carbohydrates to the large intestine causes rapid fermentation by gram positive lactic acid-producing bacteria and a sudden increase in organic acid production.<sup>226</sup> The cecal pH level rapidly decreases, and the lactic acid concentration rapidly increases.<sup>226</sup> Rapid organic acid production overwhelms the buffering capacity of the large intestine, not only by directly depleting the buffers found in the contents but also by reducing the efficiency of buffer secretion. Bicarbonate secretion is linked to absorption of volatile fatty acids, which are produced in low amounts by fermentation of soluble carbohydrates. The contents of the large intestine become profoundly acidic, resulting in unfavorable conditions for the microbial flora. Lactic acid-producing bacteria flourish, whereas the gram negative bacteria, especially the *Enterobacteriaceae*, are killed in large numbers by the acids. Large quantities of endotoxin are released from the dying bacteria.<sup>226</sup>

The osmotic load from lactic acid produced in the large intestine is an important factor in the development of diarrhea because organic acids such as lactic acid are poorly absorbed. Mild cases of carbohydrate overload may result purely from osmotic diarrhea. In more severe cases the acidic contents of the large intestine are toxic to the mucosa, causing necrosis of the mucosal tissues similar to that seen in ruminal acidosis. Mucosal ulceration allows absorption of large quantities of endotoxin and lactic acid produced by the massive die-off of acid-intolerant microbes and fermentation of soluble carbohydrates, normally poorly absorbed by intact mucosa.<sup>227</sup> Systemic inflammation resulting from endotoxemia may be overwhelming, and profound metabolic acidosis may occur. Secretory diarrhea caused by the direct effects of acid luminal contents on the mucosa, as well as the effects of inflammatory mediators on enterocyte secretion, worsens the acidosis and dehydration. Systemic inflammation resulting from endotoxemia, along with intestinal inflammation, adversely affects intestinal motility, and ileus develops. Ileus and gas production from fermentation of carbohydrates may cause severe distention of the large intestine and signs of abdominal pain. Laminitis is a frequent complication of endotoxemia and lactic acidosis. In fact, carbohydrate overload is used to induce laminitis as an experimental model because of the consistency of the laminitis produced.<sup>225-227</sup>

### CLINICAL SIGNS AND DIAGNOSIS

Clinical signs of colitis from carbohydrate overload can vary according to the amount of carbohydrate ingested and accommodation of the flora to a high carbohydrate diet. Mild cases may result in a transient osmotic diarrhea, with no systemic effects. Severe cases are characterized by signs similar to those described for other forms of colitis, including abdominal pain, moderate to severe diarrhea, and dehydration. Signs of endotoxemia and sepsis are frequently present in severe cases. Elevated heart and respiratory rates are common, with peripheral vasoconstriction early in the disease, followed by peripheral vasodilation as the disease progresses. Depression may be profound as a result of metabolic acidosis and endotoxemia. Abdominal auscultation and percussion may reveal ileus and intestinal tympany. Nasogastric intubation may yield significant gastric acidic reflux. Particles of grain may be noted in the gastric reflux and the feces if grain

overload is the source of the carbohydrate overload. Laminitis may complicate both mild and severe cases of carbohydrate overload, especially if the animal has had previous bouts of laminitis.

Hematologic abnormalities include neutropenia and leukopenia. Severe dehydration may result in profound hemoconcentration. Protein loss later in the course of disease may result in hypoproteinemia. Serum biochemical abnormalities include azotemia, elevated hepatocellular enzyme activity, hyponatremia, and hypokalemia. Severe hypocalcemia and metabolic acidosis are characteristic of the disease. Serum lactate concentrations are elevated in the absence of evidence of intestinal strangulation or infarction. PF analysis often reveals no abnormalities.

## SAND ENTEROPATHY

Sand enteropathy is described in more detail under the heading of Obstructive Diseases, because acute obstruction is often associated with abnormally large amounts of sand in the large intestine.<sup>228</sup> However, chronic sand-induced diarrhea is a distinct syndrome that can occur at any age as a result of the abnormal accumulation of sand in the large intestine.<sup>229,230</sup> Chronic diarrhea and signs of colic may be seen without obstruction. The pathogenesis of sand accumulation in individual horses, other than simple ingestion of large quantities, is unclear, as described elsewhere in this chapter. Presumably, the sand causes irritation and may disrupt motility, leading to diarrhea. The diarrhea is usually not severe and dehydrating and may be intermittent. Weight loss is characteristic and can be severe in some cases.<sup>229</sup> Complications may occur, such as peritonitis and acute obstruction.<sup>229</sup>

Diagnosis is usually based on the presence of abnormal amounts of sand in the feces. Because sand-induced chronic diarrhea is primarily associated with sand accumulation in the ventral colon, auscultation of the ventral abdomen immediately behind the xiphoid process may reveal characteristic sand sounds.<sup>231</sup> This technique is sensitive only if peristalsis is present. Ultrasonography may also be useful to identify sand in the ventral colon, but it is not useful to quantitate the amount of sand. Occasionally, radiography may be required to detect sand in the colon.<sup>229</sup>

## ☉ PRINCIPLES OF THERAPY FOR ACUTE DIARRHEA

The principles of therapy for acute diarrhea resulting from colitis are similar regardless of the cause and include replacement of fluid and electrolyte losses, control of colonic inflammation, reduction of fluid secretion, promotion of mucosal repair, control of endotoxemia and sepsis, and re-establishment of normal flora. The purpose of this section is to review the principles of therapy, with references to specific therapies for particular etiologies as they arise.

## FLUID REPLACEMENT AND CIRCULATORY SUPPORT

Replacement of fluid and electrolyte losses is of primary concern in treating horses with salmonellosis. Depending on the severity of the disease, fluid losses may be minimal or massive. Fluid and electrolytes can be administered orally or intravenously. Some horses with mild to moderate diarrhea may

maintain hydration and electrolyte balance by consuming water and electrolytes voluntarily. Fresh water and water containing electrolytes should be available in all cases. In many instances, periodic nasogastric intubation and administration of water and electrolytes through the tube may be sufficient to maintain hydration.<sup>232</sup> In severe cases indwelling nasogastric tubes can be maintained, and up to 8 L of fluid can be administered by the tube every 20 to 30 minutes, if ileus is not evident. However, intravenous administration of fluids is preferred in most cases, requiring significant quantities of fluid to replace and maintain hydration and electrolyte balance.<sup>233</sup> It is not unusual for patients with severe diarrhea to require large volumes (50-100 L/day) of intravenous fluids to maintain hydration. Frequent monitoring of packed cell volume, serum electrolyte concentration, venous blood gases or total serum carbon dioxide, blood urea nitrogen and creatinine, urine protein and cytology, and body weight is important to monitor hydration, electrolyte and acid-base balance, and renal function.

Isotonic sodium chloride or lactated Ringer's solution is frequently used to restore and maintain fluid and electrolyte balance. Potassium chloride can be added to the fluids and administered at a rate up to 0.5 to 1.0 mEq/kg/hr. Generally, a rate of less than 0.5 mEq/kg/hr is used. Hypertonic NaCl solutions (1-2 L of 5% or 7.5% NaCl) have been used in horses that are severely hyponatremic (<120 mEq/dL). Hypertonic solutions should not be administered to severely dehydrated horses, but they have been used clinically without complication and with considerable beneficial effect in patients with hemodynamic shock resulting from sepsis. The beneficial effects of hypertonic NaCl are short-lived (30 to 60 minutes). Isotonic solutions should be administered concurrently or immediately after administration of hypertonic NaCl solutions. Isotonic (1.3%) or hypertonic (5.0%) sodium bicarbonate solutions are used to correct metabolic acidosis. Prolonged administration of sodium-containing fluids may promote diuresis and renal water loss or accumulation of peripheral edema and should be used conservatively when a relative free water loss is noted. Administration of isotonic dextrose (5%) or 2.5% dextrose/0.45% NaCl solutions may be beneficial when free water loss (relative sodium excess) is evident.

Many horses with acute colitis are concurrently hypoproteinemic because of gastrointestinal losses and are absorbing bacterial products that induce a systemic inflammatory response. Thus plasma oncotic pressures are abnormally low in the face of increased vascular permeability. Interstitial edema formation is a clinical problem in these patients, which contributes to organ dysfunction. Crystalloid fluids, although critical for replacing water and electrolyte losses resulting from diarrhea, may actually contribute to a decline in plasma oncotic pressure as a result of hemodilution.<sup>234,235</sup> Administration of colloid solutions is helpful for volume expansion and maintenance of plasma oncotic pressures, which improve tissue perfusion and oxygenation and organ function in hypovolemic, hypotensive, and hypoproteinemic patients with or without SIRS.<sup>236</sup> Colloids are more effective than crystalloid fluids at expanding plasma volume, thus requiring smaller volumes. Moreover, the effect of colloid volume expansion is longer lasting than crystalloid fluid volume expansion, because colloids are better retained in the vasculature.<sup>235,236</sup> Natural colloids, such as plasma and purified albumin, are commonly used. In addition to its beneficial colloidal properties, plasma harvested from donor horses immunized with

rough mutants of *E. coli* (J5) or *S. enterica* var *typhimurium* may have other benefits for treatment of endotoxemia resulting from gastrointestinal disease.<sup>237,238</sup> Large volumes (6-8 L/day) may be required to significantly increase and maintain plasma protein concentration. Synthetic colloids such as dextrans, starches, or polymerized hemoglobin are also available for use in the horse. Hydroxyethyl starch (Hetastarch; 5 to 10 ml/kg of a 6% solution) increases colloidal oncotic pressures for up to 24 hours in hypoproteinemic horses<sup>234</sup> and has beneficial effects on cardiac output and other cardiorespiratory parameters, vascular permeability, interstitial fluid content, and tissue perfusion in models of hypoproteinemia and SIRS.<sup>236</sup> However, infusion of such solutions may be associated with renal failure in human patients with sepsis,<sup>239</sup> so this fluid should be used with caution in horses with sepsis. When synthetic colloids or even natural colloids are being administered, it may be more practical to monitor plasma oncotic pressure rather than plasma protein concentrations as a means of assessing the need for plasma or other colloid administration.<sup>234</sup> Hetastarch may prolong bleeding times by altering von Willebrand's factor (vWF) function; thus this synthetic colloid should be used cautiously in horses with suspected coagulopathies, active hemorrhage, or other bleeding problems.<sup>235</sup>

## INFLAMMATION

Control of colonic inflammation and secretion is a difficult and poorly studied aspect of equine acute colitis. The role of inflammation and mediators such as prostaglandins as a cause of fluid loss is well known during *S. enterica* and clostridial infection of the intestinal tract.<sup>19,39,39,108-110,240,241</sup> COX inhibitors (NSAIDs) have antisecretory effects on the inflamed intestinal tract,<sup>242,243</sup> including in the equine colon.<sup>244,245</sup> NSAIDs are commonly administered to horses with salmonellosis and other forms of colitis to reduce inflammation-associated fluid secretion. However, prostaglandins such as PGE<sub>2</sub> and PGI<sub>2</sub> are also have cytoprotective effects on gastrointestinal mucosa and are critical for mucosal repair.<sup>188,242</sup> NSAIDs used pharmacologically to inhibit colonic inflammation and secretion may in fact be detrimental to mucosal integrity and healing if not used judiciously in inflammatory diarrheal diseases. NSAIDs exacerbate colonic inflammation in humans with inflammatory colitis, impede mucosal healing in several models of mucosal injury, and have well-documented detrimental effects on colonic mucosa in horses.<sup>176,186,188,242</sup> In addition to toxicity to the colonic mucosa, gastric ulceration is not unusual in horses with enterocolitis and may be related to treatment with NSAIDs. Although the use of COX-2-selective NSAIDs should, in theory, be less likely to harm or impede repair of the colonic mucosal in patients with colonic inflammation causing diarrhea, the safety and efficacy of these medications has not been evaluated in this application. In addition, the prothrombotic adverse effects of COX-2 selective drugs<sup>246</sup> suggest that very cautious use of highly COX-2-selective medications is warranted in patients with systemic inflammation at risk for thrombosis (e.g., endotoxemia and sepsis).

In addition to NSAIDs, other drugs are occasionally used as anti-inflammatory and antisecretory therapy. Bismuth subsalicylate is commonly used in adults and foals with diarrhea. The volume required for any effect in adults with colitis is quite high (1-4 L by nasogastric tube every 4-8 hours), which often precludes its use. Metronidazole has beneficial effects in experimental models of gastrointestinal inflammation,

including NSAID toxicity,<sup>193</sup> and may be useful for treating horses with colitis; however, evidence supporting its use is lacking. Orally administered bismuth subsalicylate solutions are often used to decrease inflammation and secretion in the colon. In adult horses the volume of solution necessary to be beneficial is large (3 to 4 L, every 4 to 6 hours). Often the solution is administered twice daily instead of four to six times daily. If a beneficial effect is not achieved within 3 to 4 days of treatment, administration of bismuth subsalicylate solution should be discontinued. More frequent administration can be accomplished in foals, and clinical improvement is more often seen in foals than in adult horses.

In light of the role of reactive oxygen metabolites in colonic inflammation, free radical scavengers have been advocated to reduce the effects of these molecules. Sulfasalazine metabolites have been shown to reduce reactive oxygen metabolite-induced colonic inflammation in other species,<sup>193</sup> and sulfasalazine has been used to treat chronic inflammatory disease in horses but has not been used to treat acute colitis. The only free radical scavenger commonly used in horses with colitis is dimethyl sulfoxide (DMSO, 0.1 to 1.0 g/kg intravenously every 12 to 24 hours in a 10% solution), but evidence of efficacy is lacking.

SIRS associated with endotoxemia and sepsis frequently occurs in patients with salmonellosis. The principles of therapy for endotoxemia and sepsis are covered in detail elsewhere in this chapter. Oral administration of activated charcoal and mineral oil is commonly used to reduce absorption of endotoxin in horses with colitis. Low doses of NSAIDs (such as flunixin meglumine, 0.1 to 0.25 mg/kg intravenously every 6 to 8 hours) inhibit eicosanoid synthesis induced by endotoxin. In addition, NSAIDs are administered to prevent laminitis resulting from endotoxemia, a devastating complication of salmonellosis. It is important to remember that prostaglandins are important for mucosal healing and may worsen mucosal injury in colitis. It is generally believed that the benefits of low doses of NSAIDs administered to horses with SIRS outweigh the risks of worsening gastrointestinal damage, but judicious use is recommended.

## MUCOSAL REPAIR AND PROTECTION

Sucralfate (20 mg/kg by mouth every 6 hours) has been advocated to aid in healing of the colonic mucosa in patients with NSAID toxicity. There is evidence in experimental phenylbutazone toxicosis in foals suggesting that sucralfate administration lessens ulceration and other histopathologic lesions throughout the alimentary tract and lessens protein loss.<sup>247</sup> However, there is no evidence supporting the use of sucralfate to treat colonic ulceration in adult horses.

Misoprostol (5 µg/kg by mouth every 12 hours or 2 µg/kg by mouth every 6 to 8 hours) and other synthetic PGE analogs enhance mucosal healing in the intestine and promote recovery in experimental models of colitis.<sup>248</sup> Misoprostol may be particularly useful for treating NSAID toxicity, either the generalized form or RDUC. However, the efficacy of misoprostol in hastening mucosal healing is clinically unproven in equine colitis. The primary drawbacks of prostaglandin analogs such as misoprostol are the adverse effects of the drug, including abdominal cramping, diarrhea, sweating, and abortion in pregnant mares.

Psyllium mucilloid can be added to the diet (5 tablespoons every 12 to 24 hours) to increase the production of SCFAs in the colon. Amylase-resistant fermentable fiber such as psyllium is hydrolyzed by colonic bacteria to SCFAs such as

butyrate, which represent a major energy source for colonocytes. Butyrate and other SCFAs hasten epithelial maturation and stimulate salt (and thus fluid) absorption in the colon, improve the clinical course of ulcerative colitis, and hasten colon healing.<sup>249</sup> Psyllium is itself a source of butyrate in the colon and also promotes the movement of amylase-sensitive carbohydrates into the distal colon, which are then fermented to SCFAs. Thus psyllium is thought to be clinically useful for promoting mucosal healing in colitis.

## PAIN CONTROL

Many horses with salmonellosis or other forms of colitis have mild to severe signs of abdominal pain caused by gas and fluid distention of the colon, colonic ischemia, or infarction. Analgesia can be accomplished with NSAIDs such as flunixin, but the potential for worsening mucosal injury or nephrotoxicity may prevent the use of analgesic doses, especially in horses with suspected NSAID toxicity. Newer NSAIDs that specifically target COX-2 with minimal inhibition of COX-1 may be useful analgesics that spare the gastrointestinal mucosa. For example, meloxicam and firocoxib have analgesic properties in horses in experimental models of ischemic colic and spare the intestinal mucosa from the detrimental effects associated with nonselective COX inhibitor treatment.<sup>182,250</sup>

Xylazine or detomidine may provide temporary relief of pain. Butorphanol is a useful analgesic that can be administered either intramuscularly (0.05 to 0.1 mg/kg IM every 6 to 8 hours) or as a continuous infusion. An infusion rate of 13.2 µg/kg/hr in isotonic crystalloid fluid such as lactated Ringers' solution is often effective.<sup>251</sup> Continuous-rate infusion of lidocaine (1.3 mg/kg, IV loading dose administered slowly over 5 minutes followed by 3 mg/kg/hr infusion in isotonic crystalloid fluids) can provide analgesia, anti-inflammatory activity, and prokinetic benefits.<sup>252,253</sup>

## ANTIBIOTICS

### NEUTROPENIA

Broad spectrum antibiotic treatment is often recommended in neutropenic horses or horses with signs of septicemia. Neutropenia is associated with an increased risk of sepsis, septicemia, and septic complications, such as septic phlebitis and infection of surgical sites.<sup>254-262</sup> Sepsis, bacteremia, and septicemia are complications of enterocolitis that may be caused by *S. enterica*, *Clostridium* organisms, or other pathogenic enteric bacteria or by toxic or inflammatory injury to the colonic mucosa that breaks down the barrier, allowing absorption of microbial molecules that trigger inflammation or invasion of microbes into tissues and blood. Neutropenia weakens host defenses to render horses susceptible to infection and dissemination of organisms that breach the mucosal barrier. Although most attempts to culture bacteria from the blood of adult horses with colitis fail to isolate organisms, no detailed studies have been undertaken to determine the prevalence of bacteremia or septicemia in these patients. Disseminated aspergillosis has been reported in horses as a complication of acute colitis, demonstrating the potential for systemic infections with rarely pathogenic organisms stemming from colonic mucosal injury in the face of potential immunosuppression resulting from neutropenia.<sup>263,264</sup> Broad spectrum antibiotics lessen septic complications in human patients. However, evidence supporting this principle in horses with colitis is lacking.

### SALMONELLOSIS

Treatment with antibiotics is controversial in horses with salmonellosis. Treatment with antibiotics is not thought to alter the course of the enterocolitis, but it may lessen dissemination and severity of disease. Treatment with antibiotics directly targeted at *S. enterica* is often reserved for patients with the enteric fever (septicemia) form of salmonellosis, documented with positive blood cultures. However, some clinicians treat all cases of salmonellosis with targeted antibiotic therapy. Lipid-soluble antibiotics are ideally suited for *S. enterica* infections because the bacteria persist intracellularly. Enrofloxacin (5 mg/kg/day IV), chloramphenicol (50 mg/kg, PO every 6 hours), and cephalosporins (ceftiofur 10 to 20 mg/kg, IV every 12 hours) are preferred antibiotics for treatment of salmonellosis depending on the antimicrobial sensitivity of the isolate.

### POTOMAC HORSE FEVER

As with other causes of enterocolitis, the use of antibiotics is controversial. The risk of inducing salmonellosis or other forms of antibiotic-induced diarrhea and the difficulty of diagnosing the etiology of diarrheal diseases demand judicious use of antibiotics.<sup>54</sup> However, in patients in which the likelihood of *N. risticii* infection is high, treatment with antibiotics is often indicated before definitive diagnosis. Lipid-soluble drugs are preferred because the organism can live within cells. Oxytetracycline (6.6 mg/kg/day, IV), doxycycline (10 mg/kg, PO every 12 hours), trimethoprim-sulfadiazine (5 mg/kg trimethoprim, PO or IV every 8 to 2 hours, and 25 mg/kg sulfadiazine every 8 to 12 hours), or erythromycin-rifampin (30 mg/kg, PO every 12 hours, and 5 mg/kg, PO every 12 hours, respectively) have been used effectively to treat clinical cases.<sup>54,265-267</sup> The tetracyclines appear to be the most effective antibiotics for treatment of Potomac horse fever and are considered the treatment of choice. Treatment is most successful if initiated before the onset of diarrhea.<sup>54,266</sup>

### CLOSTRIDIOSIS

If antibiotics are being administered at the onset of enterocolitis, they should be discontinued if possible. Specific treatment with metronidazole (15 mg/kg, PO every 8 hours) is effective for treating clostridiosis in humans and appears to be effective in horses.<sup>95,268</sup> Metronidazole resistance in clinical isolates of *C. difficile* has been reported in one outbreak but appears to be rare in most human and equine cases.<sup>269</sup> Metronidazole-resistant isolates were sensitive to vancomycin, which may be effective for treating clinical cases if metronidazole resistance is suspected. However, metronidazole remains the treatment of choice. *C. perfringens* type C antitoxin has been recommended for treatment of neonatal clostridiosis, but there is no evidence of its efficacy.<sup>270</sup> Antitoxin preparations are not generally advocated for use in adult horses with clostridiosis.

### PROLIFERATIVE ENTEROPATHY

*L. intracellularis* is susceptible to a variety of antibiotics in vitro, including chlortetracycline, erythromycin, penicillin, difloxacin, and ampicillin.<sup>271</sup> Lipid-soluble antibiotics with a large volume of distribution are usually chosen to treat PE because *L. intracellularis* is an intracellular organism. Erythromycin estolate (15 to 25 mg/kg, PO every 6 to 8 hours) alone or in combination with rifampin (5 mg/kg, PO every 12 hours) is the most commonly reported efficacious treatment for PE.<sup>124</sup> Chloramphenicol (50 mg/kg PO every 6 hours)

has also been reported to be effective if erythromycin worsens the diarrhea.<sup>124</sup> Anecdotal reports suggest that administration of oxytetracycline, doxycycline, or both is also quite effective. Supportive care, including maintenance of hydration and electrolyte balance and plasma or colloid administration to increase colloid oncotic pressure in hypoalbuminemic patients, is also indicated. Affected foals are treated until clinical signs, hypoproteinemia, and ultrasonographic evidence of intestinal thickening resolve. The prognosis depends on the duration of the disease and the degree of fibrosis and destruction of the intestinal architecture.

## ANTICOAGULATION

Hypercoagulability is a common complication of enterocolitis, associated with systemic inflammation resulting from endotoxemia. Administration of heparin (20 to 80 IU/kg, SC or IV every 6 to 12 hours) may prevent thrombosis in these patients, provided antithrombin III concentrations are adequate in the plasma. Concentrated sources of antithrombin III are not available for use in horses, but whole plasma may provide an important source. Treatment with heparin is thought to decrease thrombosis, especially of the jugular vein, a serious complication of salmonellosis. Low-dose aspirin treatment (10 mg/kg, PO every 24 to 48 hours) in conjunction with heparin treatment may provide added benefit by irreversibly inhibiting platelet function.<sup>272</sup> Heparin and aspirin may have protective effects on the digital lamina.<sup>272,273</sup> Heparin may enhance the phagocytic activity of the reticuloendothelial system by enhancing the efficiency of opsonins such as fibronectin and immunoglobulin, thereby stimulating phagocytosis of products of coagulation and possibly other particles, including bacteria.<sup>274,275</sup>

## PROBIOTICS

### SALMONELLOSIS

Maintenance of the bacterial flora and antagonism of pathogenic bacteria such as *S. enterica* in the gastrointestinal tract are important defense mechanisms preventing colonization by pathogenic bacteria. The use of probiotic preparations containing beneficial bacteria prevents colonization of pathogenic bacteria, including *S. enterica var. gallisepticum*, in poultry.<sup>276</sup> Little work has been done to investigate the efficacy of these products in preventing salmonellosis in horses, but ongoing studies may provide important information in this regard. Probiotic and other preparations designed to restore normal flora to the gastrointestinal tract, such as fecal suspensions, sour milk, and yogurt, have been used clinically to shorten the course of salmonellosis, with variable results. Therefore prevention of infection by using probiotic agents and other means is important. Exposure of susceptible horses to *S. enterica* should be avoided, but this is a difficult task, especially because inapparent infections are common and the bacteria are ubiquitous in the environment. Prophylactic use of probiotic preparations, judicious use of antibiotics in susceptible horses, control of environmental conditions such as temperature, and restricted exposure to pathogenic bacteria are important factors to control clinical salmonellosis.

### CLOSTRIDIOSIS

Because altered large intestinal flora appears to play an important role in the pathogenesis of equine intestinal clostridiosis or any antibiotic-associated diarrhea, probiotic preparations

have been advocated to treat affected horses.<sup>277</sup> Sour milk, a product containing lactose-producing *Streptococcus* species, appears to markedly improve the clinical course in horses suspected of having *C. perfringens* type A infection.<sup>90</sup> Sour milk may benefit the patient by altering the flora and antagonizing enterotoxigenic *C. perfringens* type A, but it is also reported to be bactericidal against *C. perfringens* type A.<sup>90</sup> Preparations of *Saccharomyces boulardii* are effective for reducing diarrhea and the frequency of *C. difficile* recurrence in humans<sup>95</sup> and decreasing the duration and severity of disease in horses with colitis.<sup>278</sup> *Lactobacillus* preparations have a protective effect in humans and decrease the severity and duration of antibiotic-associated diarrhea.<sup>279,280</sup> However, evidence of their clinical usefulness in horses is lacking.

## ABSORBENT POWDERS AND MINERAL OIL

Absorbent powders are often used to reduce the bioactivity and absorption of bacterial toxins produced by bacterial or toxic metabolites produced by bacteria and other microorganisms (e.g., lactic acid in grain overload). Activated charcoal is indicated in cases of intoxication by arsenic and grain overload. Activated charcoal may also be administered in an attempt to reduce absorption of endotoxin and other pro-inflammatory microbial molecules in inflammatory colitis. Mineral oil may be useful to reduce absorption of cantharidin in patients with blister beetle poisoning. DTO smectite powder (Bio-Sponge™, Platinum Performance, Buellton, Calif) binds *C. difficile* and *C. perfringens* exotoxins in vitro<sup>281,282</sup> and may be useful for treating intestinal clostridiosis in horses. DTO smectite is available as a powder or paste and should be administered according to the manufacturer's instructions for 3 to 5 days.

## NUTRITION

Good nursing care and adequate nutrition are vital to the treatment of horses with salmonellosis. Salmonellosis and other severe forms of inflammatory colitis are catabolic diseases that increase caloric requirements. Normal intake of roughage to provide energy may be inadequate; however, feeding of grains should be avoided to prevent delivery of highly fermentable carbohydrate to the colon. Dietary management usually consists of restricting or eliminating long-stem roughage (hay) from the diet and feeding exclusively a complete pelleted diet (at least 30% dietary fiber). The rationale behind this recommendation is to reduce the mechanical and physiologic load on the colon. Frequent meals (4 to 6 times a day) are recommended. Corn oil (1 cup every 12 to 24 hours) can be added to the pellets to increase the caloric intake without adding roughage or grain. It is important to note that if a horse with colitis refuses to eat pelleted feed, then high-quality grass hay should be fed. In anorectic or severely catabolic patients, enteral and parenteral nutrition (total and partial) has been used successfully to provide calories and nutritional support.

## SPECIFIC THERAPIES

### STRONGYLOSIS

Treatment of *S. vulgaris* infection requires treatment of the migrating parasite larvae and the lesions produced by the parasite. Fenbendazole (10 mg/kg, PO every 24 hours for 3 days, or 10 mg/kg, PO every 24 hours for 5 days) and ivermectin (200 mg/kg PO) are effective in killing fourth-stage larvae.<sup>131</sup> Other

anthelmintics may also be effective when given at higher doses than those required to kill adult worms. The efficacy of these anthelmintics against larvae within thrombi is not known.

Thrombolytic and antithrombotic therapy has been advocated in horses with suspected strongylosis.<sup>131,138</sup> Heparin (20 to 80 IU, IV or SC every 6 to 12 hours) may be administered as an anticoagulant. High-molecular-weight heparin causes anemia by inducing aggregation of red blood cells, which is an undesirable effect in sepsis. Low-molecular-weight heparins appear to be less likely to have this effect in horses. Aspirin (10 to 30 mg/kg, PO every 12 to 48 hours) is usually combined with heparin to inhibit platelet adhesion. Aspirin may also inhibit release of platelet products, such as thromboxane, that affect the motility of the large intestine. Low-molecular-weight dextrans have been advocated as antithrombotics that act by inhibiting platelet function and coagulation.<sup>138,236</sup> The clinical efficacy of dextran administration appears to be good, but no controlled studies have been performed.

### CYATHOSTOMIASIS

Anthelmintic administration is usually the only treatment necessary for mild to moderate cases of cyathostomiasis treated early in the course of the disease (within 1 to 3 weeks of onset). Fenbendazole is effective against many larval stages, but resistance is high in some populations. Although the reported efficacy of ivermectin is variable against certain stages,<sup>283</sup> one study reported an overall efficacy of 75%.<sup>286</sup> Currently, fenbendazole (7.5 to 10 mg/kg, PO every 24 hours for 5 days) followed on day 6 by ivermectin (200 mg/kg PO) is the most commonly advocated treatment regimen.<sup>143,285</sup> Moxidectin (400 µg/kg PO every 24 hours) may also be effective against adult organisms and L<sub>3</sub> and L<sub>4</sub> larval stages<sup>286</sup> and may be useful for treating cyathostomiasis. Anti-inflammatory therapy may also be beneficial, especially in severe or refractory cases or before treatment with larvicidal medications. Pretreatment with dexamethasone or prednisolone is indicated before anthelmintic administration if heavy larval loads are suspected to prevent an acute exacerbation of the disease by rapid death of encysted larvae. Larvicidal treatment with moxidectin appears to be less likely than fenbendazole to result in tissue inflammation resulting from larval death.<sup>287</sup> NSAID administration may have limited value, but dexamethasone appears to be efficacious in refractory cases when used in conjunction with larvicidal anthelmintics.<sup>143,146</sup> Bismuth subsalicylate is often administered orally as an antisecretory agent in young animals. Supportive care may be necessary in severe cases, particularly if hypoproteinemia is severe. Administration of intravenous crystalloid fluids and plasma or other colloids is occasionally required. Proper nutritional support is also important.

### CANTHARIDIN

Supportive care is the most important principle of therapy for cantharidin toxicity. Intravenous fluid administration, maintenance of electrolyte balance (especially calcium), and prevention of further renal and urinary tract damage is important.<sup>202,206</sup> Diuresis by intravenous fluid administration is often sufficient to prevent renal failure. Furosemide is often administered after rehydration of the patient to further promote diuresis and to decrease the concentration of the toxin in the urine, which may ameliorate some of the effects on the urinary tract mucosa.<sup>202</sup> Diuresis has also been suggested to increase clearance of the toxin, but no evidence for this has

been found. Judicious use of NSAIDs may be necessary to control abdominal pain but should be reserved until the patient is rehydrated and renal failure has been ruled out. Cantharidin is lipid-soluble; therefore oral administration of mineral oil may prevent further absorption of the toxin.<sup>202</sup> Activated charcoal is often administered with the mineral oil.

### ARSENIC TOXICITY

Reduction of arsenic absorption by administration of cathartics such as mineral oil, magnesium sulfate slurries, and activated charcoal by nasogastric tube should be initiated immediately.<sup>207</sup> Chelation therapy with sodium thiosulfate 920 to 30 g in 300 mL of water (administered orally) and dimercaprol (BAL; 3 mg/kg, PO every 4 hours) is indicated.<sup>207</sup> Dimercaprol is a specific antidote for trivalent arsenicals, but its efficacy in horses is questionable. Intravenous fluid administration may help treat shock, replace fluid lost in feces, and promote diuresis but should be monitored carefully because pulmonary edema is a frequent complication. More specific treatment of renal, cardiac, pulmonary, or neurologic disease may be required.

### INTESTINAL ANAPHYLAXIS

Treatment of intestinal anaphylaxis is in principle similar to treatment of other forms of colitis, but it is often unsuccessful, owing to the rapidly progressive nature of the syndrome.<sup>211,216,223</sup> Inclusion of heparin in the intravenous fluids (20 to 80 IU/kg, IV every 8 to 12 hours) may help prevent vascular thrombosis. Administration of hypertonic saline solutions or colloids may prove useful during initial periods of shock. Early treatment with prednisolone sodium succinate (10 to 20 mg/kg IV) or dexamethasone (0.1 to 0.2 mg/kg, IV) may be essential for successful treatment.<sup>211</sup>

### CARBOHYDRATE OVERLOAD

Mild cases of carbohydrate overload may not require treatment other than exclusion of grains from the diet for several days to weeks and gradual reintroduction of grain into the diet later if extra energy is needed. Patients showing signs of colic or diarrhea without other systemic signs may benefit from administration of mineral oil, charcoal, and fluids through a nasogastric tube. Lavage of residual carbohydrate from the stomach may also be accomplished with the nasogastric tube. Often, NSAIDs such as phenylbutazone (2.2 to 4.4 mg/kg/day, IV) or flunixin meglumine (1 mg/kg, IV) are administered to prevent laminitis. Phenoxybenzamine and heparin given before the onset of laminitis may prevent or decrease the severity of laminitis.<sup>273,288</sup>

More severe cases with dehydrating diarrhea, systemic signs of endotoxemia, or metabolic acidosis require intravenous fluid support to maintain water, electrolyte, and acid-base balance in addition to the previously mentioned treatments. Large amounts of bicarbonate-containing solutions may be required. Care should be taken when administering hypertonic bicarbonate solutions because many patients may already be hyperosmotic as a result of lactic acidemia. Isotonic sodium bicarbonate 1.3% may be useful in the hyperosmotic patient. Careful attention to calcium balance is also important because severe hypocalcemia may occur. Aggressive therapy for systemic inflammation resulting from endotoxemia should be instituted. Intravenous broad spectrum antibiotics are administered to combat bacteremia and septicemia, which frequently complicate carbohydrate overload-induced colitis.

In extreme cases, especially if the patient has ingested a very large quantity of grain, surgical removal of the grain from the large intestine may be indicated, especially if surgery can be accomplished before the onset of severe clinical signs. However, administration of oral cathartics, such as magnesium sulfate slurries or mineral oil, or a combination of these is often sufficient to clear the carbohydrate from the large intestine before fermentation, mucosal damage, and absorption of endotoxin and lactic acid occur. Oral administration of activated charcoal may prevent absorption of endotoxin by binding the molecules in the lumen of the bowel. In any case, feeding of the source of the soluble carbohydrate, such as grains, should be discontinued. Low carbohydrate and protein roughage such as grass or oat hays should be fed until the microbial flora recovers. Oral administration of probiotic preparations containing lactobacillus is contraindicated; however, other sources of normal equine large intestinal microbial flora, such as fecal extracts from normal feces or *S. boulardi*, may be useful to reintroduce appropriate microorganisms. Complications from laminitis and sepsis are common and often cause death.

### SAND ENTEROPATHY

Treatment requires removal of the sand from the gastrointestinal tract, as described elsewhere in this chapter, using psyllium products and magnesium sulfate slurries administered orally. Analgesics may be required initially to relieve pain and stimulate appetite. A diet high in roughage often stimulates further passage of sand. Treatment may require several weeks to remove as much sand as possible. Prevention of the disease is important, and recurrence is not unusual.

## ISCHEMIC DISORDERS OF THE INTESTINAL TRACT

*Anthony T. Blikslager*

## STRANGULATING OBSTRUCTION

### PATHOPHYSIOLOGY

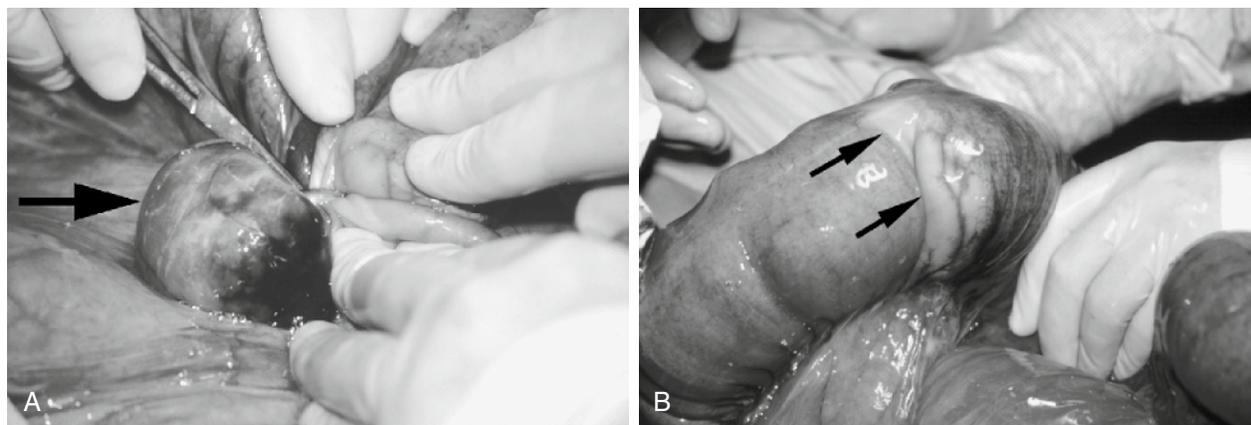

Strangulation obstruction of the intestine is characterized by simultaneous occlusion of the intestinal lumen and its blood supply. Although strangulation of the intestinal lumen results in clinical signs similar to those of simple obstruction, occlusion of the blood supply results in a more rapid deterioration of the intestinal mucosa and subsequent onset of sepsis. Although there has been a great deal of recent interest in the relevance and treatment of intestinal reperfusion injury,<sup>1-3</sup> the lesion that develops during strangulation is often severe, leaving little viable bowel for further injury during reperfusion.<sup>2</sup> Although extensive lengths of strangulated small intestine may be resected, strangulation of the large colon presents a much greater treatment dilemma because strangulated intestine usually extends beyond the limits of surgical resection.<sup>4</sup> Therefore horses with large intestinal strangulation are often recovered with extensive intestinal injury left in place. Thus subtle degrees of reperfusion injury may be very important in horses with large colon disease, warranting further work in this area in an attempt to reduce mortality.<sup>3</sup>

Strangulating obstruction may be divided into hemorrhagic and ischemic forms.<sup>5,6</sup> In hemorrhagic strangulating obstruction, which is most common, the veins become occluded before the arteries because of the greater stiffness of arterial walls. This lesion is noted by a darkened appearance in affected bowel and increased thickness as blood is pumped into the lesion. Ischemic strangulating obstruction occurs if the intestine is twisted tightly enough to simultaneously occlude both arteries and veins. In the case of the colon, some researchers suggest that this may be determined by how much ingesta is in the colon, because intestinal contents may prevent the intestine from twisting tightly.<sup>7</sup> Tissue involved in ischemic strangulating obstruction appears pale and of normal or reduced thickness because of a complete lack of blood flow (Figure 15-23). Bowel peripheral to strangulating lesions may also become injured as a result of distention, which reduces mural blood flow once it reaches critical levels. Furthermore, as this intestine is decompressed, it may also undergo reperfusion injury.<sup>8-10</sup>

## SMALL INTESTINAL STRANGULATION

### CLINICAL SIGNS

Horses with small intestinal strangulating obstruction typically have moderate to severe signs of abdominal pain that is only intermittently responsive to analgesic medications. During the latter stages of the disease process, horses may not experience much pain but rather become profoundly depressed as affected intestine necroses. Affected horses have progressive signs of sepsis, including congested mucous membranes, delayed capillary refill time, and an elevated heart rate (>60 beats/min in most cases). In addition, reflux is typically obtained after passage of a stomach tube, and loops of distended small intestine are usually detected on rectal palpation of the abdomen.<sup>11</sup> However, these latter findings are variable, depending on the duration and location of the obstruction. For example, horses with ileal obstructions tend to reflux later in the course of the disease process than horses with jejunal obstructions. Furthermore, a horse that has an entrapment of small intestine in the epiploic foramen or a rent in the proximal small intestinal mesentery may not have palpable loops of small intestine because of the cranial location of these structures.<sup>12</sup> Abdominocentesis can provide critical information on the integrity of the intestine and is indicated in horses with suspected strangulation of the small intestine.<sup>11</sup> A horse that has signs compatible with a small intestinal obstruction and also has serosanguinous abdominal fluid with an elevated protein level (>2.5mg/dl) is likely to require surgery, although these cases must be differentiated from proximal enteritis. In general, horses with small intestinal strangulation show continued signs of abdominal pain, whereas horses with proximal enteritis (discussed earlier in this chapter) tend to be depressed after initial episodes of mild abdominal pain.<sup>13</sup> In addition, horses with small intestinal strangulation continue to clinically deteriorate despite appropriate medical therapy and begin to show elevated white blood cell counts (>10,000 cells/ $\mu$ l) in the abdominal fluid, likely as the duration of strangulation increases. However, there are cases in which small intestinal strangulation and proximal enteritis cannot be readily distinguished, at which point surgery may be elected rather than prolonging the decision to perform abdominal exploration on a horse with a potential strangulating lesion.<sup>13</sup>

**FIGURE 15-23** Ischemic strangulating obstruction of the small colon by a mesenteric lipoma. **A**, Note the lipoma (arrow), which has tightly encircled a segment of small colon. **B**, After resection of the lipoma, a pale area of strangulated small colon is clearly demarcated (arrows), the appearance of which is consistent with ischemic strangulating obstruction.

## PROGNOSIS

The prognosis for survival in horses with small intestinal strangulating lesions is generally lower than for most forms of colic.<sup>14</sup> However, recent studies indicate that more than 80% of horses with small intestinal strangulating lesions will be discharged from the hospital.<sup>15</sup> Nonetheless, owners should be warned that the long-term survival rates are substantially reduced to below 70%,<sup>16</sup> in part because of long-term complications such as adhesions.<sup>18,19</sup> In addition, the prognosis is particularly low for some forms of strangulation, including entrapment of small intestine within a mesenteric rent.<sup>19</sup>

## EPIPLIC FORAMEN ENTRAPMENT

The epiploic foramen is a potential opening (because the walls of the foramen are usually in contact) to the omental bursa located within the right cranial quadrant of the abdomen. It is bounded dorsally by the caudate process of the liver and caudal vena cava and ventrally by the pancreas, the hepatoduodenal ligament, and the portal vein.<sup>12</sup> Intestine may enter the foramen from the visceral surface of the liver toward the right body wall or the opposite direction. Studies differ as to which is the most common form. In the case of entrapments that enter the foramen in a left-to-right direction, the omental bursa is ruptured as the intestine migrates through the epiploic foramen, which may contribute to the intra-abdominal hemorrhage often seen with this condition. Clinical signs include acute onset of severe colic with examination findings compatible with small intestinal obstruction. A recent study has shown that the stereotypic behavior of crib biting is a significant risk factor for epiploic foramen entrapment.<sup>20</sup> The reason for this is unclear but may be attributable to changes in abdominal pressure as the horse prepares the esophagus to ingest air. Other risk factors include increased height of the horse and previous colic surgery.<sup>20</sup> The condition was once believed to be more prevalent in older horses,<sup>12</sup> but this has since been refuted by more recent studies.<sup>21</sup> However, the disease has also been recognized in foals as young as 4 months of age.<sup>22</sup> The diagnosis is definitively made at surgery, although ultrasonographic findings of distended loops of edematous small intestine adjacent to the right middle body wall

are suggestive of epiploic foramen entrapment.<sup>12</sup> In general, thickened, amotile intestine on ultrasonographic examination is highly predictive for small intestinal strangulating obstruction.<sup>23</sup> Small intestine entrapped in the epiploic foramen may be limited to a portion of the intestinal wall (parietal hernia),<sup>24</sup> and the large colon may become entrapped within the epiploic foramen.<sup>25</sup> In treating epiploic foramen entrapment, the epiploic foramen must not be enlarged either by blunt force or with a sharp instrument, because rupture of the vena cava or portal vein and fatal hemorrhage may occur. Prognosis has substantially improved over the last decade, with current short-term survival rates (discharge from the hospital) ranging because 74%<sup>26</sup> to 79%.<sup>12</sup> Preoperative abdominocentesis has been consistently found to be the most predictive test of postoperative survival.<sup>12,26</sup>

## STRANGULATION BY PEDUNCULATED MESENTERIC LIPOMA

As horses age, lipomas form between the leaves of the mesentery and develop mesenteric stalks as the weight of the lipoma tugs on the mesentery. The stalk of the lipoma may subsequently wrap around a loop of small intestine or small colon, causing strangulation. Strangulating lipomas should be suspected in aged (>15 years) geldings with acute colic referable to the small intestinal tract.<sup>27,28</sup> Ponies also appear to be at risk for developing disease,<sup>28</sup> suggesting alterations in fat metabolism may predispose certain horses to development of mesenteric lipomas. The diagnosis is usually made at surgery, although on rare occasions a lipoma can be palpated rectally.<sup>29</sup> Treatment involves surgical resection of the lipoma and strangulated bowel, although strangulated intestine is not always nonviable.<sup>27</sup> Studies indicate that approximately 50%<sup>28</sup> to 78%<sup>27</sup> of horses are discharged from the hospital after surgical treatment.

## SMALL INTESTINAL VOLVULUS

A volvulus is a twist along the axis of the mesentery, whereas torsion is a twist along the longitudinal axis of the intestine. Small intestinal volvulus is theoretically initiated by a change in local peristalsis, or the occurrence of a lesion around which

the intestine and its mesentery may twist (e.g., an ascarid impaction).<sup>11</sup> It is reportedly one of the most commonly diagnosed causes of small intestinal obstruction in foals.<sup>30,31</sup> It has been theorized that young foals may be at risk for small intestinal volvulus because of changing feed habits and adaptation to a bulkier adult diet. Onset of acute, severe colic; a distended abdomen; and radiographic evidence of multiple loops of distended small intestine in a young foal would be suggestive of small intestinal volvulus. However, it is not possible to differentiate volvulus from other causes of small intestinal obstruction preoperatively. In adult horses volvulus frequently occurs in association with another disease process, during which small intestinal obstruction results in distention and subsequent rotation of the small intestina around the root of the mesentery. Although any segment of the small intestine may be involved, the distal jejunum and ileum are most frequently affected because of their relatively longer mesenteries.<sup>11</sup> The diagnosis is made at surgery by palpating a twist at the origin of the cranial mesenteric artery. Treatment includes resection of devitalized bowel, which may not be an option because of the extent of small intestinal involvement (similar to large colon volvulus). Prognosis is based on the extent of small intestine involved and its appearance after surgical correction of the lesion. In general, horses in which more than 50% of the small intestine is devitalized are considered to have a grave prognosis.<sup>32</sup>

### STRANGULATION BY WAY OF MESENTERIC OR LIGAMENTOUS RENTS

There are a number of structures that, when torn, may incarcerate a segment of intestine (typically the small intestine), including intestinal mesentery,<sup>19</sup> the gastrosplenic ligament,<sup>33</sup> the broad ligament,<sup>34</sup> and the cecocolic ligament.<sup>35</sup> Horses with such incarcerations exhibit presenting signs typical of a horse with strangulating small intestine, including moderate to severe signs of abdominal pain, endotoxemia, absent gastrointestinal sounds, distended small intestine on rectal palpation, nasogastric reflux, and serosanguinous abdominal fluid. However, the prognosis for many of these cases appears to be lower than for horses with other types of small intestinal strangulations. For example, in horses with small intestine entrapped in a mesenteric rent, only 7 of 15 horses were discharged from the hospital, and only 2 of 5 horses for which follow-up information was available survived long term (>5 months).<sup>19</sup> Poor outcome may result from the difficulty in untrapping incarcerated intestine, the degree of hemorrhage, and the length of intestine affected.

### INGUINAL HERNIA

Inguinal hernias are more common in Standardbred and Tennessee Walking horses that tend to have congenitally large inguinal canals.<sup>11</sup> Inguinal hernias may also occur in neonatal foals but differ from hernias in mature horses in that they are typically nonstrangulating. The nature of the hernia (direct versus indirect) is determined on the basis of the integrity of the parietal vaginal tunic. In horses in which the bowel remains within the parietal vaginal tunic, the hernia is referred to as *indirect* because, strictly speaking, the bowel remains within the peritoneal cavity. Direct hernias are those in which strangulated bowel ruptures through the parietal vaginal tunic and occupies a subcutaneous location. These direct hernias most commonly occur in foals and should be suspected when a

congenital inguinal hernia is associated with colic, swelling that extends from the inguinal region of the prepuce, and intestine that may be palpated subcutaneously.<sup>36,37</sup> Although most congenital indirect inguinal hernias resolve with repeated manual reduction or application of a diaper, surgical intervention is recommended for congenial direct hernias.<sup>36</sup>

Historical findings in horses with strangulating inguinal hernias include acute onset of colic in a stallion that had recently been used for breeding. A cardinal sign of inguinal herniation is a cool, enlarged testicle on one side of the scrotum (Figure 15-24).<sup>38,39</sup> However, inguinal hernias have also been reported in geldings.<sup>40</sup> Inguinal hernias can also be detected on rectal palpation, and manipulation of herniated bowel per rectum can be used to reduce a hernia but is not recommended because of the risk of rectal tears. In many cases the short segment of herniated intestine will markedly improve in appearance once it has been reduced and can sometimes be left unresected.<sup>41</sup> The affected testicle will be congested because of vascular compromise within the spermatic cord, and although it may remain viable, it is generally recommended that it be resected.<sup>41</sup> The prognosis in adult horses is good, with up to 75% of horses surviving to 6 months of age.<sup>39</sup> Horses that have been treated for inguinal hernias may be used for breeding. In these horses the remaining testicle will have increased sperm production, although an increased number of sperm abnormalities will be noticed after surgery because of edema and increased temperature of the scrotum.

### STRANGULATING UMBILICAL HERNIAS

Although umbilical hernias are common in foals, strangulation of herniated bowel is rare. In one study 6 of 147 (4%) horses with umbilical hernias had incarcerated intestine.<sup>42</sup> Clinical signs include a warm, swollen, firm, and painful hernia sac associated with signs of colic. The affected segment of bowel is usually small intestine, but herniation of cecum or large colon has also been reported.<sup>43</sup> In rare cases a hernia that involves only part of the intestinal wall may be found; this is termed a *Richter's hernia*. In foals that have a Richter's hernia, an enterocutaneous fistula may develop.<sup>43</sup> In one study 13 of 13 foals with strangulating umbilical hernias survived to discharge, although at least three were lost to long-term complications.<sup>43</sup>

**FIGURE 15-24** Inguinal hernia in a horse with colic. Note the enlarged testicle, which has compromised venous drainage because of herniated small intestine within the inguinal canal.

## INTUSSUSCEPTIONS

An intussusception involves a segment of bowel (intussusceptum) that invaginates into an adjacent aboral segment of bowel (intussusciens). The reason for such invagination is not always clear, but it may involve a lesion at the leading edge of the intussusception, including small masses, foreign bodies, or parasites. In particular, tapeworms (*Anoplocephala perfoliata*) have been implicated.<sup>44</sup> Ileocecal intussusceptions are the most common intestinal intussusceptions in the horse and typically affect young animals. In one study evaluating 26 cases of ileocecal intussusception, the median age of the horses was 1 year old.<sup>45</sup> Acute ileocecal intussusceptions are those in which the horse has a duration of colic of less than 24 hours and involve variable lengths of intestine, which ranged in one study from 6 cm to 457 cm in length. In acute cases the involved segment of ileum typically has a compromised blood supply. Chronic ileocecal intussusceptions typically involve short segments of ileum (up to 10 cm in length), and the ileal blood supply is frequently intact.<sup>45</sup> Abdominocentesis results are variable because strangulated bowel is contained within the adjacent bowel. There is often evidence of obstruction of the small intestine, including nasogastric reflux and multiple distended loops of small intestine on rectal palpation. Horses with chronic ileocecal intussusceptions have mild, intermittent colic, often without evidence of small intestinal obstruction. In one study a mass was palpated in the region of the cecal base in approximately 50% of cases.<sup>44</sup> Transabdominal ultrasound may be helpful in discerning the nature of the mass. The intussusception has a characteristic target appearance on cross section.<sup>46</sup> Other segments of the small intestine may also be intussuscepted, including the jejunum (Figure 15-25). In one study of 11 jejunojejunal intussusceptions, the length of bowel involved ranged between 0.4 to 9.1 m.<sup>47</sup> Attempts at reducing intussusceptions at surgery are usually futile because of intramural swelling of affected bowel. Jejunojejunal intussusceptions should be resected.

For acute ileocecal intussusceptions the small intestine should be transected as far distally as possible, and a

**FIGURE 15-25** Jejunojejunal intussusception in a horse with colic. Note the intussusceptum, which has become ischemic as a result of invagination of intestine and its mesenteric blood supply into the intussusciens.

jejunocecal anastomosis should be performed. In cases with particularly long intussusceptions (up to 10 m has been reported), an intracecal resection may be attempted.<sup>48</sup> For horses with chronic ileocecal intussusceptions, a jejunocecal bypass without small intestinal transection should be performed. The prognosis is good for horses with chronic ileocecal intussusceptions and guarded to poor for horses with acute ileocecal intussusceptions, depending on the length of bowel involved.<sup>45</sup>

## DIAPHRAGMATIC HERNIAS

Herniation of intestine through a rent in the diaphragm is rare in the horse. Any segment of bowel may be involved, although small intestine is most frequently herniated.<sup>49</sup> Diaphragmatic rents may be congenital or acquired, but acquired hernias are more common.<sup>49</sup> Congenital rents may result from incomplete fusion of any of the four embryonic components of the diaphragm: pleuroperitoneal membranes, transverse septum, body wall, and esophageal mesentery.<sup>49</sup> In addition, abdominal compression of the foal at parturition may result in a congenital hernia.<sup>49</sup> Acquired hernias are presumed to result from trauma to the chest or a sudden increase in intra-abdominal pressure, such as might occur during parturition, distention of the abdomen, a sudden fall, and strenuous exercise.<sup>50</sup> Hernias have been located in a number of different locations, although large congenital hernias are typically present at the ventral-most aspect of the diaphragm and most acquired hernias are located at the junction of the muscular and tendinous portions of the diaphragm.<sup>49</sup> A peritoneopericardial hernia has been documented in at least one horse.<sup>51</sup>

The clinical signs are usually associated with intestinal obstruction rather than respiratory distress.<sup>50</sup> However, careful auscultation may reveal an area of decreased lung sounds associated with obstructed intestine and increased fluid within the chest cavity.<sup>52</sup> Such signs may prompt thoracic radiography or ultrasound, both of which can be used to make a diagnosis. Auscultation may also reveal thoracic intestinal sounds, but it is typically not possible to differentiate these from sounds referred from the abdomen. In one report, two of three horses diagnosed with small intestinal strangulation by diaphragmatic hernia had respiratory acidemia, attributable to decreased ventilation.<sup>53</sup> Treatment of horses with diaphragmatic hernia is fraught with complications because of the need to reduce and resect strangulated bowel and the need to repair the defect in the diaphragm.<sup>54,55</sup> Because dorsal defects in the diaphragm are among the most common forms of diaphragmatic defect, it may not be possible to close the diaphragmatic hernia by way of the approach used for abdominal exploratory. However, because herniation is likely to recur,<sup>54</sup> it is appropriate to schedule a second surgery using an appropriate approach to resolve the diaphragmatic defect.

## ☞ LARGE COLON VOLVULUS

### CLINICAL SIGNS

Horses with large colon volvulus have rapid onset of severe, unrelenting abdominal pain. Postpartum broodmares appear to be at risk for this form of colic.<sup>4</sup> Once the large colon is strangulated (>270-degree volvulus), gas distention is marked, leading to gross distention of the abdomen, compromised

respiration as the distended bowel presses up against the diaphragm, and visceral pooling of blood as the caudal vena cava is compressed. Horses with this condition are frequently refractory to even the most potent of analgesics. These horses may prefer to lie in dorsal recumbency, presumably to take weight off the strangulated colon. An abbreviated physical examination is warranted in these cases because the time from the onset of strangulation to surgical correction is critical. Under experimental conditions the colon is irreversibly damaged within 3 to 4 hours of a 360-degree volvulus of the entire colon.<sup>56</sup> Despite severe pain and hypovolemia, horses may have a paradoxically low heart rate, possibly related to increased vagal tone. In addition, results of abdominocentesis often do not indicate the degree of colonic compromise,<sup>4,57</sup> and in many cases it is not worth attempting to obtain abdominal fluid because of extreme colonic distention.<sup>58</sup> Rectal palpation reveals severe gas distention of the large colon, frequently associated with colonic bands traversing the abdomen. In many cases colonic distention restricts access to the abdomen beyond the pelvic brim. A recent study has shown that plasma lactate levels below 6.0 mmol/L had a sensitivity of 84% and a specificity of 83% in predicting survival in horses with large colon volvulus.<sup>59</sup>

### SURGICAL FINDINGS

At surgery the volvulus is typically located at the mesenteric attachment of the colon to the dorsal body wall, and the most common direction of the twist is dorsomedial when the right ventral colon is used as a reference point.<sup>4</sup> However, the colon may twist in the opposite direction, twist greater than 360 degrees (up to 720 degrees has been reported), or twist at the level of the diaphragmatic and sternal flexures.<sup>4</sup> In all cases the colon should be decompressed as much as possible, and in many cases a colonic evacuation by way of a pelvic flexure enterotomy will greatly aid correction of the volvulus. After correction of the volvulus, a determination must be made as to whether the colon has been irreversibly injured. This should be based on mucosal color and bleeding (if an enterotomy has been performed), palpation of a pulse in the colonic arteries, serosal color, and appearance of colonic motility.<sup>7</sup> If the colon is judged to be irreversibly damaged, the feasibility of a large colon resection can be considered. Although 95% of the colon can be resected (that part of the colon distal to the level of the cecocolic fold), damage from the volvulus usually exceeds that which can be resected. In these cases surgeons may elect to resect as much damaged bowel as possible or advise euthanasia.<sup>7</sup>

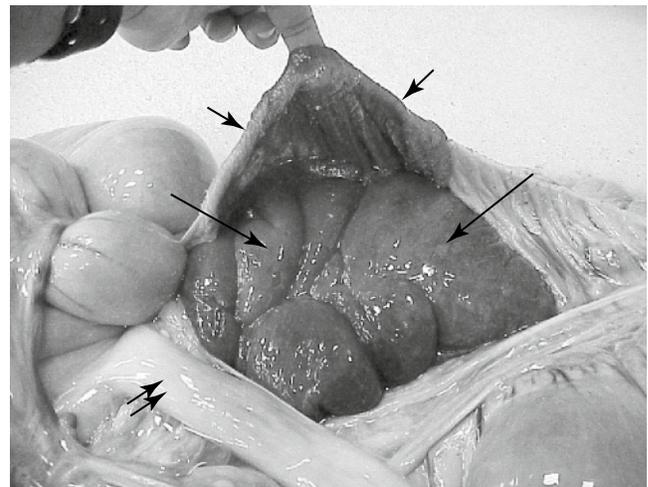

### PROGNOSIS

The prognosis is guarded to poor because of the rapid onset of this disease. In one study the survival rate was 35%.<sup>57</sup> In a more recent report, the survival rate was 36% for horses with 360-degree volvulus of the large colon compared with 71% for horses with 270-degree volvulus.<sup>4</sup> Postoperative complications include hypovolemic and endotoxemic shock, extensive loss of circulating protein, DIC, and laminitis. In addition, large colon volvulus has a propensity to recur. Although one study documented a recurrence rate of less than 5%,<sup>57</sup> some authors believe recurrence may be as high as 50%.<sup>7</sup> Therefore methods to prevent recurrence should be considered in patients at risk for recurrence, particularly broodmares that tend to suffer from the disease recurrently during the foaling season.<sup>60,61</sup>

## OTHER CAUSES OF LARGE INTESTINAL ISCHEMIA

### INTUSSUSCEPTIONS

The most common intussusceptions of the large intestine are cecocolic and cecocolic intussusceptions (Figure 15-26).<sup>62,63</sup> Both are likely attributable to the same disease process, with variable inversion of the cecum. These conditions tend to occur in young horses (63% were younger than 3 years old in one study) and may be associated with intestinal tapeworms.<sup>63</sup> Horses are seen with highly variable clinical signs, including acute, severe colic; intermittent pain over a number of days; and chronic weight loss.<sup>63</sup> These variable presentations likely relate to the degree to which the cecum has intussuscepted. Initially, the cecal tip inverts, creating a cecocolic intussusception, which does not obstruct the flow of ingesta. As the intussusception progresses, the cecum inverts into the right ventral colon (cecocolic intussusception), which obstructs the flow of ingesta and often causes severe colic. The cause of abdominal pain is often difficult to differentiate in these cases, although it is sometimes possible to detect a mass on the right side of the abdomen by either rectal palpation or ultrasound examination.<sup>62,63</sup> Treatment involves manual surgical reduction by retracting the intussusceptum directly<sup>62</sup> or by way of an enterotomy in the right ventral colon.<sup>64</sup> However, sometimes the cecum cannot be readily reduced because of severe thickening, and in other cases surgical procedures result in fatal contamination. For example, in one report 8 of 11 horses were euthanized in the perioperative period because of complications,<sup>62</sup> and in another report 12 of 30 horses were euthanized either before or during surgery. The latter included all of the horses with chronic disease because of irreversible changes to the cecum.<sup>63</sup> However, one recent report on cecocolic intussusceptions indicated that 7 of 8 horses that underwent right ventral colon enterotomy and cecal resection survived long

**FIGURE 15-26** Cecocolic intussusception in a horse with colic. An enterotomy has been made in the right ventral colon (*short arrows*) to reveal an intussuscepted cecum (*arrows*). Although this picture was taken at necropsy, an enterotomy such as the one shown in this figure can be used to exteriorize and resect the majority of the compromised cecum. Note the ileum adjacent to the colon (*double arrow*).

term,<sup>64</sup> suggesting that continued improvements in surgical techniques may improve the prognosis.

Colocolic intussusceptions are exceptionally rare but have reportedly affected the pelvic flexure and the left colons.<sup>65-68</sup> Although the condition is reportedly more common in young horses,<sup>66-68</sup> older horses may be affected.<sup>65</sup> Clinical findings may include a palpable mass on the left side of the abdomen.<sup>66</sup> Ultrasonography may also be useful. Treatment requires manual reduction of the intussusception at surgery<sup>66,68</sup> or resection of affected bowel.<sup>65</sup> Because the left colons can be extensively exteriorized and manipulated at surgery,<sup>65-68</sup> the prognosis is fair.

## ☞ RECTAL PROLAPSE

Rectal prolapse may occur secondary to any disease that causes tenesmus, including diarrhea, rectal neoplasia, and parasitism,<sup>69</sup> or prolapse can occur secondary to elevations in intra-abdominal pressure during parturition or episodes of coughing.<sup>70,71</sup> Rectal prolapses are classified into four categories (Table 15-14) depending on the extent of prolapsed tissue and the level of severity.<sup>72</sup> Type I rectal prolapse is most common and characterized by a doughnut-shaped prolapse of rectal mucosa and submucosa (Figure 15-27). Type II prolapses involve full-thickness rectal tissue, whereas type III prolapses additionally have invagination of small colon into the rectum.

TABLE 15-14

Classification of Rectal prolapse		
Grade	Description	Prognosis
I	Prolapse of rectal mucosa	Good
II	Prolapse of full-thickness rectum	Fair
III	Grade 2 prolapse with additional protrusion of small colon	Guarded
IV	Intussusception of rectum and small colon through the anus	Poor

**FIGURE 15-27** Type I rectal prolapse in a horse. Note circumferential protrusion of partial thickness rectal tissue (arrows) that is becoming congested as a result of pressure from the surrounding anus.

Type IV prolapses involve intussusception of proximal rectum or small colon through the anus in the absence of prolapse of tissue at the mucocutaneous junction at the anus.<sup>72</sup> These can be differentiated from other forms of prolapse by their appearance and a palpable trench between prolapsed tissue and the anus.

In type I prolapses most frequently seen in horses with diarrhea, the rectal mucosa becomes irritated and protrudes intermittently during episodes of tenesmus. If tenesmus persists, rectal mucosa can remain prolapsed. Rectal mucosa rapidly becomes congested and edematous under these conditions, which should be treated with osmotic agents such as glycerin or magnesium sulfate and by massaging and reducing the prolapse.<sup>73</sup> A purse-string suture may be necessary to keep the mucosa inside the rectum. Topical application of lidocaine solution or jelly, epidural anesthesia, and sedation may help reduce tenesmus that incites and exacerbates rectal prolapse. Similar treatments can be applied with type II rectal prolapses. However, these more severe prolapses may not be reducible without surgical resection of mucosa and submucosa from the prolapsed bowel.<sup>69,73</sup>

Type III and type IV rectal prolapses are more serious injuries because the small colon is involved.<sup>74</sup> In horses with type III prolapses, an abdominocentesis should be performed to determine if the injury to the small colon has resulted in peritonitis. The small colon component should be reduced manually if possible, whereas prolapsed rectal tissue typically requires mucosal or submucosal resection. Surgical exploration of the abdomen should be performed to determine the status of the small colon, although serial abdominocenteses can be used in lieu of surgery to detect progressive necrosis of bowel. Type IV prolapses are seen most commonly in horses with dystocia.<sup>72</sup> These prolapses are almost always fatal because of stretching and tearing of mesenteric vasculature, with subsequent infarction of affected bowel. Therefore euthanasia is usually warranted on the basis of physical examination findings. However, confirmation of severe small colonic injury requires abdominal exploration using either a midline approach or laparoscopy.<sup>75</sup> It is conceivable that a horse with compromised small colon could undergo a colostomy of the proximal small colon, but the compromised small colon will typically necrose beyond that which can be resected using a midline abdominal approach.<sup>73</sup>

## ☞ NONSTRANGULATING INFARCTION

Nonstrangulating infarction occurs secondary to cranial mesenteric arteritis caused by migration of *Strongylus vulgaris*<sup>76</sup> and has become a relatively rare disorder since the advent of broad spectrum anthelmintics. Although thromboemboli have been implicated in the pathogenesis of this disease, careful dissection of naturally occurring lesions has not revealed the presence of thrombi at the site of intestinal infarctions in most cases.<sup>76</sup> These findings suggest that vasospasm plays an important role in this disease.<sup>11</sup> Clinical signs are highly variable, depending on the extent to which arterial flow is reduced and the segment of intestine affected. Any segment of intestine supplied by the cranial mesenteric artery or one of its major branches may be affected, but the distal small intestine and large colon are more commonly involved.<sup>76</sup> There are no clinical variables that can be used to reliably differentiate this disease from strangulating obstruction.<sup>76</sup> In some cases massive infarction results in acute, severe colic.<sup>76</sup>

Occasionally, an abnormal mass and fremitus may be detected on rectal palpation of the root of the cranial mesenteric artery. This disease should be considered a differential diagnosis in horses with a history of inadequate anthelmintic treatment and the presence of intermittent colic that is difficult to localize. Although fecal parasite egg counts should be performed, they are not indicative of the degree of parasitic infestation.

In addition to routine treatment of colic, dehydration, and endotoxemia, medical treatment may include aspirin (20 mg/kg/day) to decrease thrombosis.<sup>11</sup> Definitive diagnosis requires surgical exploration. However, these cases are difficult to treat because of the patchy distribution of the lesions and the possibility of lesions extending beyond the limits of surgical resection. In addition, further infarction may occur after surgery. The prognosis is fair for horses with intermittent mild episodes of colic that may be amenable to medical therapy but poor in horses that require surgical intervention.<sup>11,76</sup>

## OBSTRUCTIVE DISORDERS OF THE GASTROINTESTINAL TRACT

*Anthony T. Blikslager*

### ☞ APPROACH TO THE HORSE WITH COLIC

Clinical management of colic is distinctly different from management of many other clinical syndromes because the initial focus is not on defining the definitive diagnosis but rather on determining whether the horse requires surgical exploration. Therefore the clinician must collect a series of historical and physical examination findings and decide whether these findings warrant medical management or whether referral and potential surgical exploration of the abdomen are necessary because of a suspected obstructive or ischemic lesion. For example, a horse may exhibit presenting signs of severe abdominal pain, poor cardiovascular status, and abdominal distention that may be compatible with an extensive list of differential diagnoses and, more important, may indicate the need for abdominal exploration to minimize the extent of intestinal injury. The speed with which this clinical decision can be made has a tremendous impact on the well-being of the patient,<sup>1,2</sup> because delaying surgical exploration of a horse with ongoing intestinal injury exacerbates shock induced largely by microbial toxins such as LPS traversing damaged mucosa, and this in turn correlates with mortality.<sup>3</sup>

### HISTORY

The initial clinical step in treating horses with colic is taking a thorough history. However, it may be necessary to delay this until after the physical examination and initial treatment because management of abdominal pain takes precedence. The vital components of the history that should be obtained before examination and treatment, if possible, are the duration and severity of colic symptoms, analgesics already administered, and a history of any adverse drug reactions. The two most critical factors from a history that would support a decision to refer and potentially surgically explore a horse with colic are the duration of signs<sup>2</sup> and the extent of pain.<sup>4</sup> The latter is deduced

by asking the owner about the presence and frequency of pawing, looking at the flanks, rolling, repeatedly going down and getting back up, and posturing as if to lie down or urinate, in addition to other clinical evidence of pain. Other important components of the history that should be obtained to ascertain the reason for the colic are listed in [Table 15-15](#).

### PHYSICAL EXAMINATION FINDINGS

Just as the clinician may need to postpone the complete history to allow rapid treatment of the colic, so must the clinician be able to alter the extent of the physical examination in order to treat the horse in a timely fashion. The most critical examination finding is the horse's heart rate, because this has repeatedly been shown to reflect the level of pain and provide an excellent assessment of the cardiovascular status of the horse. The heart rate is likely the single most reliable predictor of the need for surgery and survival.<sup>5</sup> Because analgesic treatments can dramatically alter the heart rate, it should be obtained, if at all possible, before administration of analgesics. Other components of the examination are specifically designed to provide additional information on the cardiopulmonary status of the horse (quality of the pulse, mucous membrane color, capillary refill time, respiratory rate, and full auscultation of the chest) and the nature of any intestinal obstruction that the horse might have (auscultation of gastrointestinal sounds, per rectal palpation of the abdomen, and presence of nasogastric reflux). Although there are classic presentations for horses with obstructions of either the small or large intestine ([Table 15-16](#)), clinical presentations of the various types of intestinal obstructions vary. For example, a horse that has a small intestinal obstruction may have several loops of distended small intestine without any evidence of nasogastric reflux, depending on the site of the obstruction (distal versus proximal), the extent of obstruction, and the duration of obstruction. Other examples include horses with large colon obstruction, which may have reflux because of direct compression of the small intestine by distended colon or because of tension on the duodenocolic ligament. The most useful diagnostic means to determine the type of intestinal obstruction is rectal palpation of the abdomen.<sup>4</sup> However, only approximately one third of the abdomen can be reached by way of the rectum, and this may be substantially less in very large or heavily pregnant horses. Nonetheless, it is worthwhile to try to determine the type of obstruction the horse has (i.e., small intestine versus large intestine and simple obstruction versus strangulating obstruction) because this information can be very helpful in determining the prognosis. In one study interns and residents at a veterinary teaching hospital were able to predict the type of lesion with a specificity exceeding 90%.<sup>6</sup> This in turn can be very helpful in educating the client about the potential findings in surgery and the likelihood that the horse will survive.

### MANAGEMENT OF ABDOMINAL PAIN

Before considering ways to manage signs of colic, the clinician should remember that such signs are very poorly localized. Therefore, although colic is most frequently associated with intestinal disease, dysfunction of other organ systems, including urinary obstruction,<sup>7,8</sup> biliary obstruction,<sup>9</sup> uterine torsion or tears,<sup>10,11</sup> ovarian artery hemorrhage,<sup>10</sup> and neurologic disease should be considered as differential diagnoses.<sup>12</sup> However, the duration and severity of colic signs are excellent

TABLE 15-15

History Findings and Their Relevance to Colic and Its Prevention		
	Risk for Colic	Potential Mechanisms
Feeding	Recent change in feed	Alteration in fluid flux or fermentation in the large colon
	Coastal Bermuda hay with a high fiber content	Obstruction of ileum by fine, fibrous hay
	Feeding round bales	Poor-quality hay
	Feeding off the ground	Horses may ingest sand in some regions of the country
	Excessive concentrate	Alteration in fluid flux or fermentation in the large colon
	Large infrequent meals	Alteration in fluid flux or fermentation in the large colon
	Bolting feed	Large boluses of feed entering the esophagus and stomach
Environment	Excessive time in stall	Insufficient intake of roughage Insufficient exercise
	Insufficient access to water	Dehydration
Exercise	Exercise-induced exhaustion	Dehydration Reduced gastrointestinal motility
Preventive care	Insufficient dental care	Poor mastication of feed
	Insufficient anthelmintic treatment	Large parasite burden
Medication	Excessive administration of NSAIDs	Mucosal damage, particularly in the stomach and colon
Previous medical history	Colic surgery	Adhesions Anastomotic obstruction

TABLE 15-16

Indications for Surgery in Patients with Colic According to Their Clinical Signs	
Indication	Clinical Signs
Refractory pain	Repeated episodes of pain despite treatment with analgesics Violent episodes of pain Persistently elevated heart rate (>48 beats/min)
Sepsis in the face of colic	Persistently elevated heart rate Weak peripheral pulse Abnormal mucous membrane color (pale, hyperemic, purple) Delayed capillary refill time (>2 seconds)
Evidence of a refractory small intestinal obstruction	Refractory pain Nasogastric reflux Distended loops of small intestine on rectal palpation
Evidence of a refractory large intestinal obstruction	Refractory pain Abdominal distention Distended large colon on rectal palpation Tight band(s) on rectal palpation
Evidence of devitalized bowel	Sepsis Abnormal abdominocentesis (TP >2.5 g/dl, TNCC >10,000/ $\mu$ l)

TNCC, Total nucleated cell count;  
TN, total protein

TABLE 15-17

Analgesics Commonly Used to Treat Colic in Horses		
Drug	Dosage	Amount for an Adult Horse
Butylscopolamin	0.3 mg/kg	150-170 mg
Xylazine	0.3 – 0.5 mg/kg prn	150-250 mg
Detomidine	0.01-0.02 mg/kg prn	5-10 mg
Butorphanol	0.01-0.02 mg/kg prn	5-10 mg
Flunixin	0.25-1.1 mg/kg every 8-12 hr*	125-500 mg

PRN, As needed.  
\*The longer treatment interval corresponds to the higher dose, whereas lower doses may be given more frequently

predictors of whether a horse requires surgical exploration of the abdomen. In fact, refractory pain supersedes all other predictors of the need for surgery in the colic patient. Once signs of colic have been recognized and categorized as to their severity, it is critical to rapidly and effectively nullify signs of pain, for the well-being of the horse and to reduce the owner's anxiety. In addition, it is becoming increasingly clear that pain is best managed before it becomes severe.<sup>13</sup> There are several classes of analgesics readily available for treatment of horses with colic (Table 15-17), including spasmolytics (N-butylscopolamine),  $\alpha_2$ -agonists (xylazine, detomidine),

opiates (butorphanol), and NSAIDs (e.g., flunixin meglumine). Although much of this information is very familiar to most practitioners, a couple of points should be emphasized. The short-duration drugs N-butylscopolamine, xylazine, and butorphanol, which provide analgesia either directly (xylazine and butorphanol) or indirectly (through cessation of intestinal spasm; N-butylscopolamine) for approximately 30 to 45 minutes, allow the veterinarian to determine if pain is recurrent within the time period of the typical examination. Alternatively, flunixin meglumine is not as potent as an analgesic, but its duration is much longer. In fact, the clinician should closely adhere to its treatment interval to prevent deleterious effects on gastrointestinal mucosa and the kidneys.<sup>14,15</sup> The recent discovery of two isoforms of COX, the enzyme inhibited by NSAIDs, has provided drugs that can more selectively inhibit pro-inflammatory COX-2, while permitting continued constitutive production of prostanoids. This may be advantageous in horses with colic, particularly in light of recent evidence of reduced intestinal recovery from an ischemic event when subjects were treated with flunixin compared with a drug that is more selective for COX-2.<sup>16</sup> The  $\alpha_2$ -agonist detomidine should be reserved for horses with severe, unrelenting pain because of its tremendous potency in horses.<sup>17</sup> In addition, it should be remembered that  $\alpha_2$ -agonists reduce the heart rate associated with a transient increase in blood pressure,<sup>18,19</sup> thereby reducing the predictive value of the heart rate and pulse pressure.

### CLINICAL PATHOLOGY

The most useful clinical pathologic tests are the packed cell volume and total protein because they can be used to substantiate clinical estimates of dehydration and correlate strongly with prognosis.<sup>2,20,21</sup> A biochemical profile is useful for assessing electrolyte imbalances and kidney and liver function, whereas blood gas analysis can be used to assess acid-base status. Horses with colic most frequently show evidence of metabolic acidosis, associated with hypovolemia or endotoxemia, but other abnormalities, such as metabolic alkalosis in association with extensive loss or sequestration of stomach Cl<sup>-</sup>, may be noted. Metabolic acidosis has been further investigated in horses with colic by measuring blood lactate, which is now an option in many laboratories.<sup>22</sup> Lactate levels have also been inferred from measurement of the anion gap, although one study noted that lactate in horses with colic did not account for the entire anion gap.<sup>22</sup> Lactate levels and anion gap closely correlate with the level of intestinal injury and the prognosis for survival.<sup>20,23,24</sup>

Other key components of the clinical pathologic evaluation of horses with colic are the abdominocentesis and complete blood count. Regarding the latter, the total white blood cell and differential counts can provide crucial evidence of colic attributable to colitis (leukopenia, neutropenia, and a left shift) rather than an obstruction (highly variable complete blood count findings). PF can be very helpful in determining the integrity of the intestine. Specifically, as the intestine becomes progressively devitalized, the PF will become serosanguinous as red blood cells are leaked into the abdomen, followed by an elevation in the total protein (>2.5g/dl) and progressive increases in total nucleated cell count (>10,000 cells/ $\mu$ l). However, these findings do not always correlate well with the condition of the intestine, particularly in horses with large colon volvulus. For example, in a study

of 57 horses with large colon volvulus, the average total protein (2.5 g/dl) and total nucleated cell count (1000 cells/ $\mu$ l) were normal despite the fact that only 36% with a 360-degree volvulus survived.<sup>25</sup> This may occur because the development of severe mucosal injury following large colon volvulus is rapid and may not allow sufficient time for protein and leukocytes to equilibrate with the abdominal fluid before the horse dies.<sup>26</sup>

Investigators have attempted to take all the variables routinely assessed during evaluation of horses for colic and develop models that can be used to accurately predict the need for surgery and the prognosis for life.<sup>2,27-30</sup> However, none of these models has taken the place of clinical decision making, although these predictive studies have added tremendously to our understanding of the importance of some prognostic factors, particularly those reflecting cardiovascular function.

### SMALL INTESTINAL SIMPLE OBSTRUCTION

Simple obstruction involves intestinal obstruction of the lumen without obstruction of vascular flow. However, because there is a tremendous volume of fluid that enters the small intestinal lumen on a daily basis,<sup>31,32</sup> the obstructed intestine tends to become distended, which in turn may cause reduced mural blood flow.<sup>33</sup> Ultimately, such distention can result in necrosis of tissues, particularly in the immediate vicinity of the obstruction.<sup>34</sup> There are relatively few causes of simple obstruction in the small intestine, and the incidence of these types of obstruction is low (approximately 3% of all referred horses in one large hospital-based study).<sup>5</sup> However, in some geographic regions this type of obstruction is prevalent. For example, in the southeastern United States, ileal impactions are relatively common.<sup>35,36</sup>

### ASCARID IMPACTIONS

Impactions caused by *Parascaris equorum* typically occur in foals younger than 6 months of age that have been on a poor deworming program and have a heavy parasite burden. Products that cause sudden ascarid death, including organophosphates, ivermectin, and pyrantel pamoate, have been incriminated in triggering acute intestinal obstruction by dead parasites.<sup>37</sup> This is a particular problem with ascarids because of the relatively large size of the adult parasite. Clinical signs include acute onset of colic after administration of an anthelmintic and signs compatible with small intestinal obstruction, including nasogastric reflux. Occasionally, dead parasites are present in the reflux. The onset of the disease varies according to the degree of obstruction.<sup>37</sup> A tentative diagnosis may be made on the basis of the history and signs referable to small intestinal obstruction. Abdominal radiographs and ultrasound may indicate the presence of multiple loops of distended small intestine but are not required if clinical signs indicate the immediate need for surgery. Initial medical treatment should include treatment of hypovolemic shock resulting from sequestration of fluid in the small intestine. Surgical treatment typically involves an enterotomy made over the intraluminal impaction and removal of ascarids. The prognosis is fair in cases that are rapidly addressed but poor in foals with evidence of hypovolemia and septic shock. In a recent study long-term survival of 25 affected horses was 33%.<sup>37</sup>

## ILEAL IMPACTION

Ileal impactions occur most commonly in adult horses in the southeastern United States. Although feeding of coastal Bermuda hay has been implicated in this regional distribution, it has been difficult to separate geographical location from regional hay sources as risk factors.<sup>38</sup> Nonetheless, it is likely that feeding suboptimal-quality coastal Bermuda hay puts horses at risk for ileal impaction, most likely because when the fiber content of this particular type of hay is high, the fibers are thin and most likely prematurely swallowed. The relationship between fiber content and eating patterns is theoretical and remains to be proved. In addition, sudden changes in feed from an alternative type of hay to coastal Bermuda hay likely put a horse at risk for ileal impaction.<sup>38</sup> Studies in the U.K. have revealed tapeworm infection as an important risk factor for ileal impaction. Based on risk analysis, the data suggested that more than 80% of the ileal impaction cases studied were associated with serologic or fecal evidence of tapeworm infection.<sup>39</sup> Because of the poor sensitivity of fecal analysis for tapeworms, a serologic test (ELISA) has been developed by Proudman et al. with a sensitivity of approximately 70% and a specificity of 95%.<sup>40</sup>

Clinical signs of horses with ileal impaction are typical for a horse with small intestinal obstruction, including onset of moderate to severe colic and rectally palpable loops of distended small intestine as the condition progresses. Because the ileum is the distal-most aspect of the small intestinal tract, nasogastric reflux may take a considerable time to develop and is found in approximately 50% of horses requiring surgical correction of impacted ileum.<sup>35,41</sup> The diagnosis is usually made at surgery, although an impacted ileum may on occasion be palpated rectally.<sup>36</sup> Multiple loops of distended small intestine frequently make the impaction difficult to palpate. Ileal impactions may resolve with medical treatment<sup>36</sup> but frequently require surgical intervention (Figure 15-28). At surgery fluids can be directly infused into the mass, allowing the surgeon to break down the impaction. Dioctyl sodium sulfosuccinate (DSS) may be included in the infused fluid to aid in disruption of the mass. Extensive small intestinal distention

**FIGURE 15-28** Intraoperative view of an ileal impaction. Note the distended appearance of the ileum as it courses toward the cecal base.

and intraoperative manipulation of the ileum may lead to postoperative ileus,<sup>42</sup> but recent studies indicate that this complication is less frequent as the duration of disease before admission has decreased.<sup>35</sup> However, an enterotomy should be considered to evacuate impacted intestinal contents and reduce manipulation. Recent studies indicate that the prognosis for survival is good.<sup>35,36</sup>

## ILEAL HYPERTROPHY

Ileal hypertrophy is a disorder in which the muscular layers (both circular and longitudinal) of the ileum thicken for unknown reasons (idiopathic) or secondary to an incomplete or functional obstruction. For idiopathic cases proposed mechanisms include parasympathetic neural dysfunction resulting in chronically increased muscle tone and subsequent hypertrophy of the muscular layers of the ileal wall. Such neural dysfunction possibly results from parasite migration.<sup>43</sup> Alternative hypotheses include chronic increases in the muscular tone of the ileocecal valve, leading to muscular hypertrophy of the ileum as it contracts against a partially occluded ileocecal valve. The jejunum may also be hypertrophied, either alone or in combination with the ileum.<sup>43</sup> Clinical signs include chronic intermittent colic as the ileum hypertrophies and gradually occludes the lumen. In one study partial anorexia and chronic weight loss (1 to 6 months) were documented in 45% of the horses, most likely because of intermittent colic and reduced appetite.<sup>43</sup> Because the ileal mucosa is not affected by this condition, there is no reason to believe that these horses experience malabsorption of nutrients. The diagnosis is usually made at surgery, although the hypertrophied ileum may be palpated rectally in some cases.<sup>43</sup> For treatment an ileocecal or jejunocecal anastomosis to bypass the hypertrophied ileum is performed. Without surgical bypass intermittent colic persists, and the thickened ileum may ultimately rupture.<sup>43</sup> The prognosis is fair with surgical treatment.<sup>44</sup>

Secondary ileal hypertrophy is most commonly noted in horses that have previously had colic surgery and that may have a partial or functional obstruction at an anastomotic site. For example, in one case report a horse developed ileal hypertrophy after surgical correction of an ileocecal intussusception.<sup>45</sup> Ileal hypertrophy was also noted in a horse in which an ileocolic anastomosis was incorrectly orientated during surgical treatment of a cecal impaction.<sup>46</sup> Horses are typically re-examined for recurrence of colic in these cases. Surgical therapy is directed at addressing the cause of small intestinal obstruction and resecting hypertrophied intestine.

## MECKEL'S DIVERTICULUM

Meckel's diverticulum is an embryonic remnant of the vitellumbilical duct, which fails to completely atrophy and becomes a blind pouch projecting from the antimesenteric border of the ileum.<sup>47,48</sup> However, similar diverticulae have also been noted in the jejunum.<sup>49</sup> These diverticulae may become impacted, resulting in partial luminal obstruction, or may wrap around an adjacent segment of intestine, causing strangulation.<sup>47</sup> Occasionally, an associated mesodiverticular band may course from the diverticulum to the umbilical remnant and serve as a point around which small intestine may become strangulated. Mesodiverticular bands may also originate from the embryonic ventral mesentery and attach to the antimesenteric surface of the bowel, thereby forming a potential space

within which intestine may become entrapped.<sup>50</sup> Clinical signs range from chronic colic, for an impacted Meckel's diverticulum, to acute, severe colic if a mesodiverticular band strangulates intestine. The diagnosis is made at surgery, and treatment requires resection of the diverticulum and any associated bands.<sup>50</sup> The prognosis is good for horses with simple impaction of a Meckel's diverticulum and guarded for horses with an associated small intestinal strangulation.<sup>50</sup>

## ADHESIONS

Adhesions of one segment of bowel to another or of a segment of intestine to other organs and the body wall typically occur after abdominal surgery and may be clinically silent, cause chronic colic attributable to partial obstruction, or result in acute obstruction. These differing clinical syndromes are attributable to the type of adhesions that develop. For example, a fibrous adhesion that does not by itself obstruct the intestinal lumen might serve as the pivot point for a volvulus, whereas an adhesion between adjacent segments of the intestinal tract may create a hairpin turn that causes chronic partial obstruction.<sup>51</sup> The number of adhesions that develop may also vary dramatically from horse to horse. Some horses may develop a single adhesion adjacent an anastomotic site or a discrete segment of injured intestine, whereas other horses may develop diffuse adhesions involving multiple segments of intestine, likely because of widespread inflammatory disease at the time of the original surgery.

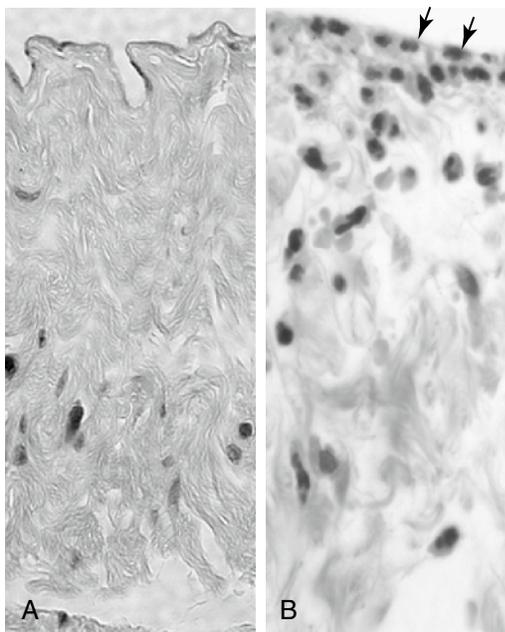

The mechanisms whereby adhesions develop are complex, but they likely involve initial injury to the serosa initiated by intestinal ischemia, reperfusion injury, and luminal distention.<sup>52</sup> Such injury involves infiltration of neutrophils into the serosa, accompanied by loss of mesothelial cells (Figure 15-29). In one study assessing the margins of resected small intestine, extensive neutrophil infiltration was documented in

the serosa, particularly in the proximal resection margin that had been distended before correction of a variety of strangulating lesions.<sup>53</sup> Regions of serosal injury and inflammation subsequently undergo reparative events similar to those of any wound, including local production of fibrin, de novo synthesis of collagen by infiltrating fibroblasts, and ultimately maturation and remodeling of fibrous tissue. Unfortunately, during this process fibrin may result in injured intestinal surfaces adhering to adjacent injured bowel or an adjacent organ. Once a fibrinous adhesion has developed, new collagen synthesis may result in a permanent fibrous adhesion. Alternatively, fibrinous exudate may be lysed by proteases released by local phagocytes, thereby reversing the adhesive process. Thus formation of adhesions may be viewed as an imbalance of fibrin deposition and fibrinolysis.<sup>54</sup>

Prevention of adhesions relies on inhibition of the mechanisms involved in adhesion formation, including reduction of serosal injury with early intervention and good surgical technique, reduction of inflammation by administration of anti-inflammatory medications, physical separation of inflamed serosal surfaces (e.g., carboxymethylcellulose, hyaluronan),<sup>55-57</sup> and pharmacologic modulation of fibrinous adhesion formation (e.g., heparin<sup>58</sup>). In addition, early return of motility in the small intestine after surgery may reduce contact time between inflamed surfaces of intestine, thereby reducing the chances of adhesion formation.<sup>54</sup>

Horses at greatest risk of developing adhesions after colic surgery appear to be those that have small intestinal disease.<sup>51,59</sup> For example, in one study of horses undergoing surgical correction of small intestinal obstruction, 22% developed a surgical lesion associated with adhesions. However, foals appear to have an increased incidence of adhesions compared with mature horses, regardless of the nature of the abdominal surgery.<sup>51</sup> For example, one study indicated that 17% of foals developed lesions attributable to adhesions regardless of the type of the initial surgery.<sup>60</sup> Studies conflict as to whether the degree of surgical intervention influences adhesion formation,<sup>51</sup> but horses that require enterotomy or resection and anastomosis were found to be at greatest risk of developing adhesions in one study.<sup>59</sup> As an indication of the importance of postoperative adhesion formation, adhesions were among the most important reasons for repeat laparotomy in postoperative colic patients.<sup>59,61</sup>

Clinical signs in horses with adhesions are highly variable, depending on whether the adhesion is causing partial obstruction, complete luminal obstruction, or involvement of intestinal vasculature. However, adhesions would be an important differential for intermittent colic in the postoperative period, particularly if such colic was not relieved by nasogastric decompression of the stomach. Continued intermittent colic should prompt abdominocentesis to determine if there is evidence of septic peritonitis, which may contribute to adhesion formation. Placement of a large-bore drain and peritoneal lavage (Figure 15-30) will help resolve peritonitis and may reduce adhesion formation by reducing intra-abdominal inflammation. If postoperative colic persists, repeat laparotomy or laparoscopy may be elected. In one study on adhesions, 70% of repeat laparotomies were performed within 60 days, suggesting that surgical colic attributable to adhesions typically occurs within two months of an initial surgical procedure. Unfortunately, the prognosis for horses with colic attributable to adhesions is low, with only 16% of horses surviving adhesion-induced colic in one study.<sup>51</sup>

**FIGURE 15-29** Histologic appearance of the serosa of equine jejunum. **A**, Normal intestine, with a clearly distinguishable layer of mesothelial cells. **B**, Jejunum after 2 hours of ischemia and 18 hours of reperfusion, showing complete loss of mesothelial cells and dense infiltration of neutrophils (arrows).

**FIGURE 15-30** Peritoneal lavage in a horse. Note the use of an intravenous administration set and a large-bore catheter placed in the dependent portion of the abdomen adjacent to the ventral midline incision.

## POSTOPERATIVE ILEUS

The definition of *ileus* is intestinal obstruction, which includes both physical and functional obstructions. However, in veterinary medicine the term is typically used to designate a lack of progressive aboral propulsion of ingesta resulting in functional obstruction.<sup>62</sup> The diagnosis of postoperative ileus is typically based on the presence of excessive nasogastric reflux and may occur after any abdominal exploratory procedure. However, horses undergoing surgery for strangulating small intestinal lesions or small intestinal obstructive lesions such as an ileal impaction are at greatest risk.<sup>42</sup> Recently, the syndrome of postoperative ileus in horses has been broadened to include those horses that may have delayed transit of ingesta through the large intestine after surgery. This large intestinal ileus may follow any type of surgery, particularly horses that have had orthopedic surgery, and is characterized by reduced fecal output (<three piles of manure/day) rather than excessive nasogastric reflux.<sup>62</sup> However, horses with excessive nasogastric reflux are unlikely to have normal fecal output, so the distinction between these two manifestations of ileus is not absolute.

Mechanisms involved in precipitating postoperative ileus characterized by small intestinal dysfunction likely involve local inflammation, reduced coordination of progressive motility, and increased sympathetic tone. A recent series of studies in the rat has shown that surgical manipulation of intestine results in delayed transit time associated with infiltration of neutrophils into intestinal longitudinal muscle and upregulation of

inducible nitric oxide synthase and COX-2.<sup>63-65</sup> The mechanisms in the horse may be similar in that extensive manipulation of the intestine resulted in abnormal intestinal motility in ponies,<sup>66</sup> and prostanoids and nitric oxide have been shown to alter or reduce intestinal motility in horses.<sup>67-69</sup>

Clinical signs of postoperative ileus subsequent to colic surgery include evidence of abdominal pain, increased heart rate, reduced gastrointestinal sounds, and reflux of fluid through a nasogastric tube. A sudden increase in the heart rate of a postoperative patient following colic surgery should prompt immediate nasogastric intubation to decompress the stomach. Treatment should include attempts at refluxing the horse at frequent intervals, rather than relying on passive flow of reflux. In addition, administration of intravenous should account for the horse's maintenance requirement (50 ml/kg/day, approximately 1L/hr in the average horse) and fluid losses resulting from reflux. In practice, this requires frequent monitoring of packed cell volume and total protein to ensure that the horse remains well hydrated. Although there have been concerns that overhydrating horses may contribute to increased nasogastric reflux,<sup>42</sup> it is critical to keep horses well hydrated to prevent hypovolemic shock. Additionally, electrolytes should be frequently monitored, particularly in light of their potential role in smooth muscle contraction and nerve excitability. Because of the important role of inflammation in postoperative ileus, including elaboration of COX-2–produced prostanoids,<sup>70</sup> administration of NSAIDs is indicated. This is particularly true if postoperative ileus is associated with endotoxemia because LPS-induced prostanoid production disrupts propulsive motility in horses.<sup>71,72</sup> Interestingly, phenylbutazone was more effective than flunixin meglumine at reducing the deleterious actions of LPS on intestinal motility.<sup>73</sup> However, caution should be exercised when administering NSAIDs in patients with postoperative ileus in light of research suggesting that complete inhibition of prostanoid production can alter motility patterns in normal equine intestine.<sup>68</sup> The advent of selective COX-2 inhibitors may provide optimal anti-inflammatory treatment in the future.<sup>74</sup>

Other treatments aimed at specifically modulating intestinal motility include lidocaine (bolus of 1.3 mg/kg followed by 0.05 mg/kg/min for 24 hours), erythromycin (0.5-1.0 mg/kg slow intravenous infusion in 1 L saline every 6 hours), and metoclopramide (0.04 mg/kg/hr).<sup>66,75,76</sup> The mechanisms of lidocaine action may include inhibition of sensory nerve activity within the wall of the intestine, reduction of postoperative pain, and novel anti-inflammatory activity. However, the presence and clinical relevance of these mechanisms in the horse remain to be determined. Nonetheless, there is good evidence to show the action of lidocaine on sensory nerves in models of diarrheal disease, suggesting distinct mechanism of action for systemic administration of local anesthetics.<sup>77</sup> Metoclopramide may stimulate intestinal motility by several mechanisms, including dopamine receptor blockade, cholinergic stimulation, and adrenergic blockade.<sup>66</sup> Although this drug has been shown to be beneficial for reversing postoperative ileus in both clinical patients and research animals, it has central nervous system excitatory side effects in the horse that make its use difficult. Nonetheless, administration of metoclopramide to horses with postoperative ileus resulted in a significantly reduced duration of reflux and shorter postoperative hospital stays compared with horses not receiving this drug.<sup>76</sup> In addition, constant infusion of metoclopramide was shown to be superior to intermittent infusion in the same study.

Recent *in vitro* studies indicate that metoclopramide effectively increases smooth muscle contractile activity throughout the small intestine tract.<sup>75</sup> Similarly, the motilin agonist erythromycin had stimulatory effects on equine small intestine, although the results were not uniform throughout the small intestine. In particular, erythromycin stimulated contractile activity in the longitudinal muscle of the pyloric antrum but inhibited contractile activity in this segment of the gastrointestinal tract.<sup>75</sup> The latter may be attributable to activation of motilin receptors on inhibitory nerves and may result in enhanced gastric emptying. *In vivo* studies on erythromycin confirmed the stimulatory action of this drug on the distal small intestine and indicated that this drug also stimulates contractile activity in the cecum and pelvic flexure. However, this was dependent on the temporal association with surgery. In particular, erythromycin stimulated contractile activity in the postoperative period in the ileum and pelvic flexure but not the cecum,<sup>78</sup> which suggests that this drug may be useful for treatment of select cases of postoperative ileus.

For horses with presumed ileus of the large colon, signs included reduced fecal output (<three piles of manure/day), reduced gastrointestinal sounds, variable presence of colic, and occasionally a palpable impaction of the cecum or large colon. Risk factors for this syndrome include orthopedic surgery; length of the operative period; and, most important, inadequate treatment with phenylbutazone, presumably as a result of insufficient control of postoperative pain.<sup>62</sup> Although treatment of large colon impaction in the postoperative period is typically uncomplicated, cecal impaction is rapidly fatal in many horses because of the difficulty in recognizing horses that have cecal dysfunction. Therefore close attention should be paid to fecal production and optimal analgesic treatment in any horse after an orthopedic procedure.<sup>62</sup> It is likely that other painful procedures, including ophthalmologic procedures, also place horses at risk of developing ileus of the large intestine.

## ☞ LARGE INTESTINAL SIMPLE OBSTRUCTION

Simple obstructions of the large intestine, such as impaction, tend to have a more gradual onset than those of the small intestine, although horses may experience acute and severe pain with some forms of colon displacement. In fact, some of these cases mimic and may progress toward large colon volvulus. Medical therapy is frequently successful in correcting large colon impactions. However, cecal impactions present much more of a dilemma because of the greater propensity of this organ to rupture, the relative difficulty of surgically manipulating the cecum, and the onset of cecal dysfunction that may prevent the cecum from emptying after surgical resolution of impaction.

### CECAL IMPACTION

Cecal impaction may be divided into two syndromes: primary cecal impactions that result from excessive accumulation of ingesta in the cecum and secondary cecal impactions that develop while a horse is being treated for a separate problem.<sup>79,80</sup> Although primary impactions typically consist of impacted, relatively dry fecal material and secondary cecal impactions tend to have very fluid contents, there is considerable overlap between the two syndromes, and each case must be approached carefully. In horses with primary cecal impactions, there is a gradual onset of abdominal pain over

a number of days reminiscent of the development of a large colon impaction. Cecal impactions should be differentiated from large colon impactions on the basis of rectal palpation findings. Cecal impactions have a propensity to rupture before the development of severe abdominal pain or systemic deterioration and therefore must be closely monitored.<sup>79</sup> Secondary cecal impactions typically develop after unrelated surgical procedures that result in postoperative pain (particularly orthopedic surgeries).<sup>80</sup> Secondary cecal impactions may be even more difficult to detect because postoperative depression and decreased fecal output may be attributed to the operative procedure rather than colic. By the time horses with secondary cecal impactions show noticeable signs of colic, the cecum may be close to rupture. In many cases there will be no signs of impending rupture.<sup>80</sup> Therefore the feed intake and manure production of all horses that undergo surgery in which considerable postoperative pain may develop should be closely monitored. A recent study indicated that horses producing less than three piles of manure daily in the postoperative period are at risk of developing a large intestinal impaction. Furthermore, horses that underwent prolonged (>1 hour) orthopedic surgery that received inadequate treatment with phenylbutazone were at considerable risk of reduced postoperative fecal output.<sup>62</sup> This is in contrast to statements indicating that NSAIDs may place horses at risk of impaction, which appear to be based largely on clinical impressions rather than risk analysis.<sup>80</sup>

The diagnosis of primary cecal impaction is based on rectal palpation of a firm, impacted cecum. In some cases cecal impactions may be difficult to differentiate from large colon impactions. However, careful palpation will reveal the inability to move the hand completely dorsal to the impacted viscus because of the cecum's attachment to the dorsal body wall. Treatment for horses with primary cecal impactions may include initial medical therapy, including aggressive administration of intravenous fluids and judicious use of analgesics.<sup>80</sup> However, if the cecum is grossly distended or if medical therapy has no effect within a reasonable period of time, surgical evacuation of the cecum by way of a typhlotomy is indicated.<sup>79</sup> The question of whether to bypass the cecum, because of postoperative cecal dysfunction and recurrence of impaction, led to techniques such as ileocolostomy to prevent ingesta from reaching the cecum. However, a recent study including a large number of cases suggests this is not necessary, possibly because of improvements in recognition and medical treatment of horses with colic.<sup>81</sup>

In horses that develop secondary cecal impactions, diagnosis is based on palpation of a markedly distended cecum filled with semifluid intestinal contents. The nature of the contents is likely related to the more rapid progression of this disease compared with that of primary cecal impaction. Surgery should not be delayed because of the risk of cecal rupture.<sup>82</sup> Following typhlotomy, aggressive medical management of the inciting cause of the impaction (such as orthopedic pain) should be addressed.

The prognosis is good for surgical treatment of all cecal impactions. However, fatalities may result from cecal rupture during prolonged medical treatment or during surgical manipulation. This complication can be avoided by early intervention. In a recent report assessing 114 horses, approximately 90% of those with long-term follow-up information available 1 year later survived regardless of whether they were treated medically or surgically.<sup>81</sup> However, a separate report indicated that all horses with cecal impaction secondary

to another disease process had cecal rupture without any signs of impending rupture.<sup>80</sup>

## LARGE COLON IMPACTION

Ingesta impactions of the large colon occur at sites of anatomic reductions in luminal diameter, particularly the pelvic flexure and the right dorsal colon.<sup>83</sup> Although there are a number of reported risk factors, most have not been proved. However, a sudden restriction in exercise associated with musculoskeletal injury appears to be frequently associated with onset of impaction.<sup>84</sup> A further consideration is equine feeding regimes, which usually entail twice-daily feeding of concentrate. Such regimens result in large fluxes of fluid into and out of the colon, associated with readily fermentable carbohydrate in the colon and subsequent increases in serum aldosterone, respectively. These fluid fluxes, which may cause dehydration of ingesta during aldosterone-stimulated net fluid flux out of the colon, may be prevented with frequent small feedings.<sup>32</sup>

Impaction of the ascending colon can be induced by the drug amitraz, an acaricide associated with clinical cases of colon impaction.<sup>85,86</sup> The importance of this is that it provides some clues as to the pathogenesis of large colon impaction. In particular, amitraz appears to alter pelvic flexure pacemaker activity, resulting in uncoordinated motility patterns between the left ventral and left dorsal colon and excessive retention of ingesta. Absorption of water from the ingesta increases with retention time, dehydrating the contents of the colon and resulting in impaction. It is conceivable that parasite migration in the region of a pacemaker may have a similar action.<sup>87</sup> Other factors implicated in large colon impaction include limited exercise, poor dentition, coarse roughage, and dehydration.

Clinical signs of large colon impaction include slow onset of mild colic. Fecal production is reduced, and the feces are often hard, dry, and mucus-covered because of delayed transit time. The heart rate may be mildly elevated during episodes of pain but is often normal. Signs of abdominal pain are typically well controlled with administration of analgesics but become increasingly more severe and refractory if the impaction does not resolve. The diagnosis is based on rectal palpation of a firm mass in the large colon. However, the extent of the impaction may be underestimated by rectal palpation alone because much of the colon remains out of reach.<sup>83</sup> Adjacent colon may be distended if the impaction has resulted in complete obstruction. Initial medical treatment should be attempted. Intermittent abdominal pain is controlled with administration of analgesics (flunixin meglumine, 0.25 to 1.1 mg/kg IV every 6 to 12 hours; butorphanol, 0.05 to 0.1 mg/kg IV every 6 to 8 hours; xylazine, 0.3 to 0.5 mg/kg IV as needed). Administration of oral laxatives such as mineral oil (2 to 4 L by nasogastric tube every 12 to 24 hours) and the anionic surfactant dioctyl sodium sulfosuccinate (DSS, 6 to 12 g/500 kg diluted in 2 to 4 L of water by nasogastric tube every 12 to 24 hours) are commonly used to soften the impaction. Saline cathartics such as magnesium sulfate (0.1 mg/kg in 2 to 4 L by nasogastric tube) may also be useful. Access to feed should not be permitted. For impactions that persist aggressive oral and intravenous fluid therapy (twofold to fourfold the maintenance fluid requirement) should be instituted.<sup>83</sup> If the impaction remains unresolved, the horse's pain becomes uncontrollable, or extensive gas distention of the colon occurs, surgery is indicated. In addition, abdominal fluid can be serially monitored to determine the onset of intestinal compromise.<sup>83</sup> At surgery

the contents of the colon are evacuated by way of a pelvic flexure enterotomy. The prognosis is good for horses in which impactions resolve medically (95% long-term survival in one study) and fair in horses that require surgical intervention (58% long-term survival in the same study).<sup>84</sup>

## ENTEROLITHS

Enteroliths are mineralized masses typically composed of ammonium magnesium phosphate (struvite).<sup>88</sup> However, magnesium vivianite has also been identified in enteroliths, along with variable quantities of Na, S, K, and Ca. The formation of Mg-based minerals is puzzling because of the relative abundance of Ca in colonic fluids, which would favor the formation of Ca-phosphates (apatite) rather than struvite.<sup>89</sup> However, elevated dietary intake of magnesium and protein may play a role. Many horses that develop enteroliths live in California and are fed a diet consisting mainly of alfalfa hay. Analysis of this hay has revealed a concentration of magnesium approximately six times the daily requirements of the horse.<sup>90</sup> Furthermore, the high protein concentration in alfalfa hay may contribute to calculi formation by increasing the ammonia nitrogen load in the large intestine. Enteroliths most commonly form around a nucleus of silicon dioxide (a flintlike stone), but nuclei have included nails, rope, and hair that have been ingested.<sup>88</sup> Enteroliths are usually found in the right dorsal and transverse colons.<sup>90</sup> Although enterolithiasis has a wide geographic distribution, horses in California have the highest incidence. In one California study, horses with enterolithiasis represented 28% of the surgical colic population, and Arabians, Morgans, American Saddlebreds, and donkeys were at greatest risk of this disease.<sup>91</sup> In a study of enterolithiasis in Texas, risk factors also included feeding of alfalfa hay and Arabian breed. However, in that study miniature horses were also found to be at risk.<sup>92</sup> Horses with enteroliths are rarely younger than 4 years old,<sup>90</sup> although an enterolith in an 11-month-old miniature horse was recently reported.<sup>93</sup>

Enterolithiasis is characterized by episodic, mild to moderate, intermittent abdominal pain.<sup>90</sup> Progressive anorexia and depression may develop. The amount of pain depends on the degree of obstruction and amount of distention. Partial luminal obstruction allows the passage of scant, pasty feces. Heart rate is variable and dependent on the degree of pain. In some cases an enterolith is forced into the small colon, where it causes acute small colon obstruction. Enteroliths may be diagnosed by abdominal radiography or at surgery. On rare occasions an enterolith may be palpated rectally, particularly if it is present in the distal small colon.

In general, surgery is required for these cases, although there are reports of enteroliths being retrieved rectally. In fact, in one study 14% of horses that required treatment of enterolithiasis had a history of passing an enterolith in the feces.<sup>91</sup> However, enteroliths are typically located in the right dorsal colon, transverse colon, or small colon. At surgery the enterolith is gently pushed toward a pelvic flexure enterotomy, but removal frequently requires a separate right dorsal colon enterotomy to prevent rupture of the colon. After removal of an enterolith, further exploration must be conducted to determine if other enteroliths are present. Solitary enteroliths are usually round, whereas multiple enteroliths have flat sides. The prognosis is good (92% 1-year survival in one study on 900 cases),<sup>91</sup> unless the colon is ruptured during removal of an enterolith. In one recent study rupture occurred in 15% of cases.<sup>91</sup>

## SAND IMPACTIONS OF THE LARGE COLON

Sand impactions are common in horses with access to sandy soils, particularly horses whose feed is placed on the ground. Some horses, especially foals, deliberately eat sand. Fine sand tends to accumulate in the ventral colon, whereas coarse sand may accumulate in the dorsal colon.<sup>94,95</sup> However, individual differences in colonic function may contribute to accumulation of sand because some horses can clear consumed sand, whereas others cannot. Distention resulting from the impaction itself, or gas proximal to the impaction, causes abdominal pain. In addition, sand may trigger diarrhea, presumably as a result of irritation of the colonic mucosa.<sup>96</sup> In horses with sand impactions, clinical signs are similar to those of horses with large colon impactions.<sup>94</sup> Sand may be found in the feces, and auscultation of the ventral abdomen may reveal sounds of sand moving within the large colon.<sup>97</sup> The diagnosis is definitively made at surgery but may be tentatively based on clinical signs compatible with a large colon impaction and evidence of sand in the feces. To determine the presence of sand, several fecal balls are placed in a rectal palpation sleeve or other container, which is subsequently filled with water. If sand is present, it will accumulate at the bottom of the container. In addition, mineral opacity may be detected within the colon on abdominal radiographs, particularly in foals, ponies, and small horses.<sup>95</sup> Abdominal paracentesis typically yields normal fluid and poses some risk because large quantities of sand in the ventral colon make inadvertent perforation of the colon more likely.<sup>95</sup> PF is often normal but may have an elevated protein concentration.

Initially, medical therapy is warranted. Administration of *Psyllium hydrophilia* mucilloid (0.25 to 0.5 kg/500 kg in 4 to 8 L of water by stomach tube) may facilitate passage of sand. This should be administered rapidly because it will form a viscous gel. Therefore an alternative method of administration is to mix psyllium with 2 L of mineral oil, which will not form a gel and can be pumped easily through a nasogastric tube. Between 2 and 4 L of water is then pumped through the tube. The psyllium leaves the oil phase and mixes with the water, forming a gel within the stomach. Psyllium is thought to act by stimulating motility or agglutinating the sand. However, a recent experimental study failed to show a benefit of this treatment.<sup>98</sup> If a severe impaction is present, the psyllium should not be given until the impaction is softened by administering intravenous or oral fluids and other laxatives. Perforation is a potential complication in horses with sand impactions because the sand stretches and irritates the intestinal wall and causes inflammation. Therefore if colic becomes intractable, surgical evacuation of the large colon should be performed. The prognosis is generally regarded as good.<sup>94,95</sup>

## LARGE COLON DISPLACEMENT

Displacement of the ascending colon is a common cause of large intestinal obstruction. The ascending colon is freely movable except for the right dorsal and ventral colons. Contact with adjacent viscera and the abdominal wall tends to inhibit movement of the ascending colon from a normal position; however, accumulation of gas and fluid or ingesta may cause the colon to migrate.<sup>99</sup> Feeding behavior, including feeding of large concentrate meals, likely plays a role in initiating displacement of the large colon. In particular, large concentrate meals increase the rate of passage of ingesta, allowing a greater percentage of soluble carbohydrates to reach the large intestine.<sup>31</sup> This in turn

increases the rate of fermentation and the amount of gas and volatile fatty acids that are produced. The production of large amounts of volatile fatty acids stimulates the secretion of large volumes of fluid into the colon.<sup>100</sup> The association between feeding concentrate and development of displacements of the large colon is illustrated by studies indicating that ascending colon displacement is more prevalent in horses fed a high-concentrate, low-roughage diet.<sup>101</sup> Abnormal motility patterns of the ascending colon have also been suggested to contribute to the development of colonic displacement. Feeding stimulates colonic motility by way of the gastrocolic reflex, but large meals may alter normal motility patterns and concurrently allow rapid accumulation of gas and fluid resulting from fermentation.<sup>31,102</sup> Migration of parasite larvae (strongyles) through the intestinal wall have also been shown to alter colonic motility patterns.<sup>103</sup> Other experimental studies have shown that *Strongylus vulgaris* infection results in reduced blood flow to segments of the large intestine without necessarily causing infarction. Electrical activity of the colon and cecocolic junction increases after infection with *S. vulgaris* and cyathostome larvae, probably reflecting a direct effect of migration through the intestine and an early response to reduced blood flow.<sup>103</sup>

Displacements of the ascending colon are generally divided into three types: left dorsal displacement, right dorsal displacement, and retroflexion.<sup>104</sup> Left dorsal displacement is characterized by entrapment of the ascending colon in the renosplenic space. The colon is often twisted 180 degrees, such that the left ventral colon is situated in a dorsal position relative to the left dorsal colon. The entrapped portion may be only the pelvic flexure or may involve a large portion of the ascending colon, with the pelvic flexure situated near the diaphragm. The colon may become entrapped by migrating dorsally between the left abdominal wall and the spleen or may migrate in a caudodorsal direction over the nephrosplenic ligament.<sup>104</sup> Occasionally, the ascending colon can be palpated between the spleen and abdominal wall, lending support to the first mechanism of displacement. Gastric distention is thought to predispose horses to left dorsal displacement of the ascending colon by displacing the spleen medially, allowing the colon room to migrate along the abdominal wall.<sup>104</sup> Right dorsal displacement begins by movement of the colon cranially, either medial (medial flexion) or lateral (lateral flexion) to the cecum. According to one author, the proportion of right dorsal displacements with medial versus lateral flexion is approximately 1:15.<sup>104</sup> In either case the pelvic flexure ends up adjacent to the diaphragm. Retroflexion of the ascending colon occurs by movement of the pelvic flexure cranially without movement of the sternal or diaphragmatic flexures.

Displacement of the ascending colon partially obstructs the lumen, resulting in accumulation of gas or ingesta and causing distention. The distention may be exacerbated by the secretion of fluid in response to the distention.<sup>105</sup> Tension and stretch of the visceral wall are important sources of the pain associated with colonic displacement. Tension on mesenteric attachments and the root of the mesentery by the enlarged colon may also cause pain.<sup>99</sup> Ischemia is rarely associated with nonstrangulating displacement of the colon. However, vascular congestion and edema are often seen in the displaced segments of colon, resulting from increased hydrostatic pressure from reduced venous outflow. Morphologic damage to the tissues is usually minor.

Clinically, displacement of the ascending colon is characterized by intermittent signs of mild to moderate abdominal pain of acute onset. However, an insidious onset of colic may

also be noted.<sup>104</sup> Dehydration may be noted if the duration of the displacement is prolonged. The heart rate may be elevated during periods of abdominal pain but is often normal. Abdominal distention may be present if the colon is enlarged by gas, fluid, or ingesta. Fecal production is reduced as progressive motility of the large intestine is absent. Left dorsal displacements are often diagnosed by rectal palpation. The left ventral colon can be felt in a dorsal position and is often filled with gas. The ascending colon can be traced to the nephrosplenic space, and the spleen may be displaced medially. Alternatively, a tentative diagnosis can be reached using abdominal ultrasonography.<sup>106</sup> The spleen can be visualized on the left side of the abdomen, but the left kidney will be obscured by gas-distended bowel. Evaluation of this technique indicates that there are very few instances of false-positive results, although false-negative results may occasionally occur.<sup>106</sup> A definitive diagnosis therefore may require surgery. Right dorsal displacements are characterized by the presence of the distended ventral colon running across the pelvic inlet and may be felt between the cecum and the body wall if a lateral flexion is present. The pelvic flexure is usually not palpable. Retroflexion of the ascending colon may produce a palpable kink in the colon. If the displaced colons are not distended by gas in the instance of right dorsal displacement and retroflexion, the ascending colon may not be palpable and is conspicuous by its absence from a normal position. PF may be increased in amount, but the color, protein concentration, and white blood cell count are usually normal. However, as the displaced segment becomes edematous, fluid leaking through the serosa into the PF increases the protein concentration.

Surgical correction of colon displacement is the most effective means of resolving this disorder. However, nonsurgical intervention has been successful in select cases of nephrosplenic entrapment of the large colon.<sup>106-108</sup> If such manipulations are to be attempted, the clinician must be certain of a diagnosis. The horse is anesthetized and placed in right lateral recumbency. The horse is rotated up to dorsal recumbency, rocked back and forth for 5 to 10 minutes, and then rolled down into left lateral recumbency.<sup>109</sup> The nephrosplenic space should be rectally palpated to determine whether the entrapment has been relieved before recovering the horse from anesthesia. Phenylephrine (3 to 6  $\mu\text{g}/\text{kg}/\text{min}$  over 15 minutes) may be administered to decrease the size of the spleen.<sup>110</sup> More recently, phenylephrine has been used in conjunction with 30 to 45 minutes of exercise to successfully reduce nephrosplenic entrapments in 4 of 6 horses.<sup>26</sup> The authors suggested that the technique be used on horses with mild to moderate colonic distention, particularly when there are severe financial constraints. There are anecdotal reports of fatal internal hemorrhage caused by rupture of large blood vessels after treatment of older horses with phenylephrine, and the drug should probably be used with caution in horses older than 15 years.

There are a number of cases in which nonsurgical interventions do not correct the problem and others in which nonsurgical manipulations correct the entrapment but result in large colon volvulus or displacement. These horses should undergo surgery promptly. The prognosis for horses with large colon displacement is good. In one study of horses with nephrosplenic entrapment of the large colon, survival was in excess of 90%.<sup>108</sup> A number of horses will suffer recurrence of nephrosplenic entrapment of the colon. Currently, the least invasive method of preventing this complication is laparoscopic closure of the nephrosplenic space.<sup>111</sup>

## FOREIGN BODY AND FECALITH OBSTRUCTION

Foreign material such as bedding, rope, plastic, fence material, and feedbags can cause obstruction and may be ingested, particularly by young horses. These foreign bodies may result in impaction with ingesta and distention of the intestine, typically in the transverse or descending colon. Young horses are usually affected. In one study the obstructing mass could be rectally palpated in three of six horses.<sup>112</sup> Fecaliths are common in ponies, miniature horses, and foals (Figure 15-31).<sup>113</sup> Older horses with poor dentition may also be predisposed to fecaliths because of the inability to fully masticate fibrous feed material. Fecaliths commonly cause obstruction in the descending colon and may cause tenesmus.<sup>112</sup> Other clinical signs are similar to those of enterolithiasis. Abdominal radiography may be useful in smaller patients to identify the obstruction, especially if gas distention around the foreign body or fecalith provides contrast. Surgical treatment is usually required.

## MURAL MASSES AND STRICTURES

Mural masses such as abscesses, tumors (adenocarcinoma, lymphosarcoma), granulomas, and hematomas (Figure 15-32) can cause luminal obstruction and impaction, typically in older horses. Impaction may result from obstruction of the lumen or impaired motility in the segment of intestine with the mass. Abscesses may originate from the lumen of the intestine, or may extend from the mesentery or mesenteric lymph nodes. Intramural hematomas form most commonly in the descending colon and cause acute abdominal pain.<sup>114</sup> Once the acute pain caused by the hematoma subsides, impaction proximal to the hematoma develops as a result of impaired motility through the affected portion of the colon. Trauma, ulceration of the mucosa, and parasitic damage are speculated causes of intramural hematomas.<sup>114,115</sup> Stricture of the large intestine occurs when fibrous tissue forms in a circular pattern around or within the intestine, reducing the luminal diameter and the ability of the wall to stretch. Strictures may be congenital or secondary to peritonitis, previous abdominal surgery, or inflammatory bowel disease.<sup>116</sup> In a report of 11 horses with inflammatory

**FIGURE 15-31** Fecalith in the small colon of a miniature horse. Note the mass being grasped by the surgeon. The small colon is distended, so that haustra cannot be identified. However, the antimesenteric tenia of the small colon is clearly visible.

**FIGURE 15-32** Intramural hematoma of unknown origin in the small colon of a horse taken to surgery for persistent signs of colic. The lack of a complete physical obstruction at this site was suggestive of a functional obstruction at the site of the hematoma.

bowel disease, 6 horses had strictures, 4 of which were in the small intestine and 2 of which were in the large colon.<sup>116</sup>

Clinical signs vary according to the degree of luminal obstruction. Partial obstruction and impaction tend to produce mild to moderate abdominal pain of insidious onset. Mural hematomas tend to produce signs of acute abdominal pain.<sup>114,115</sup> Rectal palpation of the abdomen may reveal the presence of a mass or simply the impacted segment, without the mass itself being felt. Fever, weight loss, and anorexia may be noted if an abscess or tumor is the cause. An elevated white blood cell count; hyperfibrinogenemia; hyperglobulinemia; or normocytic, normochromic anemia may be seen with abscesses or tumors. PF may reflect the cause of the mass. Tumor cells may infrequently be seen. Evidence of inflammation with bacteria may be noted if the cause of colic is an abscess or granuloma, in which case the fluid should be cultured. Hematomas may cause hemorrhage into the PF. Treatment usually requires surgical resection of the mass. Abscesses may be treated with appropriate antibiotics if the impaction can be resolved medically with oral or intravenous analgesics and laxatives. *Streptococcus* spp., *Actinomyces pyogenes*, *Corynebacterium pseudotuberculosis*, *R. equi*, anaerobic bacteria, and gram negative enteric organisms are commonly involved in abscesses.

### SMALL COLON IMPACTION

Small colon impaction is distinct from other forms of impaction in its predispositions and clinical appearance. In one study the key risk factor for impaction of this segment of the intestine was diarrhea.<sup>117</sup> This paradoxical finding may be explained by edema of the colonic mucosa associated with pro-inflammatory causes of diarrheal disease that is usually noted in the ascending colon but may extend into the transverse and small colons. Once diarrheal disease is initiated, large volumes of ingesta are rapidly expelled from the ascending colon into the small colon, which has a far smaller diameter, especially if it is edematous. This may result in the initial appearance of diarrhea, followed by intermittent episodes of colic that may be explained by impaction. The most important point

to remember is that horses should be closely assessed for impaction even if diarrheal disease is present. Other parameters that are typically helpful for assessing the severity of colic, such as heart rate, were not predictive of obstruction in horses with small colon impaction.<sup>117</sup> Horses may be treated medically during the early stages with fluids, laxatives, and analgesics. The key clinical sign that indicates the need for surgery appears to be abdominal distention, associated with distention of the large colon. Other clinical signs, such as elevations in heart rate and refractory colic, are less pronounced in this disease. Postdiarrheal disease is not the only form of small colon impaction. These impactions can be formed as simple collections of ingesta or in response to luminal narrowing.

### ATRESIA COLI

Atresia of a segment of the colon is a rare congenital abnormality in horses.<sup>118</sup> The heritability and causes of the condition are unknown. One potential mechanism for development of the lesion is intestinal ischemia during fetal life, which secondarily results in necrosis of a segment of intestine.<sup>118</sup> Clinical signs include a failure to pass meconium and colic within the first 12 to 24 hours of life. Secondary abdominal distention results from complete intestinal obstruction, and abdominal radiographs may reveal gas-distended colon. The diagnosis is made at surgery. Any portion of the colon may be absent, but the distal segment of the large colon or the proximal small colon (or both) is usually most severely affected. If sufficient tissue is present, anastomosis to the proximal blind end of the colon may be attempted.<sup>118</sup> The prognosis depends on the segment of the colon that is absent but is usually poor because of an absence of distal colon.

### ILEOCOLONIC AGANGLIONOSIS

Ileocolonic aganglionosis, commonly known as *overo lethal white syndrome* (OLWS), occurs in white foals with over-spotted parents. Affected foals are either completely white or have very little pigmented hair around the muzzle, base of the tail, or hooves. They are homozygous for an abnormal endothelin receptor B (EDNRB) gene that results in altered neural crest cell migration or survival, which affects progenitor cells for melanocytes and intestinal ganglia.<sup>119,120</sup> Most, but not all, heterozygotes have a frame overo phenotype.<sup>121</sup> Rarely, an OLWS-affected foal may be born to a solid-colored mare. Homozygous foals have aganglionosis of the submucosal and myenteric ganglia of the distal portion of the ileum and large intestine.<sup>122</sup> This results in a foal that appears normal at birth but develops signs of intestinal ileus and colic within 12 to 24 hours. The eyes are blue, and the skin is pink. A genetic test is available to identify horses that are heterozygous for the defective EDNRB gene.

## NEOPLASIA OF THE ALIMENTARY TRACT

Dana N. Zimmel

Neoplasia in the alimentary tract of the horse is uncommon.<sup>1</sup> Primary and metastatic neoplasia can affect multiple locations within the oral cavity and gastrointestinal tract (Boxes 15-1 and 15-2). Neoplasia is not limited to geriatric horses. The

average age of horses with squamous cell carcinoma is 8.6 to 14.6 years.<sup>54,55</sup> The alimentary form of lymphoma occurs most commonly in horses younger than 5 years of age.<sup>56</sup> One recent study found that the Arabian breed is 4.5-fold more likely to have intestinal neoplasia than other breeds.<sup>20</sup> Identification of benign versus malignant tumors is imperative to justify treatment and predict survival.

**CLINICAL SIGNS**

The clinical signs associated with alimentary neoplasia are related to the tumor location. Clinical signs of oral neoplasia include enlargement or ulceration of the mandible or maxilla.<sup>57</sup> Neoplasia of the tongue results in weight loss, quidding, dysphagia, halitosis, and nasal discharge containing feed material.<sup>7, 8, 9</sup> Tumors of the esophagus cause dysphagia, ptyalism, choke, intermittent colic, fever, weight loss, and halitosis.<sup>11,58,59</sup> Gastric neoplasia may be associated with abnormal chewing and swallowing behavior, anorexia, weight loss, abdominal distention, and intermittent fever.<sup>18</sup> Abdominal neoplasia has been implicated in 4% of horses with intermittent or chronic colic.<sup>60,61</sup> Altered stool character, ventral edema, and recurrent fever have been associated with intestinal neoplasia.<sup>56</sup> Weight

loss is the most common clinical sign of horses with intestinal neoplasia.<sup>20</sup> Acute signs of abdominal discomfort may occur with intestinal obstructions resulting from malignant and benign neoplastic disease.

Paraneoplastic syndromes do occur in the horse. The most common syndromes described are cancer cachexia, ectopic hormone production, anemia, leukocytosis, thrombocytopenia, hypergammaglobulinemia, fever, and neurologic abnormalities.<sup>62</sup> Horses with cancer cachexia have profound weight loss despite adequate consumption of calories.

## ☞ DIAGNOSTIC EVALUATION

Diagnosis of alimentary neoplasia can be challenging. Data collected from a complete blood count, biochemistry panel, and urinalysis may support the diagnosis of neoplasia but rarely confirms it. Normocytic normochromic anemia is indicative of chronic disease and is the most likely cause of anemia associated with neoplasia. Blood loss anemia (through the gastrointestinal tract) and immune-mediated hemolytic anemia (lymphoma)<sup>63</sup> are less frequent causes of anemia associated with abdominal neoplasia. Peripheral eosinophilia has been reported in association with multisystemic eosinophilic, epitheliotropic disease with lymphoma.<sup>16</sup> Leukocytosis and hyperfibrinogenemia are common findings.

Serum chemistry can confirm hypoalbuminemia caused by inflammation of the bowel wall. Hyperglobulinemia can be characterized with serum electrophoresis. This test is non-specific for chronic inflammation. A few cases of lymphoma have been identified with monoclonal spikes in globulins.<sup>64</sup> Ectopic hormone production may result in hypercalcemia (calcium >14 mg/dl). Hypercalcemia has been associated with alimentary neoplasms such as lymphoma, multiple myeloma, carcinomas, and ameloblastoma.<sup>54,65</sup> Hypoglycemia (blood glucose <70 mg/dl) can occur with neoplasia of the pancreas or liver.<sup>54</sup>

Rectal examination may reveal an abdominal mass, thickening of the intestinal wall, lymph node enlargement, or a gritty texture in horses with carcinomatosis.<sup>54</sup> Lymphoma can be detected using rectal biopsy in some cases.<sup>47</sup> A fecal occult blood test is nonspecific for neoplastic disease, but it can detect blood loss through the gastrointestinal tract. Occasionally, abdominocentesis may be used to identify neoplasia if the tumor exfoliates cells into the abdomen. Squamous cell carcinoma, adenocarcinoma, and mesothelioma have been detected in PF.<sup>11,50,51,66</sup> It is common for the PF to be characterized as an inflammatory exudate or modified transudate without any neoplastic cells present. Hemoperitoneum is attributed to neoplasia in 18% of cases in a retrospective study of 67 horses. The neoplastic conditions identified included granulosa cell ovarian tumors (three); metastatic melanoma (two); multicentric hemangiosarcoma (two); and one case each of metastatic squamous cell carcinoma, splenic lymphoma, ovarian lymphosarcoma, pheochromocytoma, and a neuroendocrine tumor.<sup>67,68</sup> Abdominocentesis accurately predicted neoplasia in 11 of 25 cases in another study.<sup>69</sup> D-xylose absorption tests can be used to identify malabsorptive diseases that can include lymphoma.<sup>47,70</sup>

Specific immunoglobulin testing for IgM deficiency may aid in the diagnosis of lymphoma.<sup>71</sup> DNA cell cycle analysis of suspect neoplastic cells has been used to detect lymphoma in equine patients confirmed to have the disease. This method of evaluating fluid or tissues aspirates may increase the accuracy with which neoplasia is diagnosed in the future.<sup>72</sup>

A complete evaluation of the oral cavity may include using a full-mouth speculum, radiographs, endoscopy of the pharynx, and biopsy. Evaluation of the esophagus and stomach with a 3-meter endoscope may aid in the identification of intraluminal masses. Pleuroscopy has been used to biopsy extraluminal masses surrounding the esophagus. Contrast radiography can assist in the diagnosis of neoplasia within the wall or outside of the esophagus.<sup>58,73</sup> Ultrasonography of the stomach, small intestine, cecum, and large colon is useful in detecting intestinal wall thickness, abdominal masses, and

excessive PF.<sup>74</sup> Irregular cauliflower-like masses can be visualized on the body wall and are consistent with peritoneal mesothelioma.<sup>33</sup> Identification of neoplasia in the liver, kidney, or spleen may support the finding of metastasis to other parts of the gastrointestinal tract or lymph nodes. Laparoscopy and exploratory laparotomy are often required to obtain a final diagnosis.<sup>75</sup>

## ☞ SPECIFIC NEOPLASIA

### LYMPHOMA (LYMPHOSARCOMA)

Lymphoma, the most common neoplasia in the horse, has been divided into four categories.<sup>20</sup> Only the intestinal-alimentary form is discussed in this section. Lymphosarcoma is discussed in detail in Chapter 14. The condition was once called *lymphosarcoma*, but oncologists today prefer *lymphoma* because there is no benign form of this disease.<sup>54</sup> Lymphoma originates from lymphoid tissue and predominantly affects the small intestinal and intestinal lymph nodes. Chronic weight loss resulting from malabsorption, intermittent colic, and fever is the most common clinical finding.<sup>76,31</sup> Chronic diarrhea has been reported in some cases.<sup>77</sup> Paraneoplastic pruritus and alopecia have been identified in one case of diffuse lymphoma.<sup>78</sup> Peripheral lymphadenopathy is not generally noted, but enlargement of the intestinal lymph nodes may be evident on rectal examination.<sup>56</sup> Immunohistochemical staining can classify most tumors as of T-cell or B-cell origin, which may be helpful in determining prognosis.<sup>79</sup> Large colon resection for treatment of lymphoma has increased short-term survival in two horses.<sup>40</sup> The use of chemotherapy in two pregnant mares extended their lives long enough for normal parturition.<sup>80,81</sup>

### SQUAMOUS CELL CARCINOMA

Squamous cell carcinoma is a malignant tumor of the gastrointestinal epithelium. It is the second most common neoplasia in the horse and the most common oral neoplasia; however, the incidence of occurrence is rare.<sup>11,18,59</sup> In the oral cavity squamous cell carcinoma may affect the lips, tongue, hard palate, pharynx, and oral mucosa.<sup>82,83</sup> Treatment for squamous cell carcinoma in the oral cavity may involve surgical resection, iridium-192 brachytherapy, 5-fluorouracil, or intralésional cisplatin or carboplatin.<sup>2,84-86</sup> The prognosis for survival is good if complete removal of the tumor is possible. One report of reoccurring squamous cell carcinoma on the lip with metastasis to the lymph nodes was successfully treated with piroxicam over 58 months.<sup>87</sup> Metastasis beyond the regional lymph nodes is rare for oral squamous cell carcinoma.

Squamous cell carcinoma is the most common tumor of the stomach and esophagus.<sup>12,18</sup> It can invade these areas and metastasize to the lymph nodes and lungs. Abnormal masses were palpated on rectal examination in four of five horses with gastric squamous cell carcinoma.<sup>18</sup> Hypertrophic osteopathy secondary to gastric squamous cell carcinoma has been documented in one horse.<sup>88</sup> Treatment by surgical resection is not possible in most cases.<sup>54</sup>

### ADENOCARCINOMA

Adenocarcinoma is a malignant tumor that can occur in the small intestine, cecum, and large colon.<sup>13,21</sup> The tumor arises from the glandular crypts of the gastrointestinal tract. It has

been reported in middle-aged and older horses. Metastasis to the lymph nodes, liver, and lungs can occur. Intestinal adenocarcinoma has been reported to metastasize to the bone and was diagnosed with Tc-99m hydroxymethylene diphosphate.<sup>33,36</sup> In a study of 34 cases of intestinal neoplasia, 11 (32%) were adenocarcinomas with 9 (82%) involving the small intestine. After surgical removal only three horses survived to discharge. Only one horse survived longer than 5 years.<sup>20</sup> The short-term prognosis for resectable adenocarcinoma is fair, and the long-term prognosis is poor.<sup>37</sup>

### LEIOMYOSARCOMA

Leiomyosarcoma is a malignant tumor of the smooth muscle lining the gastrointestinal tract. It has been reported in the stomach, small intestine, and rectum.<sup>15,26,27,45,69</sup> In one case report gastroscopy could not identify a gastric mural mass found during exploratory surgery. Another report describes a favorable outcome for surgical resection of a leiomyosarcoma that was protruding from the anal sphincter in a 4-year-old Quarter Horse.<sup>45</sup> Prognosis for survival is favorable if surgical resection is possible. There is a single case review of a leiomyosarcoma invading the mandible and maxilla.<sup>4</sup>

### LEIOMYOMA

Leiomyoma is a benign tumor of the smooth muscle of the gastrointestinal tract. It can occur in the stomach, small intestine, omentum, and small colon.<sup>42,44,89</sup> Clinical signs are consistent with intestinal obstruction. Surgical resection and anastomosis of the affected portion of the intestine has been performed without complications.

### LIPOMA

Lipoma is a benign tumor that occurs in older horses (10 to 26 years) and arises from mesenteric adipocytes. The tumor grows on a stalk that wraps around the intestine, causing a strangulating lesion of the intestine or an intestinal obstruction. Intestinal injury has resulted from lipomas strangulating the small intestine, small colon, and rectum. Long-term survival with surgical resection and anastomosis is reported to be 50%.<sup>30,90,91</sup>

### ORAL NEOPLASIA

Oral cavity neoplasia may involve the dental tissue (odontogenic tumors), bone (osteogenic tumors), or soft tissues (see [Box 15-1](#)). Ameloblastoma occurs in horses older than 10 years of age, and it mainly affects the mandible. Ameloblastic odontoma affects younger horses and usually involves the maxilla. Both are benign but locally invasive. Radiographs may aid in differentiation between an ameloblastoma (radiolucent lesion) and ameloblastic odontoma (radiolucent lesion with partially mineralized density). Regardless of the type, the best treatment option is surgical resection, radiation therapy, or both.<sup>57</sup> Teletherapy could be used to treat oral neoplasia.<sup>92,93</sup> Teletherapy is the practice of radiation used at a distance of 80 to 100 cm from the target tissue using a linear accelerator or cobalt-60 source.

Juvenile mandibular ossifying fibroma occurs in the rostral mandible of young horses between the age of 2 months and 2 years. It may cause significant distortion of the bone.

Surgical excision of the mass has a good prognosis if diagnosed early.<sup>94,95</sup>

Melanomas, sarcoids, squamous cell carcinoma, and oral papilloma occur on the mouth and lips. Melanomas rarely metastasize, but they are commonly found in the parotid salivary glands and lymph nodes. Sarcoids are the most common skin tumor that can involve the mouth. Ulcerations of the buccal mucosa are difficult to treat. IntraleSIONAL cisplatin, cryosurgery, radiation, and laser excision have been tried with limited success.<sup>2</sup> Equine papilloma virus is responsible for the common skin wart that is found on the lips and muzzle of young horses. These lesions are self-limiting, but they can be removed with cryosurgery or excision.

## PERITONITIS

Laura H. Javicas

### STRUCTURE AND FUNCTION

A number of detailed and informative reviews describe the anatomy, physiology, and pathophysiology of the equine peritoneum.<sup>1-4</sup> The peritoneum consists of a single layer of mesothelial cells. The mesothelial lining of the diaphragm, abdominal walls, and pelvic cavity is termed *parietal peritoneum*. The visceral peritoneum forms the serosal surfaces of the intra-abdominal organs. Caudally, the peritoneum reflects over the surfaces of the pelvic organs (portions of the urogenital tract and rectum), excluding them from the peritoneal space and defining the retroperitoneal space. The peritoneal space communicates with the lumen of the uterus (and thus the external environment) by way of the fallopian tubes in females. In males the peritoneum forms a true blind sac. The vascular supply and nervous innervation of the visceral peritoneum are supplied by the splanchnic vessels and visceral autonomic nerves, respectively. Branches of the intercostal, lumbar, and iliac arteries supply the parietal peritoneum, and the phrenic and intercostal nerves provide nervous innervation. The clinical relevance is that inflammation of the parietal peritoneum is perceived as somatic pain, resulting in a splinted abdominal wall, pain on external palpation, and reluctance to move.

The peritoneal lining functions as a semipermeable barrier to the diffusion of water and low-molecular-weight solutes between the blood and the abdominal cavity.<sup>2</sup> The peritoneum secretes a serous fluid that lubricates the abdominal cavity, inhibits adhesion formation, and has minor antibacterial properties.<sup>2,3</sup> Macrophages, mast cells, mesothelial cells, and lymphocytes provide immune function within the peritoneum.<sup>1,3</sup> The peritoneal surface maintains a high level of fibrinolytic activity through the production of plasminogen activators by mesothelial cells. This function, with the lubricant properties of the PF, helps maintain gliding surfaces within the peritoneum and prevent adhesion formation. PF produced by the mesothelium tends to move ventrally and cranially, aided largely by diaphragmatic movement. PF, waste products, and foreign material exit the peritoneal cavity to enter the lymphatic system through diffusely distributed subendothelial pores or by way of the large diaphragmatic stomata, depending on particle size. Large molecules and particles greater than approximately 40,000 MW (such as bacteria) exit through the diaphragmatic stomata and ultimately enter the thoracic duct.

The term *peritonitis* refers to inflammation of the mesothelial lining of the peritoneal cavity.

## ☞ ETIOPATHOGENESIS

Peritonitis can occur in association with any insult—mechanical, chemical, or infectious—that results in disruption or irritation of the peritoneal lining, inflammation or infection of abdominal organs, or compromise of the intestinal wall.<sup>1-4</sup> Common mechanical injuries include blunt or perforating trauma to the abdominal wall, breeding and foaling accidents, and abdominal surgery. A variety of iatrogenic insults can cause peritonitis, such as abdominocentesis, enterocentesis, splenic puncture, bowel trocharization, liver biopsy, uterine biopsy, castration, and rectal tear. Chemical insults of endogenous origin include blood, urine, pancreatic enzymes, bile, gastric juice, chyme, and chyle. Talc, contrast agents, antibiotics, and lavage solutions are additional examples of chemical insults. Traumatic events often involve bacterial contamination at the time of injury, and mechanical and chemical injuries can become infected secondarily.

The most common manifestation of peritonitis is acute, diffuse, septic peritonitis following inflammation, vascular insult, perforation, or surgical manipulation (e.g., enterotomy, resection, anastomosis) of the gastrointestinal tract. The septic process in such cases involves mixed bacteria of gastrointestinal origin. Penetrating abdominal wounds also result in mixed infections. Less commonly, singular bacterial forms gain access to the peritoneum through hematogenous spread or extension from a contiguous organ or through the female genital tract. Primary monomicrobial infections have been reported involving *Streptococcus equi* subsp. *equi*,<sup>5,6</sup> *S. equi* subsp. *zooepidemicus*,<sup>7</sup> *R. equi*,<sup>6</sup> and *Corynebacterium pseudotuberculosis*.<sup>7,8</sup> Several case series involving peritonitis associated with *Actinobacillus equuli* have been reported.<sup>9-11</sup> Initial reports of *A. equuli* peritonitis originated solely in Australia, but recent cases have been reported from the United States<sup>12,13</sup> and New Zealand.<sup>14</sup> Septicemia, septic omphalophlebitis, ascending urinary tract infections, and uterine infections are additional causes of monomicrobial infection.

Most cases of trauma or intestinal perforation result in contamination of the peritoneum with large numbers of many types of bacteria. The intestinal tract contains a mixed population of bacteria, and the quantity of bacteria and prevalence of anaerobic species increase in the distal segments. Not surprisingly, mortality associated with contamination from the lower bowel is high. Hirsch and Jang<sup>15</sup> reported isolation of an infective agent from exudative equine PF in approximately 25% of attempts. Obligate anaerobic bacteria were cultured most frequently, followed by members of the Enterobacteriaceae family (predominantly *Escherichia coli*). Penicillin-resistant *Bacteroides fragilis* was isolated between 10% to 20% of cases. In another study in which bacteria were identified in equine abdominal fluid by cytologic examination or culture, *E. coli* was the organism most commonly isolated.<sup>16</sup> In human beings and laboratory animals, despite the variety of organisms initially introduced by polymicrobial contamination, established infections are characterized by only a few types of bacteria, which are often gram negative aerobes and anaerobic bacteria.<sup>3</sup> This selectivity occurs through the processes of selective reduction of bacterial populations and bacterial synergism. An example of synergism in human beings and laboratory animals is peritonitis involving *E. coli* and *B. fragilis*. The presence of

each organism is beneficial to the survival of the other, and each is important in the overall pathogenesis of the disease. *E. coli* is associated with septicemia and early mortality, whereas *B. fragilis* infection tends to result in chronic abscessation with delayed morbidity and mortality.<sup>3</sup>

Other causes of equine peritonitis include parasites, viral disorders (influenza, EVA, EIA, African horse sickness),<sup>6</sup> and neoplasia.<sup>3,17</sup> Verminous arteritis caused by strongylosis can lead to vascular damage (thromboembolism, infarction) to the intestine.<sup>3</sup> The activities of strongyles, ascarids, and tapeworms can result in perforation of the bowel and damage to other abdominal organs. There has been one report of septic peritonitis resulting from colonic perforation associated with aberrant migration of *Gastrophilus intestinalis* larvae.<sup>18</sup>

Biologic events resulting from contamination of the abdomen or injury to the mesothelial cells include release of catecholamines, histamine, and serotonin from peritoneal mast cells; vasodilation and hyperemia; increase in peritoneal vascular permeability; secretion of protein-rich fluid into the peritoneum; transformation of mesothelial cells into macrophages; and influx of polymorphonuclear cells, humoral opsonins, natural antibodies, and serum complement into the peritoneal cavity.<sup>1-4</sup> Other possible events include depression of the peritoneal fibrinolytic activity, fibrin deposits on the peritoneal surface, and inflammatory- and sympathetic-mediated ileus. These processes serve to confine contamination and infection and, with clean, minimally invasive procedures such as enterocentesis or trocharization, are effective. However, with greater severity of peritoneal contamination or irritation, these processes are magnified and become deleterious. Consequences include hypovolemia, hypoproteinemia, gastrointestinal ileus, ischemia of the bowel wall with subsequent absorption of bacteria and toxins, and ultimately adhesion and abscess formation. Equine peritoneal macrophages release a multitude of inflammatory mediators when exposed to bacterial LPS,<sup>19</sup> and endotoxemia contributes to the clinical picture. A complete review of endotoxemia is presented earlier in this chapter.

A complete pathologic description of peritonitis includes origin (primary or secondary), onset (peracute, acute, chronic), distribution (localized versus diffuse), and presence of bacteria (septic versus nonseptic).<sup>1</sup> Clinically, viewing the pathogenesis of peritonitis as a series of stages is useful.<sup>3</sup> The contamination stage, lasting 3 to 6 hours, involves introduction of bacteria into the peritoneum and initiation of the acute inflammatory response previously described. If the organisms are not eliminated, the process evolves to the stage of acute diffuse peritonitis as, regardless of the location of the initial contamination, bacteria spread throughout the peritoneum within several hours. The stage of acute diffuse peritonitis lasts up to 5 days. The inflammatory response persists and escalates with continued exudation of proteinaceous fluid and influx of inflammatory cells. Offending organisms are delivered to the lymphatic system and may be eliminated by the immune system. Alternatively, organisms can gain access to the systemic circulation in sufficient numbers to result in clinically relevant bacteremia. Following polymicrobial contamination of the peritoneum in human beings and laboratory animals, *E. coli* bacteremia commonly occurs.<sup>20</sup> This stage of the disease process is associated with the highest mortality rate because of the effects of severe peritoneal inflammation, endotoxemia, and sepsis. If the animal survives this stage but fails to eliminate infection from the peritoneal cavity, the disease enters a transitional phase referred to as the *acute adhesive*

(or *localizing*) stage, which typically occurs 4 to 10 days after the initial insult. Neutrophils are still active, macrophages are increasing in numbers, and fibrin aggregates are being organized or lysed. If infection persists beyond this point, organization of fibrin proceeds and organisms become isolated from host defenses. At this point the disease process enters the stage of chronic abscessation. This stage can begin as early as 8 days after inoculation and persist indefinitely.

## CLINICAL SIGNS

Clinical signs of peritonitis depend on the primary disease process, the duration of the problem, and the extent of peritoneal inflammation. Localized peritonitis may have few or no systemic manifestations, whereas severe localized or generalized peritonitis often is accompanied by severe toxemia, septicemia, or both. Septic peritonitis usually causes more severe clinical signs because of the systemic inflammatory response and endotoxemia. Most clinical signs are nonspecific and include fever, depression, inappetence, decreased borborygmi, and dehydration. Additional signs, reported in 30 horses (2 months to 16 years of age) with peritonitis, were colic, ileus, weight loss, and diarrhea.<sup>5</sup>

Horses with peracute peritonitis, as occurs with rupture of the bowel or rectal tear, have severe toxemia, weakness, depression or severe colic, tachycardia, tachypnea, and circulatory failure. Fever may not be present, depending on the degree of shock. Typical clinical findings include sweating, pawing, muscle fasciculations, weak peripheral pulses, red to purple mucous membranes, prolonged capillary refill time, and decreased skin elasticity. Parietal pain, characterized by reluctance to move, splinting of the abdominal wall, and sensitivity to external abdominal pressure, occurs in some acute cases. Urination or defecation may be painful for the horse; therefore urine and fecal retention may be evident on rectal examination. Palpation of the abdomen externally may elicit flinching, aversion movements, or groaning. With extensive abdominal fecal contamination, rectal examination may reveal grittiness of the serosal and parietal surface of the peritoneum because of fibrin deposition.

In horses with more chronic peritonitis, clinical signs include chronic or intermittent colic, depression, anorexia, weight loss, intermittent fever, ventral edema, exercise intolerance, decreased or absent intestinal sounds, and mild dehydration. Heart rate and respiratory rate may be normal. Fecal output may be normal; however, horses with chronic diarrhea and weight loss have been reported. Rectal examination findings may include pain on palpation of fibrinous or fibrous adhesions, intestinal impaction or distention following ileus and dehydration, an abdominal mass (abscess or neoplasia), or an impression of bowel floating in fluid. In many cases no abnormalities are evident on rectal examination.<sup>5</sup>

In cases of *A. equuli* peritonitis, clinical signs in most horses included depression, inappetence, lethargy, and mild to moderate abdominal pain acutely or weight loss in a chronic form.<sup>9,10</sup> Postpartum mares with peritonitis secondary to a uterine perforation typically exhibit fever and depression, with or without abdominal pain. Septic tenosynovitis of the tarsal sheath secondary to bacterial peritonitis resulting from gastrointestinal perforation was recently reported.<sup>21</sup> Foals with peritonitis usually exhibit signs of colic (acute or chronic) and are febrile, depressed, and inappetent. In young foals peritonitis can cause rapid metabolic deterioration, and determination

and correction of the primary problem require immediate attention. In older foals peritonitis may occur insidiously in association with *S. equi* subsp. *equi* or *R. equi* infections.

## CLINICOPATHOLOGIC FINDINGS

### HEMATOLOGY AND SERUM CHEMISTRY

Clinicopathologic abnormalities vary depending on the time of onset and severity of peritonitis. In the acute stage of septic peritonitis, leukopenia, hemoconcentration, metabolic acidemia, and azotemia predominate. After several days leukocytosis and hyperfibrinogenemia are more typical. Plasma protein concentration varies depending on the hydration status, degree of exudation into the peritoneum, and type of underlying problem. In chronic peritonitis hyperproteinemia with hyperglobulinemia may be present. Though not widely available for clinical use, serum concentrations of amyloid A, an acute-phase protein, were significantly higher in horses with colic caused by inflammatory conditions, including peritonitis, compared with those that had colic caused by other conditions.<sup>22</sup> Neonates with uroperitoneum tend to develop azotemia, hyponatremia, hypochloremia, hyperkalemia, and acidemia. Foals with septic peritonitis in either the acute or chronic stage have clinicopathologic profiles similar to those of their adult cohorts.

### PERITONEAL FLUID

Abnormalities in the composition of PF occur with peritoneal inflammation, and PF analysis is principal to the diagnosis of peritonitis. Fluid should be collected in a tube containing EDTA for cytologic analysis, a sterile tube for culture, and a tube containing lithium heparin (or the anticoagulant preferred by the specific laboratory) for biochemical analysis. The clinician should evaluate PF routinely as to color, turbidity, total protein, white blood cell count and differential, and the presence of bacteria as determined by Gram stain. Normal PF is clear and straw-colored and does not coagulate spontaneously. PF becomes turbid when increased numbers of white blood cells and concentration of protein are present. Pink or red fluid indicates free hemoglobin or hemorrhage. Blood introduced into the PF iatrogenically in some cases may be differentiated from blood resulting from internal hemorrhage on the basis of the presence of platelets and hematocrit. Fluid with iatrogenic blood contamination contains platelets, whereas fluid with blood following internal hemorrhage or diapedesis often does not have platelets. Blood contamination resulting from splenic puncture often results in the packed cell volume of the sample being greater than that of the peripheral blood. Large volumes of dark brown or green fluid with a fetid odor, especially if obtained from several sites, strongly suggest bowel rupture. However, the clinician should perform cytologic examination to confirm rupture versus enterocentesis.

Because the concentration of polymorphonuclear and mononuclear cells in PF varies widely, results typically support a number of disorders rather than a specific diagnosis. Normal equine PF contains fewer than 5000 nucleated cells per microliter.<sup>23</sup> White blood cell counts in acute peritonitis (100,000/ $\mu$ L) are reported to be higher than those in chronic peritonitis (20,000 to 60,000/ $\mu$ L).<sup>5,23,24</sup> However, this is not always the case, and the white blood cell count depends most

on the cause of the peritonitis and does not always correlate with disease severity or prognosis. The PF white blood cell count can be greater than 100,000/ $\mu$ L following enterocentesis, with no clinical signs or problem.<sup>25</sup> Conversely, peritoneal white blood cell counts of fewer than 100,000/ $\mu$ L may be found in foals or horses with intra-abdominal abscesses.<sup>26</sup> The peritoneal white blood cell count can increase to greater than 150,000/ $\mu$ L after celiotomy<sup>27</sup> and can be higher if an enterotomy is done. Postoperatively, the white blood cell count normally continues to decline and returns to near normal by 5 to 7 days. Failure of the white blood cell count to decrease suggests peritonitis resulting from a postoperative complication. Finally, PF white blood cell counts greater than 500,000/ $\mu$ L indicate severe focal or generalized peritoneal sepsis. The distribution of polymorphonuclear and mononuclear cells varies in normal PF, but polymorphonuclear cells usually predominate.<sup>23</sup> With acute peritonitis polymorphonuclear cells typically increase to a greater degree than mononuclear cells, but this depends on the cause. In horses with gastrointestinal disease and endotoxemia, the number of peritoneal mononuclear cells increases, as does transformation of mesothelial cells to macrophages. In chronic cases transforming mesothelial cells may be easily mistaken for neoplastic cells, which can make diagnosis difficult.

Normal PF protein concentration is less than 1.5 g/dl.<sup>23</sup> Protein concentrations between 1.5 g/dl and 2.5 g/dl can be difficult to interpret, but levels greater than 2.5 g/dl should be considered abnormally elevated. Fibrinogen concentration increases with inflammation, and levels greater than 10 mg/dl in the PF suggest an acute inflammatory process.<sup>28</sup> Fibrinogen content will also increase as a result of blood contamination.

The presence of free and phagocytosed bacteria in PF indicates generalized suppuration, abscessation, or compromised bowel. If numerous microorganisms of mixed types are observed free in the PF, especially in conjunction with plant material, bowel rupture likely has occurred. The presence of toxic or degenerate neutrophils and bacteria within polymorphonuclear cells helps distinguish PF from intestinal contents in such cases. Fluid obtained from enterocentesis is largely devoid of white blood cells but is discolored and contains mixed microorganisms and plant material. Bacterial contamination of a sample can occur during collection of the sample, and iatrogenic contamination of a sample can result in free and intracellular bacteria, particularly if processing is delayed. In such cases the bacterial numbers are few, and the neutrophils appear healthy. In some cases of gastrointestinal perforation, the luminal material, inflammatory cells, and protein may be sequestered by the omentum and further contained by fibrinous adhesions. Abdominal fluid obtained from standard ventral paracentesis may have low cellularity and protein content but large numbers of mixed bacteria, which indicates bowel rupture. Examples include gastric rupture along the greater curvature of the stomach between the omental layers (omental bursa) and perforated gastric or duodenal ulcers in foals. Correlating all cytologic findings with clinical and clinicopathologic findings is important for interpreting the results of PF cytologic examination.

Biochemical analysis of PF may be useful in detecting sepsis when cytologic examination and culture are negative or otherwise unavailable. In a prospective study PF pH and glucose concentrations from horses with septic peritonitis were significantly lower than those from horses with nonseptic peritonitis and healthy horses.<sup>29</sup> PF pH values below 7.3,

glucose counts below 30 mg/dl, and fibrinogen concentration greater than 200 mg/dl were considered highly predictive of septic peritonitis. Serum to peritoneal glucose concentration differences of greater than 50 mg/dl were considered the most diagnostically useful test for septic peritonitis in the study. Although not validated in horses with peritonitis, PF lactate levels can be expected to increase as a result of septic peritonitis, and the blood to peritoneal lactate concentration difference may prove to have diagnostic significance. In a small study in dogs, a blood-to-fluid lactate difference equal to or less than 2.0 mmol/L was shown to be 100% sensitive and specific for a diagnosis of septic peritonitis.<sup>30</sup> Increased activities of alkaline phosphatase, lactic dehydrogenase, creatine kinase, aspartate aminotransferase, tumor necrosis factor, and interleukin-6 have been measured in the PF of horses with abdominal disorders, but the diagnostic and prognostic implications of the presence or absence of these enzymes and analytes is limited.<sup>28,29,31</sup>

One should submit PF samples in appropriate media (i.e., Port-A-Cul Vial, BBL Microbiology System) for aerobic and anaerobic cultures in an attempt to identify the pathogenic organism or organisms. Obligate anaerobic bacteria such as *Bacteroides* spp. are difficult to culture because the sample must be collected, transported, and cultured under strict anaerobic conditions. Frequently, bacterial cultures are negative when bacteria are present in PF. To enhance recovery of bacteria, one can inoculate PF into blood culture medium (i.e., Septi-Chek Columbia, Hoffmann-LaRoche Inc., Nutley, New Jersey), and if the horse has received antimicrobial treatment, one first should pass fluid through an antimicrobial removal device (i.e., A.R.D., Becton Dickinson & Co., Cockeysville, Md).

## TREATMENT

Early and aggressive therapy is required if treatment of peritonitis is to be successful. The goals of treatment are to resolve the primary problem, minimize the inflammatory response, and prevent long-term complications. In the acute phase the clinician gives primary consideration to the arrest of endotoxic, septic, or hypovolemic shock; correction of metabolic and electrolyte abnormalities and dehydration; and management of pain. In the absence of blood gas and electrolyte determinations, adequate volumes of a balanced electrolyte solution are required to correct dehydration and support the cardiovascular system. If the plasma protein concentration of the horse is less than 4.0 g/dl, the clinician should consider administration of plasma or synthetic colloids.

Flunixin meglumine should be administered for its local and systemic anti-inflammatory effects. Dosages vary depending on the severity of peritonitis, degree of toxemia, severity of pain, and hydration status of the horse and range between 0.25 mg/kg intramuscularly or intravenously every 6 to 10 hours to 1.0 mg/kg intramuscularly or intravenously every 12 hours. The higher dosage provides greater visceral analgesia, whereas the lower dosage is effective in modifying the effects of experimental endotoxemia.<sup>6,32</sup> In addition to analgesic and general anti-inflammatory effect, flunixin meglumine may be effective in retarding adhesion formation.<sup>33</sup> Heparin therapy has been recommended to prevent adhesion formation and to render bacteria more susceptible to cellular and noncellular clearing mechanisms. In experimental models using laboratory animals, heparin therapy was associated with decreased adhesions in septic peritonitis.<sup>34</sup> In the horse information

specifically related to peritonitis is lacking, but results following ischemia-reperfusion injury are mixed. One study demonstrated a decrease in adhesion formation with heparin therapy,<sup>35</sup> whereas another study showed no benefit in foals.<sup>33</sup> Low-molecular-weight heparin has been evaluated in horses and was shown to decrease the adverse effects associated with unfractionated heparin, including decreased packed cell volume and prolongation of activated partial thromboplastin time (aPTT) and thrombin time (TT).<sup>36</sup> Suggested dosages for unfractionated<sup>35</sup> and low-molecular-weight heparin have been described.<sup>37</sup>

The clinician should initiate antimicrobial therapy after making a diagnosis of peritonitis and before the results of peritoneal culture are available, because of the delay in obtaining results and the likelihood of a negative culture even in the face of peritoneal sepsis. Thus one should assume mixed infection with gram negative and gram positive aerobic and anaerobic bacteria. Intravenous administration of antimicrobials is preferred over oral or intramuscular routes in acute, diffuse, septic peritonitis because more reliable concentrations of drug are achieved in the tissues and PF than otherwise would be obtained in horses with hypovolemia or decreased intestinal motility.<sup>38</sup> The combination of a  $\beta$ -lactam antibiotic with an aminoglycoside, such as potassium penicillin (22,000 to 44,000 IU/kg intravenously every 6 hours) combined with gentamicin (6.6 mg/kg every 24 hours), is appropriate in most circumstances. Metronidazole (15-25 mg/kg orally every 12 hours) can be added to the regimen given the strong possibility of infection involving penicillin-resistant *B. fragilis*. One can modify this antimicrobial regimen when culture and antimicrobial sensitivity results become available. Peritonitis caused by *A. equuli* usually is manifested as a diffuse, suppurative peritoneal exudate.<sup>10</sup> These infections generally respond well to combination therapy with penicillin, either alone or in combination with gentamicin. Aminoglycosides and NSAIDs have the potential to induce acute renal tubular damage, particularly with concurrent dehydration and decreased renal perfusion. Therefore adequate restoration and maintenance of hydration and monitoring of renal function are important. Monitoring of white blood cell count, plasma fibrinogen, and abdominal fluid analysis often guide duration of therapy. Horses with abdominal abscessation resulting from monomicrobial infections typically require weeks to months of therapy, whereas polymicrobial infection may require many months of antibiotic treatment. Further details regarding principles of antimicrobial therapy are provided elsewhere in this text.

Abdominal drainage and lavage can help remove excess fluid, foreign materials, fibrin, and bacterial products from horses with peritonitis, and postoperative lavage decreases the incidence of experimentally induced abdominal adhesions.<sup>39</sup> Open surgical exploration provides the most effective and thorough examination of all peritoneal surfaces and is recommended if gastrointestinal perforation or ischemia is suspected or in any other case in which correction of a primary lesion is indicated. A ventral abdominal drain can be placed either at the time of surgery or in the standing horse with sedation and local anesthesia. Techniques have been described in detail elsewhere.<sup>40,41</sup>

Peritoneal lavage is typically performed with 10 to 20 L of a balanced isotonic electrolyte solution (such as lactated Ringer's solution or Normosol-R) twice a day for 3 to 5 days, until the lavage solution becomes clear, or until the catheter

becomes clogged with fibrin or omentum. Hypertonic solutions are not recommended because they can result in fluid shifts into the peritoneum. The addition of povidone iodine to a balanced solution should also be avoided because concentrations as low as 3% can induce peritoneal inflammation.<sup>42</sup> Other agents, such as antibiotics or heparin, have been suggested as components of the lavage solution, but data demonstrating their benefit are not currently available. Active (or closed suction) abdominal drains have also been advocated, with benefits and potential complications similar to those of other methods.<sup>41</sup> Lavage with a plain isotonic solution did not alter the pharmacokinetics of gentamicin administered systemically.<sup>43</sup> Thus alteration of antimicrobial dosing does not appear necessary if lavage with plain solutions is part of the therapeutic regimen. Complications associated with the use of abdominal drains or repeated peritoneal drainage include retrograde infection, local irritation, pneumoperitoneum, and subcutaneous seepage around the drain with resultant cellulitis. If the patient is hypovolemic or hypoproteinemic, the clinician should consider volume replacement and administration of plasma or synthetic colloids before removing large quantities of fluid from the abdomen.

For horses with suspected parasitic involvement, the clinician should give larvicidal doses of an anthelmintic once the condition of the horse is stabilized. Ivermectin, moxidectin, fenbendazole, and thiabendazole have been recommended as larvicidal therapies.

The decision to perform surgery rather than treat medically is controversial in horses with peritonitis and should be made on a case-by-case basis. Although surgical exploration may allow diagnosis and resolution of the inciting cause and more thorough lavage of the abdomen, the risks of anesthesia, possible additional cost of surgery, and potential for a delayed return to performance may be significant. In a recent study of horses and foals with peritonitis, survival to discharge without surgery was associated with lack of signs of abdominal pain, normal or improved rectal temperature, normal or improved borborygmi, normal fecal production, no abnormal findings on rectal palpation, no nasogastric reflux, and yellow-orange PF.<sup>44</sup> A retrospective comparison of medical and surgical treatment of postpartum mares with peritonitis secondary to a uterine tear found no significant differences among admission variables, survival rate, hospital bill, duration of hospital stay, and likelihood to foal after discharge. A limitation of this study is the ability to definitively diagnose a uterine tear in those mares treated medically; if a tear was not palpable, the diagnosis was based on exclusion of other causes.<sup>45</sup>

## PROGNOSIS

The prognosis is grave for peritonitis associated with gastrointestinal rupture. Reported survival rates for horses with peritonitis vary but can be as high as 59.7%<sup>16</sup> to 78%.<sup>44</sup> In the study with a 78% overall survival rate, 68% of horses treated medically survived. Some of the variability in reported survival percentages can be related to inclusion criteria, mainly whether or not horses with gastrointestinal rupture were included. Septic peritonitis following abdominal surgery has been associated with high mortality (56%) in some studies,<sup>16</sup> whereas no difference in short-term survival was seen in another study.<sup>46</sup> Peritonitis associated with *A. equuli* carries a very favorable prognosis, and all horses in these reports responded to medical therapy if it was attempted.<sup>9-11</sup>

# DISORDERS OF THE LIVER

## CHAPTER 16

Michelle Henry Barton

### ☞ NORMAL LIVER

#### ANATOMY

The liver is the largest organ in the body, constituting approximately 1% of the body weight in the adult horse.<sup>1</sup> The location of the liver between the gastrointestinal tract and the heart is functionally suited for its metabolic, secretory, excretory, and storage properties. In the normal horse, the liver lies mostly to the right of the median, is completely contained within the rib cage, and does not contact the ventral abdominal floor. The most cranial portion of the liver is located in the ventral third of the sixth to seventh intercostal spaces and extends caudad to the right kidney (fifteenth rib). In disease processes resulting in hepatomegaly, and in the normal equine neonate, the liver may extend beyond the caudal border of the last rib. Right liver lobe atrophy has been described as an uncommon normal anatomic variation in adult horses. However, in 1994 it was hypothesized that right hepatic lobe atrophy in horses is a pathologic condition resulting from long-term compression of the right lobe of the liver by abnormal distension of the right dorsal colon and base of the cecum.<sup>2</sup>

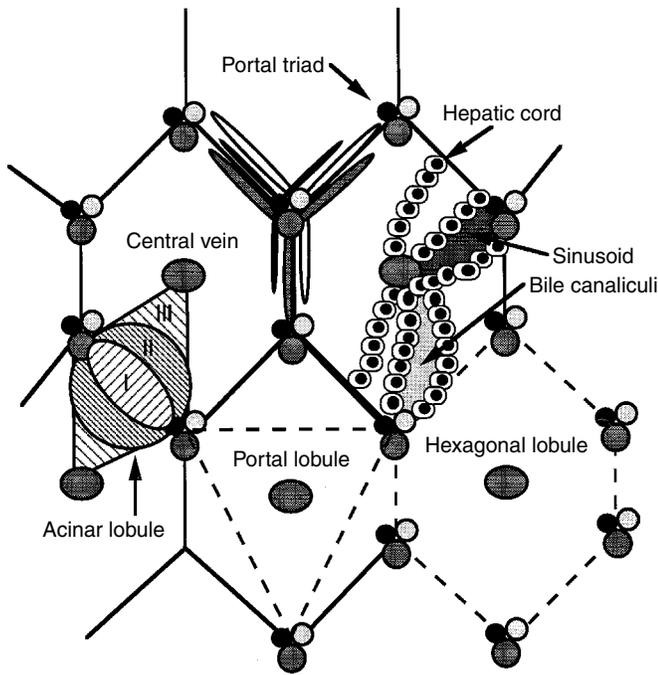

The equine liver consists of two surfaces, diaphragmatic and visceral, and is divided by fissures into four lobes: right, left, quadrate, and caudate. The visceral surface of the liver in situ is malleable and contains impressions of the organs with which it is in contact. The visceral surface also contains the hilum, or *porta* (door), of the liver, through which blood vessels, lymphatics, and nerves enter, and the hepatic duct exits. In the horse, six ligaments secure the liver in the abdominal cavity.<sup>1</sup> The *coronary ligament* has two laminae, right and left, which attach the diaphragmatic surface of the liver to the caudal vena cava and the abdominal esophagus. The two laminae of the coronary ligament unite ventrally to form the *falciform ligament*. The falciform ligament, a remnant of the fetal ventral mesentery that extends from the diaphragm to the umbilicus, attaches the quadrate and left lobes to the sternal diaphragm and ventral abdominal floor. The *round ligament*, the remnant of the fetal umbilical vein, is contained within the free border of the falciform ligament. The right and left *triangular ligaments* attach the dorsal right lobe to the right costal diaphragm and the dorsal left lobe to the tendinous center of the diaphragm. The *hepatorenal ligament* connects the caudate process of the quadrate lobe to the right kidney and the base of the cecum.

#### HISTOLOGY

At the hilum of the liver, a tree of connective tissue consisting of collagen and fibroblasts enters the hepatic parenchyma. The parenchymal cells, or hepatocytes, compose approximately 50% to 60% of the mass of the liver and are epithelial cells.<sup>3,4</sup> The hepatocytes are arranged in rows, or cords, at least two cells thick that anastomose to form blood passageways called *sinusoids* (Figure 16-1). Hepatic sinusoids are larger than capillaries and are lined with endothelial cells and Kupffer's cells. Kupffer's cells are tissue-fixed macrophages and are estimated to make up 20% of the mass of the liver.<sup>4</sup> The endothelial cells make up approximately 20% of the mass of the liver.<sup>4</sup> A cleft, called the *space of Disse*, lies between the hepatocytes and the cells lining the sinusoids. The space of Disse contains fluid similar to the composition of blood but does not contain erythrocytes.

The afferent hepatic blood vessels, bile ducts, lymphatics, and nerves follow the branching connective tissue tree into the hepatic parenchyma. The liver receives approximately one third of the cardiac output. Two entirely separate sources of blood supply the liver and empty into the hepatic sinusoids: the portal vein and the hepatic artery. The portal vein contains poorly oxygenated blood that carries nutrients absorbed from the gastrointestinal tract to the liver for storage, metabolism, transformation, or packaging for export to other tissues. The hepatic artery contains oxygen-rich blood to support the metabolic and energy-generating activities of the liver. The sinusoids drain into terminal hepatic venules or central veins, which connect with the hepatic vein and caudal vena cava.

The space between contiguous hepatocytes in a cord forms a bile canaliculus through which bile excreted by the hepatocytes drains into bile ductules and ducts. The bile canaliculi thus are formed solely by the cell membranes of the hepatocytes. The bile ductules and ducts are lined with cuboidal and columnar epithelial cells, respectively, that make up approximately 7% of the mass of the liver.<sup>4</sup> The bile ducts run in the connective tissue tree, adjacent to branches of the portal vein and hepatic artery, to form a distinct portal tract, radicle, canal, or triad (see Figure 16-1). The bile ducts converge at the hilum to form the *hepatic duct*, which drains into the duodenum just distal to the pylorus. Because the horse does not have a gallbladder or a sphincter at the entry site of the hepatic duct into the intestine, the bile is unconcentrated and

**FIGURE 16-1** Histology of the liver. Roman numerals *I*, *II*, and *III* represent zones 1, 2, and 3, respectively, of the acinar lobule.

flows continuously in a direction opposite that of the blood flow in the portal vein and hepatic artery.<sup>1</sup>

The liver can be divided anatomically or functionally into lobules to facilitate histopathologic description of lesions<sup>3</sup> (see [Figure 16-1](#)). The classic hepatic lobule is delineated by abundant interlobular connective tissue that in cross-section roughly appears hexagonal. Three to eight portal tracts define the corners of the hexagon with a central vein in the center of the lobule. In contrast, the portal lobule is a functional unit describing the exocrine duties of the liver. Central veins define the three corners of the portal lobule, with a portal tract situated in the center. The acinus lobules describe the vascular supply to the hepatic parenchyma, divided according to the tissue oxygen content. Zone I of the acinus lobule is located immediately adjacent to branching hepatic arteries and portal veins, is the most metabolically active zone, and receives the best oxygen supply. Zone III is located adjacent to central veins, has high mixed-function oxidase activity, is least favorably situated with respect to oxygen content, and thus is most susceptible to toxic and hypoxic damage. Zone II is situated between zones I and III.

## PHYSIOLOGY

The liver is the main organ involved in the regulation of nutrient distribution.<sup>5</sup> The majority of nutrients absorbed from the gastrointestinal tract pass directly to the liver via the portal circulation. The incoming nutrients are metabolized for energy, transformed to other nutrient classes, packaged and exported to peripheral tissues, or stored by the liver. The liver is capable of adjusting to the carbohydrate, protein, and lipid load from the gastrointestinal tract, as well as maintaining consistent blood levels of nutrients between feedings and in response to special needs. In addition to its role in nutrient metabolism and homeostasis, the liver is involved in excretion (bile),

detoxification and metabolism of endogenous and exogenous substances, and hematopoiesis.<sup>4</sup>

## PROTEIN METABOLISM

Amino acids, which are transported to the liver via the portal or hepatic blood, may be used in the biosynthesis of intrinsic hepatocellular proteins, plasma proteins, porphyrins, polyamines, purines, and pyrimidines.<sup>5</sup> The liver synthesizes 90% of the plasma proteins, including albumin, factors involved in coagulation and fibrinolysis (fibrinogen and factors II, V, VII-XIII; antithrombin III; protein C; plasminogen; plasminogen activator inhibitor;  $\alpha_2$ -antiplasmin;  $\alpha_2$ -macroglobulin; and  $\alpha_1$ -antitrypsin), transport proteins (haptoglobin, transferrin, ceruloplasmin, hormone transport proteins), and acute phase reactant proteins ( $\alpha$ - and  $\beta$ -globulins).<sup>4</sup> The liver is the only site of synthesis of albumin and fibrinogen.

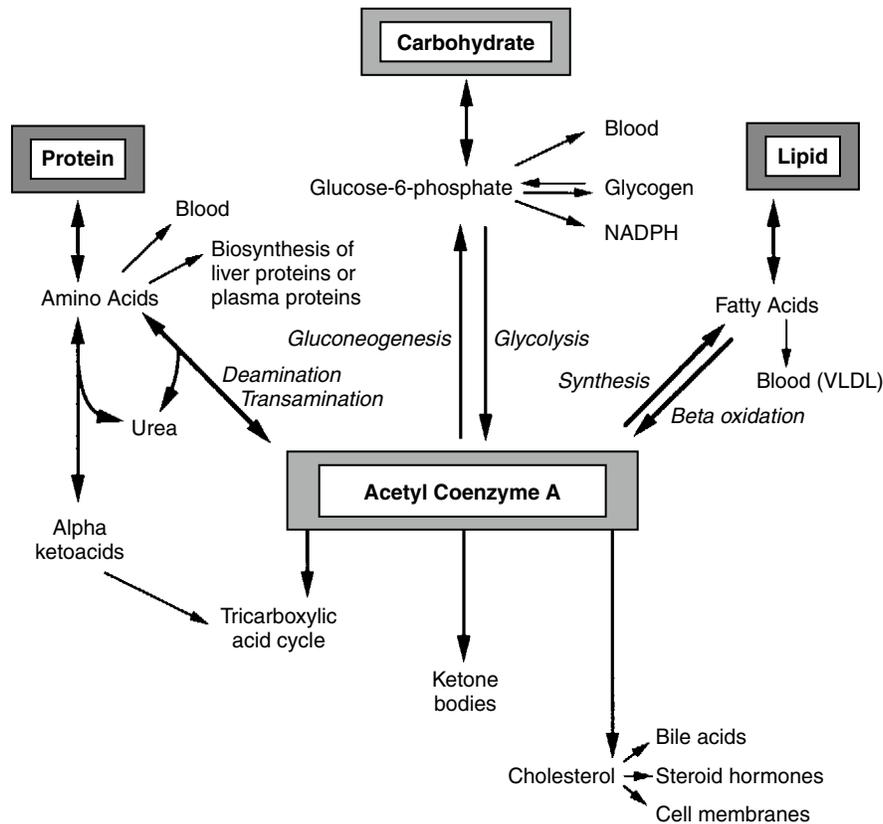

The liver is also capable of transamination, or the reversible transfer of an amino group on one amino acid to an  $\alpha$ -keto acid, thus forming a new amino acid and a new keto acid. If the liver receives an excess of amino acids or if carbohydrates are unavailable as an energy source, then the liver deaminates the amino acids and converts them to pyruvate, acetoacetate, and intermediates of the tricarboxylic acid cycle<sup>5</sup> ([Figure 16-2](#)). These intermediates may be oxidized for energy or used as precursors in *gluconeogenesis*, the synthesis of glucose from noncarbohydrate precursors. Endogenous and exogenous glucocorticoids, glucagon, and thyroid hormone act directly on the liver to increase gluconeogenesis<sup>6</sup> ([Figure 16-3](#)). Simultaneously, glucocorticoids indirectly influence liver gluconeogenesis by promoting peripheral protein catabolism, thus increasing the availability of amino acids. Insulin inhibits gluconeogenesis in the liver.<sup>6</sup>

In addition to protein synthesis and gluconeogenesis, the liver plays an important role in eliminating the major toxic by-product of amino acid catabolism, *ammonia*.<sup>5,7</sup> Tissues and intestinal microflora generate ammonia, which is subsequently released into the circulation. One method by which the liver, as well as certain peripheral tissues, eliminates ammonia is by synthesizing nonessential amino acids from  $\alpha$ -keto acids and ammonia in a reversal of deamination. A fundamental reaction in the synthesis of nonessential amino acids is the formation of *glutamate* from  $\alpha$ -ketoglutarate and ammonia ([Figure 16-4](#)). Subsequently, glutamate is used in transamination reactions to form other amino acids. Glutamate also participates in the conversion of cytotoxic free ammonia into a nontoxic transport form, *glutamine*. Glutamine may be delivered to the kidney, converted back to free ammonia and excreted, or delivered to the liver for urea synthesis.

The liver has sole responsibility for converting free ammonia or glutamine into *urea*, the principal form of amino group nitrogen excretion by mammals.<sup>4</sup> Urea is formed by the irreversible condensation of two ammonia molecules with carbon dioxide (see [Figure 16-4](#)). The reaction takes place in the hepatocyte mitochondria via the Krebs-Henseleit cycle.<sup>5</sup> The newly formed urea is released from the hepatocyte, secreted into the sinusoidal blood, and transported to the kidney as *blood urea nitrogen* (BUN) for excretion.

## CARBOHYDRATE METABOLISM

The liver is responsible for the synthesis, storage, and release of glucose.<sup>5</sup> Monosaccharides absorbed from the gastrointestinal tract are delivered via portal blood to the liver. In the

**FIGURE 16-2** Role of the liver in the metabolism of nutrients. *VLDL*, very-low-density lipoprotein; *NADPH*, nicotinamide adenine dinucleotide phosphate.

hepatocyte the majority of glucose is phosphorylated to *glucose-6-phosphate* by the enzyme hexokinase (see [Figure 16-2](#)). The remaining glucose is released into the systemic circulation. Other monosaccharides (fructose, galactose) are phosphorylated and converted in the liver to glucose-6-phosphate. The majority of glucose-6-phosphate is converted to glycogen for storage. A small amount of glucose-6-phosphate is oxidized to form adenosine triphosphate, although the major source of adenosine triphosphate in the liver is amino acid and fatty acid oxidation. Approximately half of the liver glucose enters the phosphogluconate pathway for generation of nicotinamide adenine dinucleotide phosphate, which is required as a reducing agent in the biosynthesis of fatty acids and cholesterol. Glucocorticoids, catecholamines, glucagon, and thyroid hormone increase gluconeogenesis and glycogenolysis in the liver, while insulin inhibits gluconeogenesis<sup>6</sup> (see [Figure 16-3](#)).

### LIPOID METABOLISM

Short-chain fatty acids (fewer than 10 carbon atoms) can be absorbed directly from the gastrointestinal tract, bound to albumin, and delivered to the liver via the portal circulation.<sup>5</sup> However, the majority of short-chain fatty acids are incorporated into phospholipid or triglyceride by the intestinal epithelium and transported to the liver via the portal blood. The remaining fatty acids absorbed from the gastrointestinal tract are transported as triglyceride in *chylomicrons*. After formation in the intestinal epithelial cells and absorption into lymphatics, *chylomicrons* enter the systemic circulation via the thoracic duct and subsequently are delivered to the liver.

The liver also may take up albumin-bound fatty acids released from adipose tissue.

The fate of fatty acids in the liver depends on the state of energy demand, the rate of fatty acid delivery, and hormonal influences. The primary role of the liver in lipid metabolism is to esterify free fatty acids into triglycerides for export to other tissues<sup>5</sup> (see [Figure 16-3](#)). The triglycerides are packaged with protein, carbohydrate, and cholesterol in the endoplasmic reticulum of the hepatocyte into *very-low-density lipoproteins* (VLDLs), which primarily contain triglyceride, and *high-density lipoproteins* (HDLs), which primarily contain protein and phospholipid.<sup>8</sup> The VLDLs and HDLs are released into the hepatic sinusoids. Once the VLDLs are in the systemic circulation, the adipose tissue takes them up or endothelial cell lipases alter their composition by removing triglyceride, forming *intermediate- and low-density lipoproteins*.

In addition to exporting plasma lipoprotein, the liver can oxidize free fatty acids for energy to acetyl coenzyme A (acetyl CoA), a fundamental compound in the tricarboxylic acid cycle (see [Figure 16-2](#)). The acetyl CoA thus formed also may be used in the synthesis of other fatty acids, cholesterol, steroids, and ketone bodies, acetoacetate, and  $\beta$ -hydroxybutyrate.<sup>5</sup> Furthermore, through the synthesis of acetyl CoA from glucose and most amino acids, the liver is capable of converting carbohydrates and proteins into lipids. Ketone bodies can be exported from the liver and used for energy by peripheral tissues, especially the brain, when glucose is deficient. However, overproduction of ketone bodies can be detrimental, resulting in ketoacidosis.<sup>8</sup>

Insulin and glucocorticoids closely regulate lipid metabolism<sup>6</sup> (see [Figure 16-3](#)). Glucocorticoids function primarily to

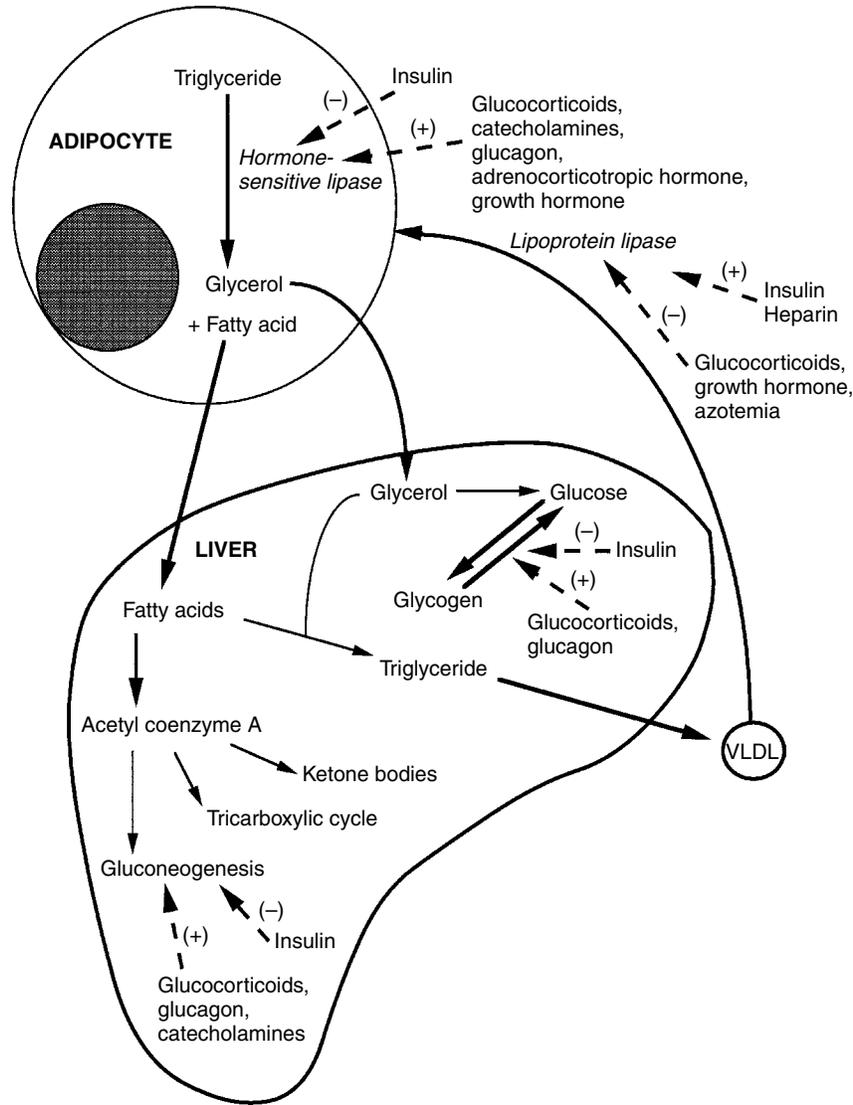

FIGURE 16-3 Hormonal control of metabolism. -, inhibitory effect; +, stimulatory effect.

increase fatty acid mobilization from the periphery, whereas insulin decreases adipose tissue release of fatty acids by activating lipoprotein lipase and inhibiting hormone-sensitive lipase. Insulin acts on the liver to increase fatty acid synthesis from glucose.

**EXCRETION OF BILE**

Bile consists of several components, including conjugated bilirubin, bile acids, cholesterol, lecithin, water, and electrolytes.<sup>4</sup> Bile is released by hepatocytes into the bile canaliculi where water diffuses passively. Bile then is transported by large bile ducts and the hepatic duct to the intestine. Water and electrolyte exchange takes place between the bile and the bile duct epithelium; however, isotonicity is maintained. Because the horse does not have a gallbladder or a sphincter at the site of entry of the hepatic duct into the duodenum, the bile is unconcentrated and flow is continuous.<sup>1</sup>

*Bile acids* compose 90% of the organic portion of bile.<sup>9</sup> Bile acids are amphoteric molecules that act as detergents. These detergents facilitate the excretion of cholesterol and phospholipid from the liver into bile and facilitate the absorption of lipids

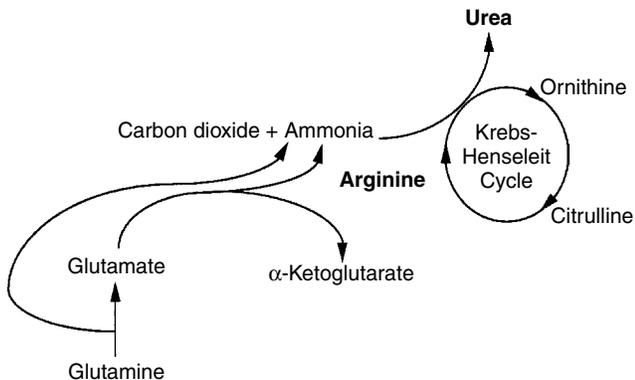

FIGURE 16-4 The urea cycle.

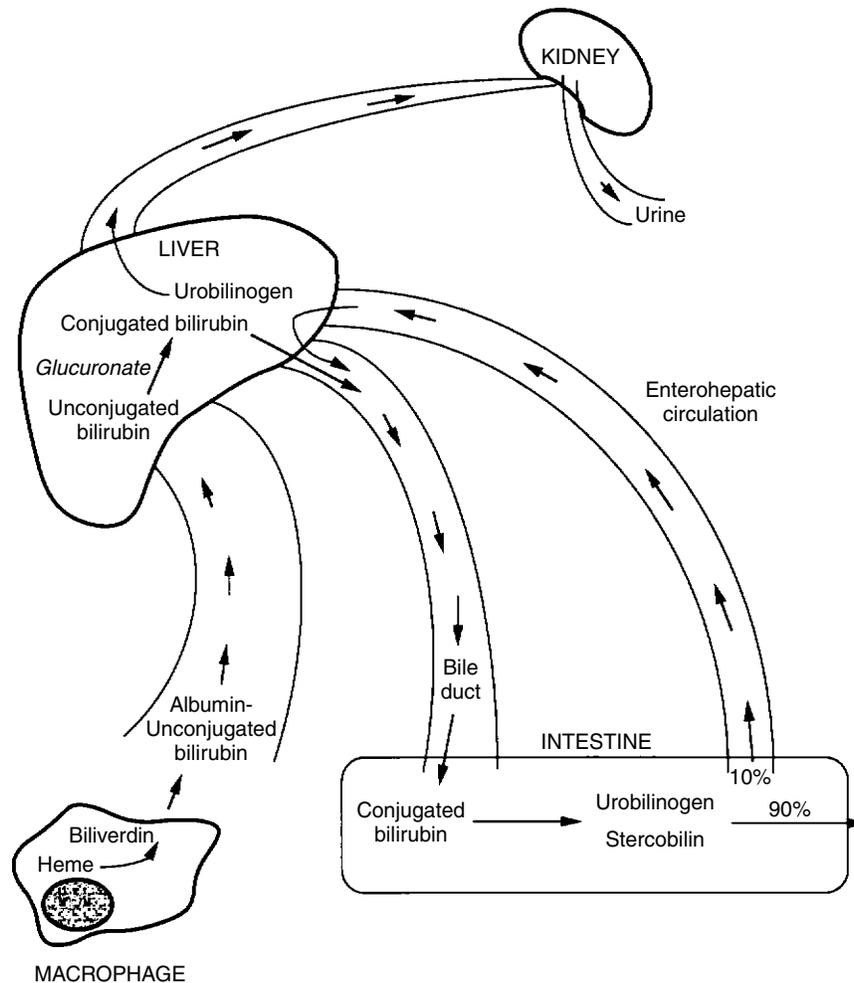

FIGURE 16-5 Metabolism and excretion of bile.

and lipid-soluble compounds (vitamins A, D, E, and K) from the intestinal tract. The principal *primary bile acids* (i.e., nondegraded) in the horse are *cholate* and *chenodeoxycholate*, both of which are conjugated with taurine.<sup>9</sup> Once secreted into the lumen of the intestinal tract, cholate and chenodeoxycholate may be reabsorbed or degraded by bacteria, forming the *secondary bile acids*, *deoxycholate* or *lithocholate*, respectively. More than 95% of the conjugated bile acids excreted in bile and released into the intestinal lumen are reabsorbed by the ileum and returned to the liver via the *enterohepatic circulation*. Deoxycholate acts as a normal bile acid and can undergo enterohepatic circulation, whereas lithocholate is only reabsorbed once. Bile acids are estimated to be recycled at least 38 times a day in healthy ponies.<sup>9</sup>

*Bilirubin* is the breakdown product of tetrapyrroles that function as electron transport pigments.<sup>4</sup> The majority of bilirubin is formed from hemoglobin and myoglobin, but non-heme pigments such as the cytochromes also serve as a source of bilirubin. Macrophages in the spleen, bone marrow, and liver (Kupffer's cells) engulf the pigments first, convert it to biliverdin (Figure 16-5), and then convert biliverdin to bilirubin and release it from the cell as free, insoluble bilirubin. This form of bilirubin also is referred to as *indirect-reacting* or *unconjugated bilirubin*. Unconjugated bilirubin is bound with albumin in the plasma to decrease its hydrophobicity and is delivered to the liver. At the surface of the hepatocyte, the

bilirubin is transferred from albumin to *ligandin*, an intrahepatic transport and storage protein.<sup>4,9</sup> Within the hepatocyte, the bilirubin is conjugated with glucuronide in the endoplasmic reticulum. *Conjugated bilirubin*, also called *direct-reacting bilirubin*, is water soluble and is excreted into the bile canaliculi. Under normal circumstances, little conjugated bilirubin escapes into the general circulation.

Microflora in the intestinal tract reduce conjugated bilirubin to *urobilinogen* and *stercobilin* (see Figure 16-5), which impart a yellow-brown color to feces. In herbivores, the presence of chlorophyll pigments in the feces masks the color of urobilinogen.<sup>10</sup> Only in the neonatal herbivore receiving a milk diet are the feces yellow. Urobilinogen is absorbed by the intestinal mucosa and transported back to the liver via the enterohepatic circulation. A small amount of conjugated bilirubin in the intestinal lumen is hydrolyzed to unconjugated bilirubin and subsequently is reabsorbed. The liver extracts most of the urobilinogen; however, a small amount spills over into the urine. Urobilinogen is concentrated in the normally alkaline urine of horses and thus is detectable.<sup>10</sup>

#### DETOXIFICATION

The liver is responsible for the *biotransformation* of numerous endogenous and exogenous compounds. Biotransformation involves a series of enzymatic reactions that alter the physical

properties or activity of compounds. Biotransformation occurs in two phases.<sup>11</sup> In phase 1, polar groups are added to the compound or existing polar groups are exposed by oxidation, hydroxylation, deamination, or reduction. In phase 2, the product of phase 1 is conjugated, usually with glucuronate or sulfate. Substrates for detoxification usually are water insoluble and biotransformation renders them more susceptible to renal or biliary excretion.<sup>4,12</sup> Examples of endogenous substances biotransformed by the liver include ammonia, bilirubin, and steroid hormones (estrogen, cortisol, aldosterone). The liver biotransforms countless exogenous substances, including many drugs, plant toxins, insecticides, and mercaptans.

Phase 1 of biotransformation occurs primarily on the enzyme-bound systems of the endoplasmic reticulum, called *microsomes*.<sup>4,12</sup> Most of these enzymes are iron-containing enzymes of the P-450 system, thus named because they absorb light at 450 nm. The P-450 enzymes are also called *mixed function oxidases*. Some substrates, referred to as *inducers*, are capable of saturating the enzymes involved in biotransformation. Enzyme saturation and induction causes hypertrophy of the endoplasmic reticulum and all contained enzymes, thus accelerating substance removal rates. Inducers not only accelerate their own removal rate but also may accelerate the biotransformation of other endogenous and exogenous substances. Examples of enzyme inducers are the barbiturates, phenylbutazone, and chlorinated hydrocarbons. Other agents presented for biotransformation, including chloramphenicol, cimetidine, organophosphates, morphine, and quinidine, may inhibit microsomal enzymes thus prolonging the effect of other substrates. Hepatic biotransformation sometimes results in the formation of a toxic metabolite from a nontoxic parent compound examples being aspirin and halothane.<sup>12</sup>

### MONONUCLEAR PHAGOCYTE SYSTEM

Hepatic macrophages, or Kupffer's cells, make up a major portion of the mononuclear phagocyte system. Cells of the mononuclear phagocyte system are derived from bone marrow myeloid progenitors and serve two main functions: (1) phagocytosis and (2) to act as antigen-processing cells for lymphocytes. Kupffer's cells respond to opsonins and synthesize a vast array of inflammatory mediators, including interleukins, tumor necrosis factor (TNF), and eicosanoids. Unlike other macrophages in the mononuclear phagocyte system, Kupffer's cells function mainly in phagocytosis and are located strategically along the hepatic sinusoids, where portal blood can be cleansed, for example, of bacterial endotoxin, before exposure to the hepatocytes and subsequently the systemic circulation.<sup>13</sup> Kupffer's cells also help cleanse systemic blood entering via the hepatic artery by removing *fibrin degradation products (FDPs)*, tissue plasminogen activators, hemoglobin, microbes, foreign antigens, and other particulate debris.

### MISCELLANEOUS FUNCTIONS

The liver serves as a storage site for several vitamins and trace minerals, including vitamins A, D, and B<sub>12</sub>; copper; and iron. Vitamin D is first converted in the liver to 25-hydroxycholecalciferol and exported to the kidney, where it is transformed into 1,25-dihydroxycholecalciferol, the active form of the vitamin.<sup>6</sup> In the fetus the liver is involved in *hematopoiesis*.<sup>4</sup> In the adult the bone marrow serves as the primary site for hematopoiesis; however, the liver may serve as an extramedullary site of hematopoiesis under intense conditions of erythrocyte regeneration or if a large portion of the bone marrow is destroyed.

## HEPATIC INSUFFICIENCY

### DEFINITION

*Hepatic insufficiency* or failure refers to the inability of the liver to perform its normal functions properly. Because the liver is involved in such a diverse array of physiologic activities, any pathologic process may hinder one or several functions without impeding others. Furthermore, most hepatic functions are not impaired until greater than 80% of the hepatic mass is lost.<sup>4,8,10</sup> The liver also has the capability to regenerate under certain conditions. If hepatocyte loss is gradual and regeneration parallels destruction, then hepatic failure does not necessarily ensue. Thus hepatic disease may be present without accompanying hepatic failure. Consequently, hepatic disease does not always manifest clinically.

### PATTERNS AND PATHOLOGY OF HEPATIC INJURY

The severity of the accompanying clinical signs and the course of hepatic disease vary depending on the pattern, location, rate, and extent of hepatic damage. Hepatic injury may be reversible (fatty degeneration, cloudy swelling), irreversible (necrosis), focal or zonal, generalized, acute, chronic, inflammatory, anatomic, or functional.

#### ACUTE FOCAL OR MULTIFOCAL HEPATIC INJURY

Focal hepatic injury occurs with uniform damage to one small area of the liver. Examples of focal hepatic injury include hepatic abscesses, solitary infarctions, and neoplastic growths. Because adequate hepatic reserve exists in the unaffected regions, clinical signs of hepatic failure rarely accompany focal hepatic injury, although evidence of hepatic disease may be demonstrable.<sup>11</sup> Acute multifocal hepatic injury is more likely to result in clinically significant hepatic disease. Acute hepatic injury may be degenerative, necrotizing, or inflammatory. Hepatic *degeneration* refers to a toxic or immunologic insult that causes hepatocytes to swell and take on an edematous appearance.<sup>14</sup> *Ballooning degeneration* is used to describe irregularly clumped cytoplasm with large clear areas.<sup>14</sup> If biliary material has been retained, then the hepatocytes appear foamy and swollen (*foamy degeneration*). *Ischemic coagulative necrosis* refers to poorly stained and mummified hepatocytes with lysed nuclei, whereas *lytic necrosis* describes osmotically swollen and ruptured cells.<sup>14</sup> Necrosis of contiguous hepatocytes that spans adjacent lobules in a portal to portal, portal to central, or central to central fashion is called *bridging necrosis*.<sup>14</sup>

Hepatic injury may be zonal, that is, affecting certain zones of the liver uniformly throughout the entire organ.<sup>11</sup> The liver often appears pale with an enhanced lobular pattern on the cut surface. The two most common types of zonal hepatic injury are centrilobular and periportal. In *centrilobular zonal injury*, the area adjacent to the central veins (zone III) is uniformly affected, whereas in *periportal* or (*paracentral*) *zonal injury*, cellular degeneration involves only a wedge around the central vein (see Figure 16-1). Hepatocytes in these locations are most susceptible to anoxic damage, because the normal oxygen tension is lowest and mixed function oxidase activity is the greatest in these areas. Examples of disease states resulting in centrilobular injury are severe acute anemia, passive congestion caused by congestive heart failure (*nutmeg liver*), and toxic hepatopathies.

Periportal (zone I acinar lobular) injury is rare but may occur with infarction of hepatic vessels, as may occur during verminous arteritis, or exposure to toxins that do not require metabolism by mixed function oxidases (e.g., phosphorus).

### ACUTE GENERALIZED HEPATIC INJURY

Acute generalized hepatic injury is often accompanied by clinical signs of hepatic failure, with the extent of damage dictating the severity of the clinical signs.<sup>11</sup> Typically, the liver appears pale and enlarged and is often friable. Acute generalized hepatic injury may be the result of infection, necrosis, inflammation, or hepatotoxic agents.<sup>4</sup> Bacterial or viral infections, parasitic infestations, or immune disorders may cause acute generalized necrosis or inflammation. Despite its cause, any process that results in an inflammatory response in the hepatic parenchyma is referred to as *hepatitis*. Acute inflammation most commonly accompanies necrosis and is characterized by the presence of neutrophils and lymphocytes in the areas of cell death or surrounding portal triads. An inflammatory process primarily involving the biliary system is called *cholangitis*, usually the result of ascending infection from the intestinal tract or after cholestasis.

### CHRONIC GENERALIZED HEPATIC INJURY

Chronic hepatic injury is accompanied by clinical signs of hepatic failure when greater than 80% of the hepatic mass is destroyed or replaced by fibrosis.<sup>4,8</sup> Fibrosis, the presence of collagen and fibroblasts, occurs when the rate of ongoing necrosis exceeds the rate of regeneration. Typically, the liver appears smaller than normal. Fibrosis commonly follows conditions resulting in chronic hypoxia, chronic inflammation, chronic cholangitis or cholestasis, metastatic neoplasia, trauma, or ingestion of antimitotic agents such as plants containing pyrrolizidine alkaloids. *Cirrhosis*, or an *end-stage liver disease*, refers to chronic hepatic disease characterized by the presence of widespread fibrosis, nodular regeneration, and biliary hyperplasia.<sup>11</sup> *Nodular regeneration*, or islands of hepatocytes, occurs when the normal architecture and blood supply of the liver are disrupted or destroyed by the presence of fibrosis. *Bridging fibrosis* implies fibrosis that extends from one portal area to another or from portal areas to central areas.<sup>14</sup> The cause of biliary hyperplasia during chronic liver disease is unknown. One form of chronic hepatic disease, called *chronic active hepatitis* (CAH), is characterized by the presence of cirrhosis plus an acute inflammatory response.<sup>11</sup>

### ANATOMIC OR FUNCTIONAL INJURY

Anatomic or functional shunts cause liver injury by anoxic damage. Additionally, if blood habitually bypasses the liver, then the liver cannot perform its normal metabolic regulatory or detoxifying functions; thus clinical signs of hepatic failure become imminent. Anatomic shunts can be either congenital or acquired, intrahepatic or extrahepatic.

### CLINICAL SIGNS OF HEPATIC INSUFFICIENCY

The clinical signs of hepatic insufficiency are highly variable, nonspecific, and depend on the extent and duration of hepatic disease (Box 16-1). Usually, greater than 80% of the liver mass must be lost before clinical signs become apparent, regardless of the cause of hepatic disease. Thus despite the duration of hepatic disease, the onset of clinical signs is often abrupt. The most common clinical signs of hepatic insufficiency in horses

#### BOX 16-1

### CLINICAL SIGNS OF LIVER DISEASE

#### Common Signs

Depression  
Anorexia  
Colic  
Hepatic encephalopathy (HE)  
Weight loss  
Icterus

#### Less Common Signs

Photosensitization  
Diarrhea  
Bilateral laryngeal paralysis  
Bleeding  
Ascites  
Dependent edema

#### Rare Signs

Steatorrhea  
Tenesmus  
Generalized seborrhea  
Pruritus  
Endotoxic shock  
Polydipsia  
Pigmenturia (yellow-brown with bilirubinuria; red-brown with hemoglobinuria)

are depression, anorexia, colic, hepatic encephalopathy (HE), weight loss, and icterus.<sup>15-17</sup> Less commonly reported clinical signs include hepatogenic photosensitization, diarrhea, abdominal pain, bilateral laryngeal paralysis, and hemorrhagic diathesis. Rarely reported clinical signs of hepatic insufficiency in horses are ascites, dependent abdominal edema, steatorrhea, tenesmus, generalized seborrhea, pruritus, endotoxic shock, polydipsia, and hemolysis. The appearance of specific clinical signs of hepatic disease often reflects the type of hepatic function (or functions) that is altered.

### HEPATIC ENCEPHALOPATHY

Hepatic encephalopathy (HE) is a complex clinical syndrome characterized by abnormal mental status that accompanies severe hepatic insufficiency.<sup>18-20</sup> Clinical signs are widely variable but represent manifestations of augmented neuronal inhibition. This syndrome occurs in patients with advanced decompensated liver disease of all types and may be a feature of acute, subacute, or chronic hepatocellular disease. HE generally is considered to be a potentially reversible metabolic encephalopathy.<sup>19</sup> Whether multiple episodes of HE could lead to irreversible neuronal damage is uncertain.

**Clinical Signs** No specific features of HE allow this syndrome to be distinguished from other causes of cerebral dysfunction. The earliest phase of HE is probably missed in most equine patients because it represents minimal behavioral changes with subtle impairment of intellect because of bilateral forebrain dysfunction<sup>21</sup> (stage I; Table 16-1). In humans, these early signs are more apparent to close friends and family members than to a physician. As encephalopathy progresses, motor function, intellectual abilities, and consciousness become impaired; generally at this stage (corresponding to

TABLE 16-1

Clinical Stages of Hepatic Encephalopathy	
Stage	Mental Status
I	Mild confusion, decreased attention, slowed ability to perform mental tasks, irritability
II	Drowsiness, lethargy, obvious personality changes, inappropriate behavior, disorientation
III	Somnolent but rousable, marked confusion, amnesia, occasional aggressive uncontrolled behavior
IV	Coma

Adapted from Gammel SH, Jones EA: Hepatic encephalopathy, *Med Clin North Am* 73:793–813, 1989.

stage II) horses become obviously affected. Clinical signs include depression, head pressing, circling, mild ataxia, aimless walking, persistent yawning, and other manifestations of inappropriate behavior. Somnolence develops. Next the horse is rousable but responds minimally or excessively to the usual stimuli. At this stage (III) the horse often manifests aggressive or violent behavior interspersed with periods of stupor. Finally, consciousness fades, the horse becomes recumbent, and coma ensues. Occasionally seizures occur during the later stages of HE, but in general they are atypical. The severity of encephalopathy corresponds to the degree of hepatic dysfunction; however, neither of these parameters correlates with type or reversibility of the underlying hepatic disease.

**Cause and Pathophysiology** By definition, the cause of HE is insufficient hepatocellular function, irrespective of the cause of the liver disease. That is, a normally functioning liver is necessary to maintain normal brain neuron and astrocyte function. With acute liver disease, HE is primarily caused by astrocyte swelling, acute cytotoxic cerebral edema, and intracranial hypertension. In chronic hepatic disease, HE develops more insidiously. Astrocytes are swollen but also show evidence of Alzheimer type II changes.<sup>22</sup> Whether acute or chronic in nature, the precise pathogenesis of HE remains unclear, and considering the numerous proposed hypotheses, the cause is almost certainly multifactorial. The following mechanisms have been suggested for the development of HE and any or all may be involved to greater or lesser degree:

1. Gastrointestinal-derived neurotoxins
2. Augmented activity of gamma-aminobutyric acid (GABA) in the brain
3. Altered expression of benzodiazepine receptors
4. Increased neurosteroid synthesis
5. False neurotransmitter accumulation after plasma amino acid imbalance
6. Increased blood manganese concentrations
7. Increased inflammatory mediator expression, principally cytokines
8. Increased permeability of the blood-brain barrier and cerebral hypertension
9. Impaired central nervous system (CNS) energy metabolism

Perhaps the oldest and most “predominant” hypothesis for HE involves the accumulation of toxic materials in the blood (derived from the metabolism of nitrogenous substrates

in the gastrointestinal tract) that bypass the liver through functional or anatomic shunts.<sup>18,21,23</sup> Accordingly, HE may be caused primarily by failure of the liver to adequately remove certain substances from the blood that have the direct or indirect ability to modulate function of the CNS. Ammonia, after the degradation of amino acids, amines, and purines by enteric bacteria, has been supported widely as a major neurotoxin of hepatic disease.<sup>22,23-25</sup> In patients with liver failure, ammonia is insufficiently metabolized through the urea cycle; thus plasma concentrations increase, and ammonia enters the CNS, where it may cause encephalopathy.<sup>23,26</sup> Evidence also points to zinc deficiency, which is important for the urea cycle, in the pathogenesis of HE.<sup>27</sup>

Ammonia has a toxic effect on cell membrane neurons by inhibition of the Na,K-dependent adenosine triphosphatase activity in nerve cell membranes, causing depletion of adenosine triphosphate.<sup>25,27</sup> Hyperammonemia also is associated with a disturbance in CNS energy production caused by alterations in the tricarboxylic acid cycle that result in a decrease in  $\alpha$ -ketoglutarate formation and increased synthesis of glutamine.<sup>28</sup> Astrocytes in the brain also detoxify ammonia by synthesizing glutamine through amidation of glutamate. Glutamine accumulation in astrocytes is a major cause of cell swelling and generation of cerebral edema in acute fulminate hepatic failure.<sup>22,27</sup> Another effect of prolonged exposure to ammonia to neuron tissue is depletion of glutamate and downregulation of glutamate receptors. Because glutamate is the major excitatory neurotransmitter on the mammalian brain, in acute liver failure, increased synaptic release of glutamate results in overactivation of glutamate receptors with resultant hyperexcitatory clinical signs. In chronic hepatic failure, downregulation of glutamate receptor activity likely contributes to the decreased excitatory transmission in HE. Hyperammonemia also induces nitric oxide and reactive oxygen species generation, which leads to accumulation of peroxides, oxidative stress, and nerve cell damage. These cumulative effects of ammonia on neural tissue certainly play an important role in the pathogenesis of HE. Experimentally, ammonia can induce encephalopathy<sup>29</sup>; because of congenital enzyme deficiencies, children with hyperammonemia have encephalopathy.<sup>24</sup> Furthermore, therapy aimed at reducing the absorption of ammonia from the intestine tends to ameliorate HE.<sup>21</sup> Although older clinical studies argued against the role of ammonia in the pathogenesis of HE because plasma ammonia concentrations correlated poorly with the severity of HE,<sup>19,30</sup> more recent reviews demonstrate that blood ammonia levels correlate strongly with the severity of HE.<sup>31</sup> Thus the actions of ammonia on the CNS are complex, and ammonia likely is involved in, but is not solely responsible for, HE.

The synergistic neurotoxins hypothesis for the pathogenesis of HE implicates not only ammonia but also other gut-derived neurotoxins, specifically mercaptans, short-chain fatty acids, and phenols.<sup>21</sup> Members of each of these classes of substances are increased in the blood of patients with hepatic failure in concentrations that alone are insufficient to induce encephalopathy. However, the combination of some or all of them may induce encephalopathy by their synergistic actions and by augmenting endogenous metabolic abnormalities,<sup>21</sup> mostly centering around inhibition of brain Na<sup>+</sup>,K<sup>+</sup>-ATPase with subsequent impaired neurotransmission.<sup>19</sup> As with ammonia, blood and brain concentrations of mercaptans correlate poorly with the stage of HE.<sup>32</sup>

Another popular theory regarding the pathogenesis of HE involves augmented activity of inhibitory neurotransmitter

systems, GABA-benzodiazepine and serotonin, and depression of the function of the excitatory glutamatergic system.<sup>27</sup> Hyperammonemia has been shown to increase GABAergic tone in patients with liver disease.<sup>22</sup> When released from presynaptic neurons, GABA binds to specific receptors on postsynaptic neurons, resulting in increased chloride ion conductance across the postsynaptic neural membrane, membrane hyperpolarization, and generation of an inhibitory postsynaptic potential.<sup>33</sup> The GABA receptor is a chloride ionophore supramolecular complex that has interactive binding sites for three classes of synergistic ligands: (1) GABA and agonists, (2) benzodiazepines, and (3) barbiturates.<sup>19,34</sup> The binding of benzodiazepine or a barbiturate on its binding site of the GABA receptor potentiates GABA-induced sedation. The GABA hypothesis of HE originally was based on a series of observations using a model of HE in rabbits in which increased GABA-like activity was identified in the serum and cerebral spinal fluid (CSF) along with an increased density of GABA receptors.<sup>33</sup>

Increased brain levels of natural benzodiazepines probably constitute one mechanism for the increased GABAergic tone in HE.<sup>27</sup> Ammonia, which acts synergistically with natural benzodiazepines, also may enhance GABAergic neurotransmission. Agonists of benzodiazepine increase the frequency of GABA-induced chloride channel openings, and barbiturates lengthen the average time that channels are open.<sup>35</sup> Results of studies using electrophysiologic and *in vitro* techniques to study an animal model of HE provide strong evidence for a functional increase in GABAergic tone that is mediated allosterically through the benzodiazepine receptor by an endogenous diazepam-like substance.<sup>36,37</sup> Clinical studies that showed improved consciousness and reduced electroencephalogram changes of HE in patients treated with the benzodiazepine receptor antagonist flumazenil support this suggestion.<sup>38,39</sup> Neurosteroids also may affect GABAergic tone through benzodiazepine receptors. Activation of benzodiazepam receptors in liver failure facilitates the entry of cholesterol into astrocyte mitochondria, where synthesis of neurosteroids such as tetrahydroprogesterone and tetrahydrodeoxycorticosterone occurs. These substances are potent positive allosteric modulators of GABA receptors that can induce profound sedation and behavioral changes.<sup>40</sup>

A separate hypothesis holds that during liver failure, true neurotransmitters in the CNS such as norepinephrine and dopamine become depleted and that false neurotransmitters, especially octopamine and phenylethanolamine, increase.<sup>20,41</sup> The net neurophysiologic effect of such changes is reduced neuronal excitation and increased neural inhibition. The mechanism of this effect is related to the increased serum concentrations of aromatic amino acids (AAA; phenylalanine, tyrosine, tryptophan) and decreased concentrations of branched-chain amino acids (BCAAs; valine, leucine, isoleucine) that occur in liver failure.<sup>42,43</sup> Serum glucagon increases in hepatic failure, leading to muscle catabolism and release of amino acids. However, hepatic metabolism of AAAs is reduced, and because BCAAs are metabolized by muscle and adipose tissue, a relative increase in AAAs and a decrease in BCAAs occurs. The decreased plasma BCAA-to-AAA ratio during liver failure and increased brain glutamine concentration (presumably a consequence of ammonia retention) are considered to promote an influx of AAA into the brain and an efflux of glutamine from the brain by exchange transport processes at the blood-brain barrier.<sup>19</sup> Phenylalanine can compete with tyrosine for tyrosine hydroxylase, resulting in decreased

production of dopamine<sup>43</sup> (Figure 16-6). The displaced tyrosine may be decarboxylated to tyramine, then converted to the false neurotransmitter, octopamine. Accumulated tyrosine also competes for dopamine  $\beta$ -oxidase and reduces the formation of norepinephrine. Phenylalanine and tryptophan in the CNS are ultimately converted to phenylethanolamine and serotonin, a false neurotransmitter and a neuroinhibitor, respectively. Tryptophan is also metabolized to serotonin and oxindole, which has a strong sedative effect.<sup>27</sup>

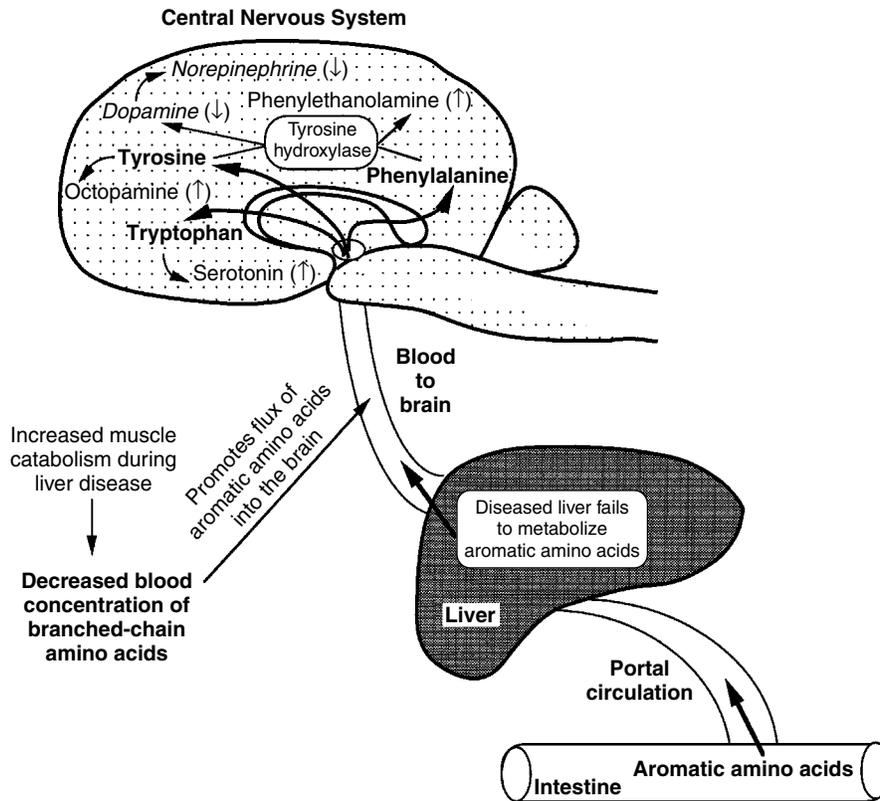

Consistent with this theory are the observations of increased serum concentrations of AAAs accompanied by increased CSF concentrations of octopamine, serotonin, and phenylethanolamine in patients with HE.<sup>41</sup> However, octopamine alone cannot induce encephalopathy and the plasma BCAA-to-AAA ratio correlates poorly with HE in human beings.<sup>44</sup> Controlled clinical trials of oral or intravenous BCAA therapy demonstrate inconsistent amelioration of signs of HE.<sup>43,45</sup>

Manganese is a trace element that is excreted by the liver. Patients with chronic liver disease have increased blood and brain concentrations of manganese. Chronic exposure to manganese causes neuronal and glial loss and Alzheimer type II changes in astrocytes.<sup>31</sup>

A recent hypothesis on the pathophysiology of HE centers on the role of inflammatory mediators in brain injury. Central to this hypothesis is the fact that human patients with acute liver failure are more likely to progress to severe HE if they concurrently have evidence of a systemic inflammatory response.<sup>22</sup> A variety of stimuli are capable of inducing astrocytes and microglial cells in the brain, as well as peripherally located mononuclear cells, to release inflammatory mediators. Several studies have demonstrated significantly increased levels of the cytokine, tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ), in patients with both acute and chronic liver disease. Furthermore, TNF concentrations correlate with the severity of HE and prognosis, and therapeutic strategies aimed at reducing TNF levels ameliorate HE.<sup>31</sup> Several key mechanisms whereby increased TNF concentrations have been shown to be involved in the pathogenesis of HE include increasing ammonia diffusion into the brain, inhibition of astrocyte uptake of glutamate and inhibition of glutamate synthetase, increased expression of benzodiazepine receptors in the brain, and increasing brain capillary fluid leakage and cerebral edema formation. It has also been demonstrated that excess manganese potentiates the production of TNF in microglia.<sup>31</sup>

Finally, alterations in cerebral blood flow and blood-brain barrier permeability leading to cerebral hypertension and edema and changes in cerebral metabolism are present in patients with HE. Although the mechanisms responsible for these changes are not fully known, changes in astrocyte function, either directly or indirectly by increased blood ammonia concentrations, are likely to be involved.<sup>22</sup>

**Diagnosis** The diagnosis of HE is based on the presence of neurologic signs of cerebral dysfunction in a horse, with physical examination and laboratory findings compatible with liver disease (see Diagnosis and Laboratory Findings of Hepatic Insufficiency). Other possible causes for the neurologic signs should be excluded because no specific features of HE allow one to distinguish this syndrome definitively from other encephalopathies. A partial list of conditions to be ruled out includes trauma, viral encephalomyelitis, rabies, moldy corn toxicity (leukoencephalomalacia), brain abscess, equine protozoal myeloencephalitis, parasite larval migrans, blister beetle toxicosis, organophosphate toxicity, nigropallidal

**FIGURE 16-6** Role of aromatic amino acids in the brain in hepatic encephalopathy. Aromatic amino acids (tryptophan, tyrosine, phenylalanine) enter the central nervous system (CNS), where they are metabolized, altering the balance of neurotransmitters. True neurotransmitters (dopamine, norepinephrine) decrease (arrow down), while “false” neurotransmitters (octopamine, phenylethanolamine) increase (arrow up). The net effect is increased neuronal inhibition and reduced neuronal excitation.

encephalomalacia, botulism, fluphenazine or other sedative overdose, and heavy metal toxicosis. Many of these conditions have other characteristic clinical signs, the absence of which would exclude them from the differential diagnosis. Access to potential toxins or drugs should be carefully gleaned from the history.

Serum electrolyte analysis, calcium and creatinine values, and a complete blood count (CBC) may aid in ruling out other encephalopathies. Serology for the viral encephalitides and toxicologic screening for organophosphates and heavy metals may be appropriate. CSF analysis may be indicated if other causes of encephalopathy are highly suspect. The CSF is normal in horses with HE. In human beings, electroencephalogram changes of symmetrical generalized slowing of cerebral electrical activity are sensitive indicators of HE; however, they are not specific for this disorder because other metabolic encephalopathies can cause similar abnormalities.<sup>18</sup> Visual evoked potentials are superior to conventional electroencephalogram in terms of specificity and ease of quantitation.<sup>46</sup> An average visual evoked potential reflects the pattern and magnitude of postsynaptic neuronal activity evoked by a visual afferent stimulus. Hepatoencephalopathy in humans is attended by a distinctively abnormal visual evoked potential trace; however, this testing would be technically difficult in horses and has not been explored. As a general rule, the brain shows no definite light or electron microscopic structural changes; however, some patients with hepatic cirrhosis and portosystemic

shunts have an increase in the number and size of astrocytes (Alzheimer type II) in the gray matter of the cerebrum and cerebellum.<sup>19</sup> These changes appear to be reversible and specific for portosystemic shunting of blood. The relevance of these changes, if any, to behavioral dysfunction of HE is unknown.

## ICTERUS

Icterus, or *jaundice*, is caused by *hyperbilirubinemia* with subsequent deposition of the pigment in tissues causing yellow discoloration. Icterus is most apparent in nonpigmented skin; mucous membranes, especially the vulvar mucosa; and the sclerae. Approximately 10% to 15% of horses normally have slightly yellow sclerae. Disease states that result in hyperbilirubinemia can be categorized as follows: increased production of bilirubin, impaired hepatic uptake or conjugation of bilirubin, and impaired excretion of bilirubin.<sup>8</sup> Increased production of bilirubin occurs with hemolysis, both intravascular and extravascular, and after reabsorption of erythrocytes after massive intracorporeal hemorrhage. This form of hyperbilirubinemia, often called *hemolytic* or *prehepatic icterus*, occurs despite a normally functioning liver, because the rate of bilirubin production by the reticuloendothelial system temporarily exceeds the ability of the liver to conjugate and excrete. Classically, this form of icterus is caused by the increased concentration of unconjugated bilirubin in the blood. However, on occasion the concentration of conjugated bilirubin also mildly increases in the blood because of hepatic spillover when the

liver processes the excessive bilirubin or the enterohepatic circulation reabsorbs it. The rate and extent of erythrocyte destruction and the rate of uptake of bilirubin determine the presence and intensity of hemolytic icterus by the liver.

Impaired uptake and conjugation of bilirubin also result in increased blood levels of unconjugated bilirubin with subsequent icterus. This form of icterus is referred to as *retention* or *hepatic icterus* and is the most common form in horses with liver disease, usually the result of acute hepatocellular disease.<sup>8,10</sup> In horses the presence of icterus is highly inconsistent with chronic hepatocellular disease.<sup>9,17</sup> In addition to hepatocellular disease, certain drugs, anorexia, or prematurity can impede bilirubin uptake and conjugation by hepatocytes, despite an otherwise normally functioning liver.<sup>4,8-10</sup> Steroids can inhibit bilirubin uptake in all species. Heparin administration to horses sometimes results in icterus and is believed to be caused in part by impaired uptake of bilirubin by hepatocytes.<sup>9</sup> Anorexia in horses causes variable degrees of hyperbilirubinemia and may be related to the half-life of ligandin.<sup>9,10</sup> Ligandin is the intrahepatic protein responsible for extracting unconjugated bilirubin from albumin in the sinusoidal blood. The half-life of ligandin is relatively short (days) and starvation in other species reduces the store of ligandin in the hepatocytes, thus impeding bilirubin uptake.<sup>4</sup> Premature and neonatal foals are also more susceptible to retention icterus, in the absence of hepatic disease. The cause of icterus in equine neonates is presumably a result of lower hepatocellular ligandin concentrations, compared with the adult.<sup>4,7</sup> In human beings, inherited or congenital deficiencies in enzymes responsible for conjugation (bilirubin-uridine diphosphate glucuronyl transferase) may result in intermittent or persistent icterus (Gilbert's syndrome or Crigler-Najjar syndrome type II) that often is not recognized until the patient is several years of age. The icterus occurs without other clinical or laboratory evidence of liver disease.<sup>48</sup> Persistent hyperbilirubinemia without anorexia, hemolysis, or evidence of acquired liver disease was reported in an otherwise healthy 4-year-old Thoroughbred gelding.<sup>48</sup> Conjugated bilirubin concentrations were normal, but total serum bilirubin concentrations ranged from 9.0 to 12.3 mg/dl during a 2.5-year monitoring period. The case most closely resembled Gilbert's syndrome.

If the excretion of conjugated bilirubin into the biliary tract is impeded, *regurgitation icterus* occurs.<sup>8</sup> Blockage of bile flow with resultant regurgitation icterus can accompany cholangitis, hepatitis, obstructive cholelithiasis, neoplastic infiltration, fibrosis, or hyperplasia of the biliary tract. Because conjugated bilirubin is water soluble, this form of icterus may be accompanied by bilirubinuria.

In hepatocellular disease, icterus most often is the result of a combined increase in both unconjugated and conjugated bilirubin.<sup>8</sup> Of the two fractions, the majority of the increase in the total bilirubin is from unconjugated bilirubin. Increases in the conjugated fraction greater than 25% of the total are usually indicative of hepatocellular disease, and increases greater than 30% are usually indicative of cholestasis.<sup>10</sup>

## WEIGHT LOSS

Significant weight loss and failure to thrive are most consistently present during chronic hepatic insufficiency. However, chronic liver disease may be present without apparent weight loss. Weight loss is due to anorexia and the loss of normal hepatocellular metabolic activities.

## HEPATOGENIC PHOTOSENSITIZATION

Photosensitization refers to abnormally heightened reactivity of the skin to ultraviolet sunlight because of the increased blood concentration of a photodynamic agent. In the case of hepatogenic photosensitization, the photodynamic agent is *phylloerythrin*. Phylloerythrin is normally formed in the gastrointestinal tract as a result of bacterial degradation of chlorophyll and is absorbed into the general circulation, conjugated, and excreted by the liver.<sup>49</sup> During hepatic insufficiency, the blood concentrations of this photodynamic agent are increased. Subsequent exposure of phylloerythrin to ultraviolet light causes activation of electrons within the molecule to an excited state, with resultant free radical formation. The local production of free radicals causes cell membrane damage and necrosis. Unpigmented areas most efficiently absorb ultraviolet light; thus the lesions of photosensitization are restricted to white skin. The skin first appears erythematous and edematous. Pruritus, pain, vesiculation, ulceration, necrosis, and sloughing may ensue.

## COLIC, DIARRHEA, TENESMUS, ASCITES, STEATORRHEA

Abdominal pain associated with acute hepatocellular disease may be a result of acute hepatic swelling, or biliary obstruction (cholelithiasis).<sup>4,50</sup> Signs of anterior abdominal pain include anorexia, bruxism, sitting like a dog, recumbency, and rolling up onto the dorsum. Palpation over the last few ribs (especially on the right) or immediately caudal to the last rib may elicit a pain response. Alterations in intestinal motility also may cause concurrent signs of colic with liver disease. McGorum et al.<sup>17</sup> reported that 10 of 25 horses with liver disease and signs of colic had clinically significant gastric impactions. Of the horses with gastric impactions, seven also had signs of HE; none of these horses survived.

Diarrhea infrequently may accompany chronic hepatic insufficiency in horses.<sup>51</sup> Alterations in the intestinal microflora, portal hypertension, and deficiency of bile acids may be involved in the pathogenesis.<sup>4</sup> Though uncommon in horses, portal hypertension can lead to increased hydrostatic and oncotic pressure in the intestinal mucosa, with resultant water and protein loss into the lumen of the bowel and the peritoneal cavity (ascites). Tenesmus may be the result of constipation but has also been reported to be a sign of hepatoencephalopathy.<sup>17</sup>

Decreased excretion of bile may result in lipid malabsorption and excessive amounts of fat in the feces, or *steatorrhea*,<sup>4</sup> which subsequently may cause osmotic diarrhea. Because the normal equine diet is low in fat, steatorrhea is rare in horses. Chronic cholestasis may cause clay-colored feces because of lack of fecal urobilinogen and stercobilin. This coloration rarely is observed in adult herbivores, because the normal fecal color is generated primarily by plant chlorophylls and not by bilirubin metabolites.<sup>10</sup>

## HEMORRHAGIC DIATHESIS

Because the liver is responsible for the synthesis of numerous factors involved in coagulation and fibrinolysis, abnormal hemostasis may be a sequela to hepatic insufficiency. Clinical signs may vary from petechial or ecchymotic hemorrhages to hemorrhage after trauma or venipuncture to spontaneous hemorrhage (epistaxis, melena, hemoptysis, hematuria, or hematomas).<sup>4,8,10,21,52</sup> Especially sensitive to hepatic disease is

the synthesis of fibrinogen and the vitamin K–dependent factors (II, VII, IX, X, and protein C), which have short half-lives. Factor VII has a half-life of only 4 to 5 hours. Other vitamin K–dependent factors and fibrinogen have half-lives in the range of 4 to 5 days. Because vitamin K is fat soluble and requires bile acids for proper absorption from the intestinal tract, vitamin K–dependent factors are affected particularly during hepatic insufficiency when bile excretion is decreased.

During hepatic insufficiency, the synthesis of protein C and antithrombin III may be altered. Decreased plasma concentrations of these two anticoagulants would result in uncontrolled clot formation and consumption of other coagulation factors. In chronic hepatic disease the plasma concentration of protein C is normal or decreased; however, antithrombin III may be normal, increased, or decreased.<sup>21</sup> Pregnant women with fatty livers have decreased antithrombin III activity, but patients with biliary cirrhosis or biliary obstruction have increased antithrombin III activity.<sup>21</sup> Horses with liver disease have increased antithrombin III activity and theoretically should tend to bleed.<sup>53</sup> Alterations in the factors controlling fibrinolysis vary in chronic liver disease.<sup>21</sup> Conditions that promote fibrinolysis—such as increased plasminogen and plasminogen activator, or decreased plasminogen activator inhibitor,  $\alpha_2$ -antiplasmin, and  $\alpha_2$ -macroglobulin—result in bleeding tendencies. Conditions that aid thrombus formation, such as decreased plasminogen, further promote consumptive coagulopathy. The fibrinolytic factors have not been evaluated in horses with liver disease.

Finally, the liver plays an important role in balancing normal hemostasis by Kupffer's cell removal of activated coagulation factors and FDPs from the general circulation.<sup>21</sup> Failure to remove activated coagulation factors further promotes coagulation, and FDPs interfere with platelet function and fibrin clot formation.

### FEVER

Horses with hepatic abscesses, acute hepatitis, CAH, obstructive cholelithiasis, fatty liver failure, or neoplasia may have constant or intermittent fevers.<sup>50,54-59</sup>

### HEMOLYSIS

Hemolysis is a rarely seen but grave prognostic indicator of fulminant hepatic failure in horses.<sup>15</sup> The exact cause of hemolysis is not known but is believed to be the result of increased erythrocyte fragility.

### PRURITUS AND SEBORRHEA

Retention of bile acids and accumulation in the skin may cause pruritus and seborrhea. This finding is rarely reported in horses.<sup>15,60</sup>

### EDEMA

Hypoalbuminemia and water retention can occur with chronic liver failure and may result in dependent edema. Because the half-life of albumin is long (19 to 20 days) in the horse, edema is a rare clinical sign.<sup>61</sup> Ponies with hyperlipemia may develop dependent abdominal edema after vascular thrombosis.<sup>58</sup> Dependent abdominal edema also may form if significant portal hypertension and ascites exist.

### ENDOTOXEMIA

The Kupffer's cell plays an important role in removing bacterial endotoxin that is normally absorbed from the lumen of the intestinal tract and carried to the liver via the portal

circulation.<sup>13</sup> Failure of Kupffer's cell phagocytosis of endotoxin may result in clinical and laboratory evidence of endotoxemia.

### POLYDIPSIA, POLYURIA, AND THE HEPATORENAL SYNDROME

Alterations in renal function, including deranged sodium concentrations, impaired water excretion, and urine-concentrating ability, may accompany severe liver disease.<sup>4,21</sup> Sodium retention results from increased blood aldosterone concentrations because of failure of hepatic biotransformation and a decrease in the effective circulating blood volume as a result of portal hypertension and hypoalbuminemia. Sodium retention raises the osmolality of the extracellular fluid, thereby stimulating the thirst center. Polydipsia has been reported in horses with chronic liver disease.<sup>62,63</sup> Despite the potential increase in exchangeable sodium, the serum sodium concentration is usually normal or decreased, as a result of superimposed water retention. The mechanism for water retention is multifactorial, but increased antidiuretic hormone, reduced effective circulating volume, and altered renal prostaglandin synthesis are most likely involved.<sup>21</sup> Sometimes the urine-concentrating ability is impaired because of reduced medullary interstitial urea, the net effect being polyuria, isosthenuria, or both.

*Hepatorenal syndrome* is characterized by acute azotemia and anuria and may occur in ponies with hyperlipemia and hepatic lipidosis (see Hyperlipemia and Hepatic Lipidosis). The pathogenesis is obscure, but speculative causes include reduced effective circulating volume, decreased hepatic inactivation of renin, and endotoxemia.<sup>21</sup>

### DIAGNOSIS AND LABORATORY FINDINGS OF HEPATIC INSUFFICIENCY

Historical information (as discussed in the section on Specific Hepatic Diseases) may be useful in the diagnosis of certain types of hepatic insufficiency. Nonspecific clinical signs and variable laboratory findings confound the definitive diagnosis of hepatic disease in horses. Paramount to the laboratory diagnosis of hepatic insufficiency in horses is knowledge of the sensitivity and specificity of the tests (Table 16-2). Because massive hepatic disease must be present before alterations are seen with some laboratory tests, and because different liver functions are variably altered by disease, the specificity of the laboratory diagnosis of hepatic disease increases with the magnitude of abnormal findings. Laboratory findings also may be useful for therapeutic and prognostic considerations.

### EVALUATION OF BILIRUBIN

Serum bilirubin concentration is not a sensitive indicator of liver disease in horses. In one report on serum biochemical changes in horses with liver disease, only one fourth of the cases had increased serum bilirubin concentrations.<sup>17</sup> The *total bilirubin* concentration in the blood, as determined by the van den Bergh test, is a combination of both unconjugated and conjugated bilirubin. Because the diagnostic value of the bilirubin concentration, when used for evaluation of hepatic disease, depends on which subfraction is increased, the concentrations of both unconjugated and conjugated bilirubin must be determined.

The serum bilirubin concentration is stable for several days, if the sample is protected against sunlight.<sup>10</sup> The total bilirubin concentration is determined first in a chromogenic

TABLE 16-2

Clinical Pathology of Liver Disease in Horses		
Test	Aberration	Normal Value
<b>SPECIFIC INDICATORS OF LIVER DISEASE</b>		
Serum sorbitol dehydrogenase (SDH)	Increases	<8 U/L
Serum $\gamma$ -glutamyltransferase (GGT)	Increases	<25 U/L
Serum bile acids concentration	Increases	<15 $\mu$ mol/L
Arginase (ARG)	Increases	
Glutamate dehydrogenase (GLDH)	Increases	
Direct bilirubin	>25% of total	0-0.4 mg/dl (0-6.8 $\mu$ mol/L)
Ammonia	Increases	(laboratory dependent)
BSP half-life	Prolonged	2.8 $\pm$ 0.5 min
Branched chain: aromatic amino acid ratio	Decreases	3.5-4.5
Urine bilirubin	Increases	
<b>NONSPECIFIC INDICATORS OF LIVER DISEASE</b>		
Total bilirubin	Increases	
Indirect bilirubin	Increases	
Lactate dehydrogenase-5 (LDH-5)	Increases	
Aspartate aminotransferase (AST)	Increases	
Alanine aminotransferase (ALT)	Increases	
Alkaline phosphatase (ALP)	Increases	
Blood urea nitrogen (BUN)	Decreases	
Globulins	Increases	
Albumin	Decreases	
Glucose	Decreases	
Prothrombin time (PT)	Prolonged	
Activated partial thromboplastin time (APTT)	Prolonged	
Triglyceride	Increases	
White blood cell count	Increases with infection or inflammation; decreases with endotoxemia	

assay by reaction for 30 minutes with a diazo reagent (sulfanilic acid and sodium nitrite) and methyl alcohol.<sup>10</sup> *Conjugated* or *direct-reacting bilirubin* is similarly determined over 5 minutes, without the addition of methyl alcohol. The amount of *unconjugated bilirubin* can then be determined by the difference between the total bilirubin concentration and the direct-reacting bilirubin. Because the unconjugated fraction is

determined arithmetically, it is appropriately called *indirect-reacting bilirubin*. In normal horses, the total bilirubin concentration is in the range of 0.2 to 5.0 mg/dl (3.4 to 85.5  $\mu$ mol/L) with conjugated bilirubin in the range between 0.0 to 0.4 mg/dl (0 to 6.8  $\mu$ mol/L).<sup>8</sup> As discussed previously, increases in the unconjugated bilirubin fraction may occur without hepatic disease. Hemolysis, anorexia, intestinal obstruction, cardiac insufficiency, Gilbert's syndrome, and the administration of certain drugs (steroids, heparin, halothane) may cause an increase in the unconjugated bilirubin concentration.<sup>9</sup> If the unconjugated bilirubin concentration is increased, then the erythron should be concurrently evaluated to rule out hemolysis as the causative factor. Hemolysis may cause the unconjugated bilirubin concentration to rise as high as 80 mg/dl (1368  $\mu$ mol/L).<sup>10</sup> Complete anorexia can cause an increase in the unconjugated bilirubin concentration within 12 hours; however, it is unlikely to rise greater than 6 to 8 mg/dl (102.6 to 136.8  $\mu$ mol/L) in horses suffering purely from anorexia,<sup>10</sup> although values as high as 10.5 mg/dl have been reported in anorexic horses.<sup>60</sup> Finally, the age of the horse and concurrent drug therapy must be considered. Neonates normally have more unconjugated bilirubin than adults. The higher bilirubin concentration in foals most likely is caused by the turnover of fetal hemoglobin to adult hemoglobin and the deficiency of liver-binding and conjugating enzymes compared with the adult.<sup>47</sup> In the absence of liver disease, prematurity or illness in foals can further increase the unconjugated bilirubin fraction.

Keeping the foregoing limitations of interpretation in mind, increases in the unconjugated bilirubin fraction in horses with hepatic disease are most likely to occur with acute hepatocellular disease.<sup>8-10</sup> Rarely does the unconjugated bilirubin fraction in acute hepatic disease exceed 25 mg/dl (427.5  $\mu$ mol/L).<sup>10</sup> An increase in the bilirubin concentration may be indicative of hepatic disease but not necessarily hepatic failure. Furthermore, a normal bilirubin value, as commonly occurs in chronic hepatic disease, does not necessarily preclude the diagnosis of hepatic insufficiency.

An increase in the conjugated bilirubin fraction in horses more reliably is indicative of hepatic disease.<sup>8-10</sup> If the conjugated bilirubin concentration is greater than 25% of the total bilirubin value, then hepatocellular disease should be suspected. If the conjugated bilirubin concentration is greater than 30% of the total value, then cholestasis should be suspected.<sup>10</sup> Conjugated bilirubin is water soluble and detectable in the urine of horses only if blood concentrations become sufficiently increased to surpass the renal threshold.<sup>10</sup> Therefore when urine tests positive for the presence of bilirubin, cholestatic disease should be suspected. Urine dipstick analysis is less sensitive than analysis with a diazo tablet.<sup>10</sup> Urobilinogen may be detected by dipstick analysis of normal horse urine, and its presence indicates a patent bile duct.<sup>10</sup> Because urobilinogen is highly unstable, it must be determined on a fresh urine sample. Dilute or acidic urine may interfere with accurate determination of urobilinogen. Reagent strips are not sensitive enough to detect the absence of urobilinogen; therefore Ehrlich's reagent must be used. The absence of urobilinogen does not necessarily indicate liver disease, but it may be compatible with failure of excretion of bilirubin into the intestine, biliary obstruction, failure of intestinal bacterial reduction (diarrhea, overuse of oral antimicrobials), or failure to reabsorb it from the ileum.<sup>4</sup> Increased concentrations of urobilinogen in the urine may be caused by the increased

production of urobilinogen by intestinal bacteria, failure of the liver to remove it from the enterohepatic circulation, portosystemic shunting, or spillover after severe hemolysis.<sup>4</sup>

### SERUM BILE ACID CONCENTRATION

The enterohepatic circulation normally removes greater than 90% of bile acids. Thus the blood concentration of bile acids may be increased with liver disease, and quantitation provides an excellent screen of liver failure and has essentially replaced foreign dye clearance (e.g., bromosulphthalein) as a functional test of the liver.<sup>9,63,64</sup> Serum bile acids are stable for at least 1 month if stored at -20° C and are measured by radioimmunoassay or by an enzymatic colorimetric method. The concentration of total serum bile acids is not affected by short-term fasting (<14 hours) but may be increased by more prolonged fasting.<sup>65</sup> The major serum bile acids in horses include ursodeoxycholic acid, chenodeoxycholic acid, and deoxycholic acid, but the exact composition of serum bile acids varies markedly among normal horses.<sup>66</sup> Reported normal mean values for horses and ponies as determined by radioimmunoassay are 8.2+/-1.6  $\mu\text{mol/L}$  (n = 9)<sup>63</sup> and 5.3+/-6.5  $\mu\text{mol/L}$  (n = 51)<sup>64</sup> and 5.0+/-28.0  $\mu\text{mol/L}$ <sup>66</sup> for the colorimetric method. Increased serum bile acid concentrations are highly specific for the presence of liver disease (may increase within 24 to 48 hours after onset of hepatic disease) but are not specific for the type of liver disease.<sup>9,67</sup> Because bile acids are 90% restricted to the enterohepatic circulation, increases in the blood may occur as a result of shunting or decreased blood flow to the liver (first-pass effect), failure of the liver to remove bile acids from the enterohepatic circulation, failure of the hepatocytes to conjugate the bile acids for excretion, or failure of excretion with subsequent regurgitation of the bile acids into the blood (biliary obstruction). Increases in the primary (nondegraded) bile acids cholate and chenodeoxycholate account for most of the increase in total serum bile acids concentration in horses with liver disease.<sup>66</sup> In relation to the severity of liver disease, a significant shift in composition of serum bile acid profile from taurocholate to free unconjugated cholate also occurs. This finding suggests that hepatocellular excretion, and not resorption, is the most sensitive step in the enterohepatic circulation of bile acids in horses.<sup>66</sup>

Fasting for longer than 3 days in mature horses caused an increase in the serum bile acid concentration of three times over baseline values.<sup>65</sup> Ligation of the bile duct caused a six-fold increase in serum bile acid concentration compared with fasted horses.<sup>65</sup> Carbon tetrachloride toxicity resulted in a three-fold increase compared with fasted horses.<sup>65</sup> Concentrations of serum bile acids greater than 50  $\mu\text{mol/L}$  in horses with pyrrolizidine toxicosis were associated with a grave prognosis.<sup>63</sup> A value less than 20  $\mu\text{mol/L}$  appears to be a good predictor in ruling out significant functional liver disease and should be included in the evaluation of horses suspected to have hepatic disease.<sup>64</sup> Serum bile acid concentrations greater than 20  $\mu\text{mol/L}$  appear to be indicative of chronic liver disease but are less effective in detecting acute hepatic disease.<sup>64</sup> It is important to note that, compared with mature horses, serum bile acids concentrations are higher in healthy neonatal foals during the first month of life and frequently exceed 20  $\mu\text{mol/L}$ .<sup>68</sup> Bile acid concentrations are highest in biliary obstructive diseases and portosystemic shunts.

### TESTS OF PROTEIN SYNTHESIS

The blood concentrations of protein or amino acids relate not only to the rate of synthesis by the liver but also to their half-life in the circulation. The half-life of albumin in horses

is long (19 to 20 days); thus a decrease in the albumin concentration is rarely detectable until greater than 80% of the liver mass is lost for more than 3 weeks.<sup>8,10,17,61</sup> It is unusual for the total serum protein concentration to decrease to less than 5 g/dl (50 g/L) in chronic liver disease.<sup>13</sup> Hypoalbuminemia is a nonspecific finding in chronic liver disease, because it may occur secondary to endoparasitism, nephrosis, malnutrition, malabsorption, circulatory failure, and many other chronic diseases.<sup>10,61</sup>

The globulin fraction often is increased in chronic hepatic disease as a result of decreased Kupffer's cell mass. Loss of Kupffer's cell function may result in wider dissemination of enteric-derived foreign antigens. Plasma cells respond to the general increased antigen load, resulting in polyclonal gammopathy.<sup>4,8,10</sup> Although the globulin fraction may be increased, it is a nonspecific finding with chronic hepatic disease, because polyclonal gammopathy can occur after numerous chronic diseases. The  $\alpha$ - and  $\beta$ -globulins may also increase with chronic liver disease. A decreased serum albumin concentration concurrent with an increased globulin concentration in chronic hepatic disease causes the total plasma protein or serum protein to appear normal. Thus serum protein fractionation is paramount. Protein electrophoresis most accurately determines fractionation of the components making up the total serum protein concentration.<sup>8</sup>

The blood concentration of amino acids may be increased after acute hepatocellular necrosis or during protein catabolic states such as illness or starvation, in response to insulin or glucagon.<sup>4</sup> Fractionation of the blood amino acids and determination of the BCAA-to-AAA ratio is rarely done in clinical practice but is more useful than evaluating either fraction separately (see Hepatic Encephalopathy). Decreases in this ratio indicate hepatic insufficiency.<sup>42</sup> The risk of clinical signs of HE may be projected from the BCAA-to-AAA (phenylalanine, tyrosine) ratio. A normal ratio falls between 3.5 and 4.5. The risk of HE is low, medium, or high if the ratio is 3.0 to 3.5, 2.5 to 3.0, and less than 2.5, respectively.<sup>42</sup>

Because the liver is primarily responsible for removing ammonia from the circulation and converting it to urea for renal excretion, increases in the blood ammonia concentration or a decrease in the BUN concentration (<9 mg/dl; 6.43 mmol/L) may be indicative of chronic hepatocellular disease.<sup>8,13,17</sup> Daily blood ammonia levels vary widely in normal horses.<sup>16</sup> The compounding effects of ammonia-generating and urea-using bacteria in the gastrointestinal tract, ammonia generation with blood storage, as well as the effects of the ration may partly account for these fluctuations. In ethylenediaminetetraacetic acid (EDTA), whole blood can be refrigerated for up to 6 hours without a significant increase in ammonia content.<sup>69</sup> The effect of the ration and handling can be evaluated by concurrently determining the blood ammonia concentration of a stable mate receiving a similar ration. Oral ammonia challenge tests have not been fully evaluated in horses; however, the sensitivity of the oral challenge test may be decreased because of the effect of enteric bacteria. Normal values for ammonia for horses vary among laboratories but have been reported in the range of 13 to 108  $\mu\text{g/dl}$  (7.63-63.42  $\mu\text{mol/L}$ ).<sup>15</sup>

No correlation exists between the blood ammonia concentration and the severity of liver disease in horses, but increased blood ammonia concentration is significantly correlated with the presence of liver disease, hepatoencephalopathy, or both.<sup>16,17</sup> Although hyperammonemia appears to be a sensitive indicator of liver disease in the horse, it is not specific

for liver disease. Encephalopathy associated with hyperammonemia without concurrent evidence of liver disease has been reported in horses with acute gastrointestinal disease.<sup>70,71</sup> Hyperammonemia has also been reported as a fatal heritable disorder in Morgan foals and is believed to be caused by a defective mitochondrial transporter protein involved in urea synthesis.<sup>72</sup> The syndrome may be accompanied by mild to moderate increases in serum liver enzyme activities.

Because the liver is also responsible for the synthesis of certain coagulation factors, evaluation of hemostatic function may be useful. Changes in hemostatic function values are not specific for liver disease and must be evaluated in light of the other laboratory findings. The vitamin K-dependent factor with the shortest half-life is factor VII; thus abnormalities are frequently first observed in the *prothrombin time* (PT).<sup>16</sup> However, adequate evaluation of hemostatic function necessitates determination of the *activated partial thromboplastin time* (APTT), the *fibrinogen* and FDP concentrations, and a platelet count. In one retrospective clinical review, almost half of the horses with liver disease had either an abnormally prolonged PT or APTT.<sup>17</sup> Typically, a 50% to 70% decrease in the blood concentration of the coagulation factors is necessary before a change in these clotting time-based assays is detectable.<sup>8</sup> Daily variation in the normal values for clotting times also hinders accurate detection of the abnormal. The clotting times may be standardized more appropriately if one concurrently determines a clotting assay on a normal horse. If the ratio of clotting time (PT or APTT) of the patient with possible hepatic disease to the normal horse's value is greater than 1.3, then the test may be interpreted as abnormal.<sup>73</sup> The sensitivity of coagulation factor deficiency during hepatic insufficiency may be increased by diluting the plasma<sup>74</sup> or by determining the concentration of specific factors, by either clot-based, chromogenic, or radioimmunologic assays. These later assays are not widely available.

Hypofibrinogenemia cannot be accurately detected by the heat block precipitation method, the most common method for determination of the plasma fibrinogen concentration.<sup>8</sup> Clotting assays using thrombin more accurately determine the fibrinogen concentration. Fibrinogen concentrations less than 100 mg/dl (1 g/L) indicate either decreased production or increased consumption of fibrinogen. The FDP concentration, as determined by latex agglutination, may be increased during hepatic insufficiency owing to decreased removal by Kupffer's cells. Concentrations of FDPs greater than 16  $\mu$ g/dl are indicative of increased production or reduced removal. The plasma concentration of several factors acting as anticoagulants or involved in fibrinolysis also may be altered in chronic liver failure (see Hemorrhagic Diathesis). Tests for these factors are primarily limited to academic and research institutions.

Thrombocytopenia with associated petechiae or nasal mucosal bleeding has been reported in horses with liver disease; therefore in possible cases of liver disease, platelet counts should also be evaluated before invasive diagnostic or therapeutic techniques.<sup>16</sup>

### TESTS OF CARBOHYDRATE METABOLISM

Changes in the blood glucose concentration rarely occur in horses with liver insufficiency.<sup>13,17</sup> Hyperglycemia may occur with stress-associated catecholamine and glucocorticoid release. Hypoglycemia (glucose <60 mg/dl; 3.33 mmol/L) may occur in acute massive hepatic failure but is more likely in chronic liver disease as anorexia progresses, glycogen stores are

depleted, and gluconeogenesis and glycolysis are impaired by increased glucagon concentrations. If glucose is administered, then blood glucose levels often remain abnormally increased, indicating tissue insulin resistance.<sup>20</sup> Insulin receptor number and binding affinity for insulin are diminished in human beings with chronic liver disease. Changes in the blood glucose concentration are not specific for liver disease and must be evaluated in the light of other laboratory findings.

### TESTS OF LIPID METABOLISM

The concentration of blood triglycerides may become increased during hepatic insufficiency because of increased mobilization from adipose tissue to support energy-requiring processes and a decreased clearance by the liver.<sup>4,10</sup> In contrast, the VLDL and esterified cholesterol blood concentrations may be decreased because of failure of liver synthesis. Compared with other species, equids are thought to possess a greater clearance capacity for triglycerides and a greater hepatic exporting capacity for VLDL. Thus changes in the blood VLDL, esterified cholesterol, or triglyceride concentrations rarely occur in horses.<sup>10</sup> An exception to this is the marked increase in blood triglyceride levels that occurs with hyperlipidemia syndrome in ponies and Miniature horses (see Hyperlipidemia and Hepatic Lipidosis). Because nonhepatic diseases may alter blood lipid concentrations, these tests are neither sensitive nor specific for liver disease in horses.<sup>10</sup> The blood cholesterol and triglyceride concentrations are normally higher in neonates, compared with adults.<sup>47</sup>

Increased mobilization of triglycerides and fatty acid oxidation by the liver may result in increased production of *ketone bodies*, acetoacetate, and  $\beta$ -hydroxybutyric acid.<sup>5</sup> Although peripheral tissues may use ketone bodies for energy, these compounds are weak acids and increased levels in the blood may result in ketoacidosis. The pathway for ketone formation is poorly developed in horses. Ketoacidosis is less common in horses than in other species.<sup>10</sup> Ketoacidosis should be suspected in horses that are acidemic and have an abnormally high anion gap. Ketones may be quantitated in the blood or urine. Because the renal threshold of ketone bodies is low, ketonuria usually precedes ketonemia. Routine urine dipsticks only detect acetoacetate.<sup>10</sup>

### LIVER ENZYMES

Acute hepatocellular necrosis or changes in hepatocyte membrane permeability result in the release of soluble cytosolic enzymes into the sinusoidal blood. Thus increased blood activity of these cytosolic enzymes may be indicative of active hepatic disease. Caution must be exercised when evaluating increases in these enzymes because not all are liver specific. Furthermore, some of these hepatocellular enzymes may be increased because of induction by drugs. Most of these enzymes are quantitated colorimetrically; thus hemolysis or lipemia may interfere with accurate evaluation. Furthermore, wide variation in values can exist because of age differences, stage of hepatic disease, and laboratory methodology. In horses the following cytosolic enzymes are liver specific and are not inducible: *sorbitol dehydrogenase* (SDH; *iditol dehydrogenase*), *arginase* (ARG), *ornithine carbamoyltransferase*, and *glutamate dehydrogenase* (GLDH).<sup>8,10</sup> Although increases in these enzymes in the blood are highly specific for hepatocellular disease, they are not specific for the type of disease. Significant increases occur after acute hepatic necrosis. Mild increases in these enzymes may occur after hepatic hypoxemia or toxemia resulting from endotoxemia, septicemia, transient intestinal

disease, hyperthermia, or administration of certain drugs (benzimidazole anthelmintics).<sup>8,10,13</sup>

SDH has been widely used in the evaluation of acute liver disease in horses.<sup>13,47,75</sup> The short half-life of this liver cytosolic enzyme makes it ideal for the evaluation of acute ongoing disease, because values usually return to baseline within 3 to 5 days after a transient hepatic insult.<sup>60</sup> Its short half-life necessitates analysis within hours of collection. Storage of serum in the freezer ( $-15^{\circ}\text{C}$ ) or refrigerator results in losses of approximately 1.0% and 3.5%, respectively, of SDH activity per day.<sup>76</sup> Although mild variations exist between laboratories, the normal blood activity of SDH in horses is usually less than 8 U/L.<sup>15</sup> Foals 2 to 4 weeks of age may have SDH activity slightly greater than those of adult horses.<sup>47,75</sup> Increases in SDH have been reported after prolonged halothane anesthesia in horses.<sup>77</sup> ARG is used in the Krebs-Henseleit cycle for urea synthesis. It is found in highest activity in hepatocytes, although minute amounts also exist in renal tissue, brain, skin, testicles, and erythrocytes. Increases in ARG are most indicative of acute hepatic necrosis. Like SDH, ARG has a very short half-life. GLDH is found in hepatocytes, renal tissue, brain, muscle, and intestinal cells. Like SDH and ARG, GLDH has the highest tissue activity in the liver, and increases of this enzyme in the blood can be considered specific for acute liver disease. The half-life of GLDH is 14 hours.

Other cytosolic enzymes include *aspartate aminotransferase (AST)*, *alkaline phosphatase (ALP)*, *lactate dehydrogenase (LDH)*, *alanine aminotransferase (ALT)*, and *isocitrate dehydrogenase (ICD)*. These enzymes are also found with high activity in other tissues, or are inducible. Thus increases in these enzymes are *not specific* for liver disease in horses. Because some of these enzymes are frequently reported in equine biochemical profiles, they may serve as a crude indicator of liver disease; however, the limitations of their usefulness must be recognized.

AST, formerly glutamic oxaloacetic transaminase (GOT), is a cytosolic- and mitochondrial-bound enzyme that catalyzes the reaction responsible for aspartate biosynthesis from carbohydrate.<sup>8</sup> Basically, all cells contain AST, but liver and skeletal muscle cells contain the highest activity. Cardiac muscle, erythrocytes, intestinal cells, and the kidney also are sources of AST. Hemolysis and lipemia will falsely increase the value of AST.<sup>8</sup> Increases are most frequently associated with muscle damage but may be seen after acute hepatic necrosis. Often the AST activity is normal in chronic hepatic disease.<sup>13</sup> The half-life of AST is long, and thus it may take longer than 2 weeks for the blood activity to decrease after acute hepatic disease. The AST value is most useful when analyzed with other tissue-specific enzymes. For instance, if a muscle-specific enzyme, such as creatine kinase, also is increased, then an increase in AST most likely has its origin in muscle. Serial AST and SDH values can be useful for the determination of ongoing hepatic disease. If the SDH and AST values were initially increased, but subsequent evaluation reveals a normal or decreasing SDH and elevated AST, then a favorable prognosis is indicated, because hepatic necrosis is most likely subsiding. The normal serum activity of AST is 98 to 278 U/L.<sup>15</sup> ICD has a distribution similar to AST.

ALT, formerly glutamic pyruvic transaminase (GPT), is responsible for alanine synthesis from carbohydrate.<sup>8</sup> Increases may be evident with acute hepatic disease, but myositis will also increase blood levels. Hemolysis will falsely increase the value of this enzyme, and microsomal enzyme inducers (i.e., glucocorticoids) will increase its production and release in the

absence of liver disease. This enzyme is not useful for predicting liver disease in horses.<sup>8</sup>

ALP catalyzes the hydrolysis of monophosphate esters. This enzyme is bound to the mitochondrial membrane and thus does not leak into the blood with changes in cell membrane permeability or necrosis. Cholestasis and certain drugs, including glucocorticoids, primidone, and phenobarbital, will induce production and release of ALP. The ALP value most likely is to be increased in chronic or cholestatic liver diseases rather than acute or hepatocellular disease. Other tissues in addition to the liver contain ALP, including bone, intestine, kidney, placenta, and leukocytes, thus increases are not necessarily indicative of cholestasis. Because of increased osteoblastic activity, foals have ALP values two to three times those of adults.<sup>10</sup> Pregnancy, hemolysis, and gastrointestinal disease will also cause increases in ALP.

LDH is the name for five major isoenzymes located in liver, muscle, erythrocytes, intestinal cells, and renal tissue. Increases in LDH are not liver specific unless the isoenzyme activity is determined. Isoenzyme 5 (LDH-5) is a useful indicator of acute hepatocellular disease in horses because values typically return to baseline within 4 days after a transient hepatic insult.<sup>60,78</sup> LDH-5 is also present in muscle, so increased serum LDH-5 activity is specific for hepatic disease if other indicators of muscle damage (i.e., creatine kinase) are normal.<sup>79</sup> LDH-5 is stable at room temperature for 36 hours.

$\gamma$ -Glutamyltransferase (GGT) is involved in glutathione metabolism and transfer of glutamyl groups.<sup>8</sup> GGT primarily is associated with microsomal membranes in the biliary epithelium. Cholestasis induces production and release of GGT. Renal tubule cells contain GGT, but this source is released into urine. The only other potentially significant source of GGT in the blood is pancreatic in origin. Because pancreatic disease is rare in horses, the blood activity of GGT is considered specific for hepatic disease in horses. Some clinicians consider GGT to be the single test of highest sensitivity when evaluating horses for evidence of liver disease.<sup>60</sup> The half-life of GGT is approximately 3 days; GGT is stable in serum for 2 days at room temperature or for 30 days if frozen. Mild increases may be evident after acute hepatocellular necrosis and may continue to rise for 1 to 2 weeks despite improvement in clinical signs.<sup>60</sup> Increases are more persistent in chronic disease, especially with cholestasis.<sup>13</sup> Foals 2 weeks to 1 month old may have greater GGT values than adults.<sup>47,75</sup> The wider variation in younger horses reflects the degree and extent of hepatic maturation. Normal values for GGT in adult horses typically are less than 30 U/L<sup>15</sup> but may be greater in racing Thoroughbreds, healthy donkeys, burros, and asses.<sup>80</sup> In chronic, non-active hepatic fibrosis and focal hepatic disease, GGT may not be significantly increased. Increased serum GGT activity has been reported in horses with cholestasis secondary to colonic displacement.<sup>79</sup>

In summary, evaluation for liver disease in horses should include quantitation of at least SDH or ARG, and GGT. However, one should not interpret normal values for these liver enzymes as absence of liver disease.

## CLEARANCE OF PHARMACEUTICALS

In addition to clearance of endogenous substances from the blood, liver function can be evaluated after injection of an exogenous substance. One such exogenous substance that is removed by the liver, conjugated, and excreted into bile is *bromsulphalein (BSP)*.<sup>10</sup> After intravenous injection of 2.2 mg

BSP per kilogram body weight, a clearance half-life is determined by periodically obtaining heparinized blood samples over 12 to 15 minutes. One should exercise caution when injecting BSP, because it can be thrombogenic and irritating if administered perivascularly. Blood samples for BSP quantitation should be collected from a site other than the injection site. Suggested collection times are 3, 6, 9, 12, and 15 minutes after injection. Collection of plasma at the suggested times is not crucial; however, recording the exact times at which the samples were obtained is important to ensure accurate determination of the half-life. The half-life of BSP, thus the rate of extraction by the liver, is determined by plotting the plasma concentrations against the collection times on semi-log paper. The normal half-life of BSP in horses is 2.8 to 0.5 minutes.<sup>10</sup>

The BSP half-life is prolonged when greater than 50% of the hepatic function is lost.<sup>8,10</sup> This function test is useful in horses, especially to distinguish hepatoencephalopathy from other causes of abnormal behavior or cerebral signs, and to test liver function in chronic liver disease when bilirubin, SDH, and GGT blood levels may be normal. Proper interpretation of the BSP half-life must take into account the state of hepatic blood and bile flow and the bilirubin and albumin concentrations.<sup>8</sup> If the hepatic blood flow is decreased significantly, as may occur with hepatic congestion or portosystemic shunts, then the rate of delivery of BSP to the liver will be decreased; thus the half-life of BSP in the plasma will be prolonged. Because BSP is bound to albumin for delivery to the liver, if the blood concentration of albumin is markedly decreased, then a higher proportion of unbound BSP will be delivered to the hepatocytes; thus the half-life of BSP will be shortened.<sup>8</sup> If the blood concentration of bilirubin is increased greatly, then the bilirubin will compete with the BSP for binding sites and conjugating enzymes in the liver; thus the apparent half-life of BSP is prolonged. If significant cholestasis is present, then the BSP excreted into the biliary tract will be reabsorbed into the circulation, causing an apparent prolongation of its clearance. Therefore although a BSP clearance test is very useful as a test of hepatic function, one must interpret the results in light of these limitations. Furthermore, because pharmaceutical-grade BSP is no longer commercially available, this test is basically limited to academic and research institutions. Quantitation of serum bile acids concentration has essentially replaced BSP clearance as an indicator of hepatic function.

The determination of the BSP clearance time has been suggested to be more useful for detecting liver disease than the BSP half-life.<sup>81</sup> It has also been suggested that the proportionality transfer constants of clearance may be more useful in predicting hepatic disease than the BSP half-life alone.<sup>82</sup> The clearance time is the amount of dye irreversibly removed from the plasma per unit time. A dose of 5 mg BSP per kilogram of body weight is given intravenously, and heparinized blood samples are obtained 2, 5, 10, 15, 25, and 30 minutes after injection. The BSP clearance time in fed normal horses is 10 ml/min/kg and 6 ml/min/kg for horses fasted 3 days.<sup>81</sup>

The *indocyanine green* (ICG; Beckmann & Dickinson, Baltimore, Md.) clearance test has replaced the BSP clearance test in human beings.<sup>4</sup> Basically, the procedure and the limitations are the same as the BSP clearance test. The ICD clearance time in fed horses is 3.5 to 0.67 ml/min/kg, and 1.6 to 0.57 ml/min/kg for fasted horses.<sup>81</sup> Although the clearance of ICG is an excellent predictor of hepatic blood flow and extraction rates, its current expense precludes its routine use in horses. Another disadvantage is that quantitation requires a spectrophotometer

that reads infrared wavelengths. These limitations have hindered evaluation of ICG clearance times as a diagnostic test of liver insufficiency in horses.

The hepatic clearance of the radiopharmaceutical technetium 99m-mebrofenin is used in human beings and small animals to assess hepatic function. In horses, the plasma clearance of technetium 99m-mebrofenin is not affected by withholding feed.<sup>83</sup>

#### OTHER NONSPECIFIC LABORATORY FINDINGS

Increased formation and release of acidic metabolic products, including ketone bodies, lactate, pyruvate, and amino acids, contribute to acidemia. Other factors that may contribute to acidemia include diarrhea and loss of renal acidification because of impaired urea synthesis. Anorexia may predispose to hypokalemia.

Although infrequently reported in horses, aldosterone and water retention may cause deranged concentrations of sodium and isosthenuria (see polydipsia, polyuria, and the hepatorenal syndrome). Azotemia may occur with hyperlipemia.<sup>62</sup>

Cholangiohepatitis, CAH, or a focal hepatic abscess may cause an inflammatory leukogram, anemia of chronic disease, and hyperfibrinogenemia.<sup>59</sup> Primary polycythemia has been reported in horses with hepatocellular carcinoma and hepatoblastoma.<sup>84-86</sup> Because fibrinogen is synthesized by the liver, widespread chronic hepatitis may mask an increase in this acute phase reactant protein.

#### DIAGNOSTIC IMAGING OF THE LIVER

*Ultrasonography* is a safe, noninvasive imaging technique that uses the reflection of high-frequency sound waves from tissue interfaces to produce a visual image. Liver ultrasonography in horses is limited by the ribs, the depth and size of the liver, and its anatomic location deep to the diaphragm and lungs.<sup>74</sup> Mechanical sector or linear array scanners with 3.0-MHz crystals are most effective.<sup>74</sup> Ultrasonography can be used to assess the right and left sides of the liver, and the liver shape, size, position, and texture. Hepatic vein walls are less echogenic than portal vein walls, and the biliary system is not normally visible. Ultrasonography is most useful for determining the general size of the liver; changes in the hepatic parenchyma, including abscesses, cysts, and neoplastic masses; and detecting dilated bile ducts or obstructions with choleliths. The common bile duct cannot be seen in a horse. Abnormal intra- or extrahepatic blood flow or vasculature may be detectable. Ultrasonography is also useful for guiding biopsy instruments into the liver (see Liver Biopsy).

*Radionuclide imaging* also may be used to detect alterations in the hepatic parenchyma or blood flow.<sup>87</sup> Radionuclide scanning noninvasively evaluates function and yields structural information. Two radionuclide scanning techniques are available to evaluate the liver: liver scan and biliary scan. In the liver scan, a technetium 99m-labeled sulfur colloid is injected intravenously. Technetium-99m is a gamma-emitting radioactive compound that is detected in the body by a gamma camera. After injection, Kupffer's cells phagocytose the technetium 99m sulfur colloid. Subsequent scanning with the gamma camera detects the radioactive emissions from the technetium 99m and resolves them into a two-dimensional image. Thus alterations in blood flow (portosystemic shunt) or hepatic masses such as abscesses, cysts, and neoplasia may be detectable. In the biliary scan, technetium 99m-labeled iminodiacetic acid is injected intravenously. The iminodiacetic

acid is extracted by the hepatocytes, conjugated, and excreted in the bile.<sup>88</sup> Subsequent scanning images the biliary system and may be useful for the detection of biliary obstruction, including atresia, cholangitis, and cholelithiasis. Because radionucleotide imaging is somewhat expensive and requires a large gamma camera, this procedure is limited to research and academic institutions.

*Operative mesenteric portography* can be performed when a portosystemic shunt is suspected. In this procedure, a celiotomy is performed, radiopaque material is injected into a mesenteric vein, and rapid, sequential survey radiographs are obtained. Simultaneous opacification of the portal vein, azygous vein, and caudal vena cava or lack of filling of the intrahepatic portal system is indicative of portosystemic shunting.<sup>87</sup>

### LIVER BIOPSY

A liver biopsy can yield important diagnostic and prognostic information. In a retrospective study of 73 horses with liver disease, a scoring system that graded the degree of fibrosis, reversible and irreversible cytopathology, inflammation, haemosiderosis, and bile duct proliferation was useful in predicting long-term survival.<sup>89</sup> A liver biopsy is performed at the right twelfth to fourteenth intercostal spaces at the intersection of a line drawn from the tuber coxae to a point midway between the elbow and the point of the shoulder. The procedure must be performed in a sterile manner. The area is clipped, aseptically prepared, injected with local-acting anesthetic subcutaneously, and a stab incision is made with a no. 15 scalpel blade. A Tru-Cut (Baxter-Travenol, St Louis) or Franklin-modified Vim-Silverman (Mueller & Co, Chicago, IL) biopsy instrument is inserted and directed cranial and ventrad through the diaphragm into the liver. Semiautomatic biopsy instruments (EZ Core, Products Group International, Lyons, CO) and automatic biopsy guns (ProMag 2.2 Biopsy System, Manan Medical Products, Northbrook, IL) equipped with 14-gauge, 16-cm needles are very helpful for a quick and accurate liver biopsy. Samples should immediately be placed in formalin for histopathologic evaluation and, if necessary, in transport media for culture of micro-organisms. Precautions to consider before performing the procedure include the risk of hemorrhage, pneumothorax, and peritonitis from bile leakage and colon or abscess puncture, as well as spread from infectious hepatitis. These complications may be reduced by performing a hemostasis profile to assess the risk of hemorrhage and by using ultrasonography to guide needle placement. Although subclinical coagulopathy has been frequently reported in horses with liver disease, clinically significant or fatal hemorrhage after performing a liver biopsy is rarely reported.<sup>16,17</sup>

### SUMMARY OF DIAGNOSTIC PROCEDURES

The most useful diagnostic tests for evaluation of hepatic disease in horses are quantitation of SDH, GGT, and serum bile acids. In the face of clinically significant liver disease, at least one of the three former serum tests typically is abnormal. Although less useful in horses, additional tests of liver disease may include quantitation of bilirubin, ALP, AST, albumin, fibrinogen, globulins, glucose, esterified triglycerides, ammonia, BUN, BSP clearance, and amino acids. Serial testing of these indices may increase their diagnostic and prognostic value. Abnormal laboratory findings should be further investigated with ultrasonography and biopsy, after evaluation of a hemostasis profile.

## TREATMENT OF HEPATIC INSUFFICIENCY

Management techniques for hepatic insufficiency are largely supportive. (Therapies for specific liver diseases are discussed in more detail under Specific Hepatic Diseases.) The basic goal of treatment is to maintain the animal until enough liver regenerates to provide adequate function. Patients with severe hepatic fibrosis respond poorly because adequate regeneration often is not possible. Horses with signs of HE that are agitated, restless, or uncontrollable must be sedated to enable therapy; however, any medication should be used judiciously because most tranquilizers are metabolized by the liver or potentiate the abnormal neural function of HE. *Xylazine* or *detomidine* in small doses are safest and most effective in these instances. Use of diazepam is contraindicated because it enhances the effect of GABA on central inhibitory neurons and may exacerbate signs of HE.<sup>27</sup> Intravenous fluids should correct fluid deficit and acid-base or electrolyte imbalances. Because most horses with HE are anorectic and blood glucose may be decreased, continuous intravenous infusion of 5% dextrose at a rate of 2 ml/kg/hr can be beneficial.<sup>90</sup> If continued more than 24 to 48 hours, then 2.5% to 5.0% dextrose in half-strength saline or lactated Ringer's solution should be substituted. In human beings, volume expansion with 0.9% saline solution enhances urinary ammonia excretion.<sup>91</sup> If bicarbonate therapy is necessary to treat acidotic patients with hyperammonemia, then the rate of administration should be monitored carefully, because too rapid of a rate may increase blood levels of ammonia.<sup>27</sup> Hypokalemia or alkalosis result in increased renal production of ammonia and increased diffusion of ammonia into the CNS; thus treatment with potassium or acidifying fluids may be beneficial.<sup>92</sup>

Therapy should also be directed at reducing the production of toxic protein metabolites by enteric bacteria or by interfering with their absorption. The administration of *mineral oil* or magnesium sulfate per nasogastric tube is safe and aids in reducing toxin absorption. HE in human beings with acute fulminant hepatic failure is almost always associated with cerebral edema. Thus recommendations for treatment of severe acute HE in human beings include elective hyperventilation; elective moderate hypothermia; use of mannitol (0.5 to 1 g/kg body weight); hypertonic saline infusion; antioxidants such as acetylcysteine, selenium, and vitamin E (25 IU/kg/day PO); and extracorporeal liver support devices.<sup>93,94</sup>

Methods to reduce the production of ammonia and other enteric toxins include the oral administration of antibiotics (neomycin, metronidazole, rifaximin, vancomycin)<sup>91</sup> or lactulose or lactitol (not available in the United States).<sup>92</sup> In horses, *neomycin* has been recommended at a dosage of 10 to 100 mg/kg PO every 6 hours.<sup>55,80</sup> This treatment significantly alters the gastrointestinal flora, may cause diarrhea in some horses, and may predispose horses to salmonellosis because most *Salmonella* spp. are not sensitive to neomycin. However, in one retrospective study in horses with liver disease, oral neomycin therapy subjectively was more helpful than lactulose in alleviating signs of HE.<sup>17</sup> *Lactulose*, a syrup containing lactose and other disaccharides, passes through the upper small intestine and is metabolized by ileal and colonic bacteria to organic acids, thereby reducing luminal pH. Proposed beneficial mechanisms of action of lactulose include increased bacterial assimilation of ammonia, decreased ammonia production, ammonia trapping in the bowel lumen, enteric microflora changes, and osmotic catharsis.<sup>19,95</sup> A dose of 0.3

ml/kg of lactulose syrup every 6 hours per nasogastric tube has been recommended for horses<sup>80</sup>; however, this therapy is expensive and may cause diarrhea. In human beings, lactulose also may be given as an enema when the oral route is unavailable.<sup>93</sup> When given orally three times a day at 333 mg/kg of body weight, lactulose (Duphalac, Solvay Pharmaceuticals, Marietta, GA) significantly decreased blood ammonia values in healthy adult horses.<sup>95</sup> None of the horses developed diarrhea, although one horse foundered on the sixth day of treatment. Fecal pH did not decrease. As an alternative or adjunct to antimicrobials or lactulose, one may attempt modification of intestinal flora with probiotics, such as *Lactobacillus acidophilus* or *Enterococcus faecium*.<sup>92</sup> Many clinicians prefer not to use oral antimicrobials or lactulose but to rely on institution of a low-protein diet. Oral and intravenous formulations of BCAAs are commercially available for use in horses (BCAA Equine Sports Inc, Lake Forest, IL; Baxter Healthcare Corp, Deerfield, IL), but controlled clinical trials in human beings have not shown this form of therapy to consistently ameliorate the signs of HE.<sup>43</sup>

A number of experimental drugs have been studied in human beings and may have a future role in management of HE in horses. Regimens to stimulate hepatic regeneration include insulin and glucagon<sup>96</sup> and cytosolic extracts from regenerating liver.<sup>97</sup> None have been shown to be definitively effective in human beings. As discussed previously, benzodiazepine receptor antagonists have been suggested to induce clinical and electrophysiologic remissions of HE in human beings with both acute and chronic liver failure.<sup>19,98</sup> This neuropharmacologic approach to treatment of HE holds great promise, although it may not be economically feasible in horses. In human beings with HE, treatment with *flumazenil*, a benzodiazepine antagonist and *bromocriptine*, a dopamine agonist, have provided either short-term or inconsistent results.<sup>93,99</sup> Zinc, levocarnitine, and ornithine aspartate enhance ureagenesis and also may reduce blood ammonia concentrations.<sup>91-93</sup> These treatments have not been evaluated in the horse.

Anti-inflammatory drugs may be beneficial and include *flunixin meglumine*, *dimethyl sulfoxide* (DMSO), and *pentoxifylline*. DMSO (0.5 to 1 gm/kg body weight, given intravenously diluted to 10% for 3 to 5 days) may help dissolve intrabiliary sludge or small calcium bilirubinate stones. *Pentoxifylline* has been shown to reduce hepatic fibrosis in human beings<sup>100</sup> and may be given to horses at 8 mg/kg every 8 to 12 hours. *Colchicine*, an antigout drug, and *cyclosporine*, a potent T helper cell immunosuppressant have been used to slow hepatic fibrosis in dogs and people.<sup>101</sup> These drugs have not been fully evaluated in horses; however, colchicine has been ineffective in cases of pyrrolizidine alkaloid toxicity.<sup>101</sup>

If any drugs are to be administered to a horse with hepatic insufficiency, it may be necessary to alter dosage. Alterations in hepatic blood flow, albumin, and biotransformation during hepatic insufficiency may prolong the half-life, as well as the dosage interval. Drugs that rely heavily on the liver for metabolism and excretion, such as chloramphenicol, erythromycin, and corticosteroids, should be avoided.<sup>12</sup>

Once the appetite returns, a horse with HE or chronic liver disease is best managed by dietary manipulation. The ration should be high in carbohydrates and low in protein, with the protein source optimally rich in BCAAs. A mixture of two parts beet pulp and one part cracked corn in molasses can be fed at a rate of 2.5 kg/100 kg body weight per day divided into six or more feedings.<sup>80</sup> Sorghum, bran, or milo can be substituted

for the beet pulp. Multiple small feedings are optimal in horses with liver disease because of impaired gluconeogenesis. Oat hay is the best roughage, followed by other types of grass hay.<sup>90</sup> Horses should be encouraged to graze grass pastures provided they are protected from the sun. Alfalfa and legumes should be avoided because of their high protein content; however, any caloric intake is important in liver failure and should be allowed even if it includes legumes. Oats, soybean meal, and fat should be avoided.<sup>102</sup> Vitamins B<sub>1</sub>, K<sub>1</sub>, and folic acid should be administered parenterally on a weekly basis. Vitamin-K therapy is most useful when cholestasis is present.<sup>4</sup>

## PROGNOSIS

The prognosis for hepatic insufficiency in horses depends on the severity and type of the underlying disease. Horses with focal or mild to moderate acute hepatic disease have the best chance for hepatic regeneration; thus they have a guarded to fair prognosis if adequate and appropriate supportive care is given. Patients with severe hepatic fibrosis and chronic liver disease have a poorer prognosis because of their inability to compensate for lost hepatic function. Regardless of the cause of liver disease, the presence of severe encephalopathy, intravascular hemolysis, profound acidosis, clinical signs of coagulopathy, diarrhea, bilateral laryngeal paralysis, markedly increased serum bile acid concentration, BSP half-life greater than 10 minutes, decreased serum albumin, and histologic evidence of bridging fibrosis have all been associated independently with a poor to grave prognosis. If a horse survives more than 5 days after an acute transient hepatic insult, then the prognosis is fair. Decreasing blood levels of SBA, GLDL, and GGT are more likely to occur in horses that survive.<sup>16</sup> Therapy is generally unrewarding in horses with severe hepatic fibrosis.

## ☪ SPECIFIC HEPATIC DISEASES

The wide variety of clinical signs with hepatic disease, coupled with the fact that the majority of the hepatic parenchyma must be affected before function is lost, makes the clinical distinction between acute and chronic liver disease a challenge. The onset of signs may be sudden, even with chronic disease. A history of progressive weight loss or “failure to thrive” may indicate chronicity. Although no single blood test is specific for distinguishing acute from chronic hepatic disease, the presence of hyperglobulinemia or hypoalbuminemia may suggest chronicity. Histopathologically, the hallmark evidence of chronicity is the presence of fibrosis. For the purpose of discussion of specific hepatic disorders in the following sections, diseases have been classified as either *acute* or *chronic* based on the known cause of the disease (Box 16-2).

## ACUTE HEPATIC DISEASES

### THEILER'S DISEASE

Sir Arnold Theiler's first described this disease in South Africa in 1918 after vaccination of horses against African horse sickness with both live virus and equine-origin antiserum.<sup>103</sup> In 1934 and 1937, a similar disease was described in the United States after vaccination of horses against western equine encephalomyelitis using live virus and equine-origin antiserum.<sup>56,104,105</sup> Despite numerous accounts of this syndrome, the exact cause of Theiler's disease remains unclear. Today this disease is one of the most commonly described causes of acute hepatic failure

## BOX 16-2

## LIVER DISEASES OF HORSES

**Acute Disease**

- Theiler's disease (Serum-associated hepatitis)
- Hyperlipemia
- Tyzer's disease
- Infectious necrotic hepatitis (Black disease)
- Cholangiohepatitis
- Acute biliary obstruction
  - Cholelithiasis
  - Colon displacement
  - Hepatic torsion
- Parasitic hepatitis
  - Parascaris equorum*
  - Large strongyles
  - Echinococcus granulosa*
  - Schistosoma
- Toxic hepatopathy
  - Plants
  - Mycotoxins
  - Chemicals
  - Drugs
  - Iron
- Viral hepatitis
  - Equine infectious anemia (EIA)
  - Equine herpesvirus-1 (EHV-1)
  - Equine viral arteritis (EVA)
  - Giant cell hepatopathy

**Chronic Disease**

- Pyrolizidine alkaloid toxicity
- Clover poisoning
- Chronic active hepatitis (CAH)
- Cholelithiasis
- Gastrointestinal obstruction
- Abscess
- Neoplasia
  - Metastatic infiltration of the liver
  - Cholangiocarcinoma
  - Hepatocellular carcinoma
  - Hepatoblastoma
  - Mixed hamartoma
- Amyloidosis
- Chronic hypoxia

**Congenital or Heritable Disease**

- Portosystemic shunt
- Biliary atresia
- Hyperammonemia of Morgans
- Glycogen branching enzyme deficiency

death, photodermatitis, hemorrhagic diathesis, fever, dependent edema, colic, and bilirubinuria may be present.<sup>56,106,107</sup> Although uncommon, some horses with Theiler's disease have an insidious history of chronic weight loss.

**Epidemiology and Pathogenesis** The disease typically occurs sporadically, but outbreaks involving multiple horses on a single farm over several months have been reported.<sup>56,106,107</sup> A pattern of seasonality may occur, with a larger percentage of cases presenting in summer and fall.<sup>56,106,107</sup> Frequently, horses with Theiler's disease have received an equine-origin biologic antiserum 4 to 10 weeks before the onset of hepatic failure, hence the name *serum-associated hepatitis*. Equine-origin biologic antisera that have been associated with Theiler's disease include vaccines or antisera for African horse sickness, eastern and western encephalomyelitis, *Bacillus anthracis*, tetanus antitoxin, *Clostridium perfringens*, *C. botulinum*, *Streptococcus equi*, subsp. *equi*, influenza, equine herpesvirus type 1 (EHV-1), pregnant mare's serum, and plasma.<sup>13,56,106,107,109</sup> Some reports suggest lactating broodmares given tetanus antitoxin after parturition are particularly prone to Theiler's disease.<sup>106-108</sup>

Reports of outbreaks in association with parenteral injection of homologous live virus vaccine or antiserum suggest an infectious blood-borne viral cause.<sup>56</sup> The history, onset, clinical signs, and histopathologic findings of Theiler's disease appear most similar to hepatitis B virus in human beings. Hepatitis B virus is present in all body fluids and excreta and is transmitted primarily by parenteral injection.<sup>20</sup> Viral surface antigen or antibody to viral core protein is detectable in 75% to 90% of human patients with hepatitis B.<sup>20</sup> Newer techniques that detect viral deoxyribonucleic acid (DNA) are even more sensitive and specific tests of infection. To date these assays have been negative in horses with Theiler's disease. Furthermore, viral isolation on horses with Theiler's disease has been unsuccessful, the disease has not been transmitted experimentally by blood or tissue inoculation, and a large percentage of horses with Theiler's disease do not have a recent history of receiving an equine-origin biologic antiserum.<sup>110,111</sup> The sum of these negative findings does not exclude the possibility of a viral cause; however, if such a cause exists, then other modes of transmission, infection, and establishment of disease must also exist.

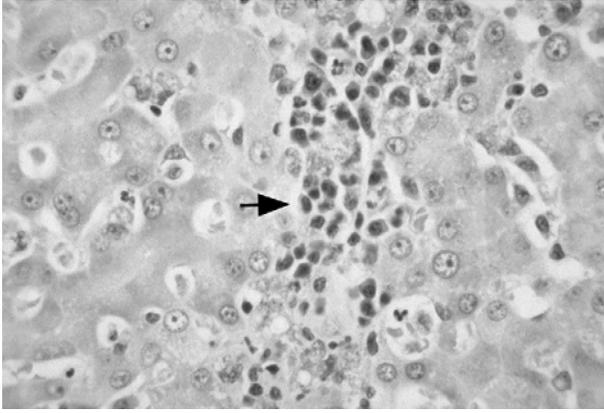

Other suggested causes of Theiler's disease include exposure to hepatotoxic substances, such as mycotoxins (aflatoxin and rubratoxin), plant toxins (pyrrolizidine alkaloids, alsike clover), drugs, or chemicals.<sup>13,108</sup> However, these causes have not been uniformly demonstrable and usually are considered separate disease entities.

Aside from widespread tissue icterus, pathologic findings are limited to the liver. The liver appears smaller than normal, but it may be large in peracute cases. Although not pathognomonic, the histopathologic findings in Theiler's disease consistently include widespread centrilobular to midzonal hepatocellular necrosis with hemorrhage (Figure 16-7),<sup>110</sup> which helps distinguish it from acute pyrrolizidine alkaloid toxicity, which has predominantly periportal changes. Moderate to severe centrilobular hepatocyte vacuolar (fatty) change and granular swelling, hemosiderosis, and bile casts may be seen.<sup>106</sup> A mild inflammatory infiltrate, primarily monocytes and lymphocytes, is present in portal triads. The occasional finding of mild to moderate biliary hyperplasia and fibroblastic infiltration is evidence of a more chronic disease course than the clinical signs alone would suggest.<sup>110</sup>

**Diagnosis** Recent inoculation with an equine-origin biologic antiserum, coupled with an abrupt onset of clinical signs

in horses.<sup>15,56,106-108</sup> Theiler's disease is also referred to as *acute hepatic necrosis*, *serum-associated hepatitis*, and *serum sickness*.

**Clinical Signs** Theiler's disease is limited to adult horses, although one report describes subclinical disease in a 2-month-old foal.<sup>107</sup> The onset of clinical signs of hepatic failure in Theiler's disease is acute to subacute and often rapidly progresses over 2 to 7 days. Most horses are anorectic and icteric; HE is reported in the majority of the cases.<sup>56,106,107</sup> Sudden

**FIGURE 16-7** Histopathology of the liver: Theiler's disease. Note the central area of hepatic necrosis (arrow).

and laboratory evidence of hepatic insufficiency, strongly suggests Theiler's disease. No single laboratory test is diagnostic. Bilirubinemia and bilirubinuria are usually present. Liver enzymes, including SDH, ARG, and AST, are increased. The BSP half-life, PT, and APTT are often prolonged, and blood ammonia concentrations are increased. Acidosis, leukocytosis, polycythemia, and increases in serum creatine kinase activity have also been reported.<sup>106-108</sup> Hemolysis may occur terminally. The histopathologic findings on a liver biopsy (see previous pathogenesis section) offer the strongest diagnostic evidence of Theiler's disease.

**Treatment** No specific treatment for Theiler's disease exists aside from general supportive care for hepatic insufficiency (see Treatment of Hepatic Insufficiency).

**Prognosis and Client Education** The prognosis is poor to grave in horses with severe HE, hemorrhage, or hemolysis. Horses that survive longer than 1 week usually recover completely, although death or progressive weight loss have been reported during the ensuing months.<sup>107</sup> A favorable prognosis is warranted if serial SDH activities are decreasing or clinical signs are waning. Increased serum activity of GGT may be sustained for several weeks, despite clinical improvement and long-term survival.<sup>106</sup> No preventative exists, aside from the judicious use of equine-origin antiserum.

## BACTERIAL HEPATITIS

**Tyzzler's Disease** *Clostridium piliforme* (formerly, *Bacillus piliforme*) is a motile, spore-forming, obligate intracytoplasmic bacterium that causes acute necrotizing hepatitis. The disease was first described by E. E. Tyzzler's in 1917 in a colony of waltzing mice.<sup>112</sup> The first documented outbreak in foals occurred in Kentucky on a single farm between 1964 and 1973, fatally infecting 23 foals.<sup>113</sup>

**Clinical Signs** In horses, Tyzzler's disease is limited to foals between 7 and 42 days of age.<sup>114-116</sup> The clinical signs are usually nonspecific and include loss of a suckle reflex, depression progressing to recumbency, fever, tachypnea, tachycardia, icterus, petechiation, diarrhea, dehydration, shock, seizures, and coma.<sup>113-118</sup> Often the foals are found dead without premonitory signs.

**Epidemiology and Pathogenesis** Outbreaks of Tyzzler's disease are sporadic; thus the disease is not believed to be contagious.<sup>116</sup> Seasonality has not been demonstrated. The disease has been reported in the United States, Canada, South

Africa, England, New England, and Australia.<sup>116,117</sup> Mice with Tyzzler's disease are infected by an oral route perinatally, with clinical signs and death occurring between 6 and 44 days of age.<sup>117</sup> *C. piliforme* is excreted in the feces of clinically healthy horses and can survive in the soil for at least 1 year.<sup>115,117</sup> Foals are infected by eating contaminated feces of their dams or by ingesting contaminated soil.<sup>115</sup> The bacteria replicate in the intestinal epithelium and reach the liver and heart by way of the lymphatics and blood supply.<sup>115</sup> In rodents and rabbits, administration of corticosteroids or sulfonamides may induce active disease.<sup>117</sup> The presence of antibody to the flagella of *C. piliforme* in the serum of healthy horses suggests that exposure to *C. piliforme* is not uncommon.<sup>119</sup>

*C. piliforme* causes acute multifocal hepatitis and enteritis. Grossly, the liver is swollen with 1- to 5-mm white foci scattered throughout the parenchyma. Tissues are icteric and petechial hemorrhages are present in many tissues. Microscopically, the foci are areas of coagulative necrosis with an associated inflammatory infiltrate consisting of neutrophils, macrophages, and lymphocytes. The organisms, best demonstrated at the periphery of the lesions by Warthin-Starry or Dieterle's silver stains, appear as long bacilli organized in bundles. In addition to hepatitis, enterocolitis, myositis, pleural effusion, pulmonary congestion and edema, and lymphoid necrosis or depletion may be present.<sup>116,117</sup>

**Diagnosis** The peracute onset and nonspecific signs confound antemortem diagnosis of Tyzzler's disease. Hematologic study may reveal hemoconcentration, leukopenia or leukocytosis, a left shift, and toxic neutrophils.<sup>114-117</sup> Other nonspecific laboratory findings include hyperfibrinogenemia, acidosis, hyperkalemia or hypokalemia, and profound hypoglycemia.<sup>114-118,120</sup> Liver enzymes are increased, including SDH, GGT, AST, ALP, and LDH-5.<sup>114-118</sup>

The definitive diagnosis is determined at necropsy by demonstration of the organism intracytoplasmically using silver stains or by polymerase chain reaction (PCR) analysis.<sup>120</sup> *C. piliforme* is fastidious and can only be grown in living tissue, such as embryonated chick eggs.<sup>120</sup> Positive serology may be supportive evidence for exposure.<sup>119</sup> Differential diagnosis for hepatic disease in foals includes iron hepatotoxicity, perinatal EHV-1, bacteremia, atresia of the bile duct, and portosystemic shunt.

**Treatment** Tyzzler's disease is highly fatal in foals. In rodents and rabbits, *C. piliforme* is sensitive to penicillin, tetracycline, erythromycin, and streptomycin. Rare reports exist of successful treatment of foals with Tyzzler's disease using penicillin, TMS, and partial parental nutrition.<sup>114,120</sup>

**Prognosis and Client Education** Tyzzler's disease in foals is considered highly fatal. No preventative exists.

## INFECTIOUS NECROTIC HEPATITIS

*Clostridium novyi* type B is the cause of *infectious necrotic hepatitis* or *black disease*. The disease is most common in sheep and cattle, but several cases have been documented in horses.<sup>54,121-124</sup>

**Clinical Signs** The onset of disease may be peracute with sudden death. Acute signs are progressive over 24 to 72 hours and include depression, reluctance to move, fever, icterus, ataxia, colic, petechiae, periods of recumbency, tachycardia, and tachypnea.<sup>54,121-124</sup> Some affected horses remain standing until a short time before death.

**Epidemiology and Pathogenesis** Reported cases of infectious necrotic hepatitis in horses have occurred in or adjacent to areas with a large population of sheep.<sup>54,121-124</sup> In sheep and

cattle, infectious necrotic hepatitis is the result of multiplication of *C. novyi* in areas of liver compromised by the migration of *Fasciola hepatica*. This fluke normally does not infest horses, but migration of any parasite through the liver may predispose the animal to infectious necrotic hepatitis. Some horses with infectious necrotic hepatitis had parasitic infestations, although migrating parasites in the liver at the time of necropsy was not evident. The onset of disease in one case occurred 48 hours after administration of mebendazole.<sup>54</sup>

The carcass blackens rapidly after death from engorgement of subcutaneous blood vessels; hence the name *black disease*. Often, necropsy findings include serosanguineous effusion in the pericardial sac and the thoracic and abdominal cavities, widespread hemorrhages and icterus, and multifocal areas (1 to 2 mm) of coagulative hepatic necrosis. Smears or histologic sections of the hepatic lesions reveal large numbers of gram-positive rods.

**Diagnosis** The acute and nonspecific nature of this disease makes antemortem diagnosis improbable. Liver-specific enzymes and bilirubin are mildly to moderately increased.<sup>54,121,124</sup> An abdominocentesis was performed on one horse and revealed serosanguineous peritonitis.<sup>54</sup> Definitive diagnosis is based on positive staining with fluorescein conjugated antiserum specific for *C. novyi* or isolation of the organism at necropsy.<sup>121,124</sup> The organism is difficult to isolate and requires rapid tissue sampling and anaerobic conditions.

**Treatment** Treatment with high doses of penicillin or ampicillin is indicated, in addition to general supportive care for hepatic insufficiency.

**Prognosis and Client Education** Most reported cases of infectious necrotic hepatitis in horses were fatal.

### MISCELLANEOUS CAUSES OF BACTERIAL HEPATITIS

Primary bacterial hepatitis is rare in adult horses. Bacterial septicemia in neonates may result in multifocal hepatitis, although clinical signs of hepatic failure rarely accompany the disease. Bacterial endotoxin, released during acute fulminant gram-negative infection or absorbed from the gastrointestinal tract after mural damage, may cause hepatic ischemia indirectly through hemodynamic alternations. Because Kupffer's cells normally phagocytose endotoxin, bombardment of the liver with endotoxin may temporarily impede the function of Kupffer's cells.

*Primary bacterial cholangiohepatitis* has been reported in horses, although more commonly it is secondary.<sup>50,125-128</sup> *Secondary cholangiohepatitis* in horses is a sequela to biliary stasis, cholelithiasis, CAH, hepatic neoplasia, pancreatitis, intestinal parasitism, intestinal obstruction, and proximal enteritis.<sup>129</sup> Clinical signs include anorexia, colic, fever, and icterus; HE may be present. Laboratory abnormalities may include leukocytosis; toxemia; hyperfibrinogenemia; and increased activity of SDH, ARG, GGT; increased direct-reacting bilirubin; and evidence of septic or nonseptic peritonitis.<sup>126,128</sup> Definitive diagnosis is based on histopathologic findings on liver biopsy and bacterial isolation. Isolates are most commonly enteric organisms such as *Salmonella* spp., *Escherichia coli*, *Citrobacter*, *Klebsiella*, *Aeromonas*, and *Acinetobacter* spp.<sup>126-128</sup> Treatment includes general supportive care for hepatic failure (see Treatment of Hepatic Insufficiency) and 4 to 6 weeks of antimicrobial therapy. The antimicrobial therapy should be based on culture and sensitivity results. Recommended antimicrobials for bacterial cholangiohepatitis in horses include trimethoprim-sulfonamide,

ceftiofur, enrofloxacin, penicillin and gentamicin, ampicillin, and chloramphenicol.<sup>50,125-128</sup>

### VIRAL HEPATITIS

**Equine Herpesvirus Infection in Foals** Pregnant mares infected with EHV-1 may abort in the third trimester or deliver stillborn or weak foals. Some foals may appear normal at birth but develop clinical signs of respiratory distress, icterus, fever, and severe depression.<sup>130,131</sup> Secondary bacterial septicemia is common. Despite profound hepatic necrosis in herpesvirus-positive foals, serum enzyme activities were not significantly different from premature foals or foals with septicemia.<sup>131</sup> Pathologic lesions of aborted fetuses or neonatal foals are similar and include severe pulmonary congestion, pneumonitis, bronchiolitis, hyaline membrane disease, and intralobular coagulative hepatocellular necrosis.<sup>130,131</sup> Intranuclear, acidophilic inclusions are present in hepatocytes and biliary epithelium. General supportive care and prophylactic administration of broad-spectrum antimicrobials are indicated. The prognosis is poor to grave. Most affected foals die within a few days of birth. Vaccination of pregnant mares is only partially efficacious for prevention.

**Equine Infectious Anemia** The causative organism of equine infectious anemia is a retrovirus that has a tropism for mononuclear phagocytes.<sup>132</sup> Although cyclic fever, anemia, icterus, edema, and weight loss are the systemic manifestations of the disease, the Kupffer's cells in the liver are a major site of infection. Icterus is due to increased erythrocyte destruction, as well as acute hepatic necrosis.

**Equine Viral Arteritis** This disease is caused by a member of the Arteriviridae family and typically is manifest clinically by depression, fever, acute upper respiratory tract infection, abortion, petechiation, and edema. After ingestion or inhalation, viral septicemia leads to vascular damage. Overt clinical signs of hepatic disease are rare, but vascular damage in the liver may cause icterus.<sup>133</sup>

**Giant Cell Hepatopathy** A disease similar to human neonatal hepatitis has been reported in aborted midterm fetuses.<sup>134</sup> Histologically, disorganization of hepatic cords, multifocal necrosis, a mild mononuclear cell infiltrate, and a large hepatocyte syncytium with 8 to 10 nuclei exist. The cause in horses and human beings is unknown but is presumably viral. Viral and bacterial isolation, viral immunofluorescence, and serologic testing have been unsuccessful in horses. Giant cell hepatopathy was reported in one foal with prolonged neonatal isoerythrolysis.<sup>134</sup>

### PARASITIC HEPATITIS

Parasitic infestation may cause focal hepatic disease but rarely overt hepatic insufficiency. After their ingestion, as embryonated eggs, larvae of *Parascaris equorum*, hatch in the small intestine, and then migrate through the liver and lungs. Focal or diffuse hepatic fibrosis may result.<sup>80</sup> Migration of *Strongylus edentatus* or *S. equinus* through the hepatic portal veins may cause focal hepatitis, subcapsular hemorrhage, and edema, followed by focal parenchymal fibrosis and capsular fibrin deposits.<sup>80</sup> Focal hepatic infarcts may occur secondary to thrombotic emboli because of migrating *S. vulgaris* in mesenteric arteries. Protozoal schizonts consistent with a *Sarcocystis* spp. other than *S. neurona* were reported at necropsy in the liver of a horse with concurrent bacterial osteomyelitis, a plasma cell tumor of the maxilla, and hepatic salmonellosis.<sup>135</sup> The canine cestode, *Echinococcus granulosa*, may form hydatid (larval) cysts in the liver, which are usually an incidental finding.<sup>136,137</sup>

Fibrosing granulomas were found in the liver, intestinal and diaphragmatic serosae, and lung of several horses submitted for necropsy.<sup>138</sup> The granulomas consisted of dense fibrous tissue surrounding a necrotic, laminated, mineralized center. The periphery of the granuloma contained a small rim of inflammatory cells. The typical architecture of the granulomas, combined with the finding of a residual eggshell typical of *Schistosoma* (a trematode) in one horse, lead to the conclusion that the granulomas were caused by chronic schistosomiasis. Although the granulomas were considered to be incidental findings of undetermined origin in most of the horses, they caused liver failure in one horse.

## TOXIC HEPATOPATHY

Numerous chemicals, drugs, mycotoxins, and plant toxins are hepatotoxic, but these rarely cause acute hepatic failure in horses. Clinical signs and routine laboratory diagnostic tests will not distinguish between these toxins; thus diagnosis largely relies on exclusion of other causes, history of exposure, and in some cases, documentation of the toxin in the blood or liver. Some substances cause fatty change, cloudy swelling, necrosis, mild inflammatory infiltration, and fibrosis, primarily in the centrilobular location where the oxygen tension is lowest. Other substances cause the same lesions periportal, in the area of initial exposure. Some substances are directly hepatotoxic, whereas others require biotransformation by the liver to toxic metabolites.

**Hepatotoxic Plants** Plants best known for causing hepatic disease in horses are those containing pyrrolizidine alkaloids. Although pyrrolizidine alkaloid toxicity can cause acute hepatic necrosis, it more often results in hepatic fibrosis (and is discussed as a separate entity under Chronic Hepatic Diseases). Other plants that have been reported to cause hepatic necrosis in horses in North America include kleingrass (*Panicum coloratum*, *P. dichotomiflorum*), lantana, lechuguilla (*Agave lechuguilla*), alsike clover (*Trifolium hybridum*), whitebrush (*Lippia* spp.), sneezeweed (*Helenium* spp.), blue green algae (*Microcystis* and *Nodularia* spp.), lupine (*Lupine* spp.), ryegrass, and some poisonous mushrooms (*Amanita* and *Galerina* spp.).<sup>101</sup>

**Chemical Hepatotoxins** Horses are rarely exposed to hepatotoxic chemicals in sufficient amounts to induce hepatic failure. Potential hepatotoxic chemicals include arsenic (pesticide), carbon tetrachloride (fumigant), chlorinated hydrocarbons (insecticide), carbon disulphide (boticide), pentachlorophenols (wood preservative, herbicide, fungicide), phenol (disinfectant, wood preservative), phosphorus (fertilizer), polybrominated biphenyl (fire retardant), and paraquat (herbicide).<sup>80</sup> All of these cause centrilobular necrosis, except phosphorus, which causes primarily periportal changes.

**Drugs** Pharmaceutical agents can have a wide range of effects on the liver depending on the drug type, dose, frequency, duration, and route of administration; age of the animal; diet; and concurrent treatment.<sup>139</sup> The hepatic damage may be acute or chronic, cholestatic, zonal, vascular, or hypersensitivity mediated. Certain drugs alter hepatocellular permeability without visible injury or loss of function.

Drugs that are intrinsically hepatotoxic reproducibly cause hepatocellular necrosis.<sup>20,80</sup> Examples of intrinsic hepatotoxic drugs that cause zonal centrilobular necrosis include carbon disulfide and carbon tetrachloride.<sup>80</sup> These drugs cause hepatocellular damage in a dose-related manner, and toxicity often results in hepatic failure. Anabolic steroids cause cholestasis with little or no evidence of hepatic damage or inflammation,

resulting in mild icterus, which is completely and rapidly reversible once the drug is discontinued.<sup>20,139</sup> Phenothiazines and macrolide antibiotics (erythromycin) cause cholestatic injury, which is accompanied by significant hepatocellular necrosis and periportal inflammation.<sup>20</sup> Recovery is usually expected after discontinuation of the drug. Some drugs, such as tetracycline, cause fatty infiltration of the liver but rarely cause liver dysfunction.

Idiosyncratic hepatotoxicity has been reported after administration of erythromycin, rifampin, tetracycline, isoniazid, halothane, fluothane, phenothiazines, dantrolene, diazepam, sulfonamides, phenobarbital, phenytoin, and aspirin.<sup>20,80,101</sup> Injury varies from mild focal hepatitis to massive necrosis. Idiosyncratic hepatopathy has a low incidence, is not dose related, and often resolves on discontinuation of the drug. Rarely, progressive liver failure ensues. Some idiosyncratic drug hepatopathies may have a pathogenesis similar to drug allergy; others may be related to biotransformation properties of the liver. For example, if an individual has enhanced biotransformation of a certain drug and the metabolite of the drug is more cytotoxic than the original unaltered drug, then hepatic damage may ensue.

Finally, some drugs induce increased hepatic enzyme activities or alter hepatocellular permeability but do not cause significant hepatic damage or clinical signs. Examples include benzimidazole anthelmintics, phenobarbital, phenylbutazone, and corticosteroids. Compared with humans and dogs, corticosteroids are apparently less likely to cause hepatopathy in horses; however, one report describes steroid hepatopathy in a horse that received an overdose of triamcinolone for treatment of pruritus.<sup>140</sup> Three weeks after the overdose, the horse developed muscle wasting, depression, polydipsia, and laminitis. Mature neutrophilia, lymphopenia, hyperglycemia, increased serum activities of AST and GGT, and multizonal hepatocellular vacuolation were reported.

**Iron Toxicity** Acute, fatal toxic hepatopathy was reported in numerous newborn foals given an oral microbial inoculum.<sup>51</sup> The syndrome is reproducible if *ferrous fumarate* is given orally.<sup>141</sup> The incidence of hepatic failure was highest when the foals were given the inoculum before nursing. Colostrum contains abundant vitamin E, an essential cofactor for glutathione. Glutathione protects against free radical damage, a proposed mechanism for iron toxicity. Thus presumably, foals that are given iron supplements before ingesting colostrum are most susceptible to iron toxicity.<sup>141</sup> This is exacerbated by high serum iron concentrations and high percent saturation of transferrin in foals during the first few 24 hours of life. Supplementation of iron during this time period results in excessive free iron and increased risk of fatal hepatotoxicity.

Clinical signs include HE, icterus, and peracute death. Laboratory abnormalities include increased blood levels of bilirubin, SDH, GGT, and ammonia, and reduced BCAA-to-AAA ratio, decreased glucose, and prolonged PT. At necropsy the liver was abnormally small; histologic study revealed massive hepatic necrosis with blood-filled reticula. Some livers had mild biliary hyperplasia and periportal fibrosis. Supportive therapy may prolong life, but most foals with iron hepatotoxicity die. Those foals that survived recovered fully.

Adult horses are less susceptible to iron toxicity; however, rare cases of haemochromatosis have been reported.<sup>142,143</sup> Haemochromatosis is characterized by tissue damage and dysfunction caused by deposition of hemosiderin in parenchymal cells.<sup>142</sup> Haemochromatosis was diagnosed in three adult

horses by histopathology and use of Prussian blue stain, which detects iron deposition (hemosiderin pigment).<sup>142</sup> Excessive dietary iron was not apparent. All three of the horses had signs and laboratory evidence of liver disease. Serum iron concentration was normal, and there was no evidence of saturation of the iron transport system in the serum. Haemochromatosis was accompanied by bile duct hyperplasia and hepatic fibrosis. All three horses died or were euthanized because of deterioration. Haemochromatosis was diagnosed in a pony receiving approximately four times the daily recommended amount of iron.<sup>143</sup> The diagnosis was confirmed by histopathology (severe periportal fibrosis, hemosiderosis, biliary hyperplasia) and increased serum and liver concentrations of iron.

**Mycotoxins** Mycotoxicosis is more common in ruminants than in horses. The two most common mycotoxins affecting horses are *aflatoxin*, produced by the molds *Aspergillus flavus* and *Aspergillus parasiticus*, and *rubratoxin*, produced by the mold *Penicillium rubrum*. *Aspergillus* spp. grow on a wide variety of feedstuffs if the temperature, moisture, and carbohydrate content are sufficient.<sup>80</sup> Aflatoxins impair protein synthesis and carbohydrate metabolism.

The degree of hepatic damage and extent of clinical signs depend on the duration and extent of exposure to the mycotoxin. Most horses refuse to eat moldy feed; thus hepatic failure is uncommon. Pathologic findings include hepatocellular necrosis, fatty change, biliary hyperplasia, periportal fibrosis, and megalocytosis. No specific treatment for aflatoxicosis exists. Administration of activated charcoal or a cathartic shortly after ingestion may impede absorption. Avoiding moldy feed best prevents mycotoxicosis.

Fumonisin B1, the mycotoxin of *Fusarium moniliforme*, is most frequently associated with contaminated corn and causes leukoencephalomalacia in horses. The mycotoxin also causes hepatocellular necrosis and periportal fibrosis. Although most horses with leukoencephalomalacia have hepatic disease, signs of leukoencephalopathy predominate and hepatic failure is rare. Recovery from hepatic disease is more likely than from the neurologic disease.

### ACUTE BILIARY OBSTRUCTION

Acute obstruction of the common bile duct causes icterus and signs of abdominal pain. Acute biliary occlusion may occur secondary to cholelithiasis (see Cholelithiasis) or colon displacement. Intense icterus, colic, and increased levels of direct bilirubin (>85.5  $\mu\text{mol/L}$ ), GGT (>400 U/L), and bile acids (>150 U/L) were reported in two horses with acute colon displacements.<sup>79</sup> These abnormalities quickly abated after surgical correction of the displaced colon. In a comparative study of cases of colon displacement, 49% of horses with a right dorsal colon displacement had increased GGT, compared with 2% of horses with a left dorsal displacement.<sup>144</sup> Torsion of the left lobe of the liver was the cause of acute colic, hepatic congestion, necrosis, and focal hepatitis in a 14-year-old Arabian gelding.<sup>145</sup> Resection of the affected lobe resulted in complete recovery.

### HYPERLIPEMIA AND HEPATIC LIPOSIS

*Hyperlipemia*, defined as a serum triglyceride concentration in excess of 500 mg/dl, occurs primarily in ponies and Miniature Horses and donkeys and may lead to fatty infiltration of the liver, often accompanied by clinical signs of liver disease and a poor prognosis. *Hyperlipidemia* refers to an increase in serum triglyceride concentration (generally less than 500

mg/dl) without grossly lactescent blood or fatty infiltration of the liver. Obesity, stress, inability to satisfy metabolic energy demands, and hormonal imbalance are the major precipitating factors for hyperlipemia.<sup>146-151</sup>

**Epidemiology and Clinical Signs** Ponies (especially Shetland ponies and mare ponies), Miniature Horses, and donkeys are most susceptible to hyperlipemia. Rarely, other breeds, such as the Quarter Horse, Paso Fino, and Tennessee Walking Horse may be affected. Affected ponies are usually obese, have a recent history of stress or weight loss, and are in late gestation or early lactation during the winter months.<sup>58</sup> In Miniature Horses and donkeys, hyperlipemia can occur at any age and frequently develops as a sequela to an underlying primary illness lasting several days. The most commonly reported primary diseases predisposing Miniature Horses to hyperlipemia are enterocolitis, endotoxemia, parasitism, pituitary dysfunction, azotemia, and neonatal septicemia.<sup>150,151</sup> The onset of clinical signs of hyperlipemia is often acute and includes icterus, anorexia, weakness, severe depression, ataxia, muscular weakness, recumbency, diarrhea, mild colic, fever, and dependent edema.<sup>58,146,148</sup> In severe cases, clinical signs of hepatic failure may prevail (see Clinical Signs of Hepatic Insufficiency). Sudden death because of hepatic rupture may occur.<sup>147</sup> Signs of predisposing primary disease in Miniature Horses may overshadow signs of hyperlipemia.

**Pathogenesis** The liver serves a unique role in energy homeostasis (see Physiology), especially in large animals in which volatile fatty acids, and not glucose, are a major energy source. Glucose is primarily manufactured in the liver from fatty acids and amino acids and is stored as glycogen for future use. If intake is decreased or energy demands are increased, then glycogen stores become depleted and the major source of energy is provided by fatty acid oxidation. Obesity sets the stage for hyperlipemia by providing excessive adipose tissue stores of fatty acids, available for immediate and rapid mobilization. Fatty acid mobilization is usually first triggered by a stress or inability to maintain energy homeostasis. Concurrent or underlying primary diseases such as enterocolitis, azotemia, infection, parasitism, or neoplasia, as well as any stressful event, such as transport or weaning, may precipitate fatty acid mobilization. Stress increases the release of catecholamines and glucocorticoids, which stimulate fatty acid release from the adipose tissue. A negative energy balance, as may occur during late gestation, early lactation, starvation, or secondary to anorexia induced by some other primary disease, exacerbates hyperlipemia by further promoting fatty acid mobilization.

After lipolysis of adipose tissue triglyceride occurs, free fatty acids, nonesterified fatty acids, and glycerol are released into the blood. Glyceride, fatty acids bound to albumin, and nonesterified fatty acids are carried to the liver, where the glyceride is converted to glucose. In the liver, free fatty acids may be oxidized to acetyl CoA and used in the tricarboxylic acid cycle, used in gluconeogenesis, resynthesized to triglycerides and stored in the liver, or used to make triglycerides that are released into the sinusoidal blood as VLDLs (see Figure 16-3). Ponies with hyperlipemia have larger-diameter VLDLs containing greater concentrations of triglycerides than normal ponies.<sup>152,153</sup> Thus hyperlipemia in ponies and Miniature Horses is from efficient hepatic synthesis of triglycerides from mobilized free fatty acids, with subsequent secretion of triglyceride-laden VLDL into the blood. Endothelial lipoprotein lipase is the rate-limiting enzyme responsible for the removal of VLDL from the blood

back into adipose tissue. In hyperlipemic ponies, the activity of lipoprotein lipase is not impaired and in fact is increased several fold.<sup>167,168</sup> Thus it is the overproduction of VLDL by the liver, not impairment of their removal, which is primarily responsible for hyperlipidemia in ponies.<sup>152,153</sup>

If the oxaloacetate supply is limited when free fatty acids are mobilized to the liver, acetyl CoA is shuttled away from the tricarboxylic acid cycle and used to make ketone bodies. Because the equine liver is quite efficient in synthesizing triglycerides and exporting VLDL, hepatic lipidosis and ketosis are less common than in other species.<sup>149</sup> However, if fatty acid mobilization and synthesis of triglycerides exceed oxidation and VLDL secretion, then hepatic lipidosis ensues. Fat infiltration disrupts hepatic function, and excessive amounts of fat in the liver can result in hepatic failure and even hepatic rupture.<sup>147</sup>

Hormonal factors may contribute to the development of hyperlipemia and hepatic lipidosis. Insulin normally impedes the development of hyperlipemia by inhibiting tissue hormone-sensitive lipase, the enzyme responsible for lipolysis of adipose tissue. Insulin also curtails the development of hyperlipemia by stimulating gluconeogenesis in the liver and by activating lipoprotein lipase, the enzyme responsible for uptake of VLDL by adipose tissue. Despite often-normal insulin levels, ponies appear to have tissue insulin insensitivity compared with horses.<sup>147</sup> Fasting in donkeys has been shown to cause a reduction in tissue sensitivity to insulin.<sup>154</sup> Glucocorticoids, catecholamines, adrenocorticotropic hormone, thyroid stimulating hormone, growth hormone, antidiuretic hormone, and progesterone may contribute to the development of hyperlipemia by opposing the biologic actions of insulin (see Figure 16-3). This may account for the high incidence of hyperlipemia during periods of increased cortisol levels (stress, pituitary adenoma, late pregnancy) and increased progesterone (pregnancy). In ponies, norepinephrine linearly stimulates the release of free fatty acids from adipose tissue, an effect that does not occur in horses.<sup>155</sup> Considering the unique effects of insulin and catecholamines on fat metabolism in ponies, it is not surprising that ponies are more susceptible than horses to the development of hyperlipemia.

Vascular thrombosis can occur secondary to hyperlipemia and fat embolism and may be seen in the lung, kidney, brain, and subcutaneous vessels. Subcutaneous thrombosis causes dependent edema. Renal nephrosis and necrotizing pancreatitis are sometimes present.<sup>58,147</sup> Renal disease most likely is a sequela of occlusive thrombosis. The exact cause of pancreatitis is not known; however, hyperlipemia precedes pancreatitis. Researchers speculate that excessive lipid is deposited in and around the pancreas, which is subsequently hydrolyzed by pancreatic lipase and released as free fatty acids. Free (unbound to albumin) fatty acids are cytotoxic; when the albumin-binding capacity is exceeded, pancreatic vascular injury occurs.<sup>156</sup>

Azotemia prevents lipid removal from the blood by inhibiting lipoprotein lipase. The degree of hyperlipidemia is directly correlated with the degree of azotemia.<sup>157</sup> Almost half of hyperlipemic Miniature Horses are azotemic.<sup>150,151</sup> Compared with ponies and Miniature Horses, hyperlipemia rarely develops in horses, though *hyperlipidemia* (triglyceride <500 mg/dl) may develop during azotemia.<sup>148,157</sup> Mild hepatic lipidosis may ensue, but hyperlipidemia rarely results in clinically recognizable disease.

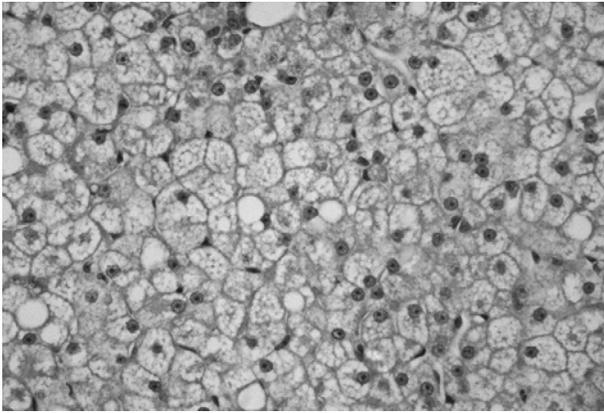

**Diagnosis** Hyperlipemia should be considered in the differential diagnosis for any obese pony or Miniature Horse

with clinical signs of severe depression, anorexia, ataxia, and icterus. The normal triglyceride level in horses and ponies should be less than 85 mg/dl but may be up to 290 mg/dl in healthy donkeys and up to 250 mg/dl in healthy pregnant pony mares.<sup>153</sup> In hyperlipemia, the blood grossly appears opalescent (Figure 16-8) and the concentrations of all lipids are increased, especially triglycerides (>500 mg/dl), nonesterified fatty acids, and VLDLs. Laboratory evidence of hepatic disease may include increased serum activity of SDH, GGT, increased concentrations of serum bile acids, bilirubin, and ammonia, as well as decreased glucose, BUN, and albumin.<sup>146</sup> In hyperlipemic Miniature Horses, only about half of affected patients have significant hepatic impairment.<sup>150</sup> The BSP half-life is prolonged. Oral and intravenous glucose challenge tests may reveal glucose intolerance because of insulin insensitivity. Metabolic acidosis is frequent, and ketoacidosis should be suspected if the anion gap is increased. Lipemia may increase serum creatinine values falsely and interfere with accurate determination of other serum chemistries. A definitive diagnosis of hepatic lipidosis is confirmed by the concurrent demonstration of increased blood concentrations of lipid, laboratory evidence of hepatic dysfunction, and ultrasonographic or histopathologic findings of fatty infiltration in the liver (Figure 16-9). The serum concentrations of creatinine and electrolytes should be determined as an adjunct to therapy. Because of the incidence of hyperlipemia in ill Miniature Horses and donkeys, monitoring blood triglyceride levels would facilitate early recognition of hyperlipidemia in these patients.

Necropsy findings in affected ponies include widespread fatty change in the liver, skeletal muscle, kidney, adrenal cortex, and myocardium.<sup>58,147</sup> The liver and kidney are enlarged, yellow, friable, and greasy. One of every five ponies with hepatic lipidosis has a ruptured liver.<sup>147</sup> Microscopically, hepatocytes are engorged with lipid. The nucleus is often displaced, and hepatocellular necrosis may ensue.

**FIGURE 16-8** Hyperlipemia. The spin hematocrit tube on the right is from a miniature horse with hyperlipemia. The hematocrit tube on the left is from an unaffected horse.

**FIGURE 16-9** Histopathology of the liver: fatty liver.

**Treatment** The major therapeutic objectives for hyperlipemia and hepatic lipidosis include the following:

1. Treatment of hepatic disease
2. Improvement of energy intake and balance
3. Elimination of stress or treatment of concurrent disease
4. Inhibition of fat mobilization from adipose tissue
5. Increased triglyceride uptake by peripheral tissues

Treatment of hepatic failure is addressed elsewhere (see Treatment of Hepatic Insufficiency). Concentrated carbohydrate feed, such as molasses-coated grain and high-quality pasture or hay, should be encouraged. Anorectic ponies should receive 5% dextrose as a continuous infusion at a rate of 2 ml/kg/hour, and enteral nutrition should be attempted. NutriFoal, NutriPrime (KenVet, Ashland, OH), and Osmolyte HN (Ross Laboratory, Columbus, OH) have successfully been used as sources of enteral nutrition in hyperlipemic Miniature Horses.<sup>150</sup> If enteral nutrition is not possible, then partial parenteral nutrition should be provided with equal volumes of 50% dextrose and 8.5% amino acids.<sup>150</sup> Monitoring blood glucose concentrations closely is mandatory, because some ponies have glucose intolerance (and excessive glucose will worsen acidosis and induce hypokalemia). Weaning suckling foals may help reduce stress and the energy demand imposed on lactating mares. Concurrent diseases amenable to therapy, such as parasitism, chronic infection, and musculoskeletal disease, should be appropriately treated with anthelmintics, antimicrobials and anti-inflammatory agents, or analgesics, respectively.

In addition to supplying immediate energy, glucose therapy stimulates the release of insulin. Concurrent carbohydrate and insulin administration have been used successfully to manage hyperlipemia in ponies.<sup>146,158</sup> The following regimen has been suggested for a 200-kg pony<sup>158</sup>: On day 1 the patient is administered 30 IU of protamine zinc insulin IM and 100 g of glucose orally (both twice daily). On day 2 the patient is administered 15 IU of insulin intramuscularly, twice daily, and 100 g of galactose once. Galactose is slowly converted to glucose; thus lactic acid production is minimized. This regimen may be continued for 3 days. Blood glucose and insulin concentrations should be closely monitored. Insulin treatment may not lower triglyceride levels, but it may help control hyperglycemia if partial parenteral nutrition is provided.<sup>150</sup> Nicotinic acid, thought to act by inhibiting hormone-sensitive lipase, has been used in cattle with fatty liver; however,

nicotinic acid has not been evaluated in ponies with hepatic lipidosis.

Heparin potentiates the activity of lipoprotein lipase and may increase triglyceride removal from the blood. However, because lipoprotein lipase activity is already at maximum rate in affected ponies, whether or not heparin provides additional benefit is questionable.<sup>153</sup> Recommended dosages range between 40 to 250 IU/kg twice daily.<sup>146,158</sup> Because of the potential for hemorrhage, heparin therapy should be used with discretion and monitored by daily hemostatic testing. If azotemia, acidosis, and electrolyte abnormalities are present, then appropriate fluid therapy is suggested.

Lipotropic agents such as choline and methionine are unlikely to be useful in horses with hyperlipemia, because triglyceride synthesis in the liver is usually sufficient.

**Prognosis and Client Education** The prognosis for hyperlipemia in equids is poor. Mortality has been estimated to occur in 60% to 100% of affected ponies.<sup>146,147</sup> Survival rate is reportedly better in Miniature Horses, and death often results from the underlying disease and not fatty liver failure.<sup>150,151</sup> Most Miniature Horses with blood triglyceride levels less than 1200 mg/dl survive.<sup>151</sup> Prevention is achieved best by providing appropriate nutrition without inducing obesity while avoiding stress and practicing good routine health care.

## CHRONIC HEPATIC DISEASES

The distinction between acute and chronic hepatic disease is difficult. Often horses with chronic liver disease display abrupt onset of signs. With the possible exception of hyperglobulinemia, no serum biochemical parameters reliably distinguish acute from chronic hepatocellular disease. Regardless of the cause or site of injury, histopathologic evidence of fibrosis develops only after chronic injury.<sup>159</sup> The following diseases are classified as chronic based on the presence of fibrosis in the liver or because the cause is known to result in gradual hepatic dysfunction.

### CHRONIC MEGALOCYTTIC HEPATOPATHY

Megalocytic hepatopathy occurs worldwide and is the most common cause of chronic liver failure in horses in certain parts of the United States.<sup>15</sup> It is caused by the ingestion of *pyrrolizidine alkaloid*-containing plants. The intoxication typically results in the delayed onset of chronic, progressive liver failure.

**Clinical Signs** The development of clinical signs of liver disease is usually delayed 4 weeks to 12 months after the consumption of pyrrolizidine alkaloid-containing plants. However, individual differences in susceptibility occur (not all horses consuming the plants develop clinical signs).<sup>160</sup> The onset of obvious hepatic failure, characterized by HE and photosensitization, usually is abrupt and occurs late in the disease despite the time interval since ingestion. Premonitory signs of insidious onset may include anorexia, weight loss, exercise intolerance, and mild to moderate icterus. Diarrhea, edema, polydipsia, pruritus, laryngeal hemiparalysis, and hemolysis also have been reported to occur late in the disease.<sup>63,80,160</sup> Sometimes oral ulcers and halitosis develop.<sup>161</sup> Although uncommon, if sufficient consumption occurs during a single exposure, then abortion or clinical signs of liver disease may develop acutely.

**Epidemiology and Pathogenesis** Numerous species of pyrrolizidine alkaloid-containing plants exist (Table 16-3).

TABLE 16-3

Pyrrolizidine Alkaloid-Containing Plants		
Species Name	Common Name	Alkaloids
<i>Senecio jacobea</i>	Tansy or common ragwort, stinking Willie	Jacobine, jacodine, senecionine
<i>Senecio riddellii</i>	Reddell's groundsel	Ridelline
<i>Senecio longilobus</i>	Threadleaf groundsel	Longilobine
<i>Senecio vulgaris</i>	Common groundsel	Senecionine, seneciphylline, retrorsine
<i>Senecio spartioides</i>	Broom groundsel	Seneciphylline
<i>Senecio integerrimus</i>	Lamb's tongue groundsel	Integerrimine
<i>Amsinckia intermedia</i>	Fiddleneck, fireweed, tarweed	
<i>Crotalaria species</i>	Rattlebox	Monocrotaline, fulvine, crispatine
<i>Echium plantagineum</i>	Viper's bugloss	
<i>Heliotropium europaeum</i>	Common heliotrope or potato weed	Heliotrine, lasiocarpine

In the United States, *Senecio jacobea*, and *S. vulgaris* are found primarily along the Pacific Coast and in the western states, *Amsinckia intermedia* in the West, and *Crotalaria sagittalis* (Figure 16-10), *Crotalaria spectabilis*, and *Heliotropium europaeum* primarily in the Southeast.

Pyrrolizidine alkaloid-containing plants are not palatable, and horses will not typically consume them unless pastures are heavily contaminated or no alternative feed source exists. Some herbicides may increase palatability.<sup>80</sup> Pyrrolizidine alkaloids are stable, and much intoxication occurs after ingestion of contaminated hay, pellets, or grain. *S. vulgaris* is a common contaminant in alfalfa hay, especially at the first cutting. Not all parts of the plant contain pyrrolizidine alkaloids, and the concentration may vary with the season.<sup>133</sup> *Amsinckia* and *Crotalaria* spp. concentrate pyrrolizidine alkaloids in their seeds; thus intoxication may occur after ingestion of contaminated oat hay or grain screenings.<sup>80</sup>

Horses and cattle are relatively sensitive to pyrrolizidine alkaloid intoxication compared with goats and sheep. Consumption of the plants at a dose of 2% to 5% of the body weight, fed at one time or over a few days, can result in acute toxicity.<sup>80</sup> The effects of pyrrolizidine alkaloids are cumulative; thus it is more common for toxicity to occur after chronic low-level exposure. Hundreds of different pyrrolizidine alkaloids exist, but only a few have proved to be toxic (see Table 16-3). The toxic pyrrolizidine alkaloids vary among plants, but they all cause the same basic lesion. Ingested pyrrolizidine alkaloids are carried to the liver via the portal circulation and are metabolized by the microsomal enzymes to toxic pyrrole derivatives.<sup>161</sup> Drugs that induce microsomal enzymes, such as mixed function oxidases, will increase the toxicity of pyrrolizidine alkaloids. The pyrroles are chemically highly reactive and capable of alkylating nucleic acids and protein; consequently the pyrroles inhibit cellular replication and protein synthesis. Because the cells cannot divide, hepatocytes enlarge, forming *megalocytes*. When the *megalocytes* die, fibrosis ensues. When fibrosis becomes extensive, the liver shrinks, develops a firm texture, and failure is inevitable.

Hepatocytes surrounding the portal triads are usually affected first. When acute massive consumption exists, extensive centrilobular hepatocellular necrosis occurs. Fibrosis around the portal vessels can cause portal hypertension, ascites, and diarrhea. Endothelial cell swelling in the portal vein

FIGURE 16-10 Picture of *Crotalaria* spp. plant containing toxic pyrrolizidine alkaloids. (Courtesy Susan White.)

is especially common with *Crotalaria* spp., further promoting veno-occlusion. Despite periportal fibrosis and veno-occlusion, portal hypertension rarely develops in horses, although it is a common manifestation of pyrrolizidine alkaloid toxicity in cattle.<sup>80</sup> Additional pathologic findings include myocardial necrosis, colitis, widespread hemorrhages, and adrenal cortical hypertrophy.<sup>63</sup> The toxic pyrrolizidine alkaloid in *Crotalaria* spp., monocrotaline, also is pneumonotoxic and may cause hydrothorax, pulmonary edema, epithelialization, and pulmonary arteritis.<sup>161</sup>

Pyrrolizidine alkaloids are rapidly excreted in body fluids such as milk and urine, and they can pass the placenta.<sup>161</sup> A report describes pyrrolizidine alkaloid toxicosis in a 2-month-old foal with a dam that consumed pyrrolizidine alkaloid-containing plants during pregnancy.<sup>162</sup>

**Diagnosis** A presumptive diagnosis of megalocytic hepatopathy can be made from history of exposure to pyrrolizidine alkaloids, clinical signs, and laboratory evidence of hepatic disease. Early in the disease, SDH and AST may be increased, but by the time clinical signs develop, these enzymes are often normal or only mildly increased. Because fibrosis occurs periportal, GGT, ALP, and serum bile acids concentration are persistently increased. Bilirubin may be increased and the BCAA-to-AAA ratio may be decreased.<sup>163</sup> The BSP half-life is

prolonged and serum bile acids are usually increased late in the disease.<sup>63</sup>

A definitive diagnosis of pyrrolizidine alkaloid intoxication requires a liver biopsy. The histopathologic findings of megalocytosis, biliary hyperplasia, and fibrosis are essentially pathognomonic. Pyrrolizidine alkalosis must be distinguished from aflatoxicosis and alsike clover toxicity. The latter two toxicities are rare compared with pyrrolizidine alkaloids and cause periportal fibrosis and biliary epithelial hyperplasia without megalocytosis. Pyrrolizidine alkaloids can be detected in feed by high-performance liquid chromatography.<sup>63</sup> Some pyrrolizidine alkaloids can be identified in liver tissue. Unfortunately, because of the prolonged delay in development of clinical signs, often the original source of contamination remains unidentified.

**Treatment and Prognosis** No specific antidote for pyrrolizidine alkaloid intoxication exists. Despite general supportive care, death usually occurs within 10 days of the onset of obvious clinical signs of hepatic failure. A serum bile acid concentration greater than 50  $\mu\text{mol/L}$  is suggestive of a grave prognosis.<sup>63</sup> Because regeneration is not possible, if extensive megalocytosis and fibrosis are present, then treatment is not warranted. Treatment with BCAA may decrease the severity of neurologic signs but does not prevent death.<sup>63</sup> If clinical signs or histologic changes are mild, then a low-protein (grass or oat hay), high-energy (molasses concentrate grain) ration may be beneficial.

Attention should be directed toward asymptomatic horses that also may have consumed the plants. The source of contamination should be identified by locating the plant in hayfields or pasture or by analysis of feed. Progress can be monitored by serial liver enzyme quantitation and biopsies. Serum GGT activity may be helpful in detecting subclinical cases of pyrrolizidine alkaloid toxicity.<sup>164</sup>

### CLOVER POISONING

Alsike clover (*Trifolium hybridum*) and red clover (*Trifolium pratense*) poisoning rarely occurs in horses pastured or fed hay containing these types of clover.<sup>165-167</sup> Both photodermatitis and liver disease have been reported. Signs of liver disease may become apparent after 2 weeks of consumption and when the diet consists of at least 20% of clover.<sup>165</sup> The likelihood of poisoning reportedly is greater when the pasture is heavily covered with the clover in full bloom during wet seasons. Although the toxic principle is not known, the disease is characterized histopathologically by the presence of biliary hyperplasia and periportal fibrosis. Minimal parenchymal lesions distinguish alsike clover poisoning from pyrrolizidine alkaloid toxicity.

### CHRONIC ACTIVE HEPATITIS

Chronic active hepatitis in horses is an idiopathic, chronic, progressive hepatopathy characterized histopathologically by biliary hyperplasia, with concomitant periportal or biliary inflammation (or both) and associated hepatocellular damage.

**Clinical Signs** The onset of clinical signs of CAH is insidious. Signs are compatible with progressive liver failure and include depression, exercise intolerance, weight loss, anorexia, colic, icterus, and fever. The signs may be intermittent. Although uncommon, some horses with CAH have moist exfoliative coronary dermatitis.<sup>59</sup>

**Cause and Pathogenesis** The exact cause of CAH in horses is not known. A similar syndrome occurs in human beings

and has been linked to autoimmune disease, chronic hepatitis B virus infection, non-A and non-B (viral) hepatitis, Wilson's disease,  $\alpha_1$ -antitrypsin deficiency, and drug allergy.<sup>168</sup> Human beings with autoimmune-associated CAH often have marked polyclonal gammopathy and hepatic actin, smooth muscle, and antinuclear antibodies.<sup>168</sup> Histologic study of the liver reveals mononuclear and plasma cell infiltrates, large areas of necrosis, and fibrosis. Extrahepatic signs of autoimmune disease, including dermatitis, arthritis, and glomerulonephritis, may be present. Some horses with CAH have polyclonal gammopathy, but this is a nonspecific finding in many types of chronic hepatic disease and is not necessarily indicative of autoimmunity. Occasionally, horses with CAH have predominantly plasma and mononuclear cell infiltrates in the liver, suggesting heightened humoral activity. The presence of coronary dermatitis in horses with CAH may be a manifestation of autoimmune disease, although this has not been confirmed by immunohistologic staining. No reports have surfaced of antinuclear antibodies in horses with CAH. In addition, viral hepatitis, Wilson's disease, and  $\alpha_1$ -antitrypsin deficiency have not been documented in these animals. Idiosyncratic drug hypersensitivity has been reported in horses, although not as a consistent feature of CAH.

In addition to the possibility of an autoimmune or hypersensitivity reaction, CAH in horses may be a manifestation of chronic cholangitis. Many horses with CAH have a suppurative inflammatory response involving the biliary system, in addition to periportal inflammation and hepatocellular necrosis.<sup>59</sup> Often the cholangiohepatitis is accompanied by biliary hyperplasia, fibrosis, and cholestasis. In some cases, coliform organisms have been isolated from the liver, suggestive of ascending infection from the gastrointestinal tract. In a large number of horses, histopathologic evidence of fibrosis, acute inflammation, and hepatocellular necrosis is seen, but no specific cause can be determined.

**Diagnosis** The diagnostic criteria for CAH in human beings include abnormally increased serum transaminase activity for longer than 6 months, abnormal immunologic findings, and characteristic histopathologic findings.<sup>168</sup> In horses, serum SDH and AST activity may be mildly increased, but GGT and ALP are often markedly increased in CAH. The serum bile acid, total protein, and bilirubin (especially the direct-reacting fraction) concentrations may be increased. Bilirubinuria may be present, and the BSP half-life is usually prolonged. Hematology may reveal an inflammatory leukogram, with or without a left shift.<sup>59</sup> Immunodiagnostics, including antinuclear antibody titer and anti-immunoglobulin immunofluorescent staining of skin lesions, may help confirm an autoimmune phenomenon.

In the face of clinical signs and the demonstration of significant laboratory findings indicative of liver disease, a liver biopsy should be obtained (see Liver Biopsy). A sample should be submitted for histopathologic examination and for bacterial isolation and antimicrobial sensitivity testing. The definitive diagnosis of CAH depends on the presence of characteristic histopathologic findings. Progressive periportal hepatocellular necrosis obscures and distorts the limiting plate, the cord of hepatocytes that surrounds the portal triad. As this destructive process continues, bands of necrotic hepatocytes and inflammatory cells connect one liver lobule to another or extend from the portal tract to the central vein. This feature is called *bridging necrosis*. As bridging necrosis progresses, fibrosis and cirrhosis prevail. Mononuclear cells may be the predominant

inflammatory infiltrate; however, neutrophils predominate if cholangiohepatitis is a feature. Biliary hyperplasia may be evidence of concurrent cholangiohepatitis.

**Treatment** General supportive care for hepatic failure (see Treatment of Hepatic Insufficiency) is indicated whenever clinical signs are apparent. Specific therapy for CAH depends on the histopathologic findings. If the liver biopsy reveals abundant plasma cells, or other diagnostic tests suggest autoimmune or hypersensitivity disease, then corticosteroid therapy may be beneficial. In human beings with autoimmune-associated CAH, corticosteroids improve appetite and attitude, reduce inflammation and serum transaminase activity, and hinder fibrosis. Despite short-term improvement, corticosteroids do not alter survival time and the long-term prognosis remains poor. In horses, initial treatment with dexamethasone at 0.05 to 0.1 mg/kg/day for 4 to 7 days, followed by a gradual reduction in dose over 2 to 3 weeks, has been suggested.<sup>80</sup> Additional treatment with prednisolone (1 mg/kg/day) may be necessary for several weeks. In human beings, azathioprine (2 mg/kg every 24 hours) has also been used to control cases refractory to steroids,<sup>168</sup> although recent studies suggest that oral bioavailability of this drug in the horse is quite low, ranging between 1% to 7%.<sup>169</sup> If the liver biopsy reveals cholangitis, then long-term (4 to 6 weeks) antimicrobial therapy is indicated. The choice of antimicrobial is best determined by culture and sensitivity results. Antimicrobials that are excreted in bile, such as chloramphenicol, ceftiofur, ampicillin, or broad-spectrum antimicrobials such as penicillin and gentamicin, are recommended. The decision for corticosteroid therapy should be carefully scrutinized in these cases of CAH.

**Prognosis** The prognosis for CAH is variable, depending on the cause and duration of disease. The presence of cirrhosis warrants a grave prognosis.

## CHOLELITHIASIS

*Cholelithiasis*, or the formation of biliary calculi, occasionally results in hepatocellular disease in horses. A *cholelith* is a calculi that develops anywhere along the biliary pathway. A *hepatolith* and *choledocholith* refer to calculi within intrahepatic ducts and the common bile duct, respectively. Hepatic failure and clinical signs occur when multiple stones are present or when they occlude the common bile duct.

**Clinical Signs** Cholelithiasis occurs most commonly in adult, middle-aged horses (6 to 15 years old), although horses as young as 3 years old have been affected.<sup>50,125,170</sup> Broodmares may be predisposed.<sup>125</sup> The most frequently reported clinical signs include icterus, abdominal pain, fever, depression, and weight loss.<sup>50,125,170-172</sup> Signs of hepatic failure, such as photosensitization, petechial hemorrhages, diarrhea, and HE, have been reported less frequently.<sup>50,125,170-172</sup> Clinical signs are often intermittent unless the common bile duct is occluded, whereupon persistent abdominal pain prevails.

**Pathogenesis** The initial step in the formation of a cholelith is precipitation or aggregation of normally soluble constituents of bile: bilirubin, cholesterol, or bile acids. In human beings, 75% of bile stones are composed principally of cholesterol and 25% are composed principally of calcium bilirubinate. The majority of calcium bilirubinate choleliths in human beings are associated with bacterial cholangitis.<sup>4,173</sup> Most choleliths in horses consist principally of calcium bilirubinate and are associated with cholangitis.<sup>50,125,170</sup>

The exact sequence of events leading to precipitation of bilirubin in bile is not entirely known; however, soluble,

conjugated bilirubin becomes unconjugated by the enzyme  $\alpha$ -glucuronidase and combines with calcium, a normal constituent of bile, to form calcium bilirubinate. Excessive formation of unconjugated bilirubin causes the formation of columnar complexes of calcium bilirubinate that subsequently precipitate. The bile duct epithelium, hepatocytes, and certain bacteria synthesize  $\beta$ -glucuronidase. The concentration of  $\beta$ -glucuronidase is normally very low in bile, and an inhibitor, glucaro-1,4-lactone, is usually present.

Whether bacterial, biliary, or hepatic in origin, increased bile concentration of  $\beta$ -glucuronidase has been demonstrated in human beings with obstructive cholangitis.<sup>4</sup> Because most choleliths in horses are composed of calcium bilirubinate and many affected horses with cholelithiasis have documented bacterial cholangitis, it seems logical that cholelith formation in horses most likely occurs subsequent to bacterial infection. Furthermore, because enteric organisms are isolated most commonly from horses with cholelithiasis, infection presumably ascends from the intestinal tract. Horses may be more prone to ascending infection because they lack an exit port sphincter to prevent backflow of intestinal contents into the biliary tree. If bile flow is decreased for any reason, then retrograde flow and infection are likely. However, the correlation of infection with cholelithiasis in horses does not necessarily prove causation. Another plausible explanation is the initial presence of a stone, precipitating cholestasis and subsequent infection. Despite its origin, cholangitis is the likely cause of fever. Chronic cholestasis because of the presence of choleliths results in increased biliary pressure, a likely cause of abdominal discomfort. If biliary pressure is not resolved, then pressure-induced periportal hepatocellular necrosis with subsequent fibrosis ensues.

At necropsy, tissues are icteric and the liver is mottled in appearance. The liver appears enlarged after acute biliary obstruction, and it appears shrunken and firm with chronic cholestasis. Choleliths range in size, are single or multiple in number, usually green-brown in color (bilirubinate), and smooth textured. Histopathologic study reveals periportal hepatocellular necrosis, fibrosis, biliary stasis, and biliary hyperplasia. Suppurative cholangitis is often present. Organisms isolated from the liver or bile consist predominately of gram-negative coliforms, though *Enterococcus* spp. has also been reported.<sup>50,125,170</sup> Nonobstructive choleliths are subclinical and only recognized at necropsy.

**Diagnosis** Cholelithiasis should be considered in the differential diagnosis in any horse with a history of fever, icterus, and abdominal pain, especially if accompanied by signs of hepatic failure. Hematology often reveals leukocytosis because of mature neutrophilia, especially if cholangitis is present.<sup>50,125,170</sup> Other nonspecific but frequent findings include hyperproteinemia and hyperfibrinogenemia.<sup>50,125,170</sup> The most common abnormal laboratory findings that suggest cholestatic liver disease include markedly increased GGT (>15 times normal); increased serum bile acids concentration; hyperbilirubinemia, with the direct-reacting fraction greater than 25% of the total value; and bilirubinuria.\* Although not liver specific, ALP often is increased greatly. Less commonly, SDH, ARG, AST, and LDH-5 are mildly to moderately increased and clotting times and the BSP half-life are prolonged.<sup>50,125,170-174</sup> Affected horses frequently have nonseptic peritonitis or peritoneal transudate.<sup>170</sup>

\*References: 50, 125, 170, 171, 173, and 174.

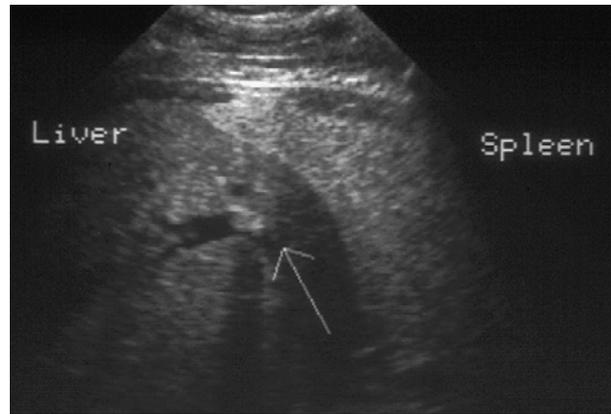

Although no single blood test was specific for cholelithiasis, hepatic ultrasonography or biopsy accurately predicted a diagnosis of cholelithiasis in all cases reviewed.<sup>170</sup> In retrospective studies of cholelithiasis, 75% of the cases had visibly dilated bile ducts, which appear as thin-walled, anechoic structures.<sup>50,125,170,175</sup> This finding contrasts with normal horses, in which the bile ducts are not detectable. Dilatation of intrahepatic biliary radicals lying adjacent to portal venous structures may be evident.<sup>175</sup> The liver may appear enlarged with increased echogenicity. Hepatoliths, which are observed in 60% of cases, are found most frequently at the level of the right sixth to seventh intercostal space,<sup>50,125,170,175</sup> appear as hyperechoic foci within the bile ducts, and may cast acoustic shades (Figure 16-11). Determination of obstruction of the common bile duct in horses is difficult, because the common bile duct cannot be seen by transabdominal ultrasonography. Hepatobiliary scintigraphy may be useful to document obstruction of biliary excretion.<sup>176</sup> Otherwise, choledocholiths can only be detected via palpation during exploratory celiotomy.

Obtaining a liver biopsy is useful for diagnostic, therapeutic, and prognostic purposes. The histopathologic findings of periportal fibrosis, biliary stasis and hyperplasia, and cholangitis are not pathognomonic for cholelithiasis; however, a liver biopsy may help rule out other causes of biliary stasis such as CAH or megalocytic hepatopathy. Concentric fibrosis around intrahepatic bile ducts is strong evidence of occlusion of the common bile duct (Figure 16-12).

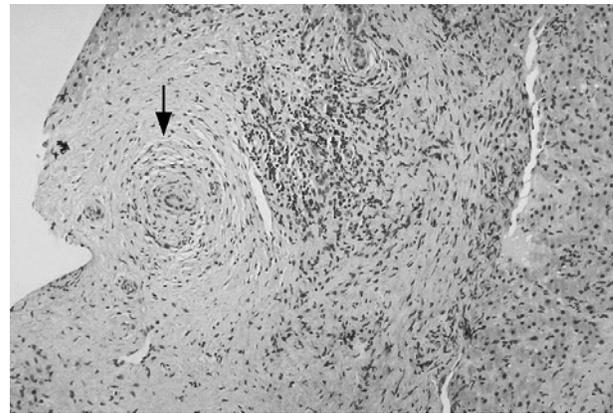

**Treatment** If clinical signs of liver failure are present, general supportive care should be provided (see Treatment of Hepatic Insufficiency). Long-term (4-6 weeks) treatment with antimicrobials is indicated. Antimicrobial selection should be guided by clinical response and by bacterial isolation and sensitivity results obtained either via a liver biopsy or culture of the bile or cholelith obtained at surgery. Penicillin-gentamicin, ceftiofur, chloramphenicol, ampicillin, enrofloxacin, metronidazole, and trimethoprim-sulfonamide have been used successfully<sup>50,125,170</sup>; however, recent reports indicate resistance of isolates from affected horses to trimethoprim-sulfonamide.<sup>170</sup> Antimicrobial therapy should be continued until complete resolution of clinical signs and laboratory evidence of inflammation. It has been suggested that antimicrobial therapy should be continued until the serum GGT activity is normal.<sup>125</sup>

Dissolution of cholesterol choleliths in human beings has been successful with long-term administration of bile acids.<sup>20</sup> Because choleliths in horses are composed primarily of biliary pigments, treatment with bile acids would most likely be unavailing and potentially harmful. Evidence indicates that DMSO dissolves calcium bilirubinate stones in human beings; thus its use may be beneficial to horses with cholelithiasis.<sup>125</sup> Use of other anti-inflammatory drugs, such as flunixin meglumine, may help speed resolution of hepatic and biliary inflammation and thus restore biliary excretion.

Surgical intervention may be necessary if the common bile duct is occluded. The decision for surgery is difficult because no direct way exists to determine the extent of occlusion of the common bile duct in horses. In one report, horses with discrete occlusive choledocholiths had persistent fever; more persistent, though mild and intermittent, abdominal pain; and significantly greater serum bile acid concentrations than did horses that were managed successfully with medical therapy.<sup>170</sup> Although cholelithotripsy may be accomplished in human beings percutaneously, via endoscopy or laparotomy,

**FIGURE 16-11** Ultrasound image of the liver showing a hepatolith (*arrow*) casting an acoustic shadow in a dilated bile duct in a horse with obstructive cholelithiasis.

**FIGURE 16-12** Histopathology of the liver: concentric fibrosis (*arrow*) around a bile duct characteristic of obstruction of the common bile duct.

exploratory laparotomy currently is the only available means for reducing a common bile duct obstruction in horses. Choledocholithotripsy (the crushing of choleliths in the bile ducts) and choledochotomy (surgical formation of an opening into the bile duct) have been performed successfully in the horse.<sup>173,177,178</sup> In one recent report on horses, external massage of the common bile duct, without choledochotomy, successfully dislodged choledocholiths into the duodenum in all of the cases in which it was attempted.<sup>170</sup> If multiple hepatoliths are distributed throughout the biliary tree, then these cannot be readily removed by surgery.

**Prognosis** The prognosis of cholelithiasis depends on the extent of hepatic fibrosis, severity of clinical signs, and number and location of choleliths. Extensive or bridging fibrosis, multiple choleliths accompanied by clinical signs of hepatic failure, hepatic atrophy, and severe HE warrant a poor to grave prognosis.<sup>50,125,170</sup> Reports of resolution of extensive fibrosis exist after re-establishment of bile flow; thus one should not consider the presence of extensive fibrosis alone to be lethal.<sup>170,179</sup> In contrast to reports of 30% survival for equine cholelithiasis,<sup>50</sup> recent reviews indicate 77% to 85% survival with medical or medical and surgical treatment.<sup>125,170</sup> If obstruction of the bile duct requires a choledochotomy, then

the prognosis is guarded because of limited access to the bile duct in a horse and the risk of choleperitoneum.

### CHRONIC CHOLANGIOHEPATITIS AND BILIARY FIBROSIS

Chronic cholangiohepatitis and biliary fibrosis most commonly are associated with CAH, cholelithiasis, and pancreatitis. Liver failure rarely results from primary idiopathic cholangitis or biliary fibrosis.<sup>56</sup> Therapy is supportive. Treatment of bacterial cholangiohepatitis is discussed elsewhere (see Bacterial Hepatitis, Chronic Active Hepatitis, and Cholelithiasis). The prognosis depends on the degree of fibrosis. Extensive fibrosis warrants a poor prognosis, although reports of reversal of hepatic fibrosis exist, especially on relief of the obstruction in cholestatic diseases.<sup>179</sup>

### NEONATAL ACQUIRED BILIARY OBSTRUCTION

Healing duodenal ulcers located adjacent to the hepatopancreatic ampulla in neonatal foals may result in extrahepatic biliary stenosis.<sup>15,180</sup> Clinical signs are compatible with gastroduodenal obstruction and include reduced suckling reflex, depression, prolonged recumbency, colic, bruxism, and firm feces. Nasogastric intubation often produces voluminous reflux. Duodenal stenosis may be confirmed radiographically by delayed gastric emptying of barium sulfate. One should consider a diagnosis of biliary stenosis if the serum levels of conjugated bilirubin and GGT are increased or if nuclear scintigraphy indicates delayed biliary excretion. Cholangiohepatitis may develop because of chronic cholestasis and may be confirmed by histopathologic examination of a liver biopsy. One must differentiate acquired biliary stenosis from congenital biliary atresia (discussed later in this chapter). Successful surgical correction of acquired biliary stenosis secondary to duodenal stricture has been described.<sup>180</sup>

Chronic cholangiohepatitis without biliary stenosis, another potential sequela to duodenitis or duodenal ulceration, should be considered in icteric foals with increased serum conjugated bilirubin and GGT.<sup>15</sup> The diagnosis is confirmed by histopathologic examination. Treatment should consist of long-term antimicrobial therapy directed by bacterial isolation and sensitivity results (see Bacterial Hepatitis).

### HEPATIC ABSCESSATION

Liver abscessation is uncommon in horses. Clinical signs of hepatic abscessation depend on the extent and location of the abscess or abscesses; however, abscesses are unlikely to result in hepatic failure. Small solitary abscesses or multifocal microabscesses usually remain subclinical. Larger abscesses may be accompanied by weight loss, intermittent fever, and anorexia.

Hepatic abscessation in foals may be hematogenous in origin as a sequela to bacteremia or ascending through the umbilical vein as a sequela to omphalophlebitis.<sup>181</sup> In the adult, bacteremia is uncommon, and hepatic infection or abscessation more likely originates in the intestinal lumen and ascends the bile duct or originates in the intestinal wall or mesenteric lymph nodes and is carried to the liver via the portal blood. The latter is a likely sequela to primary abdominal or mesenteric abscessation because of *Streptococcus equi* subsp. *equi*. In one retrospective study of abdominal abscesses in horses, only two of 25 horses had solely hepatic abscesses, although some horses had abscesses involving several abdominal

structures.<sup>182</sup> In a description of three adult horses with hepatic abscesses, disease was postulated to result from primary inflammatory bowel disease, as a sequela to abdominal surgery, and secondary to penetration of a foreign body from the colon.<sup>183</sup> Laboratory diagnosis of hepatic abscessation is difficult. Smaller abscesses may not result in sufficient hepatocellular damage to impede liver function. Laboratory abnormalities characteristic of chronic inflammation and infection, including anemia of chronic disease, hyperfibrinogenemia, hypergammaglobulinemia, and mature neutrophilia, may occur with larger abscesses. Increased serum activity of liver-specific cytosolic enzymes or serum bile acids concentration rarely occurs unless liver abscessation is extensive. Ultrasonography of the liver may reveal focal changes in echogenicity. A liver biopsy should be guided by ultrasound to avoid penetration of the abscess. One should direct long-term antimicrobial therapy by culture and sensitivity results. Common isolates from abdominal abscesses in horses include *S. equi*, sups. *equi*, *S. equi* subsp. *zooeidemicus*, and *Corynebacterium pseudotuberculosis*.<sup>182</sup>

### HEPATIC NEOPLASIA

Primary hepatic neoplasia is rare in horses. A retrospective survey in 1952 indicated that hepatic tumors accounted for only 1% of all equine neoplasms.<sup>184</sup> Of the documented primary hepatic neoplasms in horses (cholangiocarcinoma, hepatocellular carcinoma, hepatoblastoma, and mixed hamartoma), cholangiocarcinoma is the most common.<sup>57,85,86,184-188</sup> Hepatic neoplasia in horses is more likely to occur after metastasis of some other primary tumor, especially lymphosarcoma.<sup>74</sup> Because clinical signs of hepatic failure usually are not apparent and laboratory findings are nonspecifically indicative of chronic inflammatory disease, antemortem diagnosis of hepatic neoplasia is difficult.

In one report, *cholangiocarcinoma* accounted for 9 of 10 primary liver neoplasms in horses.<sup>184</sup> Cholangiocarcinoma originates from the bile duct epithelium and is distinguished from hepatocellular carcinoma by its tendency to form multiple foci, its firm texture, and a whitish color produced by abundant fibrous stroma. The primary mass is typically solitary, with multiple intrahepatic secondaries. Extrahepatic metastasis is common, with transperitoneal lymphatic spread to the peritoneum and diaphragm and hematogenous spread to the lungs.<sup>186</sup> In human beings, dogs, and cats, a causative relationship appears to exist between cholangiocarcinoma and liver fluke infestation or a history of biliary tract disease.<sup>186</sup> A report describes cholangiocarcinoma in a horse after treatment for prolonged septic cholangiohepatitis.<sup>176</sup> Aberrant expression of the protein products of the tumor suppressor gene, p53, was reported at necropsy in one horse with cholangiocarcinoma.<sup>189</sup> Loss of function of p53 has been described in other types of carcinomas and may have contributed to malignancy. Microscopically, cholangiocarcinoma is adenocarcinomatous, producing cuboidal or columnar-lined ductules and acini. The neoplastic bile ducts do not contain bile but may contain mucus.

The clinical presentation and progression of cholangiocarcinoma in horses is not well documented, but this disorder appears to be more common in older horses.<sup>184</sup> One case report describes a 10-year-old mixed-breed horse in which the presenting signs included anorexia, weight loss, pyrexia, mild icterus, tachypnea, severe dependent edema, and abdominal distention.<sup>188</sup> Abnormal clinicopathologic

findings included mature neutrophilia; hyperfibrinogenemia; anemia; moderately increased serum bilirubin, GGT, and SDH; and nonseptic peritonitis and pleuritis. Neoplastic cells were not detected in the body cavity effusions. Definitive antemortem diagnosis of cholangiocarcinoma was made by histopathologic examination of a liver biopsy. Necropsy revealed multiple extrahepatic metastases on the serosal surfaces of the intestine and spleen, diaphragm, omentum, pleural surfaces, and lung.

*Hepatocellular carcinoma*, or hepatoma, has been reported in several horses, the majority of which were less than 3 years of age.<sup>84-86,187</sup> Hepatocellular carcinomas are usually solitary and multilobulated. Extrahepatic metastasis occurs transperitoneally and hematogenously to lungs. Microscopically, the neoplastic cells resemble hepatocytes and retain cord arrangement. However, the normal liver architecture is lost, and sometimes the cells are difficult to differentiate. Mitotic figures are uncommon. Possible causative factors in other species include heredity, parasitism, chemical and plant carcinogens, and viral hepatitis.<sup>186</sup>

Reported clinical signs of hepatocellular carcinoma in horses include depression, anorexia, weight loss, intermittent diarrhea, and abdominal distention.<sup>84-86,187</sup> Abnormal laboratory findings included absolute erythrocytosis; persistent hypoglycemia; sanguineous peritoneal effusion; and increased serum SDH, GGT, LAP, and indirect-reacting bilirubin. In one case, absolute erythrocytosis was attributed to erythropoietin secretion by the carcinoma (inappropriate secondary erythrocytosis).<sup>86</sup> The same horse had a high serum concentration of  $\alpha$ -fetoprotein, a globulin normally synthesized only by embryonic fetal liver cells that is commonly detectable in human patients with hepatocellular carcinoma.

Two case reports describe malignant *hepatoblastoma* in young horses.<sup>57,190</sup> Hepatoblastoma is an embryonic tumor of the liver with a wide range of histologic patterns that include both epithelial and mesenchymal elements. Clinical signs included emaciation, pyrexia, and pleural effusion. Laboratory abnormalities included mature neutrophilia, erythrocytosis with normal erythropoietin levels, hypergammaglobulinemia, hyperfibrinogenemia, and increased serum activity of GGT and ASP. In one of the cases, transabdominal ultrasonography identified abnormal hepatic architecture. Increased serum  $\alpha$ -fetoprotein may serve as a tumor marker but cannot be used alone to confirm a diagnosis.<sup>190</sup>

A *mixed hamartoma* was described in the liver of a late-term aborted equine fetus.<sup>203</sup> Histologically, the lesion appeared to be a proliferation of large hepatocyte-like cells with eccentric nuclei and voluminous cytoplasm, abnormal bile ducts, and fibroblastic fibrocystic interstitial tissue, with complete lack of structural organization.

## HEPATIC AMYLOIDOSIS

Amyloidosis refers to a group of diseases that are characterized by the extracellular deposition of a proteinaceous fibril substance, *amyloid*, in the tissues. Amyloid deposits are composed of nonbranching fibrils in  $\beta$ -pleated sheet conformation formed by the proteolytic cleavage of precursor proteins by the mononuclear phagocyte system. Depending on the organ of deposition, amyloid distorts normal tissue architecture and may lead to functional impairment. In horses, the liver and spleen are the most common organs involved in systemic amyloidosis.<sup>191</sup> Two forms of systemic amyloidosis exist and are distinguished by the type of precursor protein and

subsequent protein fibril. The precursor in *reactive* or *secondary* systemic amyloidosis is serum amyloid protein AA, an acute phase protein produced by hepatocytes in response to chronic infection or inflammation. The AA fibrils are identified in tissues by green birefringence in polarized light, after staining with Congo red, which is lost after treatment with potassium permanganate. Most often in horses, hepatic amyloid deposits are AA fibrils and have been associated with severe parasitism or chronic infection and inflammation.<sup>191,192</sup> One horse in which the liver was the principal organ of amyloid deposition presented for evaluation of chronic weight loss.<sup>192</sup> An antemortem diagnosis of hepatic amyloidosis was not made; however, laboratory abnormalities included severe hypoalbuminemia, polyclonal gammopathy, and large numbers of ascarid and strongylid eggs in the feces. Histopathologically, the liver revealed extracellular deposits of AA amyloid periportally and adjacent to the sinusoids in the space of Disse. The amyloid deposits were accompanied by hepatocytic atrophy and a mild mononuclear cell infiltrate.

*Systemic primary, immunocytic, or idiopathic amyloidosis* is caused by the deposition of amyloid light chain fibrils. The precursor proteins in primary amyloidosis are the variable region of immunoglobulin light chains. The amyloid fibrils also stain with Congo red, but staining is retained after potassium permanganate treatment. *Local immunocytic amyloidosis*, with deposition in the upper respiratory mucosa or skin, is more common in horses than systemic primary amyloidosis. However, at least one reported case of systemic primary amyloidosis in a 14-year-old Thoroughbred mare with chronic weight loss and cutaneous nodules exists.<sup>193</sup> Amyloid deposits were identified in the liver, myocardium, spleen, gastrointestinal mucosa, pulmonary interstitium, pancreas, and arterial walls.

## CHRONIC HYPOXEMIA

Right-sided heart failure causes the pressure in the caudal vena cava to rise. Retrograde pressure increases in the hepatic central veins, causing hypoxemia and pressure necrosis of the adjacent hepatocytes. Chronic passive congestion may cause fatty change, atrophy, and fibrosis.

## CONGENITAL OR HERITABLE ABNORMALITIES

### PORTOSYSTEMIC SHUNT

Portosystemic shunts may be intrahepatic or extrahepatic, congenital or acquired. Few reports have documented congenital extrahepatic portosystemic shunts in foals.<sup>87,194</sup> The vascular shunts allow blood within the portal system to bypass the liver and drain into the systemic circulation, directly or indirectly, via the caudal vena cava or the azygous vein. In the reported cases, age at presentation varied between 2 and 6 months. Vague intermittent neurologic signs of blindness, ataxia, and severe depression were consistent with HE. Growth appeared to be stunted. These clinical signs are caused by the altered hepatic blood flow and hepatic insufficiency secondary to hepatocellular atrophy.

Laboratory abnormalities in the reported cases varied, but the most consistent findings included a decreased BUN, prolonged BSP half-life, and increased blood ammonia concentration. Liver biopsies revealed hepatocellular atrophy and necrosis, fibrosis, and biliary hyperplasia.<sup>87</sup> Antemortem

diagnosis was confirmed by operative mesenteric portography or nuclear scintigraphy (see Diagnostic Imaging of the Liver). Surgical correction was attempted unsuccessfully in one case.<sup>195</sup> Necropsy examination revealed small, firm livers. The location of the shunt (or shunts) in reported cases varied, but all were extrahepatic, involving a direct connection between the mesenteric veins and the caudal vena cava. Alzheimer type II astrocytes were visible in the brain in one case and were consistent with HE.<sup>194</sup>

Acquired portosystemic shunts are rare in horses. One report describes an 11-year-old Thoroughbred with HE that subsequently was determined to have a functional portosystemic shunt secondary to vascular thrombosis of the portal vein.<sup>195</sup>

### BILIARY ATRESIA

At least two cases of extrahepatic biliary atresia in foals have been documented.<sup>196,197</sup> An antemortem diagnosis was not possible in either case; however, veterinary attention was sought at 4 weeks of age in both foals for anorexia, depression, lethargy, poor weight gain, colic, polydipsia, polyuria, pyrexia, and icterus. Laboratory evaluation of one of the foals was consistent with biliary obstruction, as indicated by a mildly increased serum activity of SDH and markedly increased activity of GGT and conjugated bilirubin.<sup>196</sup> Necropsy of both foals revealed a large, firm liver. Although not specifically documented in one case, both the entrance to the bile duct and the main bile duct were absent in the other foal.<sup>196</sup> Histologically, both livers appeared similar and consistent with extrahepatic biliary atresia. Bile canaliculi were present and distended, with associated degenerative hepatocytes. Biliary proliferation was extensive and surrounded by fibrous tissue with interdispersed islands of hepatocytes. No bile was found in the proliferative bile ducts, and the portal triad ducts were absent.

In horses, extrahepatic biliary atresia is believed to be congenital. In human beings, other possible causes include neonatal sclerosing cholangiohepatitis, excretion of a biliary toxin, deficit of bile flow in utero, or lumen destruction because of ductal vascular insufficiency.<sup>197</sup> Despite the cause, extrahepatic biliary atresia induces intrahepatic biliary hypertrophy, an abortive attempt to establish continuity. The biliary hypertrophy displaces hepatocytes, causing periportal and perlobular hepatocellular degeneration, fibrous replacement, and ultimately, loss of normal hepatic architecture. Although an antemortem diagnosis was not possible in either equine case, hepatobiliary scintigraphy (see Diagnostic Imaging of the Liver) successfully detected total biliary obstruction in a neonatal lamb with biliary atresia.<sup>88</sup>

### SEROUS CYSTS

Serous hepatic cysts have been reported and usually are an incidental finding at necropsy.<sup>11</sup>

### GLYCOGEN BRANCHING ENZYME DEFICIENCY

Autosomal recessive inheritance of glycogen branching enzyme deficiency has been reported in Quarter Horse foals (see the chapter on Musculoskeletal Diseases for a detailed discussion). The nonsense mutation of the affected gene, glycogen branching enzyme 1, prevents synthesis of functional enzyme. Affected foals died before 2 months of age. Clinical signs vary from stillbirth, seizures, and persistent recumbency to cardiac or respiratory failure. Leukopenia, intermittent hypoglycemia, increased creatine kinase, GGT, and AST are

common laboratory findings. Histopathology of the liver demonstrates abnormal periodic acid–Schiff (PAS) positive globular or crystalline intracellular inclusions and reduced glycogen branching enzyme activity.<sup>198</sup>

# EQUINE OPHTHALMOLOGY

## CHAPTER 17

David A. Wilkie

### EXAMINATION

The equine eye presents particular challenges for diagnostic and therapeutic approaches. However, the basic principles of a complete ophthalmic examination hold true. **Box 17-1** lists the equipment required for a routine ophthalmic examination. One should perform the initial ophthalmic examination in a well-lighted environment and before tranquilization. The examiner assesses facial, orbital, and eyelid symmetry; looks for ocular discharge (serous, mucoid, mucopurulent) or blepharospasm; and evaluates the cranial nerves, specifically cranial nerves II through VII. A complete ophthalmic examination includes assessment of pupillary light and menace response, maze testing, globe position and mobility, sensation of ocular and adnexal structures, and eyelid position and function. To evaluate direct and consensual pupillary light responses accurately often requires a bright focal light source (3.5-V halogen) and a darkened examination area.

Further examination or therapy may require some form of tranquilization, regional nerve blocks, and topical anesthesia. Detomidine (Dormosedan, Pfizer Animal Health, Exton, Pa.) administered intravenously at 0.01 to 0.02 mg/kg or xylazine (Rompun, Haver-Lockhart, Shawnee, KS) at 0.5 to 1.0 mg/kg combined with butorphanol tartrate (Torbugesic, Bristol Laboratories, Inc., Evansville, Ind.) at 0.01 mg/kg administered intravenously provide a synergistic analgesic effect and facilitate examination, sample collection, intraocular pressure determination, nasolacrimal irrigation, lavage tube placement, and minor surgical procedures. If one intends to determine intraocular pressure (IOP), it is important to note that intravenous administration of xylazine significantly lowers the IOP.<sup>1</sup>

Sensory innervation of the globe and adnexa is from the trigeminal nerve (cranial nerve V), and motor innervation is from the facial nerve (cranial nerve VII). The ophthalmic nerves blocked most frequently are the auriculopalpebral branch of cranial nerve VII and the supraorbital (frontal) branch of cranial nerve V. Blocking of these nerves provides akinesia and anesthesia of the superior eyelid, respectively. One can palpate the auriculopalpebral nerve as it courses over the zygomatic arch in the area of the temporofrontal suture. Using a 25-gauge,  $\frac{5}{8}$ -inch needle, one blocks the nerve by injecting 3 to 5 ml of mepivacaine (Carbocaine, Winthrop Laboratories, New York, N.Y.) over the zygomatic arch in this area. One blocks

the supraorbital nerve as it emerges from the supraorbital foramen of the frontal bone by palpating the foramen, inserting a 25-gauge,  $\frac{5}{8}$ -inch needle into the foramen, and injecting 2.0 ml of mepivacaine; one infuses another 1 to 2 ml subcutaneously while removing the needle. Additional sensory nerves that are occasionally blocked include the infratrochlear, lacrimal, and zygomatic branches of cranial nerve V.<sup>2</sup> Alternatively, local infiltration of anesthetic can be used to provide anesthesia of a specific area. Finally, a retrobulbar nerve block may be performed for standing surgical procedures or to assist with general anesthesia. A retrobulbar block is performed using an 8-mm spinal needle. The needle is placed posterior to the dorsal bony orbital arch and directed ventrally and posterior to the globe. When the needle comes into contact with the dorsal rectus muscle of the eye, the globe will be seen to deviate dorsally. The needle is advanced just past the dorsal rectus muscle into the orbital muscle cone, and 5 to 8 ml of carbocaine is injected.

A complete ophthalmic examination can now be performed (see **Box 17-1**). The practitioner should obtain samples for bacterial or fungal culture or evaluation of tear production before instilling any topical solution or ointment on the eye. Aqueous production of tears is measured by using commercially available Schirmer tear test strips, with normal wetting being 20 mm or greater in 30 seconds. For a complete ophthalmic examination, the pupil should be dilated. This is performed using 1% tropicamide (Mydracyl® Alcon Laboratories, Fort Worth, Texas) and will take 15 to 20 minutes for adequate dilation. Failure to dilate the pupil will result in abnormalities of the lens and posterior segment being overlooked. Using a bright focal light source, the practitioner now examines the conjunctiva, nictitans, cornea, anterior chamber, iris, pupil, and lens. The practitioner evaluates the ocular media (cornea, aqueous humor, lens, and vitreous) for clarity and transparency; assesses the position and size of the lens, shape and mobility of the pupil, and appearance of the corpora nigra; and examines the eye for irregularities, vascularization, and pigmentation. Although it is possible to examine the whole anterior segment using a Finoff transilluminator with or without magnification, a new handheld monocular slit lamp that attaches to an otoscope or ophthalmoscope handle is available (HSL-10, Heine, United States). The handheld slit lamp provides magnification and an appreciation for depth

## BOX 17-1

**EQUIPMENT FOR BASIC EQUINE  
OPHTHALMIC EXAMINATION**

Bright, focal light source: 3.5-V halogen light with Finoff illuminator

Direct ophthalmoscope

Indirect 20-D 5× lens

Handheld slit lamp: HSL-10 attaches to direct ophthalmoscope handle (Heine, United States)

Magnifying loupe, 2×-4×

Dressing forceps

Open-ended urinary catheter (3.5 French) for nasolacrimal catheterization

No. 5 French catheter for cannulation of nasolacrimal duct at nares

Sterile fluorescein strips

Sterile rose bengal strips

Schirmer tear test strips

Sterile culture swabs

Kimura spatula for obtaining cytologic sample

Glass slides

Sterile eyewash

Proparacaine 0.5% (Alcaine): topical anesthetic

Tropicamide 1% (Mydracil): short-acting dilating agent

Sedation: Xylazine (Rompun)

Butorphanol tartrate (Torbugesic)

Detomidine (Dormosedan)

Mepivacaine (Carbocaine): local nerve blocks

Modified from Wilkie DA: Ophthalmic procedures and surgery in the standing horse, *Vet Clin North Am Equine Pract* 7:535-547, 1991.

and three-dimensional anatomy from the anterior vitreous forward. Fluorescein staining of the cornea detects the presence of corneal ulceration, and the appearance of fluorescein at the nares indicates a patent nasolacrimal system. Some ophthalmologists also use rose bengal to stain the cornea. Rose bengal will stain damaged or devitalized corneal epithelial cells and may be more sensitive than fluorescein for early fungal or herpetic disease. After instillation of topical anesthesia (proparacaine 0.5%, Alcaine, Alcon Laboratories, Fort Worth, Texas), the clinician can cannulate the nasolacrimal puncta using a 3.5F urinary catheter and irrigate the nasolacrimal system. Alternatively, one can irrigate the nasolacrimal system in retrograde fashion, cannulating the duct using a 5F catheter at the nasal opening. Using thumb forceps, one can grasp the nictitans and examine the palpebral and bulbar surfaces for foreign bodies, mass lesions, or other abnormalities. Conjunctival and corneal cells are collected for cytologic study using

a Kimura spatula after administration of topical anesthesia. If available, Tonopen Vet (Reichert Ophthalmic Depew, N.Y.) can be used to determine ocular pressure.

To examine the posterior segments of the eye (vitreous, optic nerve, retinal blood vessels, and tapetal and nontapetal fundus), the clinician should perform both direct and indirect ophthalmoscopy. A new monocular indirect ophthalmoscope, the PanOptic ophthalmoscope (Welch Allyn Inc., Skaneateles Falls, N.Y.) allows those more familiar with the technique of direct examination to perform indirect ophthalmoscopy. The clinician evaluates the size and color of the optic nerve, number and size of retinal blood vessels, pigmentation of the nontapetal fundus, the presence or absence of hyporeflexive or hyper-reflective changes of the tapetal fundus and the vitreous for opacities or degeneration.

## OCULAR ULTRASONOGRAPHY

### TECHNIQUE

Ocular ultrasonography is performed directly through the cornea or the eyelids or by using an offset device. The optimal transducer for ocular ultrasonography is a 10- to 20-MHz probe, but one can use a 5- to 7.5-MHz probe. Ultrasound biomicroscopy (UBM) can be performed using 25- to 100 MHz probes, allowing detailed imaging of the cornea, limbus, iridocorneal angle, and anterior uvea. Sedation, auriculopalpebral nerve block, and topical anesthesia generally are required. Sterile, water-soluble lubricating jelly works well as a contact material, provided one irrigates the cornea afterward.

### NORMAL ANATOMY

With use of a 5- to 7.5-MHz probe, the cornea and a portion of the anterior chamber are lost in the near artifact unless an offset device is used. With a probe of 10 MHz or higher, the anterior chamber and cornea can be visualized. The anterior and posterior lens capsules are visible as an echodense line at the 12 and 6 o'clock positions, whereas the remainder of the normal lens is anechoic. The iris, corpora nigra, and ciliary body are often visible. The vitreous body is normally anechoic. The posterior eye wall is visible as a concave echodensity, with the optic nerve head visible as an echodense area at the posterior pole with an anechoic optic nerve posteriorly. The orbital contents are best visualized using a 7.5-MHz transducer to evaluate the extraocular muscle cone, optic nerve, and associated structures.

### INDICATIONS

Ocular ultrasound is indicated for evaluation of intraocular contents when one or more of the ocular transmitting media are opaque, including opacification of the cornea, aqueous and vitreous humors, and the lens. The most common indications for ocular ultrasound are in eyes with a cataract to evaluate for a retinal detachment, after traumatic hyphema to assess posterior segment damage, or in eyes with severe corneal opacification. In addition, ocular ultrasound can be used to evaluate the orbit in instances of exophthalmos or orbital trauma. UBM can be used to determine depth of a corneal lesion such as a squamous cell carcinoma or to examine an anterior uveal mass for extent of involvement.

**FIGURE 17-1** A, Severe blepharoeidema associated with facial trauma. B, A temporary tarsorrhaphy was performed standing to prevent exposure and desiccation of the cornea and conjunctiva.

## 🌀 EYELIDS

### CONGENITAL

Diseases of the equine eyelid are common. Congenital lesions include coloboma, agenesis, dermoid, and entropion.<sup>3,4</sup> Of these, entropion is the only frequently occurring disease. Entropion is inward rolling of the eyelid margin that results in facial hairs coming into contact with the cornea, leading to irritation, conjunctivitis, and possibly secondary corneal ulceration. Causes include prematurity or dehydration in foals with enophthalmos, ocular pain resulting in spastic entropion, and primary conformational problems. Manual reduction and frequent topical ocular lubrication with artificial tear ointment is the initial treatment of choice and may be the only treatment required in some foals, especially if the entropion follows dehydration. If the entropion is severe or does not respond to manipulation, the clinician may place two or three temporary vertical everting mattress sutures to position the eyelid correctly.<sup>3</sup> It is important to avoid overcorrection, which could lead to the inability to close the eyelids during blinking. Suture placement is at and perpendicular to the eyelid margin, tacking this to the periocular skin over the orbital rim. Monofilament, 3-0 to 5-0 nylon suture is preferable; the sutures are removed after 10 to 14 days. The clinician must treat associated corneal disease to prevent secondary infection and subsequent scar formation. Entropion requiring more aggressive surgical intervention in the form of skin excision is rare. Severe or recurrent entropion is correctable by excising an elliptic portion of eyelid skin in the affected area and reapposing the skin edges (Hotz-Celsus procedure).

### ACQUIRED

Common acquired conditions involving the equine eyelid include trauma and neoplasia.

### TRAUMA

Eyelid trauma includes contusions and lacerations.<sup>5</sup> Commonly associated with eyelid trauma are corneal abrasions or lacerations; anterior uveitis; and, if the trauma involves the

medial canthus, nasolacrimal system damage. Eyelid contusions often result in blepharoeidema and hemorrhage. Although mild blepharoeidema does not require therapy, recovery can be hastened by using systemic flunixin meglumine (Banamine, Schering Corp., Kenilworth, New Jersey), cold compresses in the acute phase, and warm compresses beginning the day after the injury. In addition to the aforementioned therapy, severe blepharoeidema may also require a temporary tarsorrhaphy and elevation of the head to protect the tissues and resolve the swelling (Figure 17-1).

Eyelid lacerations are more serious and usually require immediate therapy (Figure 17-2). The vascular supply to the eyelid is extensive, and many apparent avascular segments of eyelid recover after repair. If possible, primary wound closure is preferable. It is important to remove all debris from the wound before closure, disinfect the eyelid surface and adjacent tissues with a 1:25 to 1:50 dilution of povidone-iodine solution, avoid excessive tissue débridement, and under no circumstances amputate a pedicle of eyelid. Loss of eyelid margin, whether iatrogenic or the result of trauma, leads to severe, chronic corneal irritation; vascularization; ulceration; and fibrosis (Figure 17-3). In addition, reconstructing an eyelid margin from the adjacent skin after amputation of the normal eyelid margin is difficult.

One should suture lacerated eyelids using a two-layer closure, ensuring accurate anatomic apposition of the wound edges and eyelid margin. Minor surgical repairs can be performed using sedation and local nerve blocks, but the horse may require general anesthesia if the injury is severe. First, suture the deeper, conjunctival layer using 5-0 to 6-0 absorbable suture in a horizontal mattress pattern beginning away from and working toward the eyelid margin, taking care to avoid penetrating the conjunctiva so that the suture does not come into contact with the cornea. The practitioner then closes the skin with 5-0 to 6-0 nonabsorbable monofilament suture. The eyelid margin is the most important part of wound closure and is closed first to ensure accurate apposition. The author prefers to use a cruciate suture pattern at the eyelid margin and a simple interrupted pattern for the remainder of the skin closure. Failure to perform a two-layer closure or achieve precise apposition of the eyelid margin may result

**FIGURE 17-2** Traumatic laceration of the inferior lateral eyelid margin.

in ulcerative keratitis or other secondary complications.<sup>6</sup> Postoperative therapy includes administration of antibiotics for 5 to 7 days for systemic effect; tetanus toxoid; warm, moist compresses; and flunixin meglumine if inflammation and swelling are a problem. Topical medication is not required for eyelid injuries unless corneal or anterior segment damage accompanies the injury. The practitioner must evaluate eyelid function, and the eyelid must provide adequate protection to the cornea. If the blink response is impaired, the cornea should be protected with topical lubricants as often as possible. Advanced blepharoplastic techniques for repair of severe eyelid trauma with resulting loss of tissue are beyond the scope of this chapter but are discussed in detail elsewhere.<sup>3</sup>

### NEOPLASIA

The most common neoplasms of the equine eyelid are sarcoid and squamous cell carcinoma. In addition, melanoma, mast cell tumor, lymphosarcoma, basal cell carcinoma, and papilloma can affect the eyelid (Figure 17-4). The differential diagnosis for eyelid neoplasms includes parasitic diseases such as ocular habronemiasis and other causes of granulomatous skin disease. Treatment of eyelid neoplasia depends on the location, size, tumor type, age and purpose of the horse, cost, surgical skill, and equipment available. Treatment modalities include surgical excision, radiation therapy, intralesional chemotherapy, hyperthermia, immunotherapy, cryosurgery, or a combination of these. The aim of therapy is to eliminate or halt progression of the tumor while maintaining eyelid function and preserving the eye and vision. Complete excision with primary closure is the optimal treatment but often cannot be achieved because of limitations on availability of tissue for reconstruction and the extensive and aggressive nature of many eyelid neoplasms. If the veterinarian cannot appose eyelid margins after tumor excision, more involved blepharoplastic techniques, such as advancement skin flaps, may be indicated (Figure 17-5).

**Squamous Cell Carcinoma** Squamous cell carcinoma (SCC) involving the eyelid is usually erosive and ulcerative.<sup>5</sup> The medial canthus is the most common site of origin (see Figure 17-6). Invasion of adjacent soft and bony orbital tissue is possible if the disease is untreated. Treatment of ocular SCC is discussed in detail in the sections on conjunctiva and third eyelid.

**FIGURE 17-3** Failure to repair a superior eyelid laceration has resulted in contracture of the pedicle and exposure of the cornea.

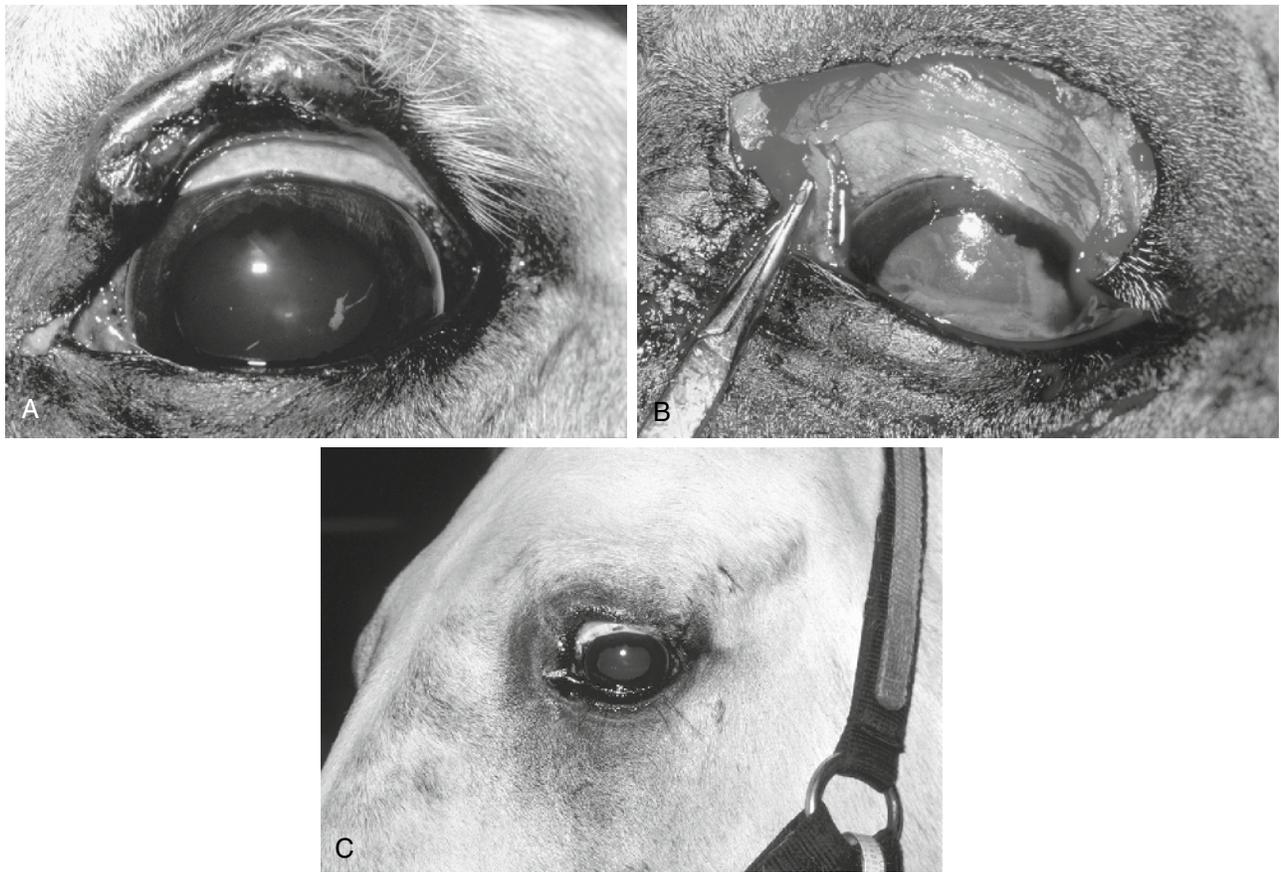

**Sarcoid** Periocular sarcoid is the second most common eyelid neoplasm of the horse. The average age of an affected horse is 4 years, and smooth and warty sarcoids occur. Orbital invasion and bony involvement are possible. Surgical excision is associated with frequent recurrence and often is combined with cryosurgery, hyperthermia, chemotherapy, or irradiation to ensure complete tumor destruction. Of all treatment modalities, radiation is the most expensive and yields the best overall success.<sup>7</sup>

Intralesional immunotherapy with cell wall extracts of bacillus Calmette-Guérin (BCG) in oil has been used effectively in repeated injections 3 weeks apart. A total of four doses usually is required for complete tumor regression, with the overall response reported to be 69%, provided the injection was intralesional.<sup>7</sup> Injection of cell wall extracts of BCG is associated with local inflammation and tumor necrosis. During this period of inflammation, the clinician must protect the globe to prevent corneal desiccation or ulceration. The use of live BCG organisms or whole killed organisms has been associated with anaphylactic reaction and death and is discouraged. Adverse systemic reactions to cell wall extracts of BCG are rare, but premedication with systemic corticosteroids is advised.

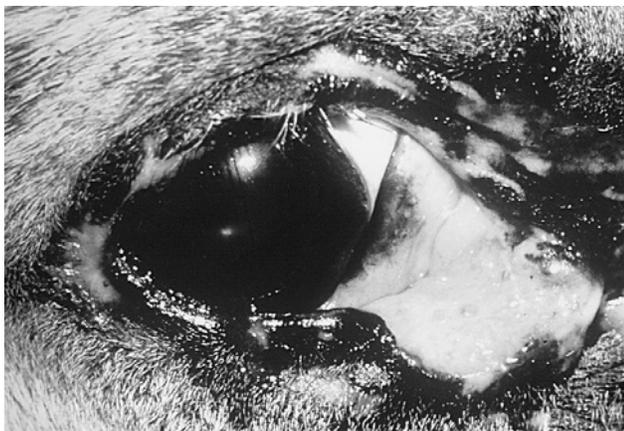

Intralesional chemotherapy with cisplatin in an oil-water emulsion has been reported to result in regression of equine sarcoid.<sup>8</sup> A series of four injections, spaced 2 weeks apart, with a mean dose of cisplatin of 0.97 mg/cm<sup>3</sup> of tumor mass resulted in tumor regression in all treated horses. In addition, 87% of horses treated for sarcoids were relapse free at a 1-year follow-up. A larger study of intralesional cisplatin reported a cure rate of 96.3% for sarcoids and 88% for SCC at 4 years after treatment.<sup>9</sup>

### CONJUNCTIVA AND THIRD EYELID

The conjunctiva is divided into bulbar and palpebral surfaces. The conjunctiva merges with the cornea at the limbus, with the eyelid at the eyelid margin, and the bulbar and palpebral conjunctiva join to form the fornix. The conjunctiva has normal resident bacterial and fungal populations. The most common isolates from the equine conjunctiva vary according to

**FIGURE 17-4** A, Melanoma of the superior eyelid. B, An excisional biopsy is performed, and the resulting defect cannot be closed by primary closure of the eyelid margins. C, An advancement graft is performed to reconstruct the superior eyelid.

**FIGURE 17-5** Squamous cell carcinoma involving the medial canthus and inferior eyelid of a 19-year-old Appaloosa.

geography, season of the year, and investigator.<sup>10-12</sup> In general, isolates of gram positive organisms—*Corynebacterium*, *Bacillus*, *Staphylococcus*, and *Streptomyces*—are more common than gram negative organisms from normal equine conjunctiva.<sup>11</sup> Fungi are isolated more commonly in the summer and autumn and have been reported to be present in 95% of normal horse conjunctiva samples.<sup>12</sup> In addition, fungi are isolated

more frequently from stabled horses, which likely relates to the immediate environmental and husbandry conditions.<sup>11</sup>

Congenital diseases of the equine conjunctiva are uncommon, conjunctival dermoid being the most common congenital abnormality. A dermoid is a congenital tumor of skin and associated glands, hair, and hair follicles that can affect the cornea and adjacent conjunctiva. A dermoid that is irritating the globe or adnexa should be surgically removed by superficial keratectomy or conjunctivectomy.

Unlike the small animal patient, horses rarely acquire infectious conjunctivitis. Organisms reported to result in infectious conjunctivitis in the horse include equine herpesvirus type 2,<sup>13</sup> *Mycoplasma* spp., *Chlamydia*, *Moraxella equi*, and mycotic and viral agents.<sup>3</sup>

Foreign bodies and trauma are common causes of conjunctival irritation and damage and often are associated with concurrent eyelid and corneal injuries. The clinician directs treatment to eliminate the cause, treat any conjunctival or associated eyelid or corneal damage, and prevent secondary infection. A complete ophthalmic examination is necessary in all animals with evidence of ocular trauma. Conjunctival foreign bodies should be considered in any horse with a recurrent corneal erosion, ocular pain, or conjunctivitis. The clinician should examine the superior and inferior fornices and the bulbar and palpebral surface of the nictitans after topical administration of 0.5% proparacaine. Magnification is essential to detect foreign bodies. In addition, irrigation of

the nasolacrimal system may yield foreign material associated with chronic conjunctivitis or dacryocystitis.

Severe chemosis with conjunctival prolapse and exposure may result from self-trauma, especially associated with being recumbent for a prolonged time. Treatment includes systemic anti-inflammatory drugs; artificial tear ointment to protect exposed conjunctiva; elevation of the head; and, in severe cases, repositioning of the conjunctiva and a temporary tarsorrhaphy until the swelling resolves (see Figure 17-1).

## PARASITES

Common parasites of the equine conjunctiva include *Thelazia lacrymalis*, *Habronema* spp., and *Onchocerca cervicalis*.<sup>14</sup> In a necropsy sample the prevalence of *Thelazia* organisms in the conjunctival sac of horses is highest in young animals, with 43% of 1- to 4-year-old horses being affected.<sup>15</sup> In most instances infection is not associated with clinical signs, but chronic conjunctivitis, seromucoid discharge, and conjunctival nodules can occur.<sup>3</sup> The adult parasite may be visible on ophthalmic examination of the cornea and conjunctival fornix, and larvae may be visible on examination of centrifuged samples of nasolacrimal washes. Treatment includes removal of the adult worms, irrigation of the nasolacrimal system, topical corticosteroids to reduce inflammation, and fly control. The topical organophosphates echothiophate, 0.03% to 0.06% every 12 hours, or isofluorophate, 0.025% every 24 hours for 7 days, have been reported to kill the parasite.<sup>16</sup> Systemic treatment with fenbendazole at 10 mg/kg orally every 24 hours for 5 days also is reported to be effective against *Thelazia* organisms.<sup>17</sup>

Ocular manifestations of equine cutaneous habronemiasis result when the house or stable fly deposits the larvae of the *Habronema* spp. on or around the eye.<sup>3,18,19</sup> The resulting granuloma is associated with inflammation, intense pruritus, and epiphora. Yellow, caseous granules are notable throughout the granulation tissue. Histologically, eosinophils and mast cells predominate. Diagnosis is based on clinical signs, location, season of the year, and histologic findings. Clinical appearance can simulate squamous cell carcinoma. Histologically, the differential diagnosis is equine cutaneous mastocytosis.<sup>3,19</sup> Ocular lesions are most common at the medial canthus and may involve the skin, nasolacrimal duct, third eyelid, or conjunctiva. Treatment of equine cutaneous habronemiasis varies, and no single treatment is routinely successful.<sup>18</sup> Surgical excision, cryosurgery, local and systemic corticosteroid therapy, systemic ivermectin (single dose, 0.2 mg/kg intramuscularly), various larvicidal treatments in the form of topical and systemic organophosphates, and various topical formulations containing ronnel or metrifonate with a dimethyl sulfoxide vehicle are used<sup>3,18,19</sup> (Table 17-1). Dimethyl sulfoxide serves as a vehicle and has anti-inflammatory effects, possibly related to its ability to detoxify hydroxyl radicals generated by neutrophils. The aim of therapy is to kill the larvae while controlling the resulting inflammation. In addition, fly control is an essential part of an overall management program.

The blood-sucking midge *Culicoides nubeculosus* transmits *O. cervicalis* microfilariae. After transmission the immature microfilariae migrate through lymphatics and can travel to ocular and adnexal tissues. The prevalence of equine onchocerciasis increases with age, with an overall prevalence of 50% to 60%.<sup>14,20-22</sup> The prevalence of onchocerciasis on histologic examination of the lateral bulbar conjunctiva is 10.8%. The presence of conjunctival microfilaria does not correlate with

TABLE 17-1

### Topical Preparations Used to Treat Equine Cutaneous Habronemiasis

Ingredients	Amount
Ronnel solution (33%) <sup>13</sup>	60 ml
Thiabendazole (33%) <sup>13</sup>	120 g
9-Fluoroprednisolone acetate <sup>13</sup>	60 mg
Dimethyl phthalate (24%) <sup>13</sup>	30 ml
Dimethyl sulfoxide <sup>13</sup>	500 ml
Nitrofurantoin ointment <sup>14</sup>	225 g
Ronnel solution <sup>14</sup>	20 ml
Dimethyl sulfoxide <sup>14</sup>	20 ml
Dexamethasone solution <sup>14</sup>	20 ml
Nitrofurazone ointment (0.2%) <sup>15</sup>	135 g
Trichlorfon (12.3%) <sup>15</sup>	30 ml
Dexamethasone (2 mg/ml) <sup>15</sup>	30 ml
Dimethyl sulfoxide <sup>15</sup>	30 ml

TABLE 17-2

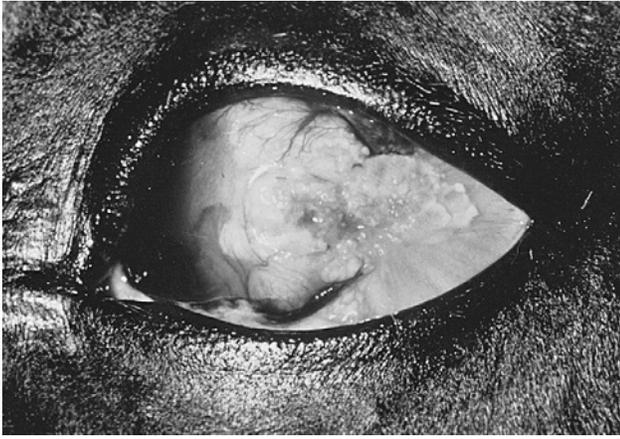

### Systemic Treatment of Ocular Onchocerciasis

Drug	Dose
Diethylcarbamazine	4.4-6.6 mg/kg/day orally for 21 days
Levamisole	1.1 mg/kg/day orally for 7 days
Ivermectin	0.2-0.5 mg/kg intramuscularly

clinical abnormalities. Ocular onchocerciasis has been proposed as a cause of keratitis, conjunctivitis, equine recurrent uveitis, and depigmentation of the temporal bulbar conjunctiva.<sup>22</sup> The pathogenesis is thought to involve the death of the microfilariae, release of antigens, and development of hypersensitivity in susceptible horses. Treatment is indicated in those horses with active conjunctivitis, keratitis, or uveitis attributable to onchocerciasis and includes anti-inflammatory agents such as topical corticosteroids and systemic flunixin meglumine; topical echothiophate iodide 0.025%; and systemic diethylcarbamazine, levamisole, or ivermectin<sup>3</sup> (Table 17-2).

## NEOPLASIA

Neoplasms affecting the conjunctiva and third eyelid include SCC, lymphosarcoma, melanocytoma, mastocytoma, hemangioma, and angiosarcoma.<sup>3,16</sup> Diagnosis and characterization of adnexal neoplasms are based on history, signalment, location, appearance, and histopathologic examination. Routine surgical biopsy is performed with sedation, local nerve blocks, and topical anesthesia. Most adnexal neoplasms are benign or locally invasive, the exception being ocular angiosarcoma, which is reported to have a high incidence of metastasis.<sup>23</sup> Treatment of adnexal neoplasms varies according to tumor type, location, and size; use of the animal; treatment modalities

**FIGURE 17-6** Squamous cell carcinoma affecting the temporal conjunctiva, limbus, and cornea.

available; and cost. The aim of treatment is to eliminate the tumor, restore normal anatomy, and maintain function of the eye and associated structures.

SCC is the most common tumor of the equine eye and adnexa (Figure 17-6). Involvement can be unilateral or bilateral, with the third eyelid and medial canthus affected most frequently.<sup>16,24</sup> Involvement of the corneal limbus, sclera, conjunctiva, and other adnexal structures also has been reported.<sup>16,24,25</sup>

The mean age of onset for SCC is 9.8 years for all horses compared with 3.8 years for ocular sarcoidosis.<sup>25</sup> The incidence of ocular SCC is higher in draft-breed horses and Appaloosas than in light horses,<sup>26,27</sup> and sexually intact males and females have a decreased incidence.<sup>26</sup> Adnexal hypopigmentation and increased exposure to actinic radiation<sup>25,26</sup> are hypothesized to predispose horses to develop ocular SCC.

Ocular SCC is malignant and locally invasive with the potential to metastasize.<sup>22,28</sup> Metastases to local and cranial mediastinal lymph nodes, parotid salivary glands, and the thoracic cavity occur in 10% to 15% of patients.<sup>27</sup>

Treatment of ocular SCC varies and must be designed for the individual patient. Surgical excision,<sup>25</sup> radiofrequency hyperthermia,<sup>29</sup> cryotherapy,<sup>30</sup> immunotherapy,<sup>30</sup> radiation therapy,<sup>25,28-30</sup> intralesional chemotherapy,<sup>8,31</sup> laser surgery,<sup>5</sup> or a combination of these<sup>29,30</sup> have been used with success. Location, size, and depth of the tumor; visual status; financial commitment; purpose of the animal; and the presence or absence of metastatic disease influence the choice of therapy.

If possible, complete surgical excision is curative and is the preferred therapy. Difficulty arises with surgical excision when preservation of the globe and ocular and adnexal anatomy and function are required. Complete excision of the third eyelid is possible and often can be performed using sedation and local nerve blocks. To prevent possible herniation of the orbital fat, the clinician should appose the bulbar and palpebral margins of the third eyelid conjunctiva after excision using 5–0 to 6–0 absorbable suture in a simple continuous pattern.

Most SCCs are radiosensitive and can be treated successfully with sources of  $\beta$ - or  $\gamma$ -radiation. The major disadvantage of less expensive modes of radiation therapy, such as strontium 90 (<sup>90</sup>Sr), a source of  $\beta$ -radiation, is the size limit of tumor amenable to treatment. With <sup>90</sup>Sr, for example, half the  $\beta$ -radiation produced is lost after passage through 1 mm
